Abstract—The presence of nitrate and other redox-active anionic contaminants in terrestrial ecosystems poses a significant risk to humans and other forms of life on Earth. The purpose of the present study was to test a potential *in situ* system, using poly-(D) glucosamine (chitosan) adsorbed to mineral surfaces under redox-active conditions in order to degrade nitrate to lower oxidation states. Chitosan is a linear polysaccharide derived from the chitin found in the shells of shrimp and other shellfish. Five different loadings of chitosan (0, 0.075, 0.25, 0.50, and 1.0 g/L; labeled C0, C1, C2, C3, and C4, respectively) were adsorbed to ferruginous smectite (SWa-1) to form chitosan-SWa-1 composites (CSC) in the pH range 5.8–4. The CSC was then reduced by Na₂S₂O₄ in a citrate-bicarbonate buffered dispersion and washed free of excess salts under inert-atmosphere conditions. Upon addition of the nitrate, the solution pH remained slightly acidic, ranging from 5.5 to 4.7. Samples were analyzed for Fe(II) content, reacted with a NaNO₃ solution, and then re-analyzed for structural Fe(II) content. Supernatant solutions were analyzed for nitrate, nitrite, and ammonium. In samples C1 to C4, extensive concentrations of nitrite were observed in the supernatants with a corresponding increase in the reoxidation of structural Fe(II), proving that a coupled redox reaction had occurred between the nitrate and the structural Fe in the clay mineral. The most efficient loading, defined as the largest percentage of adsorbed nitrate reduced to nitrite, occurred in sample C1. The total amount of nitrate reduced and Fe(II) reoxidized followed the trend 0 = C0 < C2 < C3 < C4 ≈ C1. Chitosan showed the potential to reverse the surface charge of constituent clay minerals, thereby enabling the CSC to remove nitrate anions from aqueous mineral systems *via* redox reactions with structural Fe(II) in clay minerals.

Key Words—Clay, Chitosan, FTIR, Iron Reduction, Nanocomposite, Nitrates, Nitrites, Nontronite, XRD, Zeta (ζ) Potential.

INTRODUCTION

Nitrates are classified among the most harmful of pollutants in natural waters and soils (Freeze and Cherry, 1979; Bowen *et al.*, 2007; Rabalais, 2002; Camargo and Alonso, 2006; Howarth, 2008), affecting human health (Burow *et al.*, 2010). Nitrate is a highly soluble anion and this greatly enhances the risk of widespread exposure (Thomson, 2001). Nitrates are commonly transported from contaminated water *via* green plants to the tissues and internal organs of livestock and, thus, to meat consumed by humans.

Once ingested, nitrates accumulate in the body and cause a number of chronic diseases or genetic mutations (Ward *et al.*, 2005). For decades, efforts to devise effective methods for removing nitrates from the human environment and from nature in a way that is highly efficient and acceptable from economic, industrial, and environmental points of view have met with limited success only. Nitrate remediation technologies that have actually been used were recently reviewed by Bhatnagar and Sillanpää (2011), and include zero-valent iron

(Fe(0)) (Cheng *et al.*, 1997; Sohn *et al.*, 2006; Ahn *et al.*, 2008; Liu *et al.*, 2014) or zero-valent magnesium (Mg(0)) (Kumar and Chakraborty, 2006), ion exchange (Chabani *et al.*, 2006; Samataya *et al.*, 2006), reverse osmosis (Schoeman and Steyn, 2003), electro dialysis (Hell *et al.*, 1998), catalytic denitrification (Pintar *et al.*, 2001), adsorption (Öztürk and Bektaş, 2004; Bhatnagar *et al.*, 2010), and biological denitrification (Soares, 2000).

Natural denitrification processes, including microbial activity, are well known but their efficiency and versatility are still questionable (Seitzinger, 1988; Korom, 1992). Abiotic remediation of saturated zones by reducing agents such as a zero-valent Fe powder or green rust are highly efficient (Huang *et al.*, 1998; Westerhof *et al.*, 2003; Sohn *et al.*, 2006; Hwang *et al.*, 2011). Immense nitrate depletion from Danish soil under anoxic and oxic conditions was reported by Ernstsén (1996) and Ernstsén *et al.* (1998), who offered a new potential mechanism for nitrate removal from soils. Those authors found that the nitrates were reduced abiotically by structural Fe(II) in the clay minerals, which they proposed to have been created through biotic reduction.

A complex method which couples adsorption, ion exchange, and redox reactions was shown recently to

DOI: 10.1346/CCMN.2014.0620504

reduce nitrate with redox-activated Fe-rich clay minerals, which contain octahedral Fe³⁺ (Su *et al.*, 2012). Iron in ferruginous smectites and nontronites can be reduced chemically or biologically following redox reaction 1 (Stucki *et al.*, 1987, 1988, 1992, 2007; Stucki and Kostka, 2006; Stucki, 2013):

Fe(II) is redox active and can react with nitrate according to reaction 2:

where nitrate is reduced to nitrite and ferrous iron is reoxidized back to ferric iron with a 2 e⁻ exchange in an acidic environment. This indicates that a promising pathway for nitrate removal is the reaction of nitrate with abiotically reduced structural Fe in clay minerals. A major problem, however, which was documented by Su *et al.* (2012), is that the clay mineral surfaces are negatively charged and, thus, repel the nitrate anion. This coulombic repulsion largely prevents natural redox interactions between nitrates and clays. This problem can be circumvented, however, by reversing the charge at the clay mineral surface. This is accomplished by adsorbing an organic polycation onto the smectite, which creates a new, positively charged interface to the surrounding solution. This charge reversal enhances the anion exchange-adsorption capacity (Breen, 1999; Radian and Mishael, 2008; Bleiman and Mishael, 2010; Zadaka *et al.*, 2010; Su *et al.*, 2012). Su *et al.* (2012) showed that polydiallyldimethylammonium (PDADMAC)-exchanged smectite provided a significant increase in nitrate uptake. This clay-polymer nanocomposite from ferruginous smectite SWa-1 (abbreviated PSC) facilitated extensive interaction with and reduction of nitrate. The optimum PDADMAC loading was 0.25 mg/g clay. While that study clearly demonstrated that a reaction can occur between reduced-Fe smectites and nitrate, the practicality of such a method has yet to be demonstrated because PDADMAC is a synthetic polycation and does not exist in any significant concentration in nature.

Chitosan (Figure 1) is a biopolymer (linear polysaccharide, poly-(D) glucosamine) derived by 50% or more de-acetylation of chitin, which is a naturally occurring biopolymer (N-acetylglucosamine polymer) synthesized by living organisms (shrimp, crabs). This link to a natural substance makes chitosan an appealing

Figure 1. Structure of chitosan, an organic polycation derived from chitin.

alternative to more synthetic polycations for reversing the charge on the clay minerals. The solubility of chitosan in aqueous acidic media is high and its functional groups (–NH₂, –OH, and –CO–) become protonated and able to interact with either negatively or positively charged ions or sites (Rinaudo, 2006). The protonated amino groups are attracted to the negatively charged clay surface by coulombic forces (Bleiman and Mishael, 2010) while also exposing many positively charged groups to the surrounding solution. The chitosan-exchanged smectite composite could be used for many different environmental applications (Fu and Qutubuddin, 2001; Dutta *et al.*, 2004; Bhatnagar and Sillanpää, 2009; Monier *et al.*, 2010; Ngah *et al.*, 2011), including the adsorption or sequestration of negatively charged heavy metals and radionuclides (Jeon and Park, 2005; Miretzky and Cirelli, 2009; Bleiman and Mishael, 2010; Dinu and Dragan, 2010; Fu and Wang, 2011; Prakash *et al.*, 2013), inorganic/organic pollutants (Churchman, 2002; Su *et al.*, 2012), and/or dyes (Crini and Badot, 2008; Auta and Hameed, 2014).

The purpose of the present study was to investigate the potential for abiotic redox remediation of nitrate in the natural environment by using a biopolymer, chitosan, prepared from naturally occurring chitin, instead of synthetic PDADMAC for reversing the surface charge of the smectite.

MATERIALS AND METHODS

Materials

The smectite used in this study was ferruginous smectite (sample SWa-1, Grant County, Washington, USA, from the Source Clays Repository of The Clay Minerals Society), which was fractionated to <2 μm, Na-saturated, and freeze-dried (Na-SWa-1). The unit-cell formula of this mineral was reported by Manceau *et al.* (2000). The chemicals used were analytical-reagent grade from Thermo Fisher Scientific (Chicago, Illinois, USA), except sodium dithionite powder was only available in technical grade. Chitosan with average molecular weight of 100,000–300,000 Da was obtained from Acros Organics, a division of Thermo Fisher Scientific (Pittsburgh, Pennsylvania, USA).

Methods

Five different loadings of chitosan with Na-SWa-1 were prepared as described below. The structural Fe in the clay mineral was then reduced using citrate-bicarbonate (C-B)-buffered sodium dithionite at 70°C for 4 h (Su *et al.*, 2012). (The C-B solution was prepared by combining 1.0 M sodium bicarbonate and 0.9 M sodium citrate dihydrate at a v/v ratio of 24:1.) Materials prepared in this way were reacted with sodium nitrate solution and the resulting solutions were analyzed for nitrate, nitrite, and ammonium, and the structural Fe(II) content was measured, all using the methods of Su *et al.*

(2012). These oxygen-sensitive samples were handled or stored under an oxygen-free environment as described in detail by Pentrák *et al.* (2013) and Stucki *et al.* (2014).

Preparation of CSC. A 1 g portion of the freeze-dried Na-SWa-1 was added to a 50 mL polycarbonate centrifuge tube (septum-sealable reaction tube described by Pentrák *et al.*, 2013; and Stucki *et al.*, 2014) and dispersed in 200 mL of deionized water (DI) (18 MOhm-cm resistivity) water to make a 5 g/L dispersion. A 3 g/L chitosan stock solution was prepared by dissolving 0.75 g of chitosan powder in 250 mL of 2% v/v acetic acid (Bleiman and Mishael, 2010). Aliquots from the chitosan stock solution were then combined with a sample of the smectite dispersion to achieve chitosan loadings of 0, 0.075, 0.25, 0.5, or 1.0 g/L. The chitosan solution was acidic with a pH of ~3 and the resulting composites in solution were also slightly acidic ranging from 5.8 (least chitosan loading) to 4 (highest chitosan loading), and the amino groups remained protonated (Bleiman and Mishael, 2010). Each of these mixtures was shaken for 2 h to achieve maximum dispersion, centrifuged, and the supernatant discarded (Table 1). The remaining solids were labeled C0, C1, C2, C3, and C4, respectively.

Characterization of CSC. The composites prepared were characterized by zeta (ζ) potential measurements, X-ray diffraction (XRD) analysis, and Fourier-transform infrared spectroscopy (FTIR). The ζ potential and XRD methods were described by Zadaka *et al.* (2010) and Su *et al.* (2012), respectively. The FTIR spectra in the middle infrared (MIR) region (4000–400 cm⁻¹) and in the near infrared (NIR) region (12000–4000 cm⁻¹) were recorded in transmission and reflectance modes, respectively, using a Nicolet 6700 FTIR spectrometer from Thermo-Fisher Scientific (Madison, Wisconsin, USA). For the MIR region, 128 scans and a DTGS detector were used to analyze samples prepared as KBr pellets (1 mg of the sample powder, 200 mg KBr) pressed up to 670 MPa and heated overnight at 150°C to minimize water content in the sample and KBr. For the NIR region, sample powders were placed directly in the cup of a Smart Diffuse Reflectance Accessory. The raw spectra of both regions were processed using the Thermo Scientific OMNICTM software package.

Chemical reduction of structural Fe in CSC. The centrifuged CSC solid was re-suspended in 20 mL of DI water and then 10 mL of the C-B buffer was added. The reaction tube was closed using the septum cap, preheated in a water bath to 70°C, and held for 1 h, all while purging with O₂-free Ar (Su *et al.*, 2012). The septum cap was removed, 200 mg of sodium dithionite powder was added, the cap was reinstalled, and the O₂-free Ar purge was re-established. After 4 h at 70°C, the reaction mixture was removed from the bath and allowed to cool for 1 h. The cooled mixture was disconnected

Table 1. Chitosan adsorption, ζ potential, and *d* spacing of chitosan-adsorbed/exchanged smectite composites (CSC); amount of nitrate taken up by oxidized and reduced CSC; and amount of nitrite created and Fe(II) reoxidized in reduced CSC.

from the purge gas and centrifuged at $5000 \times g$ for 15 min. Using a controlled-atmosphere liquid exchanger (CALE) (Pentrák *et al.*, 2013; Stucki *et al.*, 2014), the reduced CSC was washed once with deoxygenated 1 M NaCl and three times with deoxygenated 0.005 M NaCl.

Nitrate reaction with oxidized and reduced CSC. The reaction tube with washed and centrifuged CSC was weighed before and after the addition of ~ 30 mL of 0.001 M NaNO_3 ; the precise mass of nitrate added to the CSC was then calculated from the weight of solution added by assuming a liquid density of 1.00 g/cm^3 . The CSC was re-suspended into the solution by vortex mixing and allowed to react with the NaNO_3 while shaking overnight. The reacted mixture was centrifuged and the supernatant (reacted solution) decanted into an empty, septum-sealed reaction tube under an O_2 -free Ar atmosphere, using the CALE apparatus, and stored in the glove box under an Ar atmosphere until analyzed for N speciation (see below). The reaction tube containing the CSC was also stored in the glove box until analyzed for the Fe(II)/total Fe ratio (see below).

Nitrogen and Fe oxidation-state analysis. The supernatant from the CSC- NaNO_3 reaction mixture was analyzed by the accelerated diffusion method of Khan *et al.* (1997) and Mulvaney *et al.* (1997), as adapted by Su *et al.* (2012), to determine $\text{NH}_4^+\text{-N}$, $\text{NO}_3^-\text{-N}$, and $(\text{NO}_3^- + \text{NO}_2^-)\text{-N}$. The amount of structural Fe(II) in the CSC that was reoxidized to Fe(III) by the nitrate was also measured by submitting the reacted gel to the 1,10-phenanthroline/UV-Vis method (Komadel and Stucki, 1988). Fe(II):total Fe ratios were also confirmed by Mössbauer spectroscopy at 77 K using a Webb Research, Inc. (Edina, Minnesota, USA) spectrometer equipped with a Janis Model SHE-850-5 closed-cycle cryostat and operating in triangular waveform mode with a ^{57}Co source. Spectra were calibrated with respect to a $7 \mu\text{m}$ $\alpha\text{-Fe}$ foil.

RESULTS AND DISCUSSION

Characterization of CSC

ζ potential. The ζ potential or effective surface charge of the smectite became increasingly more positive compared to CSC sample C0 as the loading of the chitosan polymer increased (Figure 2) in the sample order $\text{C1} < \text{C2} < \text{C3} < \text{C4}$; loadings of 0.25 g/g and above (samples C2 to C4) produced a net positive charge overall. The attractive force for nitrate adsorption or exchange increased in all cases, in the same sample order.

The ζ potential of the Na-SWa-1 with no chitosan added (sample C0) was -38.82 mV and with the highest chitosan loading (sample C4) was $+72.94 \text{ mV}$ (Table 1), which represents an overall change in surface charge of $+111.76 \text{ mV}$. A similar trend was observed in the previous study (Su *et al.*, 2012) in which PDADMAC

was the polycation and the change in surface charge was $+95.82 \text{ mV}$. The effect of chitosan on the surface charge was, thus, comparable with PDACMAC. This trend not only follows the extent of chitosan loading, but also the extent of chitosan adsorption on the clay surface, which reached a maximum of 0.195 g/g of smectite (Figure 2).

X-ray diffraction

Chitosan intercalation into the clay mineral was characterized by means of XRD measurements (Table 1). A sharp (step-function) increase in d spacing was observed with the adsorption of 0.14 g polymer/g clay and remained constant up to a loading of 0.195 g polymer/g clay ($\text{C0} \approx \text{C1} \ll \text{C2} = \text{C3} \approx \text{C4}$). The basal d spacing in montmorillonite (Mnt) (with one layer of entrapped water molecules) is known to be $\sim 1.25 \text{ nm}$ (Usuki *et al.*, 1993; Darder *et al.*, 2005; Radian and Mishael, 2008); with polymer loading this increased to $\sim 1.8 \text{ nm}$, indicating intercalation between the clay layers (Figure 3). Previous experiments have shown that basal spacing of chitosan in SWy-2 increased in two steps; at low loading to 1.46 nm (corresponding to one polymer chain entering the layers) and at higher loading to 2.18 nm (corresponding to two polymer chains entering the layers) (Darder *et al.*, 2005; Bleiman and Mishael, 2010). In the present case, only one significant increase was observed, which may indicate that only one polymer layer intercalates (perhaps hydrated due to the larger d spacing) within the SWa-1. This means that partial exfoliation does not occur and surface area may not increase significantly.

Fourier transform infrared spectroscopy (FTIR)

MIR region. The XRD results were confirmed by FTIR spectroscopy. The MIR spectrum (Figure 4) of sample C0 (Na-SWa-1) contained the typical stretching (ν) and bending (δ) vibrations of OH and Si-O groups common for Fe-bearing smectites, as well as OH vibrations of

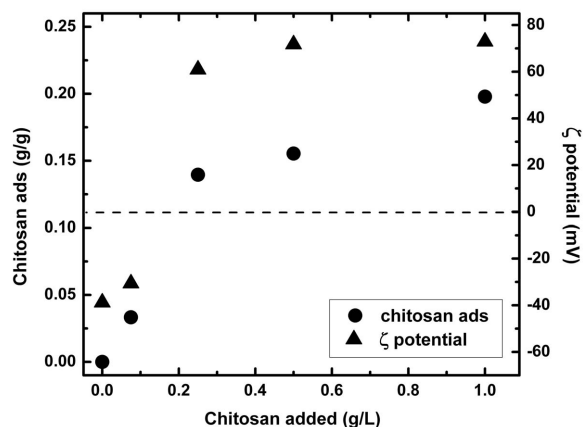

Figure 2. Effect of chitosan loading on its adsorption (ads) to CSC and the resulting ζ potential.

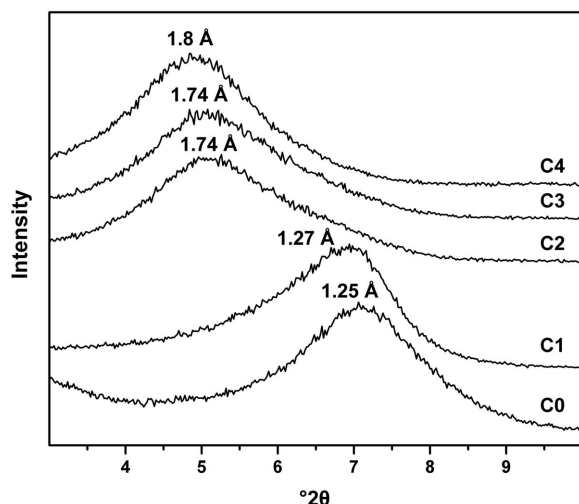

Figure 3. Oriented XRD patterns of Na-SWa-1 (C0) and CSC samples (C1, C2, C3, and C4).

water molecules adsorbed on the smectite surface and water associated with exchangeable cations in the interlayer space (Farmer, 1974; Yan and Stucki, 2000; Madejová and Komadel, 2001; Bishop *et al.*, 2002; Frost *et al.*, 2002; Madejová, 2003). Because the KBr pellets were heated overnight, the water content was somewhat attenuated (Pentrák *et al.*, 2012). The intensities of both water bands (at ~ 3400 and ~ 1630 cm^{-1}) depend critically on the surrounding atmosphere (Yan *et al.*, 1996; Brtáňová *et al.*, 2012; Pentrák *et al.*, 2012) or on the type of intercalated organic or inorganic material

(Czímerová *et al.*, 2004; Pálková *et al.*, 2009; Madejová *et al.*, 2011; Brtáňová *et al.*, 2012, 2014).

Vibrational modes from functional groups of the chitosan included: a broadened band near 3350 cm^{-1} (Figure 4), attributed to OH and NH stretching vibrations; aliphatic C-H stretching bands at 2923 cm^{-1} and 2883 cm^{-1} (Madejová *et al.*, 2009b, 2011); carbonyl stretching modes of secondary amides at 1654 cm^{-1} ; and bending modes of the amide (N-H) group near 1597 cm^{-1} (Brugnerotto *et al.*, 2001). A group of bending vibrations of C-H associated with amide and C-C skeletal groups were clearly recognizable in the chitosan spectrum at 1419 cm^{-1} and 1380 cm^{-1} , respectively (Figure 4). Further, the stretching vibrations at 1320 cm^{-1} , 1071 cm^{-1} , and 1030 cm^{-1} belong to coupled $\nu(\text{C-O-N})$ and $\nu(\text{C-O})$ modes, and the bands at 1321 cm^{-1} and 1261 cm^{-1} represent symmetric stretching vibrations of CH_3 groups of tertiary amide and $\nu(\text{C-O-H})$, respectively (Paulino *et al.*, 2006; Abugoch *et al.*, 2011). Bonds associated with the glycosidic ring provided two sharp bands at 1153 cm^{-1} and 896 cm^{-1} (Mucha and Pawlak, 2002).

The FTIR patterns for CSC samples C1–C4 clearly are combinations of the spectra for the unaltered SWa-1 and the pure chitosan. These results offer clear evidence of chitosan adsorption to and/or exchange in the smectite, supported by the changes in XRD d spacings described above, which indicated the insertion of chitosan into the interlayer space (Table 1). The spectrum for sample C1 was only slightly affected by the presence of chitosan due to the very small amount of

Figure 4. MIR spectra of Na-SWa-1 (C0), CSC samples (C1, C2, C3, and C4), and chitosan alone.

chitosan (0.032 g/g of clay; Table 1). Bands arising from chitosan were much more prominent in the spectra of samples C2 (0.138 g chitosan/g of clay), C3 (0.153 g chitosan/g of clay), and C4 (0.195 g chitosan/g of clay), which increased in intensity as the amount of chitosan loading increased. This conclusion was further supported by broadened bands at 3406 cm^{-1} and 3258 cm^{-1} , resulting from the coupled OH stretching vibrations of chitosan and water molecules. Not surprisingly, CH_2 stretching vibrations occurred in the 3000 cm^{-1} – 2800 cm^{-1} region (Madejová *et al.*, 2009b, 2011; Pálková *et al.*, 2011) and CH_2 bending vibrations near 1320 cm^{-1} attributed to the pyranose ring of the chitosan structure (Pawlak and Mucha, 2003). Another piece of evidence for the presence of chitosan in the CSC arises from the intense and broadened band at 1633 cm^{-1} , which includes, in addition to the bending mode of water molecules, vibrations from carbonyl ($\sim 1700\text{ cm}^{-1}$) and C=O in amide ($\sim 1660\text{ cm}^{-1}$), respectively (Osman and Arof, 2003). Bending modes from -NH- amide and - NH_2 amine groups were observed near 1516 cm^{-1} , while bending modes from OH and CH in the ring had maxima at 1415 cm^{-1} , 1305 cm^{-1} , and 1338 cm^{-1} (CH_3 in amide group) (Paulino *et al.*, 2006). On the other hand, a prominent shoulder appeared in the 1200 cm^{-1} – 1050 cm^{-1} region due to -C-O-C- vibrations in glycosidic linkages (Madejová *et al.*, 2009b; Bleiman and Mishael, 2010; Kumirska *et al.*, 2010; Su *et al.*, 2012). The rising chitosan content was also marked by the reversal of the relative peak intensity ratio of the

deformation bands for Fe-O-Si and Si-O-Si at 461 cm^{-1} and 429 cm^{-1} , respectively.

NIR region. The NIR spectrum of sample C0 contained overtones and combination vibrations of OH groups. A complex band at 7062 cm^{-1} was composed of the first overtone of the smectite structural OH groups ($2\nu\text{OH}$) and the first overtone of the stretching vibrations of water molecules (Figure 5, C0). The combination vibrations of AlFeOH and FeFeOH were found at 4468 cm^{-1} and 4366 cm^{-1} , respectively (Madejová *et al.*, 2009a).

The rising chitosan content in the samples from C0 to C4 (Figure 5) was reflected in the NIR spectra with a similar trend to that observed in the MIR region (Figure 4). In the OH overtone region, chitosan OH groups influenced the final shape and position of the OH bands, which caused a small shift from 7062 cm^{-1} (Figure 5, C0) to 7040 cm^{-1} (Figure 5, C4). The intensity of these OH bands decreased in the order $\text{C0} > \text{C1} > \text{C2} > \text{C3} > \text{C4}$, indicating a lower degree of hydration as the chitosan content increased. Lower hydration was also reflected in the considerable loss of intensity in the band at 5248 cm^{-1} (combination vibration of water molecules ($\nu + \delta_{\text{H}_2\text{O}}$)). A slight shift of this band to 5235 cm^{-1} also indicated a weakening in the bonding of water molecules to the composite structures. This occurrence could be explained as a weakening in the strength of H-bonds between water molecules and the basal oxygen atoms and the exchanged Na^+ cations as the polymer content in the composites increased (Xue *et al.*, 2007; Madejová *et al.*,

Figure 5. NIR spectra of Na-SWa-1 (C0), CSC samples (C1, C2, C3, and C4), and chitosan alone.

2011). The presence of a slight progressive growth of combination bands from the NH and CH groups of chitosan in the 5000 cm^{-1} to 4600 cm^{-1} and in the 4500 cm^{-1} to 4000 cm^{-1} regions (Madejová *et al.*, 2009b, 2011) was also further evidence for increasing chitosan content in the composites (Figure 5).

Oxidized CSC reaction with NO_3^-

The extent and type (adsorption vs. redox) of reaction between nitrate and oxidized CSC samples were measured by monitoring the amount of nitrate, nitrite, and ammonium in solution after completion of the reaction. Neither ammonium nor nitrite was detected. The amount of nitrate removed from solution by the oxidized CSC increased with increasing loading of chitosan into the smectite (Figure 6), as would be expected due to the increasingly more positive ζ potential. The amounts ranged from 0 in sample C0 to 0.5 mmol/g in sample C4 (Table 1). All of the nitrate lost from solution in this case was assumed to be adsorbed to the CSC because no redox reaction was possible between structural Fe(III) and NO_3^- . This outcome was consistent with the earlier finding of Su *et al.* (2012) using a different polycation (PDADMAC) for charge reversal. In that study, nitrate attraction to the surface also increased with polycation loading.

Sample C1 presented an interesting phenomenon. In spite of having a negative ζ potential of -30.6 mV , nitrate was still attracted to it. The reason for this must be because, even though the entire negative charge on the smectite had not been neutralized by the chitosan, apparently a sufficient number of positively charged sites had been established to screen some of the nitrate from the negatively charged surfaces. The d spacing (1.27 nm) of sample C1 confirmed that a small amount of chitosan polymer was probably intercalated into the interlayer space of the smectite (Figure 3, Table 1).

Figure 6. Nitrate (1.0 mM NaNO_3) removal from solution by reaction with oxidized CSC samples (C1, C2, C3, and C4).

Reduced CSC reaction with NO_3^-

Nitrate removal from solution. When nitrate was reacted with reduced CSC, the amount of nitrate removed from solution (Figure 7) was extensive and followed the same trend with increasing chitosan loading as observed in the oxidized samples (Figure 6, Table 1). While the ζ potential of the reduced samples was not measured, the fact that nitrate was attracted to them (those with adsorbed polycation) is *prima facie* evidence that the charge was indeed reversed by the chitosan to levels that approximated those observed in the oxidized samples. No measurable reaction or adsorption was observed between nitrate and reduced sample C0.

These observations are consistent with the nitrate-removal results of Su *et al.* (2012) using PSC (Figure 7). The extent of nitrate removal in that study, however, was about half as much as observed in the present study, indicating that chitosan creates a more attractive environment for nitrate removal than does PDADMAC. This is in agreement with the unique anion exchange characteristics of smectite-chitosan composites reported previously (Darder *et al.*, 2005; Bleiman and Mishael, 2010).

Nitrate reduction and Fe(II) oxidation. Not only was nitrate removed, but the presence of structural Fe(II) in the reduced CSC samples created the possibility that nitrate could be reduced. Solutions were, therefore, analyzed for nitrite and ammonium (two reduction products of nitrate). While no ammonium was detected in the solutions, nitrite was found in all reduced CSC samples except C0 (Figure 8). As in the case with oxidized C0, the reduced C0 had no polycation present to reverse the charge and, thereby, attract nitrate and reduce it.

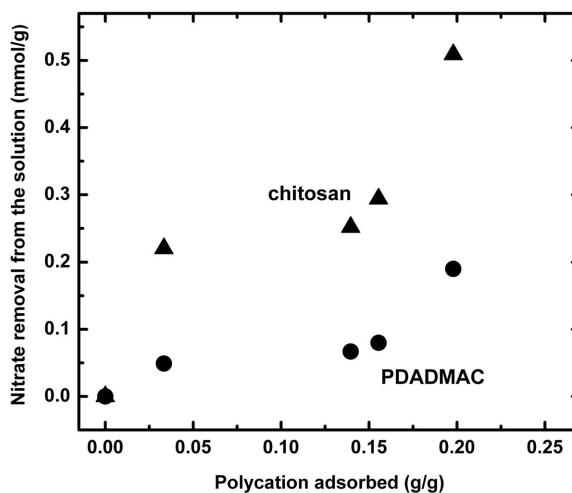

Figure 7. Nitrate (1.0 mM NaNO_3) removal from solution by reaction with reduced CSC (C1, C2, C3, and C4), compared with results from Su *et al.* (2012) for the polycation PDADMAC-SWa-1 composites (PSC) in the reduced state.

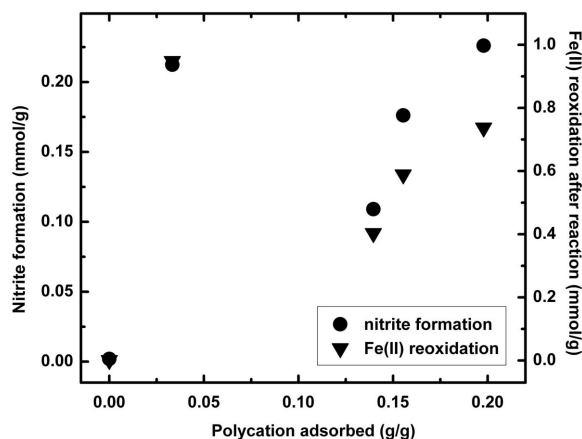

Figure 8. Nitrite formation and Fe(II) reoxidation as a function of chitosan adsorbed in the CSC samples after reaction with 1.0 mM NaNO_3 solution.

The nitrite clearly arose through the chemical reduction of nitrate by structural Fe(II) (equation 2). This is abundantly evident by plotting the amount of Fe(II) reoxidized *vs.* the amount of nitrite formed. The two measurements followed each other step by step (Figure 8). In fact, a near-linear correlation was observed (Figure 9), consistent with the hypothesis that a redox reaction between nitrate and structural Fe had occurred to produce nitrite. A plot of the amount of nitrite in solution *vs.* nitrate adsorbed/exchanged (Figure 10) revealed that $\sim 95\%$ of the nitrate was reduced to nitrite and released to solution at low loadings, whereas at greater loadings the percentage was closer to 50%.

The slope of the correlation in Figure 9 revealed that the stoichiometry of the reaction was ~ 4 moles of Fe(II) oxidized for each mole of nitrite formed. Equation 2 predicts that the relationship should be 2:1 instead of 4:1, so the nitrite found in solution does not account for

Figure 9. Nitrite formation as a function of Fe(II) oxidation in reduced CSC.

all of the Fe(II) that was oxidized. No definitive explanation for this seemingly anomalous result was found, but several possibilities were considered.

(1) Perhaps more nitrite was formed than was measured in solution, with the remainder being retained as an adsorbed or exchanged anion on the CSC complex. This explanation is a possibility in samples C2 to C4, but sample C1 does not fit within that hypothesis because almost all of the nitrate adsorbed was found in the form of nitrite in solution (Figure 10); yet, twice as much Fe(II) was reoxidized than was expected. In the other reduced CSC samples, the solid phase contained abundant sites for anion exchange and adsorption, and would have had the ability to capture some of the nitrite. In fact, adsorbed/exchanged nitrate may have become reduced in place and the nitrite product held in that same site. Then, if an exchange equilibrium occurred for the nitrite between the solution and solid phases, the amount observed in solution would clearly have been only the fraction determined by the equilibrium constant (which has yet to be well explained). These arguments for CSC samples C2 to C4 are not persuasive, however, because such a phenomenon would have increased the observed stoichiometry above 4:1 (*i.e.* less nitrite being measured in solution than was actually produced), but it remained about the same at 4:1 (Figure 9, Table 1).

(2) Other undetected reduction products may have formed. Among these are ammonium, which, even though not found in solution, could have been retained in the solid phase as an exchanged cation on any exposed smectite surface. Other gaseous reduction products (N_2 , N_2O , NO) may have been produced, but no attempt was made to capture gaseous products for analysis. Again, CSC sample C1 seems to be inconsistent with this explanation because the amount of nitrite measured accounted for 95% of the nitrate lost from solution. In

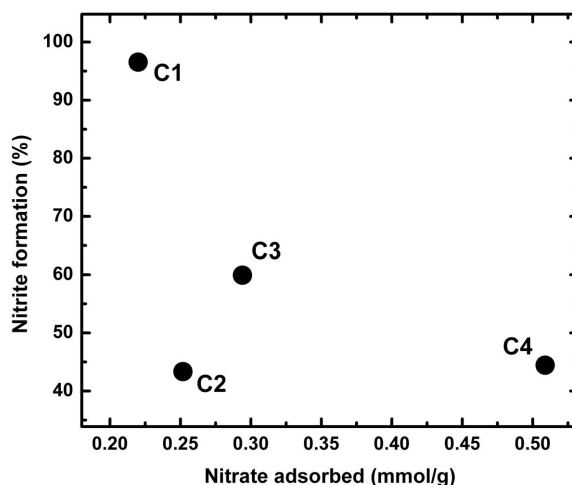

Figure 10. Nitrite in solution (as % of nitrate adsorbed) as a function of nitrate adsorbed in reduced CSC samples.

this particular case, the nitrate may have never actually completed the adsorption process before being reduced by the structural Fe(II).

(3) Some reoxidation may have occurred during sample handling due to atmospheric oxygen contamination or some other unidentified oxidant. While this is also a possibility, two factors argue against it. First, a study by Stucki *et al.* (2014) demonstrated that <2% of the total Fe(II) becomes reoxidized during the handling procedures, and the amount in question here is as much as 15% (0.5 mmol/g). This could not account for the 4:1 vs. 2:1 difference in Fe:N stoichiometry. Second, one would not expect such oxygen contamination to be so well controlled or so consistent as to preserve the stoichiometric ratio at ~4:1. Nevertheless, this possibility is not ruled out.

(4) Another possible explanation is that the reaction is more complex than indicated by equation 2, and involves a three- or four-electron reduction mechanism. Future studies will probe this question more completely, with a view to understanding better the discrepancy in stoichiometry.

Bimodal behavior in reduced CSC. The behavior of reduced CSC sample C1 did not fit the same relationship as the other reduced samples, as already mentioned. This is clearly seen in Figures 8–10. The reduced C1 sample contained the smallest amount of chitosan among the four polycation-treated samples, but its nitrite yield (0.212 mmol/g CSC) and extent of Fe(II) reoxidation (0.936 mmol/g) were approximately the same as in sample C4, that with the largest amount of chitosan (Figure 8, Table 1). The amount of nitrite formed decreased abruptly between samples C1 and C2, then built back up as the polycation loading increased, until in sample C4 it returned to about the same level as in sample C1.

In the relationship between nitrite in solution and the amount of Fe(II) reoxidized (Figure 9), sample C1, in spite of being the least loaded with polycation, plotted very near to sample C4. It also was the most efficient sample for reducing nitrate to nitrite, as indicated by >95% of the nitrate lost from solution being converted to nitrite (Figure 10).

This behavior is probably the consequence of the manner in which chitosan interacts with the smectite surfaces and the electron transfer pathway from structural Fe to the nitrate. This trend was also observed in the case of PDADMAC (Su *et al.*, 2012), and explained in terms of polymer coverage: at low polycation loadings, nitrate adsorption is somewhat promoted by the adsorbed polycation; the low loadings enable optimal electron transfer from uncovered clay surfaces to the adsorbed nitrate, however.

Working hypothesis for the reduction process. The following working hypothesis for the nitrate reduction

process was developed (see Figure 11). At low chitosan levels (0.075 g/L), the surface of the smectite is populated with islands of polycation monolayers (Figure 11,C1). Nitrate anions are attracted toward these islands and, due to their proximity to the smectite surface as they approach the islands, react with structural Fe(II) to produce nitrite, perhaps with adsorption being only a transient state. The nitrite is then released back into the surrounding solution according to its equilibrium constant.

As loading levels increase, the polycation forms clusters and/or multi-layer stacks that cover the physical surface more completely, and create more adsorption sites for nitrate from solution (Figure 11,C2). Most of these sites, however, are further from the basal surfaces than at the lower-loading level and are, thus, more shielded from the redox activity at the physical surface and less susceptible to reaction with structural Fe(II) in the clay layer. In this case, electron transfer also depends more strongly on diffusion or shuttling through the polycation. The complex becomes more heavily populated with adsorbed nitrate anions, and only some of them become reduced. The others remain adsorbed.

The XRD results are also consistent with this hypothesis, which showed that the layers were only partially expanded at low loadings, giving a *d* spacing of 1.27 nm; whereas at high loadings the *d* spacing increased to 1.75–1.80 nm, which is consistent with multi-layering of the polycation within the interlayer region (Figure 3, Table 1).

The size and complexity of the polycations introduce uncertainties as to their exact location and total

Figure 11. A schematic diagram of the redox reaction mechanism of nitrate reduction and nitrite generation in the presence of PSC.

compensating charge. Their presence solely between the superimposed smectite layers has not been confirmed and, in fact, their existence on edge and outer particle surfaces also are indeed probable. Further investigations are needed to confirm a clear description of the polycation configuration and the pathway for electron transfer from structural Fe(II) to nitrate in solution.

SUMMARY AND CONCLUSIONS

Results from this study provide clear evidence that the combination of charge reversal and structural Fe reduction activates smectite surfaces towards nitrate reduction. The linear polysaccharide poly-(D) glucosamine (chitosan) with an acidic pH of ~3 effectively increases the positive charge of the smectite surface, and the resulting composites in solution were also slightly acidic ranging from 5.8 (C1) to 4 (C4). Upon addition of the nitrate solution, the pH remained slightly acidic ranging from 5.5 to 4.7. The chemically reduced chitosan-smectite composite (CSC) is also highly active toward nitrate reduction, giving a stoichiometry of four moles of Fe(II) oxidized for each mole of nitrate reduced rather than the expected value of 2:1. No conclusive explanation is given for this difference, but further research is needed to understand better the complexities of the redox reaction mechanism and the configuration of the polycation on the clay surfaces. The reductive capacity of the reduced CSC is not linear with chitosan loading, but is high at low loading, drops abruptly, then builds back up as the loading increases. Future studies should pursue the optimum surface coverage by the polycations. These results indicate that clay minerals can be utilized to promote redox reactions with anionic redox-active species as well as those that are cationic.

ACKNOWLEDGMENTS
