The studied zircons were subdivided into three groups. The group 1 (almost 70% of studied grains) includes euhedral grains with thin oscillatory zoning, group 2 (25% of population) consists of euhedral grains with low fluorescent cores surrounded by oscillatory zoned rims, and group 3 (5% of population) contains almost unzoned rounded low fluorescent grains. The groups 1 and 2 show week compositional zoning with slight decreasing of REE concentration towards the rim. They include the following minerals shown in the order of decreasing frequency: apatite, sphene, feldspars, crystalized melt, ilmenite and quartz. They possess relatively high Th/U ratios (0.3-2), are enriched in HREE and are similar to zircons of magmatic origin [2, 3]. Group 3 zircons have low Th/U ratios (0.05-0.25), are markedly depleted in HREE suggesting equilibrium with garnet and are likely of metamorphic origin.

We conclude that zircons of group 1 and 2 were likely crystallized *in situ* in basaltic flows and are good candidates for absolute dating.

Weathering and pore water evolution in the foreland of retreating glacier, SW Spitsbergen

M. KWAŚNIAK-KOMINEK, M. MANECKI, G. RZEPA AND J. CZERNY

AGH University of Science and Technology, al.Mickiewicza 30, 30-059 Cracow, Poland (*correspondence: monika.kwasniak@gmail.com)

Chemical weathering and soil forming processes which are associated with retreating glaciers contribute to high chemical denudation observed in polar regions. Retreating glaciers uncover fresh regolith, initial evolution of which may be dominated by few simple processes. The area of this study is the foreland of Werenskiold glacier near SW coast of Spitsbergen. This glacier has been countinuously retreating during the last century by several meters a year [1]. The objective of this study is correlation between the chemistry of pore waters and the mechanisms of alternation or dissolution of minerals present in regolith with respect to the distance from the glacier front (age of exposure). This is a part of large research effort on weathering, soil formation and initial microbiological activity on a foreland of Arctic glacier initiated with the International Polar Year in 2007.

Werenskiold glacier basin is eroded in metamorphic rocks which belong to Precambrian Hecla Hoek Succession. These are mostly carbonates, quartzites, phyllites, shists, greenshists and amphibolites [2]. In accordance with other studies, the carbonate dissolution dominates in the youngest glacial sediments while silicate weathering is relatively significant in the oldest sediments. The composition of water can be explained mostly by dissolution/crystallization accompanied with redox reactions. Alterations of minerals identified with optical microscopy, XRD and SEM-EDS include dissolution of carbonates and oxidation of pyrite accompanied with formation of clays. Systematic changes between water samples correlate with distance from the glacier front (with the age of soils): e.g. the pH decreases from 8, 6 to 7, 7 while TDS increases from 133 to 748 mg/L. Inverse modeling with PHREEQC was used to propose the mechanisms of mineral transformation. The waters evolve from carbonate-dominated to sulfate-dominated. This might indicate that with time, pore waters reach the equilibrium with carbonate minerals while being countinuously supplied with SO_4^{2-} from sulfides oxidation.

The research is supported by MNiSW grant N N307 473638.

Roles of sulfate and Fe^{III} reduction on microbial community development

M.J. KWON[1,2], M.I. BOYANOV[1], D. ANTONOPOULOS[1], J. BRULC[1], K. KEMNER[1] AND E.J. O'LOUGHLIN[1]

[1]Biosciences Division, Argonne National Laboratory, Lemont, IL 60439 USA (mankwon73@gmail.com)

[2]Korea Institute of Science and Technology (KIST) – Gangneung Institute, Gangneung 210-340 S. Korea

To better understand the roles of sulfate- and/or iron-reduction on microbial community development, bicarbonate-buffered batch systems were created with acetate or lactate as the electron donor. Added electron acceptors included 2-line ferrihydrite, goethite, or lepidocrocite, in the presence or absence of sulfate. The batch systems were inoculated with the native microbial community present in a subsurface sediment. The rate of Fe^{III} reduction was low in the absence of sulfate. However, the rate and extent of Fe^{III} reduction increased more than 10 times with 10 mM sulfate. Sulfate reduction occurred concurrently with Fe^{III} reduction suggesting abiotic Fe^{III} reduction by sulfide. X-ray absorption fine-structure (XAFS) analysis confirmed the formation of ferrous sulfide as the major secondary mineral phase in these incubations. The rates of sulfate and Fe^{III} reduction were significantly faster with lactate than with acetate. Lactate promoted both sulfate and Fe^{III} reduction in all incubations, while acetate stimulated sulfate and Fe^{III} reduction only in ferrihydrite and goethite incubations. Acetate oxidation was coupled with sulfate and Fe^{III} reduction; however, lactate was rapidly fermented to acetate and propionate, followed by propionate oxidation coupled with sulfate reduction. Terminal Restriction Fragment Length Polymorphism (T-RFLP) yielded unique microbial community profiles. The presence of sulfate resulted in distinct community development likely due to the proliferation of acetate- or propionate-utilizing, sulfate-reducing bacteria. During the experiment, the community in lepidocrocite incubations evolved in a very different way compared to those in the other Fe^{III} (hydr)oxide incubations indicating that the nature of the Fe^{III} (hydr)oxide can affect microbial community development. However, after the complete consumption of sulfate the microbial community compositions in all incubations (except lepidocrocite plus acetate incubation) were similar to each other. These results show that the availability of sulfate, the type of Fe^{III} (hydr)oxide present, and the added electron donor can have a strong effect on the development of subsurface microbial communities.

Deciphering the evolution of continental crust: Insights through Laser Ablation Split-Stream (LASS) petrochronology

ANDREW R.C. KYLANDER-CLARK* AND BRADLEY R HACKER

University of California, Santa Barbara, 93106-9630 (*correspondence: kylander@geol.ucsb.edu)

One of the biggest challenges in the determination of the timing and rates of continental subduction is tying the age of a particular mineral to the conditions (i.e. pressure, temperature, fluid composition) at which that phase grew. Recent advances in microbeam techniques have greatly increased our understanding of crustal evolution by enabling this linkage. The most common target for U-Th-Pb petrochonology is zircon: its REE pattern reveals the coexistence of garnet (depleted HREE) and plagioclase (positive Eu/Eu*) and cathodoluminescence imaging can be used to link the ages and trace-element concentrations of spot analyses. The age of monazite can also be linked to certain conditions: most commonly, yttrium zoning is used a proxy for growth in the presence or absence of garnet.

Here we present a more accurate, comprehensive, and simplified procedure to obtain petrochronologic data and thus assess the P–T–t conditions of any individual spot analysis. The LASS—laser ablation split-stream—technique consists of concurrent analyses of single laser ablation spots on both a multi-collector (U-Th-Pb age) and single-collector (trace-element data) ICP-MS. LASS allows both rapid (<1 minute/spot analysis) and high-precision (<1%/age population) measurements and an unambiguous link between mineral age and (re)crystallization conditions.

The Western Gneiss Region of western Norway provides the perfect natural laboratory to exemplify the advantages of LASS petrochronology. Zircons from a garnet-bearing gneisses show >20 Myr of (re)crystallization, however, REE data show that these zircons grew under three distinct conditions: 1) garnet-poor prograde growth at 425.8 ± 4.6 Ma, 2) garnet-rich peak growth at 406.9 ± 5.7 Ma, and 3) garnet-breakdown retrograde growth at ~400 Ma. Without LASS, making this distinction would be nearly impossible. Monazite can also reveal complex age/element zoning; monazite analyzed from a meta-pelite yield high-Nd cores of 413.6 ± 3.9 Ma, Low-Nd mantles of 401.1 ± 4.4 Ma, and high-Y, low-Sr rims of 393.5 ± 3.4 Ma.

REE mineralization of high grade REE-Ba-Sr and REE-Mo deposits in Mongolia and China

J. KYNICKY[1]*, XU. CHENG[2], A.R. CHAKHMOURADIAN[3], E. REGUIR[3], H. CIHLÁŘOVÁ[1] AND M. BRTNICKÝ[1]

[1]Mendel University in Brno, 613 00 Brno, Czech Republic (*correspondence: jindrich.kynicky@mendelu.cz)
[2]Peking University, Beijing 100871, China (*correspondence: xucheng1999@hotmail.com)
[3]University of Manitoba, Winnipeg, Manitoba, Canada (*correspondence: chakhmou@cc.umanitoba.ca)

The exact causes and mechanisms responsible for the uniquely high levels of REE in carbonatites relative to any other igneous rock remain debated. To investigate these mechanisms, a large suite of REE-bearing carbonatites from Mongolia (Mushgai Khudag, Lugiin Gol, Omnot Olgii, Khurimt Khad Tolgod) and China (Daluxiang, Maoniuping, Huanglongpu, Huayangchuan, Bayan Obo) was examined.

All carbonatites are predominantly composed of medium- to coarse-grained calcite (60-90%). Accessory non-carbonate phases include mainly apatite, alkali feldspars, fluorite, phlogopite, sulphates and sulphides. The principal REE hosts are fluorocarbonates (<20 vol. %) and monazite (<5 vol. %).

Fluorocarbonates occur as complex intergrowths of bastnäsite with parasite or synchysite. Bastnäsite-(Ce), synchysite- (Ce) and monazite-(Ce) also rarely occur as discrete crystals. There is a structurally controlled compositional variation among the major REE minerals, but carbonatites from different deposits feature almost identical REE-HFSE mineralization patterns.

Chondrite-normalized whole-rock REE profiles exhibit a steep negative slope and lack detectable anomalies. The REE minerals show consistent enrichment in light REE [$(La/Nd)_n$=1.0–3.4]. In this respect, the carbonatite-hosted REE mineralization differs from that in the world's largest REE deposit at Bayan Obo, where the $(La/Nd)_n$ ratios are more variable and generally lower. The REE distribution patterns of individual REE minerals are similar, with the exception of Huanglongpu and Huayangchuan, where REE mineralization is associated with Mo and Mo-Th mineralization. At these two localities, whole-rock and mineral-specific REE patterns are broadly similar, but the latter show some enrichment in heavy REE.

We propose a similar mineralogical model for all investigated deposits with the exception of Bayan Obo. The high-grade carbonate-hosted REE deposits at Daluxiang and Maoniuping are nearly exhausted, but the little-explored Huanglongpu-Huayangchuan cluster has a definite potential as a viable REE resource of the future. Small- to medium-sized deposits in southern Mongolia may also have some economic value owing to their overall high grade (7-15 wt. % REE_2O_3) and a healthy global REE market.

Origin of the seamounts near Futuna Island, SW Pacific

S. LABANIEH[1], G. CHAZOT[1], J. ETOUBLEAU[2], Y. FOUQUET[2], L. DOSSO[1] AND C. HEMOND[1]

[1]IUEM, UBO, Brest, France
[2]IFREMER, Brest, France

Futuna Island, located in the SW pacific, is bordered by the North Fiji fracture zone, the active Tonga and Vanuatu subduction zones and associated Lau and North-Fiji back-arc basins, and the currently active Samoan hotspot. A cruise was conducted in August 2010 with the aim to map and sample the oceanic basement near Futuna Island. Bathymetric mapping reveals complex seafloor morphology with multiple areas of numerous seamounts and several very large and isolated caldeiras.

We measured major and trace elements and Pb isotopic ratios on samples collected from dredges or Nautile dives. Lavas collected on the seamount province range from sub-alkaline basalts to trachy-andesites, with SiO_2 content ranging from 45.6 to 60.1 wt%. Lavas exhibit variable La/Yb ratios that define a spatial gradient: north-western lavas are enriched in Light Rare Earth Elements (LREE) compared to Heavy Rare Earth Element (HREE) (La/Yb from 2.2 to 9.9) while south-eastern lavas are depleted in LREE (La/Yb from 0.74 to 1.1). In a Pb isotope diagram, lavas cover a fairly large array ($^{206}Pb/^{204}Pb$ from 18.0 to 19.0) and define a mixing trend. La/Yb and Pb isotopic ratios are positively correlated. We suggest that seamounts near Futuna Island are due to partial melting of an Indian-like mantle that has been variously metasomatised by an enriched end-member composed of Samoan plume material and a component similar to the subducting Louisville ridge basalts. The mixing proportions of end-members are geographically controlled by the infiltration in the mantle of the Samoan plume through the tearing of the Pacific plate at the junction between the Tonga arc and the North-Fiji fracture zone.

Multiple sulfur isotopes in basalts: Chemical geodynamics in the South Atlantic mantle

J. LABIDI*, P. CARTIGNY, J.J. BOURRAND AND N. ASSAYAG

Laboratoire de Géochimie des Isotopes stables, IPGP, 1 rue Jussieu, 75005 Paris (*correspondence: labidi@ipgp.fr)

Sulfur isotopes have placed significant constraints on past and present external cycle of sulfur. For example, the disappearance of non-zero $\Delta^{33}S$ values in archean sediments at 2.4 Ga show strong evidence for the atmosphere oxygenation [1].

Present day oceanic crust and sediments show a large range of $\delta^{34}S$: from -40‰ to +30‰, mostly between -7‰ and +5‰. The recycling of these crustal components in the mantle source of MORB may thus be identified with sulfur isotopes. Yet, the deep part of the sulfur cycle remains comparatively unconstrained: Only two studies have reported $\delta^{34}S$ of MORB (n=16; $\delta^{34}S_{MORB} = +0.8 \pm 1‰$)[2][3].

Using an improved method allowing quantitative recovery of sulfur from basaltic glasses, we report the first measurements of the four sulfur stable isotopes in 19 MORB from the South Atlantic ridge. The external precision and accuracy are ± 0.01‰, 0.25‰ and 0.20‰ in 2σ for $\Delta^{33}S$, $\delta^{34}S$, and $\Delta^{36}S$ respectively.

$\delta^{34}S$ values of our samples are all negative (mean $\delta^{34}S$ = -0.89 ± 0.6‰, 1σ) except for one sample at +1.1‰. The variability of $\delta^{34}S$ in our dataset is 3‰, which is significantly larger than the analytical precision. This enables us to discuss the $\delta^{34}S$ variability in MORB in terms of a meaningful geological tracer. We suggest than this variability rather reflect source heterogeneity rather than magmatic processes as it is correlated to radiogenic isotopes enrichments.

$\Delta^{33}S$ and $\Delta^{36}S$ of our samples are slightly but significantly non-equal to 0‰ and are of the same sign: -0.025‰ and -0.200‰ respectively (mean values). Both mixing with/within a subducting slab and/or revised terresrial original $\Delta^{33}S$ and $\Delta^{36}S$ could explain this feature. The respective contribution of these two extreme scenarios will be discussed at the conference.

Hydrothermal synthesis of lentil shaped $ThSiO_4$ nanoparticles

S. LABS, H. CURTIUS, D. BOSBACH

Institute of Energy and Climate Research, Forschungszentrum Jülich GmbH, 52425 Jülich, Germany (*correspondence: s.labs@fz-juelich.de)

We synthesized thorite ($ThSiO_4$) by a hydrothermal route for which we have adapted the protocol used by Fuchs and Hoekstra [1]. All samples were investigated by XRD and show the successful formation of $ThSiO_4$, molecular composition was confirmed by EDX. IR as well as DTA measurements suggest the well known phenomenon of the presence of H_2O in the crystal lattice in some samples. Complete new insight was obtained through SEM investigations, which reveal a rather unusual morphology of the synthesized $ThSiO_4$. Particles are uniform in size, lentil shaped and are 150 – 400 nm along the longest dimension. After heating up to 1000°C the shape and size of the particles remains merely unchanged.

The size of the nanoparticles, as well as their consistency can be influenced by synthesis temperature, concentration and pH-value. Therefore, particle growth most probably follows kinetically controlled mechanisms. However, further investigations and comparison to calculated data are essential. With the synthesis of $ThSiO_4$ being successfully accomplished, work on substituting Th for U is in progress, currently we are investigating the potential of UF_4 as a precursor for this matter.

Recycling of juvenile supracrustal rocks in Mesozoic batholiths: Implications for crustal growth

JADE STAR LACKEY

Pomona College Geology Department, 185 E. Sixth Street, Claremont, CA, 91711, USA (*correspondence: jsl04747@pomona.edu)

The Mesozoic batholiths of the circum-Pacific region represent voluminous production of granitic crust; however, the proportion of these granitic batholiths that are re-worked, continental crust, versus young, recycled supracrustal rock (volcanogenic sedimentary rocks or ocean crust), remains uncertain.

Oxygen isotopes are particularly well suited to detect recycling of young rocks that have been hydrothermally altered at Earth's surface before being buried and re-melted. Moreover, because such rocks may be recycled before significant ingrowth occurs in radiogenic isotope systems, $\delta^{18}O$ and radiogenic systems can be decoupled.

Oxygen isotope studies of zircon in the Sierra Nevada batholith (SNB), California [1], show the highest $\delta^{18}O$ values (typically >7.0‰) in the Early Cretaceous western SNB, and the largest range of values, 5.3–8.7‰. $\delta^{18}O$ is commonly anti-correlated with radiogenic systems, indicating a significant (up to 20%) component of juvenile rocks in early arc magmas. In contrast, eastern SNB magmas, including the Late Cretaceous Sierra Crest magmatic centers, are typically lower $\delta^{18}O$ (<6.5‰) and vary by less than 1‰; radiogenic systems suggest greater input of age rock, likely lithospheric mantle [2], and not North American continental crust. The overall pattern of lower and more uniform $\delta^{18}O$ with time shows increasingly efficient magmatic recycling of pre-existing wallrock and hybridization with mantle derived magmas that averaged out $\delta^{18}O$ heterogeneity in the Sierran arc.

Thus, the contribution of juvenile supracrustal rocks to Mesozoic batholiths appears more significant that previously thought. Moreover, when accreted terranes are recycled in convergent margin arcs, an intermediate refinement step facilitates the conversion of juvenile arc terranes to granitoid crust. Recent work in other Mesozoic batholiths shows similar reworking of such rocks, suggesting the process is common operative, and an important step in the conversion oceanic arcs to continental crust.

Carbon storage technology potentials and difficulties

K. LACKNER

(kl2010@columbia.edu)

The challenges of capture and purification of carbon dioxide from flue gases or from the air is a subject that has received significant attention. Of equal impotance is addressing what to do with the carbon dioxide once it has been purified. Work on the subsequent safe and permanent disposal of carbon dioxide has focused on underground injection or the production of solid mineral carbonates. However, such permanent storage represents an enormous challenge mainly because of the sheer volume of emissions. This talk will also address storage technologies and put them in perspective with regard to technical difficulties, storage capacity, permanence of storage, storage safety and the ability to account for the stored carbon.

Sequestration of trace elements during nucleation and growth of serpentine minerals under hydrothermal conditions

ROMAIN LAFAY*, GERMAN MONTES-HERNANDEZ AND EMILIE JANOTS

Institut des Sciences de la Terre (ISTerre), UJF-CNRS, F-38041 Grenoble, Cedex 9, France (*correspondence: romain.lafay@ujf-grenoble.fr, german.montes-hernandez@obs.ujf-grenoble.fr)

Serpentinites observed in oceanic crust and exhumed mafic rocks contain high levels of trace elements or fluid mobile elements relative to primitive mantle. The concentrations in these elements are controlled by fluid-rock interactions and they represent excellent markers of mass transfert in complex geodynamics systems. Serpentinization processes have been experimentally investigated at different geological conditions, but, rare experimental studies have considered the presence of trace elements during nucleation and growth of serpentine minerals.

In the present study, serpentine nanofibers of chrysotile were nucleated-grown from H_2SiO_3-$MgCl_2$-NaOH hydrothermal system, referred as '*silica-gel system*' (300°C, Mg/Si=1.5, 76bar and pH>13). Liquid-solid distribution coefficients (K_D) for B, Cs, As, Sb and Li were estimated by fitting the experimental sequestration isotherms for each trace element (see for ex. [1]). Additionnnaly, small static-batch reactors were also used to simulate a more realistic serpentinization hydrothermal conditions in presence of the same trace elements. In this '*olivine system*', olivine (San Carlos) alteration was investigated at different physicochemical conditions of T (150-200°C), pH (0.5-13.5), particle size (1-150μm), liquid/solid weigh ratio (5-15), reaction duration (0.25-3 months). Trace element concentration in the fluid was fixed at 200mg/L.

Preliminary results by FESEM, XRDand BET reveal that the presence of trace elements has not significant effect on textural properties of chrysotile nanofibres grown from silica-gel system. Concerning the olivine system, three nanocrystal morphologies (conical, cylinder in cylinder and fibrous) of chrysotile and associated brucite nanoparticles were clearly observed at high pH (>13). Conversely, slight alteration of olivine was observed at low pH (<2) at the same T, particle size, reaction time and liquid/solid ratio conditions. More details for both experiment types (silica-gel and olivine systems) will be reported in [2].

Understanding O_2-deficient and CO_2-enriched gas production and migration in the subsurface above a coal post-mining area through *in situ* gas monitoring and modelling

S. LAFORTUNE, A. CHARMOILLE AND Z. POKRYSZKA

INERIS (French National Institute for Industrial Environment and Risks), Parc Technologique ALATA, BP 2, 60 550 Verneuil-en-Halatte, France (firstname.name@ineris.fr)

Context

INERIS works for 3 years on the characterization of O_2-deficient and CO_2-enriched gas production and migration processes above a former coal mining area where gas emissions occur at surface and which is close to a peat bog. The main objectives of this work were to determine the composition and origin of the emitted gas and the dynamics of its migration from the subsurface rock strata to the surface.

Study and results

In 2009, analyses (gas concentrations and $\delta^{13}C$ isotopic signatures) were performed during spells of low barometric pressure and gas flux was determined at surface of the studied area. Analyses were performed on field and in lab. Results have shown that emitted gas cannot be from mine or peat origin, respectively because it does not contain methane but CO_2 and because isotopic signatures do not match.

In 2010, a continuous gas monitoring was setup on field during a 6-month period. $\delta^{13}C$ isotopic signature of CO_2 was also monitored on field and gas/water samples have been collected for further analyses in lab. Results have shown that CO_2 emissions dynamics is linked to barometric pressure changes. We have also demonstrated that emitted gas cannot come from groundwater degassing, because dissolved gas quantity is not sufficient to explain gas concentrations measured at surface. That means that CO_2 is produced above the water table, in the saturated zone. A modelling study has shown that pyrite oxidation associated to carbonate dissolution is probably the reaction scheme that produces CO_2. Then main fractures lead CO_2 towards surface.

Scope of the presentation

The presentation will detail the methodological and metrological approaches that have been used in this study to characterize gas production and migration in the subsurface above a coal post-mining area. We will present our results, discuss the different gas origins that have been examined, describe migration processes and explain our conclusions.

Tracing crustal recycling in the mantle sources of the Cape Verde and Azores plumes using stable Mo isotope measurements

Y.J. LAI*, T. ELLIOTT AND M. WILLBOLD

Bristol Isotope Group, Dept. of Earth Sciences, Univ. of Bristol, Queens Road, Bristol, BS8 1RJ, UK (*correspondence: Y.J.Lai@bristol.ac.uk, tim.elliott@bristol.ac.uk, M.Willbold@bristol.ac.uk)

Constraining the role of crustal recycling is key to understanding the causes of mantle heterogeneity. In the past, radiogenic isotopes (Sr, Nd, Pb and Hf) and stable isotopes (Li) have been used as tracers to study this process, but none yield unequivocal signatures of recycling. In this study, we investigate the Mo stable isotope system as a new, potential tracer of recycled crust. Recent studies (see summary in [1] and unpublished data in [2-3]) have shown that the isotopic composition of Mo becomes fractionated in low temperature environments, with a notable offset of $\delta^{97}Mo$ between seawater (+1.6‰) and Mn-crust (-0.5‰). Mo isotopes could therefore be a potential tracer for deep mantle recycling of crustal components that have experienced low-temperature alteration on the Earth's surface. Literature $\delta^{97}Mo$ values of igneous rocks define a narrow range of $\delta^{97}Mo$ (-0.06 to +0.17 ‰) yet the uncertainties related to the analytical methods used so far (2S.D. < 0.1‰) do not allow much resolution of primary signature within this small range. Here we present Mo isotopes in oceanic island basalts from Cape Verde Islands and Azores archipelago that were determined using a newly-devised, higher-precision MC-ICPMS method (2S.D. is 0.03‰). Systematic variations of $\delta^{97}Mo$ values with key trace element ratios (i.e. Pr/Mo) indicate that the mantle sources of the Cape Verde and Azores contain various amounts of components that must have experienced alteration on the Earth surface in the past.

Soil carbon build-up during soil formation, influenced by different forms of land use

G.J. LAIR AND W.E.H. BLUM

Institute of Soil Research, Dep. Forest and Soil Sciences, University of Natural Resources and Life Sciences Vienna (BOKU), Austria, (georg.lair@boku.ac.at, winfried.blum@boku.ac.at)

Soil carbon is the result of solar energy and one of the two important non-living components of soils, influencing physical, chemical and biological soil characteristics. Moreover, organic carbon is the driving force of mineral weathering and soil formation [1].

Based on a chronosequence of alluvial soils in the Danube River Basin near Vienna/Austria (covering an age range from approximately 50 – 6000 years of soil formation; [2]), carbon build-up under different forms of land use (forest, grassland and agricultural cropping) is shown, looking into the vertical C distribution as well as its influence on aggregate formation and distribution within different soil aggregates. The influence of N on C-build-up in the Chernozem-soils is discussed.

Imaging nanoparticle transport through porous media using magnetic resonance imaging

SUSITHRA LAKSHMANAN[1,*], W.M. HOMES[2], W.T. SLOAN[3] AND V.R. PHOENIX[1]

[1]Department of Geographical and Earth Sciences, University of Glasgow, G12 8QQ, UK (*correspondence: lakshmanan.susithra@ges.gla.ac.uk, Vernon.Phoenix@ges.gla.ac.uk)

[2]Wellcome Surgical Institute, University of Glasgow, UK (wmh5b@udcf.gla.ac.uk)

[3]Department of Civil Engineering, University of Glasgow, UK (w.sloan@civil.gla.ac.uk)

While most renowned for its use in the medical sciences, magnetic resonance imaging (MRI) has tremendous potential for revealing transport processes in engineered and geologic systems. Its ability to non-invasively image inside materials that are opaque to other imaging methods is a particular strength. Here, we report on the application of MRI to image nanoparticle transport through porous geologic media. Commercially available paramagnetically tagged (Gd) nanoparticles are used; the paramagnetic tag making the nanoparticle visible to MRI.

Nanoparticle transport was imaged as nanoparticles migrated through packed columns of quartz and dolomite sands and gravels. These images were calibrated using T_2 parameter maps to provide fully quantitative maps of nanoparticle concentration at regular time intervals throughout the column (T_2 being the spin-spin relaxation time of ^{1}H nuclei). Positively charged nanoparticle transport was significantly retarded in dolomite compared to quartz due to electrostatic attraction between nanoparticle and dolomite surfaces. Data was evaluated with CXTFIT to estimate solute transport parameters. MRI data fitted well to CXTFIT models of nanoparticle transport, indicating MRI was collecting usable and reliable datasets.

The kinetics of calcite precipitation in the presence of alginate was investigated using the constant composition technique. In the concentration range investigated (0.0002 to 0.005 g L^{-1}), alginate inhibits calcite precipitation. The extent of inhibition increased with increased alginate concentration and decreased solution supersaturation.

Alginate adsorption, derived from normalized calcite precipitation rates, is described satisfactorily by the Langmuir adsorption model.

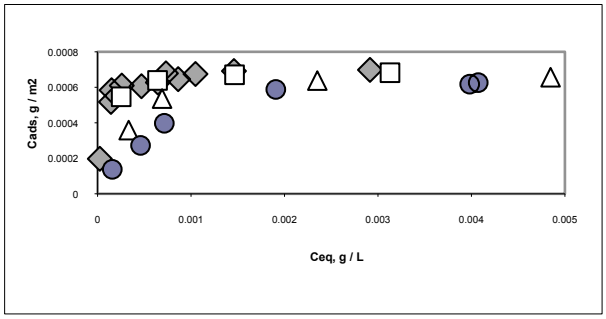

Figure 1: Alginate adsorption isotherms for four supersaturation values: Rhombs, σ = 1.40; squares, σ= 2.02; triangles, σ = 2.65; circles, σ = 3.55.

At lowest supersaturation, alginate adsorption onto calcite probably reaches its maximal uptake of 7.5E-4 g m^{-2}, corresponding to surface coverage of one molecule for each 200 to 300 nm^2, depending on the molecular mass of alginate. This means that one alginate molecule can be bound over 100 to 150 Ca surface sites. Initially, on the surface of the inhibited calcite.

XPS identified alginate but after further time in solution, when the system had recovered, XPS demonstrated that it disappeared from the surface, presumably buried under the newly formed calcite.

The alginate affinity constant decreases with increasing supersaturation, evidence for incomplete adsorption. A simple model based on competition between growth and desorption effectively describes the observed change in the adsorption constant.

Molybdenum and vanadium abundances in banded iron formation and the onset of oxidative continental weathering

The enrichment and isotopic composition of molybdenum in black shales provide insight into the history of atmospheric oxygenation via the coupling of molybdenum supply with the oxidative weathering of terrestrial sulfides [e.g. 1, 2]. However, the fidelity of preservation of Mo oxidative proxies in black shales may also be related to the degree to which euxinic conditions enable their capture [3, 4]. Similar to molybdenum, vanadium is also enriched in sediments deposited under euxinic conditions [4], but its marine supply should be independent of the oxidative weathering of terrestrial sulfides. Here we consider their combined history in order to better understand the black shale Mo record [2] in terms of changing oxidative sources and euxinic sinks in the geological past. We present a complimentary dataset for Mo and V abundances in banded iron formations (BIF), where the ferruginous conditions necessary for BIF deposition preclude euxinia, and sequestration of Mo and V likely occur by adsorption of their anions onto highly reactive ferric hydroxides. While V abundances remain relatively stable throughout the Precambrian, notable Mo enrichments are observed ca. 2.5-2.3 Ga; combined, these data point to the importance of changing sources, and reaffirm assertions that the Great Oxidation Event was marked by increased marine Mo supply driven by oxidative continental weathering. The BIF dataset is further evaluated in light of experimentally-determined Mo- and V- iron oxide partition coefficients that enable back-calculation to dissolved Mo and V concentrations in paleoseawater.

The speciation of marine particulate iron adjacent to active and passive continental margins

PHOEBE J. LAM[1], DANIEL C. OHNEMUS[2] AND MATTHEW A. MARCUS[3]

[1]Dept. of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA 02543 (*correspondence: pjlam@whoi.edu)
[2]MIT-WHOI Joint Program in Oceanography, Woods Hole, MA (dan@whoi.edu)
[3]Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA 94720 (mamarcus@lbl.gov)

We use synchrotron chemical-species mapping techniques to compare the speciation of marine particulate iron collected in two open ocean environments adjacent to active and passive continental margins. Chemical-species mapping combines the spatial information provided by microfocused X-ray fluorescence (XRF) mapping with chemical information gleaned from single particle X-ray absorption near-edge structure (XANES) spectroscopy to allow a rapid and statistically meaningful assessment of the speciation of a large number of heterogeneous micron-scale iron-rich particles. It is especially good for detecting spectroscopically distinct rare species that could not be detectable by other methods.

We find that the average oxidation state of marine particulate iron determined by chemical-species mapping is comparable to that determined by standard bulk X-ray Absorption Near Edge Structure spectroscopy. Fe (II)-containing minerals such as biotite, hornblende, and magnetite contribute up to 45% of total suspended marine particulate iron in the Northwest Pacific, with the balance comprised of Fe (III) compounds. Depth profiles of the mineralogy and oxidation state of marine particulate iron trace the source of iron to the volcanic Kuril-Kamchattka continental margin about 600km away. In contrast, particulate iron in the eastern tropical North Atlantic, which receives the highest dust deposition on Earth, is dominated by weathered and oxidized Fe compounds, with Fe (III) comprising 90% of total iron. The balance is composed primarily of Fe (II)-compounds, but we detected individual pyrite particles in some samples within an oxygen minimum zone in the upper thermocline. Several lines of evidence point to the adjacent Mauritanian continental shelf as the source of pyrite to the water column. We find that the speciation of suspended marine particulate iron reflects the mineralogy of iron from the adjacent continental margins.

Cd behaviour in arctic estuarine systems using Cd isotopes and concentrations analysis

M. LAMBELET[1], M. REHKÄMPER[1], T. VAN DE FLIERDT[1], Z. XUE[1], K. KREISSIG[1], B. COLES[1], P. ANDERSSON[2] AND D. PORCELLI[3]

In the oceans, Cd exhibits a behaviour that is similar to the nutrient phosphate: the concentrations are low at the surface due to uptake by organisms, and higher in deep water where regeneration of biological debris occurs [1]. This behaviour is reflected in Cd isotope data, as surface waters commonly display large isotopic fractionations and heavy Cd isotope compositions [2].

Rivers are a significant source of marine Cd, but the behaviour of the element in estuaries is only poorly understood. Therefore, we have determined the Cd isotopic compositions and concentrations of 19 water samples collected along the Arctic Siberian Shelf during the ISSS-08 cruise.

The results for the majority of the samples are in accord with conservative mixing between river water and seawater. Six samples, however, deviate from the mixing trend. One displays a very light Cd isotope composition, which is in accord with release of anthropogenic Cd from particles. This interpretation is based on the light Cd isotope compositions reported for anthropogenic Cd in previous studies [3]. The remaining five samples also exhibit “excess” Cd and the isotope data indicate that this reflects release of natural Cd from particulates at intermediate salinities.

These observations emphasize the importance of trace metal stable isotope analyses for investigations of marine biogeochemical cycles. For Cd, the isotopic data (i) corroborate the reactive behaviour of Cd in estuaries, where Cd is released from particles and (ii) indicate that they may be a useful tool for tracing anthropogenic Cd in the environment.

Zircon U-Pb and Hf isotopic data from granitic rocks of Taiwan

C.Y. LAN[1]*, T. USUKI[1], K.L. WANG[1], T.F. YUI[1], J.H. YANG[2], W. LIN[3] AND P.S. HSIEH[3]

[1]Institute of Earth Sciences, Academia Sinica, Nankang, Taipei, Taiwan, ROC (*correspondence: kyanite@earth.sinica.edu.tw)

[2]State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing,, PROC (jinhui@mail.igcas.ac.cn)

[3]Energy and Environment Research Laboratories, Industrial Technology Research Institute, Hsinchu, Taiwan, ROC (waynelin@itri.org.tw)

South China is famous for its widespread, voluminous Mesozoic Yanshanian igneous activity. Taiwan is situated at the eastern margin of South China. The timing and genesis of granitic rocks of Taiwan are curcial to understand the crustal evolution of Taiwan and thair relationship with South China.

In this study, six granitic rocks were collected from the Tailuko metamorphic basement of Taiwan for *in situ* zircon U-Pb dating and Hf isotopic measurement. They include four metagranites and one paragneiss from northern Taiwan and one metagranite from southern Taiwan. The metagranites present two magmatic age groups, 191±10 Ma [1]. and 84-90 Ma. Their relict zircon cores present Early Cretaceous to Early Permian ages with minor Paleoproterozic age. However, no unique magmatic age is found from the paragneiss. Its relict ages vary from Cretaceous to Late Carboniferous with minor Paleoproterozic ages and the youngest age being 88 Ma. The Early Jurassic metagranite outcropped in southern Taiwan gives positive zircon epsilon Hf (t) values, ranging from +8.6 to +11.8. Their T_{DM}^{C} Hf model ages of zircon range from 0.5 to 0.7 Ga. The Late Cretaceous metagranites outcropped in northern Taiwan yield positive to negative epsilon Hf (t) values, ranging from -3.8 to +6.5 and vary among different localities. Their T_{DM}^{C} Hf model ages of zircon range from 0.8 to 1.4 Ga and vary among different localities. Similar geochemical properties can be observed among the metagranites, such as initial Nd isotopic values, amount of normative corundum and peraluminosity [2]. Trace elements analyses on zircons are carried out for two Late Cretaceous metagranites. They exhibit REE patterns similar to magmatic zircons.

Our studies identified Middle Neoproterozoic and Middle Neoproterozic to Middle Mesoproterozoic Hf model age for the Early Jurassic metagranite from southern Taiwan and Late Cretaceous metagranites from northern Taiwan, respectively. These findings are consistent with the occurrences of Neo-proterozoic magmatism in the Yangtze and Cathaysia blocks.

Eoarchaean crustal evolution of the North Atlantic craton

PENELOPE J. LANCASTER*, CRAIG D. STOREY AND CHRIS J. HAWKESWORTH

University of Bristol, Dept. of Earth Sciences, Wills Memorial Building, Queen's Rd., Bristol BS8 1RJ, UK (*correspondence: penelope.lancaster@ucd.ie)

Recent studies suggest extraction of juvenile crust from the mantle has been globally continuous throughout Earth's history, but the crustal record is biased by preservation, particularly from supercontinents [e.g. 1, 2]. As a result, crust older than the first supercontinent at *c*. 2.7 Ga is now rare and frequently strongly reworked. However, younger sedimentary rocks may preserve fragments of Archaean basement by sampling wide areas, including those which have since been buried or destroyed, thereby providing a more complete record of the ancient crust. Of these sedimentary rocks, coarse basal units are most likely to preserve local basement, constraining the likely geographical distribution of those source areas and providing greater context for any detrital material.

Detrital zircons have been analyzed from basal units of the Meso/Neoproterozoic to Cambrian Stoer, Sleat, Ardvreck and Morar groups in NW Scotland to evaluate basement source ages and isotopic signatures. Widespread crustal extraction is recorded in Hf model ages between 4160–1410 Ma, peaking at c. 3350 Ma, with significant crystallisation and/or reworking between 3670–1070 Ma, peaking at c. 2700 Ma. Similar crystallisation and model ages have been identified around the North Atlantic Craton, suggesting a shared, but not consanguineous, origin. All four units contain Hf model ages that imply partial reworking of Eoarchaean crust, and model ages as old as 4200 Ma from the basal Ardvreck Gp. indicate the existence of much older crust in Scotland and the greater North Atlantic Craton. Such consistency around the craton reinforces the conclusion that crustal extraction and crystallisation are continuous, large-scale processes, and have been since the very earliest Earth.

Microbial utilization of the products of serpentinization at the Lost City hydrothermal field

SUSAN Q. LANG[1]*, GRETCHEN L. FRÜH-GREEN[1], STEFANO M. BERNASCONI[1], DAVID A. BUTTERFIELD[2], MARVIN D. LILLEY[3], GIORA PROSKUROWSKI[3] AND SABINE MÉHAY[1]

[1]Department of Earth Sciences, ETH Zürich, 8092 Zürich, Switzerland
[2]JISAO, University of Washington, Seattle, WA 98195, USA

The Lost City vent field (30°N, Mid-Atlantic Ridge) is characterized by extreme conditions: venting of pH 9-11, <90°C, metal-poor and hydrogren-rich fluids and formation of carbonate-brucite hydrothermal structures that reach up to 60 m high. Fluid-rock reactions in the underlying ultramafic rocks result in high concentrations of a number of chemical species proposed to be of abiological origin (hydrogen, methane, C_2^+ alkanes, formate) [1, 2]. Lost City is a possible analog to Early Earth or Martian environments and is potentially important to understanding the origin of life. For these reasons, a primary research focus has been to investigate the microbial communities that are sustained in this environment and examine their potential link with abiotically produced carbon species. We demonstrate here that in locations where microbial sulfate reduction is believed to be important, up to 50% of the microbial biomass in the carbonate chimneys is derived from mantle carbon. Conversely, mantle carbon contributes only ~10% of the biomass in locations that are minimally impacted by sulfate reduction. We argue that the difference can be attributed to the ability of sulfate reducing bacteria to convert formate to dissolved inorganic carbon which is then accessible by other microbial species such as the more abundant *Methanosarcinales* [3, 4].

Natural organic matter as major sorbent for arsenic in a peatland

P. LANGNER, C. MIKUTTA* AND R. KRETZSCHMAR

Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland (*christian.mikutta@env.ethz.ch)

Arsenic (As) is a potentially toxic trace element, which is typically associated with metal-(hydr)oxides, silicates or sulfides in organic-rich soils and sediments. Natural organic matter (NOM) has also been suggested as important sorbent for As [1, 2] but the binding mechanisms are still elusive. In order to investigate the importance of NOM relative to reactive Fe species for As binding, we studied the solid-phase speciation of As and Fe in a minerotrophic peatland in Switzerland that contains high natural concentrations of As.

Anoxic peat samples were analyzed by bulk As and Fe K-edge X-ray absorption near edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) spectroscopy at ~80 K. The EXAFS spectra were analyzed by means of principal component analysis and target testing followed by linear combination fitting. We focused our speciation analysis on shallow (<0.4 m) peat layers with 358-1810 mg As kg^{-1} and peat layers from greater depth (1.5-2.6 m) with 106-469 mg As kg^{-1}. Both depth intervals differed significantly in the molar S/Fe ratio of the peat: 0-1 at depths <0.4 m and 2-7 for 1.5-2.6 m depth.

Speciation analysis of As revealed that close to the peat surface As was mainly present as realgar (As_4S_4), As(III)-NOM complexes, and As(III)/As(V) sorbed to Fe(III)-(hydr)oxides. In the deep peat layers, however, As was entirely in its trivalent oxidation state and mostly coordinated to 2-3 S atoms of NOM ($R_{As\text{-}S}$ = 2.26 Å). The Fe speciation in the upper peat layers was dominated by Fe(III)-(hydr)oxides, chlorite, and Fe(III)-NOM complexes, indicating the presence of low-Fe/high-S microenvironments with high As activities. In the deep peat layers Fe(III)-NOM complexes and pyrite (FeS_2) were detected as main Fe species. Although these phases were shown or hypothesized to immobilize As(III), nearly all As was bound to sulfhydryl groups of NOM.

Our results suggest that As binding to sulfhydryl groups of NOM is the major As-NOM interaction scheme under sulfate-reducing conditions. This mechanism seems to impair As sequestration pathways involving Fe species such as the formation of As-bearing pyrite, the precipitation of arsenopyrite (FeAsS), or the formation of ternary As(III)-Fe(III)-NOM complexes.

Exploring fracture dominated flow and spatially variable chemical weathering in the Boulder Creek Critical Zone Observatory, Colorado, USA

ABIGAIL L. LANGSTON[1,2]*, GREGORY E. TUCKER[1,2], ROBERT S. ANDERSON[1,3] AND SUZANNE P. ANDERSON[1,3]

[1]Department of Geological Sciences of Colorado
[2]CIRES
[3]INSTAAR

The spatial and temporal evolution of saprolite development on hillslopes controls soil production and sediment supply to rivers. We study the interaction between fluid flow and chemical weathering in the Boulder Creek watershed, a 1160 km^2 catchment that ranges in elevation from 4120 m at 1480 m. We developed our understanding of the formation of saprolite in a granitic mountain catchment by modelling the subsurface flow paths in an environment dominated by fracture flow. Two-dimensional hillslope hydrology models were constructed in a Richards equation-based model to visualize flow paths in the unsaturated zone. We expect fracture density and fracture size in the bedrock to exert the strongest control on both the depth of water penetration into the bedrock, and its residence time in the subsurface. The importance of fractures on the routing of water and development of saprolite in the unsaturated zone will be explored further through XRD and XRF analysis of selected samples of soil, saprolite, and bedrock collected along road cuts at specific points relative to the local fracture system

Geochemistry of tonalites formed by partial melting of eclogites: Experimental modelling

T. LARIKOVA[1]*, A. HOLZHEID[2] AND PH. KEGLER[2]

[1]Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry IGEM RAS, Staromonetny 35, Moscow, Russia, (larik@igem.ru)
[2]Institute of Geosciences, University of Kiel, Germany

Processes of the partial melting of the metagabbroic rocks (eclogites) in subduction zones may lead to tonalites formation. Experiments aimed to study the formation mechanisms of the clinopyroxene-plagioclase symplectite textures that usually occur during decompression of eclogites. Piston cylinder experiments were performed at 700ºC and 9-11-13 kbar (corresponding to T-minima of wet basalt solidus) at the experimental petrology laboratory of the University Kiel. Run durations varied from 18 hours to 16 days. As fluid phase 0.1 M NaCl-H_2O was used. Starting material was unaltered bimineral (garnet+omphacite) eclogite from the Marun-Keu complex (Polar Urals), formed at 670-690ºC and 16-18 kbar.

During the experiments, the eclogitic garnet grains remained stable, but the composition of their rims changed. Primary omphacites were unstable and were partly or totally recrystallised. As a result, clinopyroxene and plagioclase intergrowth (often accompanied by hornblende) was formed. The compositions of newly formed minerals are in very good agreement with symplectites of the Marun-Keu eclogites. In the association with the symplectites, melt (quenched glass) was found. The melt formed domains, which are sometimes surrounded by a Cpx rim. Also the melt was found as a part of the newly formed symplectitic intergrowth and as a rim around primary eclogitic garnets. The melt (glass) corresponds to a tonalitic composition, with SiO_2 varying from 54 to 71 wt% and Al_2O_3 from 22 to 12 wt% accordingly. Furthermore, the melt contains up to 14 wt% of a fluid phase; the fluid amount increases with decreasing SiO_2 content. Trace elements compositions of the melt domains were obtained by ion microprobe. They show general depletion of the studied elements (exept for Sr) compared to the initial eclogites that correspond to MORB, while Sr is clearly enriched. Moreover a peak in Eu content is noticable.

In summary, our experimental results show formation of tonalitic melt with unusual low trace element content by partial melting of eclogite in equilibrium with garnet and newly formed clinopyroxene at 700°C.

The authors thank DFG (SFB 574), DAAD and RFBR for financial support.

A novel ion exchange separation for Cu prior to stable isotope analysis by MC-ICPMS

F. LARNER[1]*, M. REHKÄMPER[1,3], B. COLES[1,3], K. KREISSIG[1], D. WEISS[1,3], B. SAMPSON[2], C. UNSWORTH[3] AND S. STREKOPYTOV[3]

[1]Dept. of Earth Science & Engineering, Imperial College London, SW7 2AZ, UK (*correspondence: fiona.larner04@imperial.ac.uk)
[2]Dept. of Medicine, Imperial College London, W6 8RF, UK
[3]Natural History Museum, London, SW7 5BD, UK

The acquisition of stable isotope data with a precision of better than ±0.10‰ using multi-collector inductively coupled plasma mass spectrometry (MC-ICPMS) requires that target elements are separated from the sample matrix to enhance sensitivity, avoid spectral interferences and minimize matrix effects.

At present, the isolation of Cu is generally performed using anion exchange chromatography, with Cu in the +2 oxidation state. These methods suffer from the incomplete separation of Cu from matrix elements and multiple stages of column chemistry are therefore often required to produce a sufficiently purified Cu sample for isotopic analysis. Such problems appear to be particularly prominent for biological materials because (i) of the major interference of $^{40}Ar^{23}Na^{+}$ on $^{63}Cu^{+}$ and (ii) samples with high organic content appear to increase the overlap between the elution of Cu^{2+} and the bulk sample matrix.

To avoid these problems, we have developed a novel procedure that makes use of the different distribution coefficients of Cu (I) and Cu (II) to anion exchange resin, to significantly improve the separation of Cu from biological materials. The method was found to yield sufficiently pure Cu fractions for isotopic analyses after a single pass through the anion exchange columns and it routinely achieves recoveries of 100% ± 2%. Subsequent isotopic analyses of the Cu by MC-ICPMS, using admixed Ni for mass bias correction, yielded accurate Cu isotope data with a reproducibility of about ±0.05‰ (2s) for pure standard solutions and ±0.10‰ (2s) for samples.

Schwertmannite and Fe oxides formed by biological low-pH Fe(II) oxidation versus abiotic neutralization

L. LARSON[1], F. LUAN[1], L. TROYER[2], T. BORCH[2,3] AND W. BURGOS[1]*

[1]Dept. Civil Environ. Eng., Pennylvania State University, University Park, PA 16802, USA (*correspondence: wdb3@psu.edu, lnl5053@psu.edu, ful6@psu.edu)
[2]Dept. Chemistry, [3]Dept. Soil Crop Sci., Colorado State University, Fort Collins, CO 80523 (thomas.borch@colostate.edu, troyerld@lamar.colostate.edu)

We studied the mineralogy of three low-pH coal mine drainage (CMD) sites in central Pennsylvania. Water from one site was used in discontinuous titration/ neutralization experiments to produce Fe (III) minerals by abiotic precipitation for comparison with the field precipitates that were produced by biological low-pH Fe (II) oxidation. Sediments were characterized using X-ray diffraction, Fe K-edge extended X-ray absorption fine structure spectroscopy, and scanning electron microscopy with energy dispersive spectroscopy. Even though the hydrology and concentration of dissolved metals of the CMD varied considerably between the three field sites, the sediment mineralogy of the three iron terraces was found to be very similar. Schwertmannite was the predominant mineral phase precipitated at low-pH (2.5–4.0) along with lesser amounts of goethite. Schwertmannite particles occurred as micron sized spheroids with characteristic 'hedgehog' morphology at all sites. No trace metal incorporation was detected in sediments from the field sites, and no metals (other than Fe) were removed from the CMD at any of the field sites. Minerals formed by abiotic neutralization/precipitation (pH 4.4 – 8.4) were found to contain (in order of predominance) ferri-hydrite, schwertmannite and goethite. In contrast to low-pH precipitation, substantial trace metal removal occurred in the neutralized CMD. Biological low-pH Fe (II) oxidation can improve CMD treatment by reducing armouring and clogging of downstream limestone beds. A further benefit is that solids formed under these conditions may be of industrial value because they do not contain trace metals.

Towards the geochemical tricorder: Trends and needs in subsurface geochemical sensor systems for energy recovery and carbon management

STEVE LARTER AND LLOYD SNOWDON

PRG, University of Calgary, Calgary, Canada (slarter@ucalgary.ca Lloyd.Snowdon@ucalgary.ca)

Chemical and fluid property analysis of reservoir fluids extracted from reservoirs under *in situ* reservoir conditions (ISRC) is a holy grail of reservoir geochemistry. This is especially important in heavy oil fields where the petroleum often will not flow at native ISRC and is equally important in sampling fluids from CO_2 storage programs to provide monitoring capabilities. Great advances in our ability to sample and characterize reservoir fluids that flow under ISRC have been made in the last decade with dynamic well testing systems coupled to optical spectrometers leading the way currently. While developments have been dramatic and successful, current tools cannot provide the molecular information necessary for many organic or inorganic geochemical applications. Given our capabilities to send advanced analytical instrumentation across the solar system it is surprising that more sophisticated instrumentation is not used a mere few kilometers below our feet! We anticipate that reservoir geochemistry associated with carbon management and downhole sensors for CO_2 and storage reservoir water chemistry to be a large research and development area in the next decade as monitoring and verification of the quantities of large volume carbon dioxide storage programs becomes routine.

We summarize our own attempts to develop instrumentation for direct sampling and geochemical or fluid property analysis of reservoir fluids (oils, waters, gases) *in situ* and describe key technical boundaries to be crossed in terms of sensor technologies and proxy methods for determination of key flow and geochemical properties of hydrocarbon and aqueous fluids associated with energy recovery and CO_2 storage activities. We describe new approaches to sampling and assessing oil viscosity appropriate for *in situ* analysis in heavy oilfields and define *in situ* sensor specifications for performing reservoir geochemical applications such as permeability barrier detection and production allocation in petroleum reservoirs.

Chemistry of Li-Na-K-OH-H_2O brines up to high concentrations and temperatures

A. LASSIN[1]*, C. CHRISTOV[2], L. ANDRÉ[1] AND M. AZAROUAL[1]

[1]BRGM, 3 av. C. Guillemin, B.P. 36009, 45060 Orléans cedex 2, France (*correspondence: a.lassin@brgm.fr)

[2]GeoEco Consulting 2010, 514 E. Barham Drive, San Marcos, CA, USA, hristovi@sbcglobal.net

Lithium interest for industrial production has been increasing during the last few years. This alkali metal is of primary importance in the battery production for electricity storage, in vehicles and electronic devices. Because of very high solubility of lithium in water, the chemical behaviour of lithium minerals is mainly described in binary aqueous systems [1, 2] or at standard temperature [3-5]. Indeed, the chemistry of highly saline aqueous solutions is highly non-ideal and very complex. Its characterization requires specific approaches. The ion-specific interactions model developed by Pitzer [6] is particularly well suited for dealing with ionic strengths ranging from low up to very high salinities, *i.e.* above several tens of moles per kg of water.

In this work, we studied the Li-Na-K-OH-H_2O chemical system, and determined the relevant Pitzer interaction parameters using the procedure developed by André *et al.* [7]. In the binary LiOH-H_2O system, this set of parameters allows the description of the phase diagram for temperatures ranging from 0 to 240°C and for salinities up to saturation, *i.e.* up to 8 mol/kgw. In the ternary LiOH-KOH-H_2O and LiOH-NaOH-H_2O systems, phase diagrams can be satisfactorily described up to 30 mol/kgw, and 100°C, and up to 20 mol/kgw, and 150°C, respectively.

The set of parameters determined in this study should allow the description of the chemical behaviour of the quaternary LiOH-KOH-NaOH-H_2O system over a wide range of salinities and temperatures. The model presented here is a first step towards the possibility for optimizing the lithium extraction processes from natural hypersaline brines, geochemical resources, and industrial waste aqueous solutions.

Geochemical investigation of gabbroic xenoliths from Hualalai Volcano, Hawaii

J.C. LASSITER* AND R. GAO

Geological Sciences Dept., Jackson School of Geoscience, Univ. Texas, Austin, TX, USA (*correspondence: lassiter1@mail.utexas.edu)

The 1800-1801 Kaupulehu flow from Hualalai Volcano, Hawaii, contains abundant gabbroic and ultramafic xenoliths. These xenoliths provide insights into the plumbing systems of Hawaiian volcanes as well as constraints on the composition of the ~110 Ma Pacific crust and lithosphere upon which the Hawaiian Islands are constructed.

Clinopyroxenes from the majority of the Kaupulehu gabbros have convex-upward REE patterns consistent with derivation through fractional crystallization from LREE-enriched Hualalai magmas with little trapped interstital melt. Calculated parental melts have REE patterns spanning the entire range of Hualalai lava compositions. A small subset of xenoliths with LREE-enriched clinopyroxenes appear to be trapped Hualalai melts that crystallized as a closed system. The Hualalai-derived xenoliths have Sr-Nd-Pb isotopic compositions that span the full range reported for Hualalai lavas. These gabbros provide a nearly complete record (minus the stratigraphic context) of Hualalai magmatic history.

A small subset (~15%) of the Kaupulehu gabbros have LREE-depleted pyroxenes that crystallized from melts with MORB-like compositions. These xenoliths have unradiogenic $^{87}Sr/^{86}Sr$ (~0.7025-0.7028) and radiogenic $^{143}Nd/^{144}Nd$ (0.5130-0.5132) and overlap the field defined for Pacific MORB. Lead isotope compositions ($^{206}Pb/^{204}Pb \approx 18.0$-18.4) are generally less radiogenic than present-day Pb-isotope values reported for MORB from ODP Site 843 west of Hawaii, which suggests that the ODP 843 lavas may not be representative of the composition of the lower, less altered portions of the local Pacific crust beneath Hawaii. In particular, the MORB-related gabbros have lower $^{208}Pb/^{204}Pb$ for a given $^{206}Pb/^{204}Pb$ than the trend defined by Site 843 lavas [1], and overlap with post-erosional lavas from the Honolulu Volcanic Series. If the MORB-related gabbros are isotopically similar to the lithospheric mantle beneath Hawaii, then a role for lithospheric mantle in the generation of post-erosional lavas cannot be excluded based on the Pb-isotope compositions of Site 843 lavas, as some studies have previously concluded [2].

Sudbury asteroid impact triggered the emplacement of endogenous magma that produced a giant Ni-Cu-PGE deposit

RAIS LATYPOV

Department of Geosciences, University of Oulu, Oulu, FI-90014, Finland (*correspondence: rais.latypov@oulu.fi)

The Sudbury impact structure, Canada, comprises the up to 5 km thick Sudbury Igneous Complex (SIC) that is widely interpreted as an impact melt sheet produced by melting of target crustal rocks [1-6]. The Sudbury structure is renowned for showing clear evidence of asteroid impact and for hosting the largest known reserves of Ni, Cu and PGE sulfides that are closely associated with the SIC [6]. Two groups of igneous bodies closely associated with the SIC are thought to be representative of its initial magma composition. These are glassy dykes and sills that occur in the roof rocks (Onaping melt bodies) and dioritic dykes that cut the underlying basement rocks (Offset dyke). However, these two groups of igneous bodies have distinctly different major and trace element compositions, posing the question as to which magma produced the SIC. The quenched glassy texture of the Onaping bodies is indicative of their formation as superheated melts generated by asteroid impact [7]. Compositional changes of this initial impact melt by subsequent intra-chamber processes such as fractional differentiation [8], assimilation [9] or liquid immiscibility [4, 6, 10-11] do not lead to the magma compositions parental to the Offset dykes. The Offset dykes can therefore only represent an external, endogenous magma from below [12] that mixed with an impact melt to form the hybrid magma parental to the SIC. Identical ages for the SIC and Offset dykes indicate that emplacement of the endogenous magma was initiated by the Sudbury impact event. This suggests that Sudbury asteroid impact triggered endogenous magmatism that gave rise to formation of a giant Ni-Cu-PGE deposit.

Effects of absorbing aerosols on accelerated melting of snowpack in the Tibetan-Himalayas region

WILLIAM K.M. LAU

Laboratory for Atmospheres, NASA/GSFC, Greenbelt, MD 20771 (william.k.lau@nasa.gov)

The impacts of absorbing aerosol on melting of snowpack in the Hindu-Kush-Tibetan-Himalayas (HKTH) region are studied using NASA satellite and GEOS-5 GCM. Results from GCM experiments shows that a 8-10% in the rate of melting of snowpack over the western Himalayas and Tibetan Plateau can be attributed to the aerosol elevated-heat-pump (EHP) feedback effect (Lau *et al*. 2008), initiated by the absorption of solar radiation by absorbing aerosols accumulated over the Indo-Gangetic Plain and Himalayas foothills. On the other hand, deposition of black carbon on snow surface was estimated to give rise to a reduction in snow surface albedo of 2 - 5%, and an increased annual runoff of 9-24%. From case studies using satellite observations and re-analysis data, we find consistent signals of possible impacts of dust and black carbon aerosol in blackening snow surface, in accelerating spring melting of snowpack in the HKHT, and consequentially in influencing shifts in long-term Asian summer monsoon rainfall pattern.

Small-scale processes and mantle source heterogeneity recorded in melt inclusions from the Mid-Atlantic and Gakkel ridges

MURIEL LAUBIER* AND CHARLES H. LANGMUIR

Earth and Planetary Sciences, Harvard University, Cambridge, MA 02138, USA
(*correspondence: laubier@eps.harvard.edu)

Melt inclusions sample magmas that are less homogenized than lavas and provide new insights on magma generation, transport and mantle heterogeneity. Remarkably, at mid-ocean ridges few exhaustive studies of individual areas have taken place for olivine-hosted inclusions, to constrain to what extent major and trace elements provide coherent signal that reveals mantle composition and processes. We are carrying out such studies of ridges with very different spreading characteristics, from the FAMOUS segment (Mid-Atlantic Ridge) and the ultra-slow spreading Gakkel Ridge (Arctic Ocean). One aim is to test the hypothesis that melt inclusions record melts from various depths in the melting column, such that the most depleted melts are also high in Si and low in Fe.

188 new melt inclusions from 14 samples in the FAMOUS area display a large variability in major and trace elements that extends that of the lavas to more depleted compositions. Among them, high-Al, low-Si melts, found both as melt inclusions and lavas, are characterized by a strong depletion in the most incompatible elements and distinctively low MREE/HREE ratios. Although high-Al melts show evidence of assimilation of crustal plag-bearing cumulates, their trace element signature requires a distinct residual mantle formed by previous melt extraction in the garnet field. The low Si contents of the most depleted inclusions suggest that they reflect deep source processes, and not the 'top of the melting column'.

The Gakkel Ridge is the slowest spreading ridge on Earth, and should have a tens of km thick lithosphere that would be expected to influence melt inclusion compositions. The robust western volcanic zone has a continuous magmatic ridge, the sparsely magmatic zone consists largely of peridotite, and the eastern volcanic zone consists of isolated volcanoes. Large geochemical variations in the lavas along the ridge and within segments indicate small extents of melting (F), melt focusing and mantle source heterogeneity. Melt inclusion work will be reported on samples from all domains. The comparison between slow and ultraslow spreading ridges will constrain the changes in the melting dynamics, transport and sampling of mantle heterogeneity between the two environments.

Drillcore imaging spectroscopy for exploration and mining

C. LAUKAMP, I. SONNTAG, T. CUDAHY, M. HAEST AND A. RODGER

CSIRO, Kensington WA 6151, Australia
(*correspondence: Carsten.Laukamp@csiro.au)

Automated drill core logging techniques that measure the visible and infrared reflectance (e.g. line profiling systems such as HyLogging™) are increasingly used for mineral exploration and mining [1, 2]. Additionally, imaging spectrometers allow to capture mineralogical and textural information across the visible and infrared wavelength range (0.4 - 2.5µm). However, the automated extraction of mineral abundances and compositions from the resulting large spectral data sets is difficult and pure statistical methods can lead to questionable mineralogical conclusions.

This paper presents a case study using samples from orogenic gold deposits hosted by Archean greenstone belts of Western Australia, and iron-oxide copper gold deposits in the Mount Isa Inlier (Australia), to showcase the mineral feature extraction method [3, 4] for the interpretation of reflectance spectroscopic data and its application for drill core imaging spectroscopy. In this method mineral endmembers are not extracted from the analysed image, but are derived from physicochemical constraints characteristic for the minerals of interest. This enables the comparison of different samples and doesn't require spectral libraries for the interpretation of the reflectance spectra. Based on the image processing software ENVI™, routines were developed to create a suite of mineral maps, which show the spatial distribution and compositional changes of hydroxylated silicates and carbonates. The acquired mineral maps were compared with thin section petrography, SEM and electron microprobe work, and used to determine mineral phases that are visually difficult to identify in the greenschist to amphibolite facies host rocks. The results can be used to 1) better understand cross cutting and phase relationships of Au-related alteration assemblages (e.g. prehnite, white mica composition), and 2) improve the interpretation of automated drill core logging techniques, to deliver objective core logging results. The developed method is aimed to be globally applicable to a wide variety of mineral mixtures and geological settings.

The effect of sulfur on PGE solubility in silicate melts

V. LAURENZ[1]*, R.O.C. FONSECA[1], C. BALLHAUS[1], K.P. JOCHUM[2] AND P.J. SYLVESTER[3]

[1]Steinmann Institut, Rheinische Friedrich-Wilhelms Universität Bonn, Bonn, Germany (*correspondence: laurenz@uni-bonn.de)
[2]Max Planck Institut für Chemie, Abt. Biogeochemie, Mainz, Germany
[3]Department of Earth Sciences, Memorial University of Newfoundland, St. John's, Newfoundland, Canada

The solubility of platinum-group elements (PGE) in silicate melts depends on oxygen partial pressure, temperature, pressure and melt composition. In addition, sulfur plays an important role for PGE geochemistry in the Earth's mantle. Due to their chalcophile character, PGE are thought to be predominantly hosted by sulfides in the Earth's mantle. However, little is known about the the possible effect of sulfur partial pressure (pS_2) on the solubility of PGE in silicate melts. In addition to oxygen, dissolved S^{2-} may associate as a possible ligand with the PGE and enhance their solubility in a silicate melt relative to a S-free melt. A better understanding of the influence of sulfur on PGE solubility in silicate melts will provide deeper insights into the processes leading to the enrichment of PGE in sulfide in a sulfide-melt/silicate-melt system, as observed in sulfides of magmatic PGE ore deposits (e.g. Merensky Reef, Bushveld Complex).

In order to experimentally investigate the effect of S^{2-} on the solubility of PGE in silicate melts, a natural picrite was equilibrated with Ru or Pt metal at 1300°C in a 1 atm vertical gas mixing furnace under controlled pS_2 and pO_2. Sulfur fugacity was held below sulfide saturation. Run products were quenched to silicate glasses, which were subsequently analyzed for major elements and dissolveld S by EMP. Ru or Pt concentrations were determined by LA-ICP-MS to allow the detection of heterogeneities such as discrete metallic nanonuggets.

Experiments show that the solubility of Ru or Pt in the picritic melt is enhanced up to a factor of 20 in sulfur-bearing systems when compared to S-free melts at identical pO_2. Our results appear to indicate that Ru and Pt, and possibly other PGE as well, bond with S^{2-} anions dissolved in the silicate melt. This observation has important implications for ore-forming processes: The proportion of Ru or Pt associated with the S^{2-} ligand will be extracted straight into an exsolving sulfide melt, once sulfide saturation is reached. This leads to the observed enrichment of PGE in sulfide liquids forming magmatic sulfide ore deposits. Our results imply that our current understanding of PGE enrichment processes in sulfide melts have to be re-thought.

Himalayan erosion rates and ^{10}Be systematics in the Ganga basin

JÉRÔME LAVÉ[1], MAARTEN LUPKER[1], PIERRE-HENRI BLARD[1], CHRISTIAN FRANCE-LANORD[1], DIDIER BOURLÈS[2], JULIEN CHARREAU[1], LAETITIA LEANNI[2], RAPHAËL PIK[1] AND NICOLAS PUCHOL[1]

A key parameter to understand the evolution of the Himalayan orogen and its impact on Earth surface processes is the mass of material removed from the system through physical erosion and sediment export. Himalayan erosion rates have been widely derived from thermochronological exhumation studies, river incision rates and sediment budgets covering both long-term exhumation rates and short-term events. Cosmogenic nucleids provide the opportunity to study large-scale basin average erosion rates at intermediate time scale [1, 2]. However, the use of ^{10}Be has yet remained limited for the major Himalayan basins [3].

Here we report ^{10}Be measurements from river sediments covering the Ganga basin that drains the central part of the Himalayan range. Sediments were collected between 2004 and 2010 at the Himalayan front in the main trans-Himalayan rivers, in the floodplain southern cratonic tributaries, and finally in the Ganga (Bangladesh) which integrates the whole basin. ^{10}Be concentrations measured at the Himalayan front range from (8 to 55)·10^3 at. g^{-1} and vary (up to a factor 2) interannually for most of the rivers. In Bangladesh, four different samples yield in contrast similar concentrations (~20·10^3 at. g^{-1}), close to the average of the upstream mountain-outlets values. Those results suggest several preliminary conclusions: (1) The sediment contribution of the southern tributaries of the Ganga is limited to <1%, consistently with their much higher ^{10}Be concentrations and erosion rates of ~0.008 mm. yr^{-1} for the Indian craton. (2) No systematic evolution of the average ^{10}Be concentrations is observed during floodplain transfer as it would be expected from long time transfer in the Ganga plain [4]. (3) Mixing and diffusion during transfer are, however, sufficiently efficient to smooth the lateral and temporal variations and to provide, in Bangladesh, a well constrained mean erosion rate of 1.3 ±0.3 mm. yr^{-1} for the central Himalayas.

[5]ESPM Department, University of California, Berkeley, CA 94720, USA (cpallud@berkeley.edu)

Recent works have shown the existence and importance of chemoautotrophic denitrification via sulfur and iron. Relatively little is known, however regarding the environmental importance of these processes in anoxic sediments. Our goal was to investigate the potential of the two alternative nitrate-reducing processes and compare them to the classical, heterotrophic denitrification in freshwater (riverine) and coastal sediments.

Potential nitrate reduction rates in these sediments ranged from 200 to 700 nmol NO_3^- cm^{-3} h^{-1}. The addition of Fe (II) together with nitrate had little to no effect on total nitrate reduction rates. We observed however a significant effect on the rate of nitrite production in certain sediments; nitrite production was lower in the presence of Fe (II). We hypothesize that Fe (II) reacts, either biotically or abiotically, with nitrite that is produced during heterotrophic denitrification.

Sediments that were supplied under anoxic conditions with nitrate showed high nitrate reduction rates as well as sulfate release rates. No sulfate was supplied to these sediments and exceeded porewater flushing of sulfate indicating the coupling of nitrate reduction with sulfide oxidation resulting in the production of sulfate. The sulfate production rates reached values as high as 60 nmol SO_4^{2-} cm^{-3} h^{-1} and could make up for 15% of the nitrate reduction rates.

This study shows that nitrate reduction linked to iron oxidation in the investigated freshwater and coastal sediments, with ample carbon and high heterotrophic denitrification is of minor importance. The role of nitrite reduction by Fe (II) is under investigation. Sulfide oxidation by nitrate reduction appears to play a significant role in nitrogen cycling, potentially accounting for 1-15% of the nitrate reduction rates.

Anthropogenically induced changes in groundwater flow regimes in shallow high arsenic aquifers: Evidence from ^{3}H & ^{14}C data

M. LAWSON[1,2], C.J. BALLENTINE[1], D.A. POLYA[1]*, C.L. BRYANT[3] AND A. BOYCE[4]

[1]SEAES University of Manchester M13 9PL, UK (*correspondence: david.polya@manchester.ac.uk)
[2]ExxonMobil Upstream Research Company, Houston, USA
[3]Radiocarbon Facility, East Kilbride G75 0QF, UK
[4]SUERC, East Kilbride G75 0QF, UK

An estimated 100 million people in Asia are exposed to hazardously high concentrations of naturally occuring arsenic (As) in groundwater [1]. Although regional groundwater flow in high As aquifers is driven by topographically controlled hydraulic gradients, groundwater abstraction is thought to have altered the natural flow regime by developing transient flow paths, changing the location and mode of recharge, and the timescales over which these various processes operate [2]. The Nadia district of West Bengal is an example of such an area where there has been massive groundwater abstraction for 10s years. In contrast, the Kean Svay district of Cambodia has been relatively undeveloped, and as such provides a useful analogue for the assessment of conditions prior to massive groundwater abstraction [3]. We present here isotopic data collected from these two contrasting areas.

In Cambodia, ^{3}H data indicates that, even in the absence of extensive groundwater abstraction, there is considerable interaction between surface waters and the underlying shallow (< 20 m) groundwater operating over < 50 year timescales. Dissolved inorganic carbon (DIC) ^{14}C ages, however, indicate longer mean groundwater residence times of 100s to 1000s years at depths > 55 m. In West Bengal, groundwater contains a clear contribution of tritium active recharge to depths of as deep as 63 m in 90% of the samples. This is consistent with younger mean residence times of groundwater at depths of up to 100 m obtained from DIC ^{14}C ages. ^{14}C ages of dissolved organic carbon (DOC) are younger at greater depths in West Bengal compared to that present in Cambodian groundwaters. These data suggest that groundwater pumping practices may play a key role in the groundwater DOC composition which may ultimately influence the temporal evolution of groundwater arsenic.

Halogen concentrations and $\delta^{37}Cl$ in apatite as a fluid probe to decipher fluid-rock interaction

G.D. LAYNE[1], T. JOHN[2], M.J. WHITEHOUSE[3], H. AUSTRHEIM[4] AND C. KUSEBAUCH[2]

[1]Department of Earth Sciences, Memorial University, St. John's, NL Canada (gdlayne@mun.ca)
[2]Institut für Mineralogie, WWU Münster, Germany
[3]Swedish Museum of Natural History, Stockholm, Sweden
[4]Physics of Geological Processes PGP, University of Oslo, Norway

Fundamental questions associated with fluid-rock interaction concern fluid flow in low-permeability crystalline rocks – How are fluids channelled? What is the geochemical signature of fluid flow on a regional scale? To better understand flow pattern formation and reaction front propagation, we need chemical tracers for the fluids involved (e.g. halogen ratios and $\delta^{37}Cl$) and fluid-composition indicative minerals that provide fluid probes. Apatite is a typical accessory vein-mineral in hydrothermal systems over a wide range of conditions. Apatite also reacts rather sensitively to changes in fluid composition by dissolution-reprecipitation, making it a reasonable candidate as a fluid probe. A primary advantage of apatite is that it routinely incorporates measurable concentrations of halogens.

We have performed ion microprobe (Cameca IMS1280, Nordsims facility) halogen isotope and elemental ratio measurements *in situ* on examples of 1) a hydrous shear zone cross cutting a dry gabbro (Kråkeneset, Norway) and, 2) the regional-scale scapolitization of gabbroic rocks (Bamble Sector, Norway). Within the shear zone sequence of study (1) we found a linear decrease in apatite F/Cl from 14, 000 $\times 10^{-3}$ in gabbro to ~2, 000 $\times 10^{-3}$ in sheared rock, while I/Cl decreased from ~30 $\times 10^{-6}$ to ~4 $\times 10^{-6}$. Conversely, apatite Br/Cl increased from ~0.2 $\times 10^{-3}$ to 1.1 $\times 10^{-3}$ from the most pristine gabbro to the centre of the shear zone. $\delta^{37}Cl$ in the gabbro apatites ranges from –1.0 to –0.5 ‰, and those of the shear zone cluster around +0.3 ‰. This implies a single fluid infiltration event that changed its composition during progressive fluid rock interaction.

In study (2), the least metasomatized gabbro has apatite F/Cl ~2, 000 $\times 10^{-3}$, I/Cl of ~5 $\times 10^{-6}$ and Br/Cl of ~0.9 $\times 10^{-3}$. Overprinting apatite (Cl-Ap) has F/Cl ~1.5 $\times 10^{-3}$, I/Cl of ~0.27 $\times 10^{-6}$ and Br/Cl of ~0.013 $\times 10^{-3}$, subsequently replaced by OH-Ap with F/Cl ~250 $\times 10^{-3}$, I/Cl of ~2-3 $\times 10^{-6}$ and Br/Cl of ~0.08 $\times 10^{-3}$. Apatite of the least metasomatized gabbro has $\delta^{37}Cl$ values of ~ –1 ‰, Cl-Ap of –0.2 ‰ and OH-Ap of +1.1 ‰. While the $\delta^{37}Cl$ values describe a continuous trend, the halogen ratios clearly require two distinct fluid events.

Open system U-Th ages of Red Sea corals indicate the activity of freshwater aquifers at the last interglacial

BOAZ LAZAR[1] AND MORDECHAI STEIN[2]

[1]Institute of Earth Sciences, The Hebrew University, Jerusalem 91904, Israel (boaz.lazar@huji.ac.il)
[2]Geological Survey of Israel, Malkhe Israel St., Jerusalem 95501, Israel (motistein@gsi.gov.il)

The Red Sea-Gulf of Aqaba is part of the 'Levantine corridor' where *H. sapiens* possibly migrated 'out of Africa' between 130, 000-100, 000 years BP. This 'corridor' however, lies currently in the heart of the most hyperarid desert belt on Earth, which imposes a formidable barrier to the supposed hominids migration. Yet, many fossil coral reefs scattered along the Red Sea show clear evidence for extensive interaction with fresh groundwater that resulted in recrystallization of the corals' primary aragonite skeleton to calcite. Thus, dating the age of recrystallization constrains the period when the Red Sea coastal aquifers were recharged with freshwater. However, traditional U-Th dating of corals requires close isotopic system. Therefore, we developed an open-system U-Th dating method and estimated the age of recrystallization of the tectonically uplifted fossil reef terraces along the shores of Aqaba. We found that ~140, 000 years ago, these reefs interacted with fresh groundwater and possibly also at ~118, 000 y. Apparently, the Red Sea region was wetter during the last interglacial than its current hyperarid conditions, thus facilitating the 'Levantine corridor' as the route of *H. sapience* 'out of Africa'.

Concentration of Ge in thermophilic cyano-bacterial community

E.V. LAZAREVA[1]*, A.V. BRYANSKAYA[2], O.P. TARAN[3], M.S. MELGUNOV[1], S.E. PELTEK[2] AND S.M. ZHMODIK[1]

[1]Institute of Geology and Mineralogy SB RAS, Pr. Koptug, 3, Novosibirsk, 630090, Russia (*correspondence: lazareva@igm.nsc.ru)
[2]Institute of Cytology and Genetics SB RAS, Pr. Lavrentyeva, 10, Novosibirsk, 630090, Russia
[3]Boreskov Institute of Catalysis SB RAS, Pr. Lavrentyeva, 5, Novosibirsk, 630090, Russia

It is known that Ge is a widely dispersed trace element. The crustal abundance of Ge ranges from 1 to 1.7 ppm. Higher concentrations are found in silicates, polymetallic sulfide ores, coal and petroleum [1].

This study consideres Ge accumulation in thermophilic cyano-bacterial communities. Numerous hot springs are localized in Barguzin Basin (Baikal Rift Zone). The presence of microbial communities is found in all the outlets of thermal waters. We studied 7 hot springs, which are alkaline hydrotherms with SO_4-HCO_3-Na and SO_4-Na water composition. Hot springs waters have a similar composition and different content of HS^- and Rn. The structure of dominant microorganisms in investigated communities is similar. It presented of filamentous forms: bacterium *Chloroflexus aurantiacus* and cyanobacterial genera *Phormidium*, *Leptolyngbya*, *Mastigocladus* and *Oscillatoria*.

Ge is concentrated in the cyano-bacterial communities, which grows in sulphide-less, Rn-bearing hot springs. Ge content in the microbial community of Garga and Uro hot springs is in average 270 and 350 ppm in dry weight (up to 1000 ppm), Rn content in waters is 110 and 60 Bk/L respectively. It is characteristic that the Ge is accumulating in parallel with radionuclides: ^{226}Ra, ^{228}Ra, ^{210}Pb in Garga cyano-bacterial mat (4000, 4000, 3000 Bk/kg in dry weight) and ^{210}Pb (700 Bk/kg) in the Uro microbial community. Previously was shown that organic compound of Ge exerted an antimutagenic effect on γ-ray-induced mutations in *Escherichia coli* [2]. Biological role of Ge currently not fully known, we proposed that Ge-accumulation in the thermophilic microbial communities in Barguzin Basin may be due to antimutagenic mechanism protected from high concentration of radionuclides.

[3]University of Minnesota, St. Paul, MN, USA (kyoo@umn.edu)

A multitude of scientific publications have emphasized the importance of an organic carbon (C)-mineral complexation mechanism as a crucial factor in C stabilization and sequestration. Carbon-mineral complexation is strongly controlled by mineral surface area, mineralogy, pH, redox, polyvalent cations, ionic strength, and the chemical composition of organic matter. These factors vary spatially as a function of geomorphologic, hydrologic, and microbiological processes. Soil horizons and sediments with abundant Fe and Mn oxides/hydroxides have high mineral surface area and thus a high capacity to complex C, reducing its susceptibility to microbial degradation. Additionally, both sediment and hydrological fluxes transport mineral surface area in both solid and dissolved phases.

At the Christina River Basin-Critical Zone Observatory (CRB-CZO), one of six observatories funded by the National Science Foundation, we investigate how Fe- and Mn- redox coupling affects the C cycle under varying redox conditions across a wide range of landscape positions and uses, such as floodplain forest, upland forest, and agriculture.

This investigation will demonstrate preliminary data from a number of state-of-the-art *in situ* monitoring sensors, such as redox probes, soil moisture and temperature probes, gas probes (O_2, CO_2), pressure transducers and DO/temperature sensors, that have been installed within the White Clay Creek Watershed. In addition, we are conducting an extensive field sampling and analysis of soil cores, soil pore waters, stream water, and groundwater. The water samples are being analyzed for pH, temperature, DO, Fe^{2+}, conductivity, turbidity, TDS, DOC, TOC, NO_3, C, N, δD, $\delta^{18}O$ major anions, major cations, and metals. Soils samples will be examined for total chemical composition, C%, C isotopes, and mineral surface area. Selected samples will be analyzed by XRD, SEM, EPR, Mossbauer Spectroscopy, and molecular analysis on microbial communities.

Cu isotope fractionation in primary and secondary copper minerals from the Coka Marin and Bor mining areas (East Serbia)

M. LAZAROV[1]*, S. WEYER[1], A. PAČEVSKI[2] AND I. HORN[1]

[1]Institute für Mineralogie, Leibniz Universität Hannover, Callinstr. 13, 30167 Hannover, Germany (*correspondence: m.lazarov@mineralogie.uni-hannover.de)
[2]Faculty of Mining and Geology, University of Belgrade, Dusina 7, 11000 Belgrade, Serbia

The Coka Marin and Bor mines (east Serbia) belong to porphyry-copper deposits of the Carpathian-Balkan orogen belt connected with late Cretaceous calcalkaline magmatism. Hand specimens of massive sulphide and polymetallic ores were analysed for major and minor elements by EPMA. Several representative copper minerals were hand picked and their Cu isotope composition was measured using MC-ICP-MS.

Microscope and microprobe analyses showed complex copper mineral diversity. Copper minerals are generally homogeneous, but they display differences in their chemical compositions, like variable enrichment of Sb in enargite and the formation of tetrahedrite followed by variable enrichment of Fe and Zn.

Majority of primary copper sulphide minerals and native copper display a relatively narrow range of $\delta^{65}Cu$ around 0 ± 0.5‰. The Cu isotope compositions of secondary Cu sulphates and carbonates are systematically heavier by more than 2‰. These differences in $\delta^{65}Cu$ between primary and secondary copper minerals can be observed even within a single specimen. The best explanation implies that Cu isotope fractionation takes place during partial remobilisation of Cu under oxidising conditions.

Due to complex mineral composition and intimate intergrowth of copper minerals, it is not always possible to separate mineral phases even with careful hand picking. Therefore, *in situ* measurement by femtosecond LA-MC-ICP-MS will be performed in order to identify Cu flux on mineral scale.

Enzymatic extracellular superoxide in microbial Mn(II) oxidation

D.R. LEARMAN AND C.M. HANSEL*

School of Engineering and Applied Sciences, Harvard Univerisity, Cambridge, MA 02138 (*correspondence: hansel@seas.harvard.edu)

Manganese (Mn) oxide minerals are among the strongest sorbents and oxidants in the environment, controlling the fate of contaminants, degradation of recalcitrant carbon, and cycling of nutrients. We have recently shown that a common marine bacterium, *Roseobacter* sp. AzwK-3b, oxidizes Mn (II) through an indirect pathway, via enzymatic production of extracellular superoxide during exponential growth. Superoxide production and Mn (II) oxidation in cell-free filtrate was inhibited in the presence of proteases, suggesting that superoxide production is due to a soluble protein. NADH enhanced Mn (II) oxidation and inhibition by the oxidoreductase inhibitor DPI suggested that an NADH oxidase is involved in extracellular superoxide production, and subsequent Mn (II) oxidation, by this species.

Here we present new findings revealing the proteins and genes involved in extracellular superoxide production by *Roseobacter* AzwK-3b. A soluble fraction of proteins demonstrated the ability to oxidize Mn (II), which was also substantially enhanced by the presence of NADH and inhibited by superoxide dismutase (SOD). Global protein analysis using GeLC-MS/MS identified several soluble proteins related to oxidoreductases (e.g. ferredoxin-NADH reductase, NADH ubiquinone oxidoreductase). These types of proteins have previously been implicated in the production of extracellular superoxide by pathogenic bacteria. These proteins are currently being targeted by site-directed transposon mutagenesis. In-gel assays of this soluble protein fraction also showed a protein band active for Mn (II) oxidation. Surprisingly, we observe differences in Mn (II)-oxidizing proteins when *Roseobacter* is grown under different nutrient conditions. In the presence of a minimal medium, Mn (II)-oxidizing proteins are only detected when *Roseobacter* is grown in the presence of Mn (II). Using a comparative protein approach, we are identifying differences in the proteins produced under these two conditions, which will identify the protein involved in Mn (II) oxidation.

In combination, our past and current efforts have identified a new pathway for Mn (II) oxidation that is linked to a putative NADH oxidoreductase. Our current efforts will reveal the protein and genes involved in extracellular superoxide production by *Roseobacter*. Considering the abundance of *Roseobacter* in marine environments as well as the versatility of superoxide to act as both a metal oxidant and reductant, this research has large implications in the processes driving metal cycling within marine waters.

Measuring $\delta^{13}C$ in siderite and organic matter of lake sediments

O. LEBEAU, V. BUSIGNY, C. CHADUTEAU, D. JEZEQUEL AND M. ADER

IPGP-Sorbone Paris Cité, Univ. Paris Diderot, UMR7154 CNRS, Paris, France (olebeau@ipgp.fr)

The evolution of Earth surface biogeochemistry is still not completely understood. Among the various tracers available, the isotope compositions of C and N in Archean rocks are increasingly used but their interpretations remain ambiguous. The study of present stratified water body (oxic at the surface and anoxic in the deeper part) and of their sediments may help us to better interpret the isotopic signal from old sediments. Lake Pavin (French Massif Central) is permanently stratified with anoxic Fe-rich bottom water and can be regarded as an analogue of Archean oceans before the Great Oxidation Event (~2.5 Ga). We aim at analyzing C and N isotope of particulate matter sinking in the water column together with sediment cores from various water depths, in order to understand modifications related to early diagenesis within the water column and surface sediments. In this preliminary study, we develop protocols allowing the measurement of $\delta^{13}C$ values in both organic matter and siderite (Fe-carbonate) from sediment samples.

For organic matter analysis, the removal of siderite is necessary. Previous studies have shown that carbonate dissolution with HCl should not be used because immature organic matter can be partially attacked. Diluted HCl attacks (0.5, 1 and 2M) were tested on two siderite-free Pavin sediment samples. Despite a loss of carbon, no fractionation of C isotopes occurred. A siderite-rich sediment sample will be treated in the same way to check whether siderite is completely dissolved or not.

For C and O isotope analysis of siderite, the presence of organic matter might be problematic. Tests on mixtures of yeast with siderite show that organic matter reacts with phosphoric acid and modifies C and O isotopes signal of siderite. Organic matter removal with NaOCl 3.5% and H_2O_2 30% has been tested on the mixtures. While both reactants removed efficiently organic matter, siderite was also partially oxidized, but without $\delta^{13}C_{carb}$ and $\delta^{18}O_{carb}$ modifications. The chemical treatments thus improved greatly the siderite analysis. Vacuum pyrolysis and low temperature plasma ashing will also be tested to check if they can remove organic matter without destabilizing siderite.

Variability of the element content in clays of the Poznan series

D. LECH*, I. BOJAKOWSKA, P. BRAŃSKI AND I. JAROŃ

PGI-NRI, 00-975 Warsaw, Poland
(*correspondence: dariusz.lech@pgi.gov.pl)

Introduction

Miocene-Pliocene sediments of the Poznań series, occurring in central and northern Poland, were formed in a vast inland alluvial-lacustrine basin. In these series three lithostratigraphic horizons are distinguished: green clays, gray clay, and flamy clays.

Methods

129 samples were collected from 18 deposits of clays in order to characterize the variability of elements in clays of the Poznan series. In the samples after the full acid digesting, the contents of As, Ba, Cd, Co, Cr, Cu, Mn, Mo, Ni, Pb, Sn, Sr, Ti, V, Zn, Al, Ca, Fe, K, Mg, Na, P and S were determined using ICP-OES method, the Hg was determined by AAS.

Results

Differences were found in the element contents in Poznan clays depending on their lithotype. Green clays have higher average contents of Cr, Ni, Sr, Zn, Ca, Mg, Na, K, gray clays - higher content of Hg, Ba, Ti, and lower contents of Fe, Ca, Mg, Cr and V, and a flamy clay is marked by higher contents of As, Cu, Fe, Mn, P. Higher levels of the some elements in green clays are associated with the marine environment - Sr, Mg, Na and K. It was noted the variability of elements in clays depending on the region of their occurrence. Clays occurring in the northern part of the basin have higher contents of Na and Sr. In the western part of the basin clays contain less V, Cu, Fe and Mn than clays occurring in other parts of the reservoir. It was observed decline the content of Ba, Hg, K and P in clays in an easterly direction, while increasing Ca content. Clays occurring in northern coastal zone reservoir, fed from the East European Craton area, contain more Na, Sr and Ca as compared to clays located in the southern part, fed from an old Sudeten massif, characterized by a higher content of Ti and low contents of Fe and Ca. The clays formed in the reservoir, for which feeding area were mostly young Western Carpathian orogenic areas, contain more Cu, Zn, V and Mg.

Conclusions

It has been found differences in the contents of elements in the clays of Poznan series depending on their lithological variety and the region of deposition.

Rhodochrosite gemstones: Contrasting origin and evolution of related fluids

P. LECUMBERRI-SANCHEZ[1]*, R.L. ROMER[2], V. LÜDERS[2] AND R.J. BODNAR[1]

[1]4044 Derring Hall, VirginiaTech, Blacksburg, VA 24061 US
(pilar@vt.edu, rjb@vt.edu)
[2]GFZ, Telegrafenberg, D-14473, Potsdam, Germany
(romer@gfz-potsdam.de, volue@gfz-potsdam.de,)

The Wutong (Guanxi Province, China) and Sweet Home (Colorado, USA) are Pb-Zn-Ag deposits of similar mineralogy, originally exploited for Ag, and both are prolific producers of gem-quality rhodochrosite. The Sweet Home Mine is in the Colorado Mineral Belt (which includes several giant porphyry-Mo deposits), and the genesis of the Sweet Home deposit has been linked to the Mo deposits. Converesely, potential genetic relations of the Wutong Mine are unknown. The comparison between their fluid source and evolution provides a frame to understand which factors are critical in the formation of rhodochrosite gemstones.

At Wutong, narrow ranges in Sr and Pb isotopic compositions indicate that these elements were predominantly contributed by the same fluid source. Low variability in C and O isotopic compositions in rhodochrosite is additional evidence of a fairly simple fluid evolution, unaffected by strong mixing or partitioning events. Sweet Home Mine shows contrasting results: the wide Sr range suggests that several fluid sources contributed to the bulk Sr, and the distribution of C and O isotopic compositions may point to contributions from magmatic and meteoric derived fluids [1]. The Pb isotopic compositions in both deposits reflect as well the contrasting geologic history of the Pb source rocks.

Wutong fluid inclusions (FI) indicate that temperature and salinity decrease with time during the paragenesis, consistent with a magmatic fluid trend. The only observed exception to this trend is found in primary FI in fluorite where the temperature decreases but fluid salinities are higher than in previous or later generations. Pre-fluorite FI contain CO_2 while FI post-fluorite lack CO_2. The syn-fluorite peak in salinity and the disappearance of CO_2 in FI can be explained by several processes in the system including changes in pressure, boiling or mineral precipitation.

Magmatic fluids are responsible for the formation of Wutong. Despite the more complex history of Sweet Home, additional fluid sources do not seem to be a requirement for the formation of gem-quality rhodochrosite.

Geochemical and synchrotron study of Barberton Greenstone Belt cherts (3.5-3.2 By), South Africa

M. LEDEVIN[1]*, A. SIMIONOVICI[1], N. ARNDT[1] AND F. WESTALL[2]

[1]ISTerre, BP53, 38041, Grenoble Cedex 9, France (*correspondence: morgane.ledevin@ujf-grenoble.fr)
[2]Centre de Biophysique Molléculaire, CNRS, rue Charles Sadron, 45071, Cedex 2, Orléans, France

To understand the formation of Archean cherts and the information they provide about conditions at the sea floor, we studied samples from four sites in the Barberton Greenstone Belt (3.5-3.2 By), South Africa. We identified cherts with three different origins: direct precipitation from seawater, precipitation in fractures from silica-rich hydrothermal fluids, and replacement of preexisting rocks at or near the surface.

Petrological criteria allow us to define specific chemical markers: rocks preserving sedimentary structures (e.g. laminations) have trace element patterns with high HREE and low LILE contents, and a strong negative Sr anomaly. In comparison, cherts precipitated in fractures have lower HREE and higher LILE contents, with a strong positive Ba anomaly. In one sample, the laminated portion has the chemical characteristics of the first type and a white fracture-filling chert has the features of the second type.

Another part of our study focused on petrology and rheology of Barberton cherts: both macro- and micro-structural observations are used to understand early physical behavior of chert, silica precipitation, and silicification processes. Field observations revealed complex rheological behavior, from ductile to brittle deformation, sometimes both in the same chert layer, with extremely fast diagenetic and induration processes, and some evidence of an early colloidal silica phase. Close correlation between micro-scale element repartition and microstructure by high-resolution analyses (RAMAN, X-Ray microfluorescence, cathodoluminescence, synchrotron) are currently underway.

In parallel, a petrological-geochemical study on siliceous chemical precipitates in modern volcanic lakes is being undertaken. The geochemical signatures of both Archean and modern cherts will then be used to infer physico-chemical conditions at the Archean sea floor and fractionation processes during silica transfer from fluids to rocks.

Determining the geographical origin of ginseng using strontium isotopes, multielements, and metabolite analysis

A.R. LEE[1], G. MUKESH[1], W.J. SHIN[1], M.S. CHOI[2], Y.S. BONG[1] AND K.S. LEE[1]*

[1]Korea Basic Science Institute, Ochang Center, Chungbuk 363-883, Korea (*correspondence: kslee@kbsi.re.kr)
[2]Chungnam National Univ. Daejeon 305-764, Korea (mschoi@cnu.ac.kr)

Asian ginseng (*Panax ginseng* C.A. Meyer) is widely used as an Oriental medicine in East Asian regions, particularly Korea and China. To develop a method to distinguish ginsengs cultivated in Korea with those cultivated in China, we analyzed multielements, strontium isotope ratios ($^{87}Sr/^{86}Sr$), and metabolite profiles in 35 ginseng samples collected from Korea and China. A multivariate statistical approach was performed to analyze the multiple elements and the ^{1}H nuclear magnetic resonance (NMR) data. Discriminating between the ginsengs from the two countries was generally successful when both the $^{87}Sr/^{86}Sr$ ratios and rare earth element contents were used together. Moreover, principal components analysis derived from the ^{1}H NMR data revealed a significant separation between the ginsengs originating from the two countries. The major metabolites responsible for differentiation were sugars such as glucose, xylose, and sucrose. The results suggest that this multi-platform approach offers a comprehensive method to distinguish the origin of ginsengs.

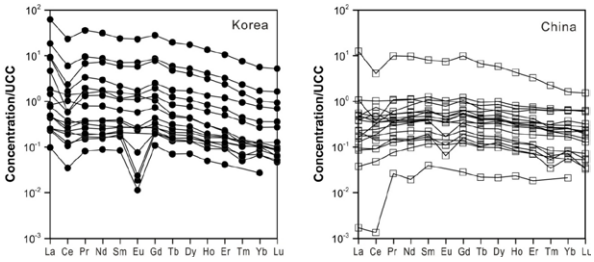

Figure 1: Upper continental crust (UCC)-normalized rare earth element (REE) patterns for the Korean (a) and Chinese (b) ginsengs.

Identification of the oldest carotenoid breakdown products in the geological record

C. LEE[1,2]* AND J.J. BROCKS[1]

[1]Research School of Earth Sciences, Australian National University, Canberra, Australia 0200
[2]Geological & Planetary Sciences, California Institute of Technology, Pasadena, CA 91125
(*correspondence: carinal@caltech.edu)

Carotenoids are often difficult to study in the geological record because of their low preservation potential. Preservation of the hydrocarbon equivalents of carotenoid molecules is rare due to their tendency to break into smaller units or undergo complex aromatisation and rearrangement reactions [1]. In rare instances where intact C_{40} carotenoid hydrocarbons are preserved by suitable diagenetic conditions, they are often subsequently cleaved into smaller fragments by increasing temperatures during burial of the host sediment (catagenesis).

Upper sections of the 1.64 billion year old (Ga) Barney Creek Formation (BCF) in the McArthur Basin of northern Australia preserves more than 22 different C_{40} carotenoid derivatives, including the hydrocarbons β-carotane, γ-carotane, and lycopane [2]. However, the C_{40} structures disappear in deeper strata, although reasons for this disappearance were unknown. It could either be a result of diagenesis, increasing thermal maturity, or change in the biological source organisms.

We simulated the natural degradation of the carotenoid hydrocarbon, β-carotane, by way of hydrous pyrolysis. Hydrous pyrolysis of β-carotane generated a mixture of systematic thermal cleavage products that were used as a new elution standard [3].

We were able to successfully identify β-/γ-carotane breakdown fragments even in deeper sections of the BCF. Given an intermittent disappearance and reappearance of these carotane fragments, as well as gradually declining concentrations with depth, we conclude that the combination of diagenesis and thermal maturity caused carotenoid decline. The fragments identified at 287 m depth in drill core GR-7 now represent the oldest evidence for non-aromatic carotenoids in the geological record.

Copper systematics in arc magmas and implications for the origin of continents, the Pb-paradox, and copper porphyry deposits

C.-T.A. LEE[1], E.J. CHIN[1], R. BOUCHET[1,2], P. LUFFI[1], R. DASGUPTA[1], D. MORTON[3], V. LE ROUX[4], Q.-Z. YIN[5], F. ALBAREDE[2] AND J. BLICHERT-TOFT[2]

[1]Rice University, TX, USA (ctlee@rice.edu)
[2]Ecole Normale Superieure, Lyon, France
[3]University of California, Riverside, CA, USA
[4]Woods Hole Oceanographic Institute, MA, USA
[5]University of California, Davis, CA, USA

Redox evolution during magma differentiation plays an important role in making continents, ore deposits, and the composition of the atmosphere. A powerful tracer of redox is S due to redox-sensitive speciation, but because S is easily disturbed by late-stage alteration, it is difficult to use as a robust tracer. However, Cu's unique affinity for sulfide makes it sensitive to S speciation and overall magma oxidation state. Here, we show that Cu in primitive arc and mid-ocean ridge basalts are similar and that the majority of arc magmas become depleted in Cu during differentiation. Thus, sulfide saturation and hence low oxygen fugacity generally characterize mantle melting and early magma differentiation in mid-ocean ridges and even most arcs. The fact that global continental crust is also depleted in Cu not only requires a missing Cu reservoir but also suggests that high oxygen fugacities are not critical in forming continental crust. We show that the missing Cu in arcs and continental crust is represented by sulfide-bearing pyroxenites formed as deep crustal cumulates that eventually founder into the mantle due to their high densities. Such foundering drives the residual crust towards felsic compositions and creates low U/Pb pyroxenite reservoirs in the deep mantle. Thus, the radiogenic Pb isotopic composition of the Earth's upper mantle is more likely attributed to continent formation than to protracted core formation. Instead of oxidized or metal-rich mantle sources, Cu-porphyries probably derive from Cu-rich pyroxenites. These pyroxenites are most prone to re-melting during arc thickening, but because the pyroxenites are given to foundering, the window for Cu-porphyry formation is narrow. An important implication of this work is that subduction does not lead to efficient oxidation of the mantle. Therefore, oxygenation of the Earth's atmosphere is not controlled by evolution of mantle redox.

The evolution of Zn and Cd isotopes in the South China Sea

DER-CHUEN LEE[1]*, SHUN-CHUN YANG[2,3] AND TUNG-YUAN HO[3]

[1]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan (*correspondence: dclee@earth.sinica.edu.tw)
[2]Dept of Geosciences, Nat. Taiwan Univ., Taipei, Taiwan
[3]Research Center for Environmental Changes, Academia Sinica, Taipei, Taiwan

Isotopic compositions of Zn and Cd for biogenetic particles and seawater samples from the South China Sea (SCS) have been determined in order to better constrain how do Zn and Cd isotopes evolve in the SCS. In general, the $\delta^{66/64}$Zn increases from -0.25‰ in the surface to 0.05‰ in the thermocline, and remains constant at 0.13‰ in the deep ocean. As for biogenic particles, they have the δZn of 0.04‰, suggesting that phytoplankton prefers heavy Zn isotopes. As a result, the vertical profile of Zn isotopes in the SCS appears to be governed by biological pump that transports heaver Zn into the deep ocean.

In contrast, the $\varepsilon^{114/110}$Cd in the seawater decreases from 9.6ε in the surface to 5.0ε in the thermocline, and remains constant at 3.5ε in the deep ocean. This seems to reflect the preferential uptake of light Cd isotope by phytoplankton in the surface water. However, the biogenic particles have the Cd isotopic signature of 9ε, comparable to that of the anthropogenic aeolian inputs, suggesting that the biological fractionation is perhaps insignificant in the SCS. Consequently, the vertical profile of Cd should reflect that of anthropogenic inputs to the surface ocean, and are subsequently transported into deeper ocean by vertical advection.

The diatom-dominated (during our sampling) SCS biogenic particles have similar Cd but heavier Zn relative to the surface water, consistent with previous findings that Cd is assimilated while Zn is mainly adsorbed in extracellular level by the phytoplankton.

Geochemical characteristics of the Nakdong River, Korea

GYEONGMIN LEE, JIYEON KIM AND YEONGKYOO KIM*

Department of Geology, Kyungpook National University, Daegu, 702-701, Korea (*correspondence: ygkim@knu.ac.kr)

The geochemical compositions of the river waters are influenced by many different factors including weathering and anthropogenic activity. Therefore, the informations on geochemical characteristics of river waters are required to get insight into the geological and hydrogeochemical processes of the river.

The Nakdong River is the second largest but the longest river in Korea. The length of the river is 506.17 km and the drainage area of the Nakdong basin is 23, 384.21 km^2. The water samples of river and tribuatry waters were collected three times in November, May, and July to see the effect of precipitation because July belongs to rainy season. The basin area of this river can be divided into two groups based on the geology: granitic and gneissic rocks in upstream region and sedimentary and granitic rocks in downstream one.

Piper diagram shows that the geochemical patterns changes from Ca-SO_4/Ca-HCO_3 type to Na-SO_4 one from upstream to downstream, showing the increase of the anthropogenic effects, and the influence of the different geology seems to be very small. The concentrations of the cations are in the order of Ca>Na>Mg>K, and those of anions are HCO_3>SO_4>Cl>NO_3, indicating that weathering is the main process controlling the geochemical compositions of the Nakdong River, especially in the upsteram region. The concentrations of Na abruptly increase at the sampling locations near Daegu, which is the third largest city in Korea, indicating a significant pollution by anthropogenic activity. The concentrations of cations in waters sampled in different months are in the order of November>July>May. However precipitation affects anion compositions differently. The concentrations of HCO_3 and Cl have the same trend as cations, but those of SO_4 and NO_3 are in the order of July>May>November, indicating possible influence of precipitation on the concentrations of these two anions.

Pilot scale feasibility test for *in situ* chemical oxidation and biodegradation process to remediate the diesel contaminated millitary site, Korea

HAJUNG LEE, INSU KIM, KYOUNGBAE BAEK AND MINHEE LEE

Department of Earth Environmnetal Sciences, Pukyong National University, Daeyon 3 dong, Namgu, Busan, 608-737, Republic of Korea (skyworld87@nate.com)

Pilot scale experiment was performed by using the *in situ* chemical oxidation and biodegradation process to remediate the diesel contaminated military site, Korea. The soil at this site was composed of sandy loam and silt loam and the initial average TPH concentration of soil was 5202.8 mg/kg.

The *in situ* chemical oxidation process was carried out on a pilot scale test site (2.5 m x 2.7 m x 1 m), by using 17.5 % hydrogen peroxide solution as an oxidizer. Five injection wells (IW-1, IW-2, IW-3, IW-4 and IW-5) and one extraction well (EW-1) were installed in the test site. The injection rate of hydrogen peroxide solution was 140 ml/min for 5 hours per day. The pumping from extraction well proceeded every 30 minutes. Total amount of H_2O_2 injected was 718 L and 400 L was extracted from the extraction well. After stabilizing the site for 7 days, indigenous microorganisms were cultivated from the contaminated soil and 86 L of solution having cultured microorganisms were added to the site, which was already treated by the chemical oxidation process, for 2 days (May 15th and 20th, 2010).

As a result of chemical oxidation process, TPH concentration of the treated soil decreased by 2138.1 mg/kg (59 % of removal efficiency). TPH concentration of site biodegraded by indigenous microorganisms for 17 days decreased by 729.6 mg/kg (92 % of removal efficiency), which was lower than Korean Soil Pollution Warning Limit (TPH : 2000 mg/kg).

From the results of the pilot scale test, it was investigated that the combination of chemical oxidation and the biodegradation process was complementary and it could effectively remediate diesel contaminated soil.

Arsenic uptake by natural sludge occurred at coal mine drainage

HYO EUN LEE[1], YOUNG JAE KIM[1], SOO-OH PARK[1], YOO HYUN SUNG[2], SAE GANG OH[3] AND YOUNG JAE LEE[1]*

[1]Department of Earth and Environmental Sciences, Korea University, Seoul 136-701, Korea (*correspondence: youngjlee@korea.ac.kr, hyonim@korea.ac.kr, jjbsnlove@korea.ac.kr, orange261@korea.ac.kr)

[2]Research and Development Team, Korea Resources Corporation, Seoul 156-406, Korea (yhsung@kores.or.kr)

[3]Office of Ecology Restoration, Mine Reclamation Corporation, Seoul 110-727, Korea (sgoh@mireco.or.kr)

Arsenic (As) is widely known as a toxic element for humans and ecosystems. Sorption of arsenic on minerals such as metal-(hydr)oxides has been known to play a key role in controlling the fate and transport of arsenic species in natural ecosystems. Despite the importance of arsenic interaction with natural minerals in ecosystems, uptake modes of arsenic by natural minerals under different physicochemical conditions are not clearly understood. Moreover, no systematic studies of arsenic uptake by naturally ocurring sludge at mine sites has been provided, especially by the combination of marcroscopic and microscopic observations.

Systematic studies, combined batch experiments with XRD, XRF, SEM, and X-ray absorption spectroscopy (XAS), have been used to investigate arsenic sorption on slugde occurred at Ham-Baek mine, South Korea. Results show that the sludeg is mainly composed of nano-sized schwertmannite (Fe_8O_8 $(OH)_6$ $(SO_4)\cdot nH_2O$). Compared to that of synthesized schwertmannite, however, XRD and SEM show that crystallinity of the sludge particles are very poor, suggesting that the surface reactivity of particles could be different. At pH 4.0 and 7.0, sorption of arsenite and arsenate on the sludge sharply increase at $[As]_{tot.} < 370$ μM, and then followed by gradually increase with increasing As concentration without reaching any plateau, indicative of Freundlich sorption behavior. At 7.0, however, the total amount of arsenate sorbed on the sludge decreases with increasing pH and ionic strength of the solution. It is found that both arsenite and arsenate uptake by the sludge is rapid and ~95% of As is sorbed on the sludge within 30 mins, suggesting that adsorption plays an important role in the initial upatke of arsenic at the sludge-water interface. XANES shows that arsenite species sorbed on the surface of the sludge particles is changed to arsenate during the duration of the experiment.

Hydrochemical and isotope study of groundwater contamination by fecal microbes

JEONG-HO LEE[1], SEONG-TAEK YUN[1]*, YONG SEOK JEONG[2], BERNHARD MAYER[3], WEON-WHA JHEONG[4] AND CHANG-HOON YOO[2]

[1]Department of Earth and Environmental Sciences, Korea University, Seoul 136-701, South Korea (*correspondence: styun@korea.ac.kr)
[2]Department of Biology, KyungHee University, Seoul, South Korea
[3]Department of Geoscience, University of Calgary, Calgary, Alberta, Canada T2N 1N4
[4]National Environmental Research Institute, Incheon, South Korea

In order to better understand the source (s) and behavior of the norovirus and other fecal microbes in groundwater systems we performed a hydrochemical and environmental isotope study in conjunction with a microbiological survey on total coliform, *E. coli*, fecal bacteria, coliphage and norovirus. In the study area with known norovirus contamination, groundwater samples were collected from 21 existing household wells and 3 multi-level monitoring wells (MLWs) installed around a latrine. The detection rate of the norovirus was high (10-19%) in household wells. Cl versus Cl/Br plots suggest that fecal microbes and potentially associated pollutants such as nitrate, chloride and sulfate are likely derived from septic effluents and animal wastes. Nitrogen and oxygen isotope ratios of nitrate in 21 groundwater samples [$\delta^{15}N_{nitrate}$ = 7.6 to 18.9‰ (avg. 13.5‰), $\delta^{18}O_{nitrate}$ = 3.6 to 13.4‰ (avg. 6.7‰)] also indicate the origin of nitrate from manure and/or sewage. Hydrochemistry data obtained from MLWs indicated the existence of one or two distinct reduction zones where denitrification occurred. In addition, groundwater from MLWs showed the frequent and considerable detection of total coliform and fecal bacteria. Detection rates of *E. coli*, coliphage and norovirus were negligible, possibly indicating that they are preferentially absorbed onto soil particles in unsaturated or saturated zones. Combined with local geologic features, we suggest that iron (hydro-)oxides in subsurface soils play a role as a sorbent of microbes. The results of this work will be helpful to evaluate the vulnerability of groundwater to fecal contamination, which can accompany norovirus and other fecal microbes.

Pb in a deep sea coral: Transfer of anthropogenic Pb to the deep North Atlantic Ocean over the last 500 years

JONG-MI LEE[1], SELENE F. ELTGROTH[2], EDWARD A. BOYLE[1] AND JESS F. ADKINS[2]

[1]Massachusetts Institute of Technology, 77 Massachusetts Ave, Cambridge, MA 02139, USA (jm_lee@mit.edu)
[2]California Institute of Technology, 1200 E. California Blvd. Pasadena, CA 91125, USA (jess@gps.caltech.edu)

Pb in the deep ocean depends on transit time distributions because its concentration and isotope composition in the surface ocean have varied significantly over time in response to anthropogenic Pb emissions. However, the use of Pb as a tracer has been limited by the lack of data in the ocean interior both in time and space. In this study, a ~500 year history of the evolution of Pb and Pb isotope ratios in the interior North Atlantic Ocean is established from a deep sea coral *E. rostrata* which was collected from ~1410m depth on the north Bermuda slope.

Coral Pb concentrations range between 1.1-4.5 nmol Pb/mol Ca from the early 16th century to the 17th century, and Pb isotope ratios ($^{206}Pb/^{207}Pb$ = 1.21, $^{208}Pb/^{207}Pb$ = 2.495) in this period agree with those found in pelagic sediments of the western North Atlantic Ocean. Slightly increased Pb/Ca ratios (~7 nmol Pb/mol Ca) are found between 1740s and 1860s, and the ratio increases rapidly from 1860s to 1997 by a factor of four. Both $^{206}Pb/^{207}Pb$ and $^{208}Pb/^{207}Pb$ ratios decrease from the mid-18th century as the Pb concentration increases, probably due to the penetration of anthropogenic Pb into the deep sea, which has lower $^{206}Pb/^{207}Pb$ and $^{208}Pb/^{207}Pb$ isotope compositions than natural Pb in this region. Comparison of this data to the 200-yr-record of surface Pb data from Bermuda corals shows that the transit time of Pb from the surface to the coral growth site is about 25 years. This estimate is consistent with that from radiocarbon measurements in the same coral. Reconstructed $\Delta^{14}C$ values also show that the bomb radiocarbon signal appears 20-25 years later than its first appearance in the surface ocean near Bermuda. However, the rise of $\Delta^{14}C$ is not as rapid in the deep as it is in the surface, potentially allowing us to reconstruct the relative effects of transport and diffusion on tracer movement from the surface to the intermediate North Atlantic Ocean.

Remediation of arsenic contaminated soil using soil washing with an acidic and reducing solution

J.H. LEE, J.G. KIM*, Y.C. CHO, C.H. LEE AND B.G. CHAE

Korea Institute of Geoscience and Mineral Resources, Daejeon 305-350, Korea (ljh@kigam.re.kr, *correspondence: jgkim@kigam.re.kr, choych@kigam.re.kr, chlee@kigam.re.kr, bgchae@kigam.re.kr)

Soil contamination with arsenic (As) is a serious environmental concern due to its highly toxicity and carcinogenic properity. Iron oxides are known a most important factor for the controlling As concentration in soil pore water. They absorb large amout of As and coprecipitate with As. We tried to develop a new washing method of As contaminated soil by the dissolution of iron oxide and desorption of As employing pH and redox potential adjustment. An As contaminated soil sample was collected at a rice paddy field near a copper smelter, Korea. The As concentration of the soil sample was determined with an aqua-regia extraction method. Washing solutions were prepared to be 0.001 – 0.1N HCl and 0 - 3 % Na-dithionite. The soil and washing solution were mixed at 1:4 ratio and the mixtures were reacted for 15, 30, 45 and 60 minutes. After the reaction, the soil and washing solution were separated with a centrifugation. The pH, Eh, and the concentrations of As, Fe and Mn of the washing solution were determined and the As concentration of the washed soil sample was also determined. The separated washing solution was treated with H_2O_2, $CaCl_2.2H_2O$ and cationic organic polymer to remove As.

The soil washing with the 0.01N HCl 3% Na-dithionite solution for 30 minutes was the most effective in the As removal from the soil reducing As concentration from 43 mg/kg to 18 mg/kg. The As concentration of the washing solution was reduce from 19.2 mg/L to 0.76 mg/L after the waste water treatment.

The stability of amino acids under redox-constrained hydrothermal conditions

NAMHEY LEE[1,2], D.I. FOUSTOUKOS[2], D.A. SVERJENSKY[1,2], H.J. CLEAVES II[2], K. KLOCHKO[2] AND R.M. HAZEN[2]

[1]Department of Earth and Planetary Sciences, Johns Hopkins University, Baltimore, MD, 21218 (namheyl@jhu.edu)
[2]Geophysical Laboratory, Carnegie Institution of Washington, 5251 Broad Branch Road, NW, Washington D.C., 20015

With the discovery of an extensive biosphere near deep-sea hydrothermal vents, the stability of amino acids at elevated temperatures and pressures is of great interest for the cycling of C and N within the crust and the overlying oceanic water column. Previous studies provide strong evidence that the decomposition properties of amino acids are very sensitive to parameters such as temperature, and catalytic reactor surfaces. However, despite the clear relevance, the redox state of the system has rarely been controlled in such studies. Here hydrothermal experiments were conducted to investigate the influence of redox conditions on the stability of glutamic acid at pressures and temperatures reflecting near-seafloor hydrothermal environments (100–250 °C, 136 bar). Reactions were conducted for 3 to 35 min. in a titanium flow-through cell. The oxidation state was controlled by equilibrating ~ 22 mmolal of H_2 (aq) with a glutamic acid solution with pH adjusted to ~10 at 25 °C. The products were identified and analyzed using gas chromatography and ionic chromatography with conductivity and electrochemical detectors. Results indicate that the reaction kinetics of glutamic acid under hydrothermal conditions is associated with conversion to the cyclic pyroglutamate via a dehydration reaction. Other products of glutamic acid included CO_2 (aq) and H_2 (aq). At temperatures above 200 °C formate was also observed, possibly produced via a decarboxylation and reduction. The conversion rate of glutamic acid to pyroglutamic acid, however, does not appear to be affected by the redox state of the system. The decomposition of glutamic acid is observed to obey first-order kinetics. From the temperature-dependent decay rate expressed by the Arrhenius equation, we obtained an activation energy of 39.6 kJ/mol with a pre-exponential factor as 74 sec^{-1}, whereas previous study estimated the activation energy of 152 kJ/mol with a pre-exponential factor as 10^{13} sec^{-1} using Pyrex glass and longer reaction times up to 15 hrs at 252 ºC [1].

Geochemical significance of ^{14}C, ^{3}H, $\delta^{18}O$, $\delta^{2}H$ and $^{87}Sr/^{86}Sr$ isotopic data in the hot spring waters of South Korea

S-G. LEE[1]*, T. NAKAMURA[2], Y.Y. YOON[1], T-K. KIM[1], T. OHTA[2] AND T. LEE[1]

[1]Korea Institute of Geoscience and Mineral Resources, Daejeon 305-350, Korea (sgl@kigam.re.kr, yyyoon@kigam.re.kr, tkkim@kigam.re.kr, megi@kigam.re.kr)

[2]Center for Chronological Research, Nagoya University, Nagoya 464-8601, Japan (nakamura@nendai.nagoya-u.ac.jp)

Despite being a non-volcanic area, South Korea has a number of the hot springs with water temperatures of more than 40°C. The occurrence of these hot springs are related with Mesozoic granites in the Korean Prninsula. The hot springs are located at the fringes of the granite body rather than the center of the Mesozoic granites. Lee *et al.* [1] reported a geochemical characteristic of the $^{87}Sr/^{86}Sr$ in the hot spring waters, and suggested that the heat source of the hot spring water might be related with granite emplacement. Most hot springs are deep-drilled wells with depths of more than 100m, and motorized pumps are used. Here we report new data for $^{87}Sr/^{86}Sr$ ratio of the hot spring waters, and also report $\delta^{2}H$, $\delta^{18}O$, ^{14}C and ^{3}H isotopic data of hot spring waters in South Korea to discuss the origin of the hot spring waters.

Environmental isotope results such as $\delta^{2}H$ and $\delta^{18}O$ reveal that hot spring water and groundwater were originated from the meteoric water. However, there was no variation in chemical compostions and $^{87}Sr/^{86}Sr$ ratio of the hot spring waters during last eight years. ^{14}C activity of DIC in the hot spring waters in South Korea ranges from 1.7 pMC to 78 pMC. Such $^{87}Sr/^{86}Sr$ and ^{14}C isotope results show that the circulation between thermal water and current meteoric water including groundwater, surface water and rainwater at the southeastern part in the South Korea should be slow. Our data indicate that the high temperature hot spring water in South Korea might be derived from paleo-groundwater reservoir with high temperature rather than circulation of the modern meteoric water heated directly by a current heat souce. This also suggests that the hot spring water in the granite area might be one of limited groundwater resources.

Zircon Hf isotopic study of the Mesozoic granitoids from Korea and Japan and tectonic implications

S.R. LEE[1]*, D.-L. CHO[1] AND F.-Y. WU[2]

[1]Geological Research Divison, Korea Institute of Geoscience and Mineral Resources, Daejeon 305-350, Korea (*correspondence: leesr@kigam.re.kr)

[2]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China

Before switching to the present-day island arc system during the Miocene, the Japanese Islands grew outboard of the older continental margin of East Asia, next to the Korean Peninsula [1]. The Hida belt, including the Precambrian rocks, represents the remant of the former Asian continental margin, but its tectonic correlation to the North China or South China cratons is uncertain. The Korean Peninsula consists of three Precambiran massifs: Nangrim, Gyeonggi and Yeongnam massifs. The first and last are considered as parts of the North China craton, while the middle as a part of the South China craton [2], though such correlations are still under debating [2, 3]. The correlative study among the Hida belt and Korean massifs thus provides some clues to the Mesozoic continental accretions of the eastern margin of the Asian continent.

In this study Hf isotopic compositions of the zircons are presented for the Late Paleozoic-Mesozoic granitoids from the Hida belt and Korean massifs. In the Hida belt, εHf (t) values range from +5 to -8 for the Triassic zircons, and from +12 to +6 for the Jurassic zircons, respectively. The εHf (t) values range from -10 to -26 for the Triassic zircons of the Gyeonggi massif, while they range from -4 to -12 for the Triassic zircons and -22 to -32 for the Jurassic zircons of the Yeongnam massif. Our data indicate that the source materials are similar to each other for the Triassic granitoids from the Hida belt and Yeongnam massif, and suggest that the Hida belt is more correlative to the Yeongnam massif (i.e. North China craton) rather than the Gyeonggi massif (i.e. South China craton). During the Jurassic, however, the source materials became more juvenile for the Hida granitoid, while they changed progressively to crustal-dominated ones for the granitoids from the Yeongnam massif. This feature suggests that the crustal thickness of the eastenmost part of the Asian continental margin (i.e. Hida belt) has extended enough to shift from continental arc setting to island arc setting during the Jurassic time.

$Cr(OH)_3(s)$ oxidation by birnessite under common groundwater pH conditions

YEONJIN LEE AND GIEHYEON LEE*

Department of Earth System Sciences, Yonsei University, 50 Yonsei-ro, Seodaemun-gu, Seoul 120-749, Korea (*correspondence: ghlee@yonsei.ac.kr, ureca0125@yonsei.ac.kr)

Contamination of soil and groundwater by hexavalent chromium (Cr(VI)), which is the 2nd most common inorganic contaminant, was generally considered to be generated from anthropogenic sources. Recently, natural groundwater contamination by Cr(VI) without any anthropogenic sources have also been reported over the world. Previous studies showed that various Mn oxides effectively oxidized aqueous- or solid-phase Cr(III) under acidic pH conditions but not under neutral or higher pH conditions. Yet, the geochemical processes causing the natural contamination of Cr(VI) have not been clearly unravelled. This study examined the oxidation of $Cr(OH)_3(s)$ by birnessite, under common groundwater pH conditions. Both solids are ubiquitous in the environment. Practically, $Cr(OH)_3(s)$ has been thought to hinder the oxidation of dissolved Cr(III) by Mn oxides because the precipitation of this solid on Mn oxide would block the reactive surface sites.

Particle suspensions were prepared with synthetic $Cr(OH)_3(s)$ and/or birnessite in 50 mM $NaNO_3$ at pH 7, 8, or 9 open to the atmosphere. The individual solid concentration was 1 g/L in every case and the solution pH was maintained with a 10 mM buffer (Na-MOPS for pH 7 and 8, CHES for pH 9). In the presence of birnessite, Cr(VI) concentrations increased with increasing pH and reached up to 209, 613, 836 µM at pH 7, 8, and 9, respectively, within a month. These Cr(VI) concentrations were substantially higher than those in the absence of birnessite at all pHs. These results indicate that birnessite could effectivly oxidize $Cr(OH)_3(s)$, where the solubility of this solid is minimum. In addition, the apparent rate and extent of $Cr(OH)_3(s)$ oxidation appeared to be controlled by several accompanied reactions, the effects of which mainly depend on the pH of the system. It is noteworthy that the rate of $Cr(OH)_3(s)$ oxidation increased with time during the first 10 hr followed by a decrease in the rate with time for the rest of the reaction. These results suggest that the overall oxidation would likely be accelerated by a reaction intermediate in the early stage of the reaction. A potential reaction pathway of $Cr(OH)_3(s)$ oxidation will be briefly discussed.

Ternary surface complexes probed by attenuated total reflection-infrared spectroscopy

G. LEFÈVRE[1]*, F. MERCIER-BION[2], Y. ZHAO[2], V. SLADKOV[2], J. ROQUES[2] AND E. SIMONI[2]

[1]LECIME, UMR7575 CNRS-Chimie ParisTech, 75005 Paris, France (*correspondence: gregory-lefevre@enscp.fr)

[2]IPNO, UMR 8608 CNRS-Université Paris-Sud 11, 91406 Orsay, France

Attenuated Total Reflection-Infrared spectroscopy (ATR-IR) is amongst the most developped spectral techniques during the last decades to study the solid/solution interfaces. Its efficiency in determining the speciation of adsorbed ions has been proved in numerous works using different metallic oxides [1]. Its advantage is to probe the system in presence of solution, avoiding the modification of the structure consequently to the dehydration. Indeed, this phenomenon can occur for inner-sphere complexes, even though it is not systematic, while for outer-sphere complexes, the dehydration step has always a dramatic effect. Another field where the possibilities of ATR-IR are underexploited is the characterization of ternary surface complexes including the mineral surface / a bridging species / a second adsorbed species. The main question which can be adressed by ATR-IR is to determine which is the bridging species, and what type of chemical groups are bonded to the mineral surface or to the other adsorbed species. In literature, such studies have been performed on goethite/sulfate/Pb (II) [2] or hematite/carbonate/U (VI) [3], goethite/glyphosate/Cu (II) [4] for example. The purpose of our current works is to characterize the surface reactivity of silica towards uranyl ions in presence of small organic molecules to evaluate the role of organic matter on the transport of radionuclides in environment. We have first studied the system silica/uranyl/acetate, using ATR to show the presence of a ternary complex. The same work with more complex organic molecules is in progress.

Composition of the earliest hydrothermal fluids circulating along the South Range of the Sudbury Igneous Complex, Canada

DARREN LEFORT[1]*, JACOB HANLEY[1] AND JUNG HUN SEO[2]

[1]Dept. Geology, Saint Mary's University, Halifax, Canada (*correspondence: darrenlefort@gmail.com)
[2]ETH Zurich, Institute of Geochemistry and Petrology, CH-8092 Zürich, Switzerland

The Garson Ni-Cu-PGE deposit (Sudbury, Ontario, Canada) is hosted along the contact of the Sudbury Igneous Complex (SIC) and underlying Proterozoic-age metasediments and metavolcanic rocks. The deposit is strongly controlled by structural features and contains magmatic sulfides hosted in discrete shear zones. The main sulfides present are pyrrhotite, pentlandite and chalcopyrite with minor pyrite.

Massive sulfides overprint early quartz veins, forming sulfide-quartz stockworks. Fluid inclusions in the quartz are predominantly aqueous (30 vol% bubble) that contain a CO_2 vapor phase that homogenize upon heating between 2.8 and 29.0ºC, indicating a relatively low pressure of entrapment. A subordinate group of three phase (liquid-vapor-halite) inclusions are also present in the samples. Microthermometry showed the presence of clathrates in the primary inclusions. Clathrate destabilization temperatures yielded salinities between 12.1 to 14.4 wt% $NaCl_{equiv.}$. Some inclusions in which clathrates were not observed yielded a wide range salinities (from ice melting T) between 1 to 21 wt% $NaCl_{equiv.}$

LA-ICP-MS microanalysis of the primary aqueous inclusions show elevated concentrations of As, Pb, Zn and Sb, but very low concentrations of Cu, Fe and S, suggesting that these fluids did not equilibrate with typical magmatic sulfides or sulfide liquids, and were trapped prior to sulfide emplacement in the shear zones. Arsenic concentration in the fluids correlates to bulk salinity suggesting that the Cl complexation of As predominates at low T and low f_{O2}.

The circulation of early-stage CO_2-NaCl-H_2O fluids through metasedimentary wall rocks (and/or formation of these fluids from contact metamorphism of those wall rocks) may have been a factor in the local secondary enrichment of the Garson ores where As may be closely correlated to PGE distribution. Additionally, detection of As-rich fluid inclusions in quartz veins predating sulfide emplacement may serve as a discrimination tool for identifying areas along the South Range in which sulfide magmas may have been later contaminated through interaction with As-bearing country rocks.

Investigation of copper and zinc speciation in pig slurry by a multitechnique approach

The fate of pollutants associated with organic wastes is a key issue. For example, pig slurry presents high concentration of Copper (Cu) and Zinc (Zn) since they are used (at high concentration) as essential micronutrients in animal feeds. As a consequence, Cu and Zn accumulation was measured in soil surface layers that had been amended with pig slurry, inducing phytotoxicity as well as groundwater quality degradation. Better prediction of the mobility and bioavailability of Cu and Zn from pig slurry spreading can be achieved by determining the speciation of these elements.

The aim of this study is to investigate Cu and Zn speciation in pig slurry. A multitechnique approach was adopted including size fractionation, XRD, SEM-EDS, µXRF and XAS.

The present study demonstrated that only 0.2% of total Cu or Zn present in pig slurry was bound to particles smaller than 0.45 µm, while 75% of total Cu and Zn was bound to particles in the 0.45–20 µm size range. µXRF highlighted the colocalisation of Cu and sulfur. In addition, geochemical modelling demonstrated that physical chemical conditions within pig slurry lagoon are compatible with the precipitation of chalcocite (Cu_2S). Finally, XANES shows that Cu speciation in raw pig slurry and size fractions is described by Cu_2S and that its oxidation state is Cu (I). These Cu speciation in pig slurry may be the main reason for the observed Cu accumulation at the soil surface. Zn speciation revealed three patterns 49% Zn bound to organic matter, 37% amorphous Zn hydroxide, and 14% sphalerite (ZnS). The detected presence Zn sulphide, was unexpected and is reported for the first time. These three Zn forms seemed to be soluble in neutral or weakly acid soil systems, so the long-term impact of pig slurry spreading could lead to Zn leaching.

Aqueous alteration of organic matter and amorphous silicate in pristine chondrites: A multiscale study

C. LE GUILLOU[1], A. BREARLEY[1], L. REMUSAT[2] AND S. BERNARD[2]

[1]Dpt. of Earth and Planetary Sciences, University of New Mexico, Albuquerque, NM, USA (corentin.san@gmail.com)
[2]LMCM, MNHN, CNRS, Paris, France

Amorphous silicates have been observed in accretion disks of young stars[1]. On the other hand, amorphous silicates are also found in chondrites[2]. Therefore, the study of nanoparticles contained in the matrices of pristine chondrites may provide major insights into the nature of the nebular dust. We have explored the relationships between organics, water and silicates *in situ* by FIB-TEM, fluorescence microscopy, NanoSIMS and STXM (Scanning Transmission X-Ray Microscopy) in four carbonaceous chondrites with various alteration degree. Our goal is to assess the nature of the precursors (i.e. the dust) as well as the subsequent hydrothermal interactions which modified the accreted components.

We evidence the presence of hydrated amorphous silicate in MET00426 (CR3.0) and, for the first time, in Renazzo (CR2). Using ATEM, we estimate that this phase contains from 5 to 10 wt. % of water and has a very heterogeneous Fe/(Fe+Mg) ratio ranging from 30 to 75 at.%. Adjacent phyllosilicates which are probably genetically derived from the amorphous silicates have similar water contents and heterogeneous Fe/(Fe+Mg) ratios.

The spatial distribution of the organics shows a clear evolution with increasing aqueous alteration degree, detectable by TEM and fluorescence microscopy. In the least altered meteorites (CRs), mainly isolated grains are found (<500 nm) which sometimes share a preferential spatial relationship with phyllosilicates. In contrast, the more highly altered Murchison (CM2) and Orgueil (CI1) show a clear dichotomy between i) isolated grains and ii) a diffuse nanoscale mixture of organics and phyllosilicates. STXM results demonstrate the strong molecular heterogeneity of both types of grains at the sub-micrometer scale.

To explain these observations, we propose a scenario where organics trapped in water ice grains are mixed with amorphous silicates during accretion. Later, water melts, hydrates the amorphous silicate and redistributes the organic constituents which are entrapped within forming phyllosilicates during aqueous alteration.

The assumption of a low pCO_2 during the Archean investigated with a 3D climate model

G. LE HIR[1]*, Y. TEITLER[1], F. FLUTEAU[1], Y. DONNADIEU[2] AND P. PHILIPPOT[1]

[1]IPGP, Université Paris 7-Denis Diderot, 1 rue Cuvier, Paris, France (*correspondence: lehir@ipgp.fr)
[2]LSCE, CNRS-CEA-UVSQ, 91191 Gif-sur-Yvette, France (Yannick.Donnadieu@lsce.ipsl.fr)

A new controversial assumption, based on banded iron formation mineralogy, supposes that the Archean atmosphere was potentially characterized by low concentrations of CO_2 [1]. To solve the young Sun problem, it hypothesized that a reduced albedo associated to less reflective clouds were able to prevent the early Earth to jump into a snowball state [1]. We have investigated the early Earth climate, using a general circulation model (GCM), to test this scenario including the ice albedo feedback [2]. Accounting for this feedback, we demonstrate that the faint young Sun problem is not solved. Hence we face again to the difficulty of maintaining a clement climate before 3Ga.

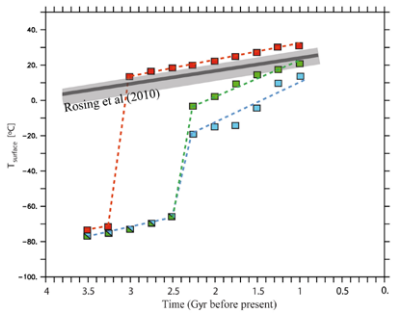

Figure 1: Surface temperature versus time assuming increasing irradiance**,** linear continental growth and a pCO_2 and pCH_4 of 900ppmv [1]. Blue, and red lines were obtained using liquid droplets size of 5 to 10μm (modern clouds), and 20μm (archean clouds), respectively [1]. The green line represents the no-clouds scenario.

Mantle source compositions of magmas from the North Atlantic Igneous Province

B. LEHMANN[1]*, A.V. SOBOLEV[1,2,3], N.T. ARNDT[1] AND C. CHAUVEL[1]

[1]ISTerre, University J. Fourier BP 53, 38041 Grenoble Cedex 9, France (*correspondence: benjamin-lehmann@hotmail.fr, alexander.sobolev@ujf-grenoble.fr)

[2]Max Planck Institute for Chemistry, Postfach 3060, 55020 Mainz, Germany

[3]Vernadsky Institute of Geochemistry, RAS, 119991 Moscow, Russia

It is widely accepted that the recycled oceanic crust plays an important role in the composition of mantle-derived magmas. In the case of North Atlantic Province, the amount of ancient oceanic crust is not well constrained. We used a new method of analysing the minor elements in olivine phenocrysts [1, 2] to determine the proportions of peridotite and eclogite in the source, and report new estimates for the lithology of mantle sources of Tertiary basalts in Northern Ireland and Scotland, which represent the oldest parts of the North Atlantic Province.

Preliminary results indicate significant and variable Ni excess and Mn deficiency in the compositions of magnesian olivine phenocrysts. This suggests a considerable but variable amount of non-peridotitic component (olivine-free pyroxenite) in the mantle sources of British Tertiary Province. Overall the estimated proportions of pyroxenite-derived melt are similar to that previously found for North Atlantic Province [1], and are markedly lower than in Hawaii.

[4]Iron Ore Exploration, VALE, 34000-000 Nova Lima-MG, Brazil

The 250-300-m-thick Carajás Formation in the Carajás Mineral Province, northeastern Brazil, consists of banded iron formation (including giant iron ore deposits) and a lower shale-siltstone member, overlying several kms of 2.76-Ga-old meta-basalt. The shale-siltstone member hosts black shale units. The black shales (drillcore from the Serra Sul exploration project) have up to 29 ppm Mo, and trace element patterns reflect variable degree of clastic and hydrogenous input for a suite of redox-sensitive elements. We studied a 20-cm-drillcore interval in detail. The systematic $\delta^{98}/^{95}$Mo isotope pattern defines a clastic end-member with about 0.2 permil for continental input and 0.9 permil for seawater input. Five samples with the most euxinic signature give a Re-Os isochron of 2703 ± 64 Ma (2s) with an initial $^{187}/^{188}$Os of -0.26 ±0.55 (MSWD 0.57). Initial Os isotope ratios for the entire black shale population indicate mixing of continental material with a high $^{187}/^{188}$Os ratio up to 1.4 with a ~chondritic Os source (e.g. hydrothermal ridge input via seawater). Some black shale samples from deeper drillcore have astonishingly heavy Mo isotope compositions up to 1.8 permil $\delta^{98}/^{95}$Mo which suggests oxidative isotope fractionation similar to what has been described from the 2.5 Ga McRae Shale in Australia, but the Carajás samples are 200 Ma older. We interpret this finding as a very early 'whiff of oxygen'.

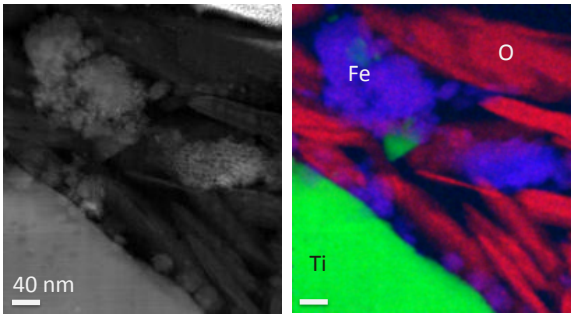
Functional group chemistry at the mineral-organic interface in soils

JOHANNES LEHMANN[1]*, DAWIT SOLOMON[1], DAVID MULLER[2], CHEE CHIA[3], HUOLIN XIN[2], STEPHEN JOSEPH[3] AND PAUL MUNROE[3]

[1]Department of Crop and Soil Sciences, Cornell University, Ithaca NY 14853, USA (*correspondence: CL273@cornell.edu)
[2]School of Applied and Engineering Physics, Cornell University, Ithaca, NY 14853, USA
[3]School of Materials Science and Engineering, University of New South Wales, Syndey, NSW 2052, Australia

We know that most organic matter enters the soil as readily recognizable plant and animal detritus, and is mineralized within short timescales of one or two years. The remaining organic C, however, is stabilized for longer timescales of up to thousands of years in the presence of Fe, Al, Mn oxide and hydroxides, phyllosilicates and other soil minerals. Changes in mineralogy can enhance the soil C storage potential several fold. It is, therefore, all the more astonishing that the precise mechanism for the interaction between minerals and C in soils is still largely unknown. One of the major limiting factors to past investigations of soil C sequestration is the fact that these processes operate well below the scale that most researchers have been able to observe. We have made significant progress over the past five years to examine C properties at sub-micrometer level using scanning transmission electron microscopy coupled with near edge x-ray absorption fine structure - STXM-NEXAFS spectroscopy, and clearly demonstrated, for the first time, the importance of the spatial distribution of organic C on a 25-100 nm scale. Here we show in addition aberration-corrected scanning transmission electron microscopy (STEM) combined with electron energy loss spectroscopy (EELS) enabling three-dimensional and high-resolution imaging, elemental identification and studies of nearest-neighbor bonding at the atomic scale of the organo-mineral interface in soils.



Uncoupled enrichment of ^{15}N and ^{18}O in nitrate – Constraints on nitrate regeneration in various aquatic environments

M.F. LEHMANN[1]*, C.B. WENK[1] AND A. BOURBONNAIS[2]

[1]University of Basel, Insitute of Environmental Geosciences, Bernoullistr. 30, CH-4056 Basel, Switzerland (*correspondence: moritz.lehmann@unibas.ch)
[2]School of Earth and Ocean Sciences, University of Victoria, Victoria, British Columbia, Canada, V8P 5C2

Measuring the nitrogen (N) and oxygen (O) isotope ratios in nitrate has been used to track N sources and transformations in freshwater and marine ecosystems. The deviation of nitrate N and O isotope values from parallel trends in $\delta^{15}N$ and $\delta^{18}O$ expected for nitrate uptake or denitrification has been taken as indication for nitrate production by nitrification. It still remains unclear, however, what controls O-isotope signatures of new nitrate in nature and, in turn, how sensitive the dual nitrate isotope signature is towards nitrate regeneration by nitrifying bacteria.

We will present nitrate isotope data from the open ocean, marine sediments, hydrothermal systems and a freshwater lake. Using a simple numerical model, nitrate isotope data are put into a quantitative framework for assessing nitrate production in net nitrate-consuming environments, and potential mechanisms involved in the generation of characteristic dual nitrate isotope signatures and anomalies in the various aquatic environments will be discussed.

Large ε_{Nd} change in South Indian seawater driven by Australian weathering at 15 Ma

S. LE HOUEDEC, L. MEYNADIER AND C.J. ALLEGRE

IPGP (Sorbonne Paris Cité, Université Paris Diderot, UMR7154 CNRS) 1 rue jussieu, 75005 Paris, France (lehouedec@ipgp.fr, meynadier@ipgp.fr, allegre@ipgp.fr)

We present Nd upper seawater data analysed on Indian Ocean carbonated oozes sediment from Site ODP 756 (located on the Ninety East Ridge, at 1518 m of water depth) and from Site ODP 762 (located on northwest Australian margin, at 1360 m of water depth). Our data cover the past 40 Ma at a resolution of two samples/Ma.

Amazingly, the records strongly mimic previous data from northern ODP Sites (ODP 757 and 707) (Gourlan *et al*. 2008; Martin and Scher, 2006).

We show that from 40 Ma to 10 Ma, the ε_{Nd} geographical distribution was homogenous over most of the Indian intermediate seawater, from a paleolatitute of 40°S up to the equator and over the entire Indian Ocean width. From 40 to 15 Ma, the ε_{Nd} value of Indian Ocean intermediate seawater recorded at all four ODP sites was almost constant, around -7 to -8 and increased by 3 ε_{Nd} units from 15 to 10 Ma. This sharp increase of ε_{Nd} is related to the enrichment by radiogenic Nd of the water mass originating from the Pacific as it flows through the Indonesian Passage. The numerous volcanic islands of this region corroborate the hypothesis of erosion and weathering of radiogenic Nd. By extending the studied area to the south, we demonstrated that this oceanic event is so strong that it can drive the ε_{Nd} of South Indian Ocean down to 40°S. With a two end-members model, we calculated that this event is characterized by an increase of ~1.7 time of the Nd transported through the Indonesian Pathway.

At 10 Ma, a large ε_{Nd} decrease (down to 6 ε_{Nd} units at Site ODP 762) is recorded. Such a large decrease was never observed in other northern Indian sites. Additional ε_{Nd} analyses on the detrital component of our two cores allow us to show that the seawater ε_{Nd} is then driven by detrital inputs linked to the weathering of Australia Continent. We estimate at about 20% the Nd contribution of this continental source to the oceanic Nd budget between 10 to 5 Ma. This could result of the beginning of the Australian drying (Bowler, 1976; Jonhson, 2009; Martin, 2006).

Long-term dynamics of differently stable soil organic matter fractions as function of soil management

PETER LEINWEBER[1]* AND SÖREN THIELE-BRUHN[2]

[1]Soil Science, University of Rostock, Justus-von-Liebig-Weg 6, 18051 Rostock, Germany

[2]Soil Science, University of Trier, Behringstraße 21, 54286 Trier, Germany

Rationale and experimental

Soil carbon is an integral part of soil organic matter (SOM), and modelling of its dynamics requires detailed information on the long-term fate of differently stable pools. Pyrolysis-field ionisation mass spectrometry (Py-FIMS) is the only method currently available that enables a rapid quantitation of ten different SOM compound classes and their thermal (biological) stability. We applied Py-FIMS to sample series from different treatments in one of the World´s oldest agricultural field experiments. First we determined temperature thresholds for 'labile' and 'stable' fractions of compound classes in laboratory incubation experiments. Next we applied these temperatures to quantitate differently stabile portions of compound classes, and test to what extent they have altered in various cropping systems from the early 1960ies until today.

Results and discussion

A kinetic model with coupled exponential functions was fitted to time series for relative abundances of compound classes. Cropping change from rye to maize led to (i) initial depletions in phenols & lignin monomers carbohydrates and N-compounds, the latter two being relatively enriched after 20 yrs, and (ii) initial enrichments in alkylaromatics, lipids and lignin dimers (for 15 yrs) followed by their net-decomposition over the next 30 yrs. This, however, was valid the labile proportions of compounds only (Fig. 1).

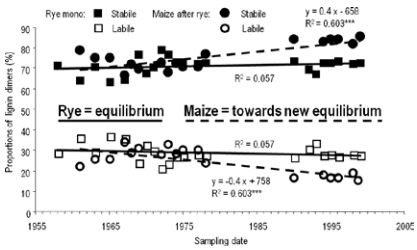

Figure 1: Proportions of labile and stabile lignin dimers in the "Eternal Rye Cultivation" as revealed by Py-FIMS.

Overall, we will demonstrate which SOM fractions were most susceptible to alterations according to cropping (rye, potato, maize) and fertilization (mineral vs. organic) practices.

Deciphering the offshore biogeochemical record of Holocene erosion in the Waipaoa watershed, New Zealand

E.L. LEITHOLD[1]*, N.E. BLAIR[2] AND L.B. CHILDRESS[2]

[1]Department of Marine, Earth, and Atmospheric Sciences, North Carolina State University, Raleigh, NC 27695, USA (*correspondence to leithold@ncsu.edu)

[2]Department of Civil and Environmental Engineering and Department of Earth and Planetary Sciences, Northwestern University, Evanston, IL 60208, USA (n_blair@northwestern.edu, lbchildr@northwestern.edu)

Continental margin sediments preserve a record of long-term changes in erosion in adjacent watersheds, and organic matter is one of the most useful components for decoding that record. ^{14}C in particular serves as an invaluable tool for resolving the relative contributions of sediment from shallow and deeper levels in the regolith, and therefore for reconstructing changes in the roles of various geomorphic processes over time. Here we report on a study of the sedimentary record preserved on the continental shelf offshore from the Waipaoa River, NZ. ^{14}C and $\delta^{13}C$analyses of bulk sediments as well as clay-sized, wood, and charcoal isolates provide evidence for a mid-Holocene episode of elevated bedrock OC input that is consistent with evidence for earthflow activity in the watershed and a stormy period in the region. Deforestation of the watershed by Polynesian settlers ca. 700 years ago is recorded by evidence for biomass burning as well as elevated levels of shallow landsliding and soil erosion. Finally, the development of deeply incised gullies following deforestation of the headwaters by European settlers is reflected by large contributions of bedrock OC to the riverine particulate carbon load during the past century. Our approach in the Waipaoa system offers promise for using biogeochemical stratigraphic records to reconstruct the influence of tectonics, climate, and human activities on geomorphic processes in watersheds around the world.

Arsenic mobilization in a high Andean watershed impacted by legacy mining

E.D. LEIVA, P.L. RÍOS, C.R. ESCAURIAZA, C.A. BONILLA, G.E. PIZARRO AND P.A. PASTEN*

Department of Hydraulic and Environmental Engineering Pontificia Universidad Catolica de Chile, Santiago, Chile (*correspondence: ppasten@ing.puc.cl)

Northern Chile is known by its water scarcity and rich mining activity. A complex mixture of contaminants from natural and anthropogenic sources limits the development of agricultural and industrial activities in the Lluta river watershed. A legacy sulfur mine site in the Altiplano is a key source of acid mine drainage on the upper section of the watershed. Tailings show high concentrations of arsenic (2-8 g/kg) (Fig 1) and sulfur (3-13 g/kg), with pH<1. The XRD analyses of tailings reveal a high proportion of elemental sulfur. Although this is a semi-arid environment (310 mm/year of precipitation), storms concentrate during the Bolivian winter. The RUSLE method estimates that ~14% of storms are erosive; thus sediments with acid formation potential are mobilized during the wet season. Downstream, mixing with neutral waters at varying proportions induce the occasional formation of Fe and Al oxides that become an arsenic repository. Fine colloids are mobilized by base flows, whereas coarse arsenic rich Fe-coated sediments are stored on the sediments. The sustainable development of water infrastructure (reservoir, irrigation works) needs to consider the interactions between hydrological, hydrodynamic and chemical processes.

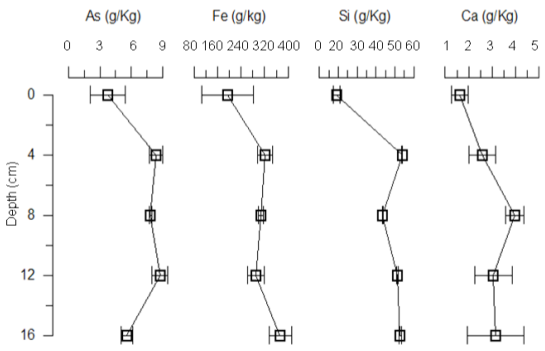

Figure 1: Geochemical analysis of tailings profile (As content and elemental associations [Fe, Si, Ca]). *Representative profile*.

Water speciation in silicate melts investigated by Raman spectroscopy: Implication for volcanic process

CHARLES LE LOSQ[1], ROBERTO MORETTI[2,3] AND DANIEL R. NEUVILLE[1]

[1]CNRS-IPGP, Université Paris 7, Paris Sorbonne Cité, Laboratoire de Géochimie et Cosmochimie, 1 rue Jussieu, 75005 Paris, France (lelosq@ipgp.fr)

[3]Istituto Nazionale di Geofisica e Vulcanologia, sezione di Napoli ‚Osservatorio Vesuviano', Italy

In addition to temperature, pressure and main chemical components, volatiles exert a strong influence on the physical properties of magmas. In particular, water plays a fundamental role in the dynamics and evolution of magmas in the deep interior and during volcano eruptions. However, water speciation in silicate melts is not fully understood. Infrared and NMR spectroscopy had provided some valuable informations about the H_2O/OH^- speciation. Nevertheless, some issues still remain unsolved about the OH^-/H_2O linkage to the silicate network.

Raman spectroscopy already allows quantifying the proportion of water dissolved in an aluminosilicate melt. Raman spectra are composed of i) a low wave number region that corresponds to vibrations of the silicate network (0-1500 cm^{-1}), and ii) a high wave-number region, which corresponds to the OH^- stretching vibrations and H_2O molecular vibrations (3100-3750 cm^{-1}). We have performed a first set of *in situ* experiments using a micro-furnace at ambient atmosphere. An evolution of the high wave-number region in function of the time and temperature is observed. New Raman peaks can be distinguished, particularly near 3650-3700 cm^{-1}. In this communication, we will present and discuss these observations between water and the silicate network in melts. Raman spectroscopy provides valuable informations to build a general model of water speciation, distinguishing the OH bonds between tetrahedral species and network modifiers for example. Results from this new model confirmed the amphoteric behavior of the water previously reported from polymeric modelling for instance, and opens new ways to study water in melts.

Near neutral seawater pH 3.45 billion years ago

[4]SEAS, Georgia Institute of Technology, Atlanta, USA

Many if not most known metabolic pathways had evolved by 3.5 Ga. The environmental conditions under which early evolution took place remain highly controversial and speculative, however. In particular, coeval ocean chemistry has been proposed to range anywhere from slightly acidic or modern like (NaCl type, pH<8.5) to strongly alkaline (Na_2CO_3 type, pH>10). Seawater pH is a key geochemical variable, which is tightly coupled to the composition of the atmosphere, and the nature and intensity of interactions between atmosphere, hydrosphere and lithosphere. Here, we extend the classical paleo-pH proxy method of boron isotopes in marine carbonates to a suite of well-preserved and extensively documented marine ferruginous cherts deposited 3.5 billion years ago. Like with carbonates, the approach is based on the large pH-dependent boron and boron isotope incorporation into solid phases, in particular Fe-(hydr)oxides. The samples are from the Pilbara craton (Western Ausltralia) that inlcude low metamorphic grade deposits showing alternation bands of pure and ferruginous silica, which are interpreted as resulting from chemical precipitation from silicon-rich seawater variably mixed with iron-rich hydrothermal fluids under quiet and probably deep water conditions.

We developed a mathematical model using Monte Carlo simulations coupled with a minimization routine to provide a set of self-consistent pH values of the hydrothermal-seawater mixture corresponding to each analyzed ferruginous band. Despite the large range of initial conditions tested and the methodological uncertainties involved, the simulations robustly converge to pH values ranging from 3.4 to 6.6. Mixing model combined with trace elements (REE) analyses imply circumneutral seawater (pH 7-9) and acidic hydrothermal fluids (pH ~3) discharging at the seafloor.

Altogether, the boron distribution and isotopic signatures of the Pilbara craton cherts are consistent with active buffering of the 3.5 Ga oceans by atmosphere-water-rock interactions not unlike those that have prevented dramatic shifts in seawater pH during the more recent geological past.

FT-ICR mass spectrometry of carbonate clusters: Magic clusters and pH effects

K.H. LEMKE[1]*, S.A. SADJADI[1] AND T.M. SEWARD[2]

[1]Department of Earth Sciences, University of Hong Kong, Pokfulam Road, Hong Kong, SAR (*correspondence: kono@hku.hk)

[2]SGEES, Victoria University of Wellington, Wellington, New Zealand

The only experimental data on solute clustering for aqueous carbonate systems stem from a recent electrochemcial study on $CaCO_3$ prenucleation-stage clusters, which suggested that nucleation of carbonates proceeds via cluster formation and aggregation [1]. However, there are no mass spectrometric studies that probe carbonate cluster distribution and composition in aqueous solutions as a function of pH or electrolyte concentration. Prompted by these recent experimental accounts of stable prenucleation carbonate clusters, we present results from Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometric experiments pertaining to the stabililty, distribution and mass composition of a range of different carbonate clusters. We also report theoretical geometries and thermodynamic data of the above carbonate clusters using DFT calculations as well as the G4 and CBS-QB3 multi-step ab initio methods. All carbonate cluster experiments have been conducted on a Bruker 7T FT-ICR mass spectrometer equipped with electrospray ionization (ESI) source and a precision leak-valve system used for solvation studies. Stable carbonate species obtained from electrosprayed solutions (0.05mM/pH=11.20) containing Na_2CO_3 salts include the pure clusters $[Na\ (Na_2CO_3)_n]^+$ ($n \leq 12$), $[Na_2\ (Na_2CO_3)_n]^{+2}$ ($n \leq 19$), $[Na\ (NaHCO_3)_n]^+$ ($n \leq 9$) and $[Na\ (NaOH)_n]^+$ ($n \leq 11$) as well as the mixed clusters $[Na\ (NaHCO_3)(Na_2CO_3)_n]^+$ ($n \leq 8$), $[Na\ (NaHCO_3)_2\ (Na_2CO_3)_n]^+$ ($n \leq 6$) and $[Na\ (NaOH)\ (Na_2CO_3)_n]^+$ ($n \leq 10$). Moreover, upon acid titration with HFor to 3.50, we were able to observe a strong pH dependence of cluster composition and size distribution, especially in the pH vicinity of bulk carbonate solution pK values, e.g. at pH=10.32. In addition, ion mass spectra exhibit several marked discontinuities or „magic clusters' indicative of highly stable carbonate clusters. Solvation energies for the stepwise attachment of water onto individual cluster species will also be presented and compared with results from ab initio calculations.

OAE2 in marine sections at high Northern palaeolatitudes?

M. LENNIGER[1]*, G.K. PEDERSEN[2] AND C.J. BJERRUM[1]

[1]Department of Geography and Geology and Nordic Center for Earth Evolution (NordCEE), University of Copenhagen, 1350 Copenhagen, Denmark (*correspondence: mal@geo.ku.dk)

[2]Department of Geography and Geology, University of Copenhagen, 1350 Copenhagen, Denmark

The mid-Cretaceous world was characterised by unusually warm polar temperatures, extensive sea floor spreading and subsequent periods of major eustatic sea-level rise. At times volcanic outgassing increased the atmospheric pCO_2 and enhanced the terrestrial weathering. Weathering and rising sea level led to increased nutrient discharge and high organic productivity in the oceans. Associated increased decomposition of organic matter promoted the removal of oxygen, leading to anoxic conditions and elevated carbon burial in the sediments, a so called 'oceanic anoxic event'.

One of the global oceanic anoxic events is the Cenomanian–Turonian boundary event (OAE2). The event is characterised by a major positive $\delta^{13}C$ excursion (ca. 2-4 ‰) in marine carbonate and both marine and terrestrial organic matter, which indicates that a major disturbance of the global carbon cycle occurred in the ocean and atmosphere system. The OAE2 is thought to be a widespread event and evidence has been found all over the world, mostly at low and mid palaeolatitudes in the proto-Atlantic. However, records of the OAE2 from high palaeolatitudes are still scarce.

The ongoing work will establish the chemostratigraphy in different depositional environments in the Nuussuaq Basin in West Greenland and investigate the palaeoceanography that prevailed during the OAE2 in the basin. Three localities in a proximal–distal transect through the Nuussuaq Basin will be investigated for $\delta^{13}C$ bulk from organic material and redox sensitive trace metals. These investigations should help to understand, if black shale deposition in the Nuussuaq Basin is linked to the widespread occurring OAE2.

Is the oxygen isotope composition of zircon robust against aqueous alteration?

C. LENTING[1]*, T. GEISLER[2], J.B. CLIFF[3], M.R. KILBURN[3] AND A.A. NEMCHIN[4]

[1]Univ Münster, Institute for Mineralogy, Münster, Germany (*christoph.lenting@uni-muenster.de)
[2]Univ Bonn, Steinmann Institut, Bonn, Germany
[3]The University of Western Australia, Crawley, Australia
[4]Department of Applied Geology, Curtin Univ, Australia

The oxygen isotope composition of zircon is often used to unravel its (pre-)magmatic history, including the presence of liquid water on the surface of the Hadean Earth [1]. However, it has recently been questioned whether zircons retain their primary oxygen isotope signature during alteration and metamorphism [2], and experimental studies are likely to be most valuable in assesing this assumption. Here we report results from oxygen isotope hydrothermal tracer experiments with a heavily radiation-damaged zircon crystal from Sri Lanka. The experiments were conducted in ^{18}O-enriched water and in an enriched 0.1M HCl solution, as well as in milliQ water at temperatures between 100 and 700°C and pressures ranging from 1 to 1.6 kbar for 1 to 140 days. Preliminary SIMS analyses of altered zones formed at 400°C in milliQ water, known to have a negative $\delta^{18}O$, yielded a weighted average $\delta^{18}O$ of -6.46 ± 0.22 ‰ (2σ, n = 7) which is significantly different to the $\delta^{18}O$ of 6.68 ± 0.15 ‰ (n = 9) obtained from unaltered zircon areas. Furthermore, Raman spectroscopic measurements from altered zones formed in the ^{18}O-enriched solutions reveal a significant red-shift of the ν_3 (SiO_4) band when compared to altered zones that formed in milliQ water at the same temperature, indicating a mass-related frequency shift of the ν_3 (SiO_4) band due to the incorporation of significant amounts of ^{18}O from solution. The Raman measurements also indicate temperature-dependent structural recovery processes inside the altered areas which are accompanied by partial loss of radiogenic Pb, as revealed by SHRIMP analyses. Our preliminary data clearly show that, in contrast to the Hf isotope system [3], the oxygen isotope composition of radiation-damaged zircon can be altered signifcantly by the interaction with an external fluid, even during weathering. This has to be kept in mind when using the oxygen isotope composition of zircon to infer its (pre-) magmatic history.

The impact of Fe(III) oxide structure on shaping metal respiring microbial communities and carbon oxidation

CHRISTOPHER J. LENTINI* AND COLLEEN M. HANSEL

School of Engineering and Applied Sciences, Harvard University, Cambridge, MA USA
(*correspondence: lentini@fas.harvard.edu)

The importance of dissimilatory iron (III)-reducing microorganisms (DIRMs) in the iron (Fe) geochemical cycle has long been recognized. Their ability to reduce and thereby dissolve solid Fe (III) phases plays an important role in the cycling of trace nutrient and contaminants. In addition, metal oxide respiration plays a significant role in controlling organic matter mineralization in metal-rich environments. Despite this importance, our understnading of the role that Fe (III) (hydr)oxide mineralogy plays in controlling microbial Fe (III) respiration is poorly understood. For instance, while current model DIRMs in culture show the ability to greatly reduce ferrihydrite, these DIRMs show diminished abilities to reduce more crystalline phases (goethite and hematite), only reducing a small percent [1].

Through enrichment experiments, we found that both the Fe (III) mineral and carbon source provided specilized ecological niches for micrrooganisms. In fact, while acetate enrichments could support the reduction of ferrhydrite, the reduction of goehtite and hematite was not detected. However, with lactate and glucose as the carbon source, the reduction of these more crystalline phases was significant (30-70%). Clone library (16S rRNA) results indicated that a model Fe (III)-reducing microoganism, *Geobacter*, was prevalent on the ferrihydrite and acetate enrichments but did not occur on the hematite-acetate or goethite-acetate enrichments. Instead, in enrichments where goethite and hemtatie showed significant reduction, lactate and glucose supported the growth of less traditional Fe (III) reducers, *Desulfovibrio* and members of the family *Enterobacteriaceae*. Fe (III) reduction by these organisms is likely driven by indirect Fe (III) reduction coupled to sulfur cycling or fermentation.

Interstingly, our results also suggest that Fe (III) mineralogy will dictate competitive advantages between metal respiration and fermentation, possibly including acetategensis. These findings suggest that the oxidation of carbon and reduction of Fe (III) will be constrained by the host Fe (III) mineralogy of sediments/soils.

Land colonisation and Earth system change: A recurring pattern

TIMOTHY M. LENTON

College of Life and Environmental Sciences, University of Exeter, UK (t.m.lenton@exeter.ac.uk)

The colonisation of the land surface by complex life has occurred in several phases, each following a common pattern. All photosynthetic land colonisers must access mineral-bound essential elements, notably phosphorus. Fungi assist in this, being particularly effective at rock weathering, and forming symbiotic partnerships with algae in lichens, or with land plants as mycorrhizae. The resulting increase in the rate of silicate weathering lowers atmospheric CO_2 and global temperature. Meanwhile the selective enhancement of phosphorus weathering increases phosphorus supply to the ocean, organic carbon burial and hence atmospheric O_2.

It is widely accepted that the rise of rooted, vascular plants, including the first forests, through the Devonian-Carboniferous accelerated silicate weathering, causing a drawdown of atmospheric CO_2 and cooling the planet into glaciations. At the same time, acceleration of phosphorus weathering likely contributed to atmospheric O_2 rise.

Prior to this, the first pre-vascular plants colonised the land in the Mid-Late Ordovician. Existing models assume they had a negligible effect on weathering, but new experiments show that mosses amplify silicate weathering by factors of 1.5 to 6. We estimate that this roughly halved atmospheric CO_2, causing sustained global cooling of ~5 °C, and triggering the Late Ordovician glaciations. Mosses were also found to amplify phosphorus weathering by a factor of ~60. This could explain the extensive shallow water phosphate deposits, black shales, and two global positive excursions in marine carbonate $\delta^{13}C$ in the Late Ordovician.

Land colonisation is hypothesised to have begun much earlier still, in the Neoproterozoic, perhaps with lichen-like symbioses. This would neatly explain, with a single cause, both the extreme climate cooling and the 'lesser oxidation' (O_2 rise) that occured at that time. Whether the $\delta^{13}C$ record or other lines evidence support the hypothesis is hotly debated, but massive phosporite deposits support increased phosphorus weathering and input to the ocean.

An outstanding puzzle is why each phase of colonisation-driven cooling was not permanent? Perhaps the increasing ratio of O_2 to CO_2 in the atmosphere reduced the efficiency of photosynthesis, thus suppressing weathering. We also suggest that enhanced phosphorus weathering could not be sustained and ecosystems shifted to internal recycling of phosphorus, thus producing pulses of organic carbon burial and O_2 rise.

Tectonic evolution of a ~800-767 Ma continental arc back-arc system in South Brazil

[3]Universidad de La Republica, Montevidéo (hmasquel@fcien.edu.uy)

In the southern region of Uruguay occur a sequence of Neoproterozoic para and orthogneisseic called Cerro Olivo Gneissic Complex. The orthogneissic unit yield crystallization ages (U-Pb SHRIMP) between 800-767 Ma. This unit is composed by a sequence of mafic gneisses, with gabbro to gabbro-diorite composition tectonically interleaved with a sequence of tonalitic and granodioritic gneisses. These rocks intrude the Chafalote paragneisses (pelite, quartzite and marbles) and were metamorphosed under high P-T conditions between ca. 676-654 Ma. Three different groups of rocks were distinguishing in the Cerro Bori Ortogneisses unit. Type I rocks are mafic gneisses with tholeiitic affinity and geochemical signatures characteristic of a back-arc setting. Type II rocks are mostly tonalitic gneisses with calc-alkaline affinity and geochemical signatures typical of a continental margin magmatic arc. Type III rocks are composed by biotite rich mafic gneisses with potassic to ultrapotassic affinity. These three rock types (I, II, III) show negative εNd values (between -2.12 and -6.67) and old TDM ages (between 1.2 and 2.0 Ga), indicating that assimilation of older crust and fractional crystallization were important during the evolution of these rocks. An Andean type magmatic arc setting with short distance between arc and back-arc is suggested for these rocks between 800-767 Ma. Thirty million years after the beginning of subduction the crystallization of a small volume of potassic and ultrapotassic rocks toke place. The nature, characteristics and ages of these rocks suggest the former existence of an ocean between Rio de La Plata and adjacent cratons (Brasilide Ocean) at a time that break up and dispersion of Rodinia supercontinent.

The ability to reduce water soluble toxic selenium oxyanions is widespread in the microbial environment [1]. Firstly, specialized dissimilatory reducers can 'respire' selenium oxyanions to elemental selenium, producing energy for growth. Secondly, different microbial groups can catalyze selenium oxyanion reduction without gaining energy for growth (e.g. sulfate reducing bacteria) [2]. Since elemental selenium and most metal selenides are insoluble, microbially catalyzed reduction is thus thought to impact selenium environmental fate to large extents. However, little definitive information is available regarding the speciation of such (suppositional insoluble) phases, in particular in natural environments. We studied such phases formed by both mixed and pure cultures in metal poor and rich environments *in situ* by X-ray Absorption Fine Structure spectroscopy (XAFS). We demonstrated that in laboratory (i.e. metal depleted) incubations, amorphous elemental selenium is formed by most species, yet that natural (i.e. metal rich) environments are often rather dominated by complex mixtures of metal selenides.

Coupling $\delta^{34}S$ [SO_4^{2-}] and [^{206}Pb / ^{207}Pb]: Origin of trace metals in the urban Orge River, France

P. LE PAPE[1,2] *, S. AYRAULT[2], J-L. MICHELOT[1] AND C. QUANTIN[1]

[1]UMR 8148 IDES, UPS11 - CNRS, Orsay, 91405, France (*correspondence: pierre.le-pape@u-psud.fr)
[2]UMR 8212 LSCE, IPSL/CEA-CNRS-UVSQ, Gif-sur-Yvette, 91198, France

Several studies reported the close relationship existing between trace metal contamination in rivers and urbanization [1]. To reduce and constrain the emissions of urban trace metals and their transport due to runoff on urban surfaces, it is necessary to quantify the contribution of the different sources. It implies to study both the origins of water as a vector of transport (urban runoff, sewer network, groundwater...), the sources of metals and those of their bearing-phases. In that context, isotopic analyses are powerful tools to discriminate water and metal sources.

The study concerns the Orge-River urban catchment, part of the Seine-River watershed (Paris, France). Four sampling campaigns have been performed at a seasonal time scale from upstream (forestry and agricultural lands) to downstream (residential and urban areas). Sampled materials were water (filtrated at 0.45 μm), suspended particulate matter (SPM) and bed sediments.

Both dissolved (<0.45 μm) SO_4^{2-} and $\delta^{34}S$ [SO_4^{2-}] ratios increased from upstream to downstream, indicating sulfate inputs. Analysis of samples representing potential sources revealed that part of this additional sulfate was related to the leakages of sewer networks. In the particulate compartment, an anthropogenic Pb enrichment was clearly detected. Indeed, as Pb contents increased along the river, the [$^{206}Pb/^{207}Pb$] ratio evolved from a natural to an anthropogenic signature. Otherwise, anthropogenic contribution was especially noticed during low waterflow periods, when SPM load was low. [$^{206}Pb/^{207}Pb$] ratio also gave information about long term dynamics of particulate Pb in the watershed, indicating that the contribution of Pb from a Pb-gasoline endmember to SPM ended during the last decade.

Coupling of both $\delta^{34}S$ [SO_4^{2-}] and [$^{206}Pb/^{207}Pb$] ratios finally provided a good indicator of anthropogenic impact.

Furthermore, the isotopic approach described above was completed with studies at the particle scale (SEM or TEM-EDX), which revealed the presence of specific urban metal-bearing particles, such as barite or phosphate phases.

Origin of isotopically heavy Fe in pyrite from 2.75 Ga Wilgie Mia BIF, Western Australia

AIVO LEPLAND[1]*, MARTIN J. VAN KRANENDONK[2] AND MARTIN J. WHITEHOUSE[3]

[1]Geological Survey of Norway, 7491 Trondheim, Norway (*correspondence: aivo.lepland@ngu.no)
[2]Geological Survey of Western Australia, 100 Plain St., East Perth WA, 6004 Australia
[3]Swedish Museum of Natural History, Box 50007, SE-104 05 Stockholm, Sweden

The 2.75 Ga Wilgie Mia Formation, Yilgarn Craton, Western Australia consists of a sequence of banded iron formation (jaspilitic chert, magnetite BIF), interlayered with minor black shales. Pyrite occurs abundantly in black shales and in trace amounts in BIFs, and has been studied for Fe and S isotopic composition using SIMS. Clustered framboidal diagenetic pyrite in shales is isotopically heterogeneous both in S ($\delta^{34}S$ from -6.9 to +4.7‰) and Fe ($\delta^{56}Fe$ from -3.3 to + 0.5‰). Analyzed BIF samples (c. 50 m stratigraphically above shale samples) exhibit a narrower range in $\delta^{34}S$ (-3 to +1‰) that overlap with $\delta^{34}S$ of secondary pyrite in veinlets in shale. Fe is considerably heavier in BIFs compared to shales with individual $\delta^{56}Fe$ measurements in three studied samples ranging from 0.6 to 1.3‰, 0.8 to 2.1‰ and 1.5 to 2.7‰. These $\delta^{56}Fe$ values from the Wilgie Mia BIF are among the heaviest so far reported from sedimentary rocks. Textural observations show that pyrite is the latest Fe phase in BIFs, post-dating both early hematite in jaspilitic chert and later hydrothermal magnetite. Pyrite formation in BIF appears to be related to hydrothermal S remobilization from shales and infiltration of framboidal pyrite derived sulfide bearing fluids into BIF. The S isotopic composition of dissolved hydrothermal sulfide was homogenized with respect to framboidal pyrite, and from this homogenized S source pyrite formed in veilets and BIFs. Previous Fe isotopic data using mineral separates [1] have indicated the presence of heavy pyrite with $\delta^{56}Fe$ values from 0.81 to 0.94‰ in the Wilgie Mia BIF. This was explained through the isotopic equilibrium of pyrite with magnetite ($\delta^{56}Fe$ from 0.37 to 0.60‰) and hematite-jaspilite ($\delta^{56}Fe$ from 0.54 to 0.72‰) [1]. As the $\delta^{56}Fe$ of many pyrite crystals studied here is heavier than predicted by equilibrium fractionation with Fe-oxides, and since pyrite is texturally late (clearly post-dating Fe-oxides) alternative fractionation mechanisms need to be considered. These may include the selective leaching of Fe-oxides by infiltrating sulfidic hydrothermal fluids, or equilibrium between magnetite/ hematite and Fe^{2+}_{aq}.

Nutrient content of mineral aeolian dust and its impacts on temperate forest nutrient cycles

E. LEQUY[1,2], S. CONIL[2], E. LECLERC[2] AND M-P. TURPAULT[1]*

[1]INRA 54280 Champenoux, France (*correspondence: turpault@nancy.inra.fr)
[2]ANDRA, 1-7 rue Jean Monnet, Châtenay-Malabry, France (sebastien.conil@andra.fr)

In Europe, mineral Aeolian dust is known to bring nutrients to Mediterranean forests [1] but its impact on acidic temperate forests has received little attention up to now. This study aims at quantifying the amount of nutrients released from Aeolian dust into the nutrient pool of two beech stands in the North of France. Mineral Aeolian dust was continuously collected in a clearing and below the canopy (throughfall and stemflow), showing deposition rates of 14±3 and 18±6 kg. ha^{-1} in 2010, respectively.

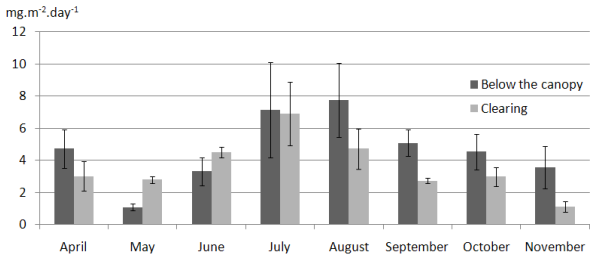

Figure 1: Aeolian dust deposition rates ($mg.m^{-2}.day^{-1}$) at the experimental site of Montiers-sur-Saulx

Particle size distribution, determined by a laser Coulter, was dominated by the fraction under 50 μm. Scanning electron microscopy and X-ray diffraction analyses of particles revealed the presence of quartz, phyllosilicates and feldspars. Our results suggest that Ca amounts released into forest nutrient pool by Aeolian dust and by soil weathering [2] are of the same order of magnitude.

Preferential partitioning of copper into the vapor phase: An artifact?

LINDA LERCHBAUMER* AND ANDREAS AUDÉTAT

Bayerisches Geoinstitut, University of Bayreuth. 95447 Bayreuth, Germany
(*correspondence: linda.lerchbaumer@uni-bayreuth.de)

Studies on natural assemblages of coexisting vapor and brine inclusions revealed that Cu (± Au, As, Mo) commonly occurs at higher concentrations in the vapor phase, which has been interpreted to be due to the formation of stable hydrosulfide-bearing complexes. Although several experimental studies proved the existence of such complexes, none of them has succeeded in reproducing conditions under which Cu fractionates into the vapor phase (i.e. $D_{Cu}^{vap/brine} > 1$). An exception seemed to be the study of Nagaseki and Hayashi [1] who claimed to have obtained $D_{Cu}^{vap/brine}$ values up to 30. However, mass balance constraints and results of identical experiments performed in our laboratory suggest that these values are wrong and in fact are below unity.

In view of recent studies demonstrating that quartz-hosted fluid inclusions can diffusively loose or gain Cu after their formation we wanted to check whether the evidence from natural fluid inclusions could be compromised. For this purpose we synthesized vapor and brine inclusions from a Cu-H_2O-NaCl-S fluid at 800 °C/1.3 kbar and reequilibrated them in a second experiment with similar fluid at 800 °C/700 bar. After each step some of the inclusions were analyzed by LA-ICP-MS. Vapor inclusions indeed experienced a dramatic increase in their Cu content (from 0.3 ± 0.04 to 5.7 ± 3.3 wt% Cu) during this procedure, while brine inclusions remained unmodified, leading to a change in $D_{Cu}^{vap/brine}$ from a true value of 0.4 ± 0.05 to an apparent value of 8.3 ± 4.9. Subsequent experiments showed that the requirements for diffusional gain of Cu in fluid inclusions are a change in pH from ≤ 1 to a more basic value in the surrounding fluid, and the presence of S in the inclusions. These requirements are also fulfilled in nature: Cooling magmatic-hydrothermal fluids experience a change from acidic to more neutral pH due to buffering along the feldspar-mica join, and natural vapor inclusions typically contain significant amounts of S. $D_{Cu}^{vap/brine}$ values >1 observed on natural boiling assemblages could thus be a secondary feature, with original values being closer to 0.1. If true, then the role of vapor transport in the formation of magmatic-hydrothermal copper deposits has been severely overestimated.

Mineralogical heterogeneities in the Earth's mantle: Constraints from Mn, Co, Ni and Zn partitioning during partial melting

V. LE ROUX[1]*[,2], R. DASGUPTA[2] AND C.-T.A. LEE[2]

[1]Woods Hole Oceanographic Institution, 266 Woods Hole Road, Woods Hole, MA 02543, USA
(*correspondence: vleroux@whoi.edu)
[2]Department of Earth Science, Rice University, MS-126, 6100 Main Street, Houston, TX 77005, USA

The first-row transition elements (FRTE; Sc to Zn) are compatible to moderately incompatible during melting in mafic and ultramafic systems. Thus, because FRTE are sensitive to changes in mineralogy and major element composition, they are promising tracers of lithological heterogeneities in the mantle source regions of basalts. However, the partitioning behaviors of some FRTE at mantle conditions are still lacking despite growing interest in the application of these tracers to magmatic systems. Here we present mineral-melt partitioning experiments at 1.5-2.0 GPa and 1300-1500 °C for divalent FRTE – Zn, Fe, Mn, Co, and Ni. Our study, for the first time, provides Zn and Zn/Fe fractionation data between peridotitic olivine, orthopyroxene, clinopyroxene and basaltic melt. Using our new partition coefficients and combining multiple ratios (Zn/Fe, Ni/Co, Mn/Fe, Mn/Zn) we assess the role of FTRE as tracers of mineralogical composition of the mantle. We show that, during melting, olivine and orthopyroxene do not significantly fractionate Mn, Fe, and Zn from each other, and melts from peridotite would be expected to have similar Mn/Fe, Co/Fe and Zn/Fe as the source. In contrast, our results for clinopyroxene and published results for garnet show strong fractionations, such that melts of pyroxenites or eclogites would be expected to have low Mn/Fe, Co/Fe, Ni/Co, Mn/Zn and high Zn/Fe compared to peridotite partial melts. We compare Zn, Fe, Co, Mn and Ni contents of natural oceanic basalts to modeled compositions of peridotitic and pyroxenitic partial melts. Most MORB and near-ridge OIB can be explained by shallow melting of peridotite, but most OIB away from ridges deviate from predicted peridotite melt compositions. We use melting and mixing models of FRTE ratios in peridotite and in MORB-like eclogite to illustrate the potential contribution of eclogite- and peridotite derived melts in individual MORB and OIB lavas. We also present a melt-melt mixing model that estimates, under the assumptions of the present model, the amount of eclogite in the source of mantle end-members HIMU, EM1, and EM2.

Microbially enhanced ore weathering and surface anomaly development

K. LESLIE[1], C. IHLENFELD[2], C. OATES[2], J. BARR[2] AND D.A. FOWLE[1]

[1]Department of Geology, University of Kansas, Lawrence KS 66049, USA (kleslie@ku.edu)
[2]Geochemistry Division, Anglo American plc, 20 Carlton House Terrace, London, SW1Y5AN, United Kingdom

Biogeochemical processes in the subsurface have been found to affect the dispersion and accumulation of metals in soils overlying buried mineralized systems [1, 4]. Specific zones of metal accumulation, along with other secondary signals (such as isotopic anomalies, high pH and redox contrast, variations in microbial activity, gas flux and electrochemical anomalies) [1-5] have been used to successfully vector towards mineralization. Several models explaining the formation of these secondary features currently exist; electrochemical processes, expulsion of groundwater, dispersion of gas, and biogeochemical cycles [1, 4]. As microbiological processes play a significant role in many of these anomaly-developing processes, we hypothesize that the presence of microorganisms will enhance the mobility of metal ions in the subsurface.

Metal release from buried mineralization was examined in flow-through columns containing a variety of ore types (Cu porphyry, Magmatic Ni, Cu-Zn VMS) and a consortium of biogeochemically relevant microorganisms (Fe, S-oxidizers, Methanogens, Methanotrophs, Sulphate-reducers and Fe-reducers). Greater metal release was observed from all ore types, in comparison to un-inoculated controls. To examine the accumulation of metals in overlying soils we added soil and rock cover to the same ore types and microbial consortium used previously. Higher metal content was associated with the soil phase in the columns that had been inoculated. These results suggest that microbial processes may control metal dispersion and accumulation in the subsurface.

Time scales of magma differentiation and implications for the growth rate of the Torres del Paine laccolith

J. LEUTHOLD[1]*, O. MÜNTENER[1], L. BAUMGARTNER[1], B. PUTLITZ[1], M. OVTCHAROVA[2] AND U. SCHALTEGGER[2]

[1]Mineralogy and Geochemistry, University of Lausanne, Switzerland (*correspondence: julien.leuthold@unil.ch)
[2]Earth and Environmental Sciences, University of Geneva, Switzerland

The spectacularly exposed Torres del Paine laccolith (Southern Patagonia) has been constructed by successive injections of mafic and granitic melt batches. The sill complex is connected, at its western border, to a dike complex, interpreted as the laccolith feeder zone. A key unknown in sill complexes is the mechanism by which individual mafic and differentiated magma pulses are linked and assembled over time. We present high precision CA-ID-TIMS U-Pb data on mafic rocks zircons to constrain the time scales of differentiation. Feeder zone gabbronorite and Px-Hbl-gabbronorite with cumulate Px and Plg textures, display distinct positive Eu anomalies. Incompatible trace elements have been modelled to establish a fractionation relationship between mafic and granitic rocks. Zircon grains from the feeder zone gabbroic units have been dated at 12.59±0.01Ma, equivalent to the laccolith top granitic units, with a reported age of 12.59±0.02Ma [1]. Detailed field and petrographic studies evidence distinct Hbl-gabbro and diorite units within the laccolith, accreted sequentially. They display ages ranging from 12.47±0.01Ma for the lower Hbl-gabbro, 12.45±0.01Ma for diorite sills and 12.43±0.01Ma for upper Hbl-gabbro and diorite, all distinctly younger than the basal granite (12.51±0.03Ma [1]). These data show that, while the laccolith granitic complex is built up by under-accretion, the mafic complex itself grows by over-accretion, via amalgamation of successive sills. Emplacement dynamics involves a complex interplay between mafic and granitic magmas generating a volume of ~100km^3 over a time scale of ~160'000 years.

[6]ESRF

Since the discovery of carbon nanotubes (NTs), there has been great interest in the synthesis and characterization of similar shaped structures like inorganic nanotubes, nanorods, or nanowires. Imogolites (Al_2SiO_3 $(OH)_4$) are natural aluminosilicate single wall nanotubes. To date, only Ge-Al imogolite analogues have been successfully synthesized 100 times more concentrated than Si-Al imogolites.

The growth mechanisms of imogolite-like alumino-germanate nanotubes were examined using a combination of local- (XAS at the Ge-Kedge and 27Al NMR) and semilocal scale techniques (in situ SAXS). A model is proposed for the precursors of the nanotubular structure and consist in rooftile-shaped particles, up to 5 nm in size, with ca. 26% of Ge vacancies and varying curvatures. These precursors assemble to form short nanotubes/nanorings observed during the aging process. The final products are most likely obtained by an edge-edge assembly of these short nanotube segments.

Two structures are revealed by SAXS: at 0.25M of Al the Al-Ge imogolite are double-walled NTs whereas at 0.5 M single-walled NTs are obtained.

First tests to reveal cyto and genotoxicity on various vertebrates cells (human fibroblasts and CHO-K1) are interesting. They show a genotoxicity for concentrations from 8 10^{-5} g/L and effects decreasing from proto-imogolite to long tubes

Fossilization of microaerophilic iron oxidizing bacteria from marine hydrothermal vents

RICHARD J. LÉVEILLÉ[1]* AND KARINE LAPLANTE[1,2]

[1]Canadian Space Agency, 6767 route de l'Aéroport, Saint-Hubert, Québec, Canada, J3Y 8Y9 (*correspondence: richard.leveille@asc-csa.gc.ca)
[2]Institut de Biologie Intégrative et des Systèmes, Université Laval, 1030 rue de la Médecine, Québec, Québec, Canada, G1V 0A6 (karine.laplante.2@ulaval.ca)

Iron oxidizing bacteria are common in modern marine and terrestrial systems, where they often display distinctive cell morphologies and are commonly encrusted by minerals, especially bacteriogenic iron oxides and silica. Putative microfossils of iron oxidizing bacteria have also been found in ancient Si-Fe deposits and iron oxidation may be an ancient and widespread metabolic pathway. Microaerophilic iron oxidizing bacteria, in particular, could have thrived on the early Earth in circumneutral environments containing small amounts of oxygen (i.e. 'oxygen oases') produced either by locally concentrated photosynthetic microorganisms (e.g. cyanobacteria) or by chemical reactions. This work seeks to better understand the fossilization and biomineral formation processes associated with these organisms. Understanding the interplay between silica precipitation and biologically induced iron mineral precipitation is a key objective of this work and is essential for understanding preserved Fe-rich biominerals and silica microfossils in the rock record on Earth and possibly on Mars, where Fe-Si-rich hydrothermal systems likely existed.

We have studied samples of Fe-Si-rich deposits from extinct hydrothermal vents along the Explorer Ridge, NE Pacific Ocean. In addition, we have performed silicification experiments using the microaerophilic iron oxidizing bacterium Mariprofundus ferrooxidans, isolated from low-temperature diffuse marine hydrothermal vents, in a Fe-enriched seawater medium at constant pH (6.5) and oxygen concentration (5%) in a controlled bioreactor system. We present the results of characterization of the ultrastructure and composition of the natural samples and experimental reaction products using optical and flurorescent microsocopy, VP-SEM-EDS, FIB milling and FEG-SEM-EDS, and TEM-EDS.

Analogues between water in granite melts and petroleum formation

MICHAEL D. LEWAN

U. S. Geological Survey, Box 25046, MS 977 DFC, Denver, CO 80225, USA (mlewan@usgs.gov)

Water is ubiquitous within the Earth's crust and has long been recognized as a critical component in deep crustal areas undergoing metamorphism [1]. Similarly, water in granite melts has been shown to be critical to granite melting points, mineral phase relations, element partitioning between melt and mineral phases, and transport properties [2]. Although the specific role of water remains an issue in petroleum formation, experimental studies on petroleum source rocks pyrolysed with and without water clearly indicate that water is an important component [3]. Petroleum formation involves two overall reactions. The first of these reactions is the thermal decomposition of kerogen, which is the insoluble and dominant organic solid phase in thermally immature source rocks. With initial heating, kerogen partially breaks down to a soluble polar-rich high-molecular-weight tarry phase referred to as bitumen. A net volume increase associated with this reaction results in the bitumen expanding into the micro-porosity to form a continuous bitumen phase impregnating the groundmass of the source rock. Experiments have shown that water is not important in this step, but water in the original micro-pores and in surrounding fractures provides a source for dissolved water in the bitumen. Similar to water dissolved in granite melts, the solubility of water in bitumen plays a significant role. It is this dissolved water in the bitumen phase and not the surrounding bulk water in fractures or voids that becomes critical in the second overall reaction, which is the thermal decomposition of the polar-rich bitumen phase to a hydrocarbon-rich oil phase. During this overall reaction, the dissolved water provides a source of hydrogen that promotes thermal cracking and facilitates immiscibility between the bitumen and oil phases. These conditions result in a net volume increase and the expulsion of the oil from the water-laden bitumen in the source rock. The ability of water in pyrolysis experiments to simulate organic phases like those observed in nature helps petroleum-formation studies move away from sole emphasis on organic components (i.e. saturates/aromatic/resin/asphaltene) and, like granite-melt studies, allows examination of the collective behaviour of both components and phases.

Asphaltene content as a measure of oil losses related to the Deepwater Horizon oil spill

M.D. LEWAN, A. WARDEN, R.F. DIAS, Z.K. LOWRY, T.M. HANNAH, P.G. LILLIS, R. KOKALY, T.M. HOEFEN, G.A. SWAYZE, C. MILLS, S.H. HARRIS, G.S. PLUMLEE AND B.D. MARSHALL

U. S. Geological Survey, Box 25046, MS 977 DFC, Denver, CO 80225, USA (mlewan@usgs.gov)

The asphaltene content of spilled oil on open and coastal waters and coastal sediments was examined as a means of determining the fate of the estimated 4.9 million barrels of oil released from the damaged BP Macondo-1 wellhead of the Deepwater Horizon platform in the Gulf of Mexico (April 20 to July 15, 2010). A particularly salient issue is where has all of this spilled oil gone? Asphaltenes are the highest molecular-weight fraction in crude oils and are the most recalcitrant to water washing, volatilization, and biodegradation. Comparing the asphaltene content of spilled oils with those of the original oil released from the leaking wellhead allows one to determine the portion of oil lost. The lost portion of oil collectively includes that removed by volatilization, oxidation, water washing, dispersion, and microbial degradation. Critical to the application of this method is that a representative sample of the original oil is available and that degradation does not significantly affect the asphaltene content of the spilled oils. Two samples were collected from a riser insertion tube at the wellhead and are considered representative of the original oil. Although asphaltenes are the most recalcitrant fraction of crude oils, their composition can change with degradation. Possible alterations to the asphaltene fraction of the spilled oils were evaluated with stable carbon isotope and elemental analyses. Spilled-oil samples were collected between May 7 and July 10, 2010 and are divided into three groups; 1) open water, 2) coastal water, and 3) coastal sediment. The open-water group consists of spilled oils floating on the water at distances greater than 5 km from the coastline. Comparing the uncorrected asphaltene contents of these spilled oils with that of the original oils indicate spilled oil in open waters may represent less than 40 wt% of the original oil, and spilled oil in the coastal waters and sediments may represent less than 20 wt% of the original oil. These preliminary results suggest that significant quantities (more than 60 to 80 wt%) of the Deepwater Horizon spilled oil were lost within the first 81 days and provide input values for mass-balance calculations regarding the fate of the spilled oil.

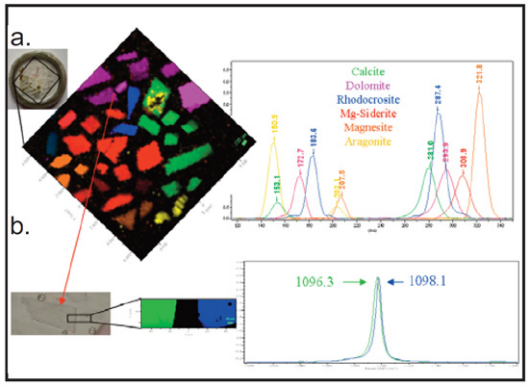
Raman spectroscopy for geological applications

RENATA LEWANDOWSKA

HORIBA Scientific, 231 rue de Lille, 59650 Villeneuve d'Ascq, France, (renata.lewandowska@horiba.com)

Raman spectroscopy is a practical exploration tool to study geological materials. This technique is a rapid and reliable way to confirm a chemical composition of samples and the particle distribution. Chemical information can be obtained without any extraction procedure or sample preparation. Thus, the analysis can be achieved *in situ* and if necessary directly at the geological site. Raman imaging can be useful to study heterogeneous samples in various fields of application of Earth Science: mineralogy, gemmology, petrology, geoarcheology, paleontology, planetology or volcanology…



The latest developments in Raman instrumentation will be presented. A new Raman microscope will be introduced that combines high mobility, multi-laser excitation and ease-of-use. Its rugged design can withstand harsh environmental conditions for analysis in the field, and it is also equipped with a fiber port for probe measurements. We will also present a new imaging mode using scanning mirrors. This technique can be used in two modes: 'macro-mapping' mode to perform Raman imaging on large sample areas or for mapping small heterogeneities in large objects that cannot be moved easily with a motorized stage, such as big geological samples.

Structural incorporation of uranium during the Fe(II)-induced transformation of ferrihydrite

JUAN S LEZAMA PACHECO[1], MICHAEL S MASSEY[2], F. MARC MICHEL[1], JOHN R BARGAR[1] AND SCOTT FENDORF[3]

[1]SLAC National Accelerator Laboratory, 2575 Sand Hill Road, Menlo Park CA 94025 jlezama@slac.stanford.edu

Fe-(oxyhydr)oxides, among the most important metal-scavenging phases in soils and sediments, can undergo structural and compositional transformations during iron reducing conditions. Understanding the geochemical cycling and interaction of iron oxides with Uranium and other redox-active radionuclides, is of prime importance in the development of state-of-the art biogeochemical models to understand the fate and transport of these hazardous elements. In this work, X-ray diffraction and EXAFS analysis have been used to characterize the transformation products and local atomic structure around uranium in synthetic iron-oxide phases obtained by the Fe (II)-induced transformation of ferrihydrite. After transformation of ferrihydrite, U (IV)-bearing compounds and Fe-oxides are observed, with U (V/VI) being structurally incorporated into multiple sites in the goethite structure. We will discuss the incorporation mechanism, in which adsorption of uranium on the ferrihydrite starting material plays a key role in incorporation of this radionuclide into the resulting crystalline iron oxide phases. Our work also suggests that bioremediation strategies such as biostimulation can drive U sequestration not only through direct reduction of U, but also through Fe redox cycling.

The differences of fluid inclusions between ore minerals and gangue minerals of Huize lead-zinc deposit, Yunnan province, China

BO LI[1,2], RUNSHENG HAN[2], XIAOCHUN GU[1], SHUMING WEN[2] AND RUI SHENG[3]

[1]Yunnan Copper Industry (Group) Co.Ltd., Kunming Prospecting Design Institute of China Nonferrous Metals Industry, Kunming 650051, China (*correspondence: libo7_211@yahoo.com.cn)

[2]Kunming University of Science and Technology, Kunming 650093, China

[3]Huaneng Lancang River Hydropower Development Co.Ltd., Kunming 650051, China.

The Huize surperlarge lead-zinc deposit is a typical deposit in the Sichuan-Yunnan-Guizhou Zn-Pb polymetallic mineralization zone, the main ore minerals and gangue minerals are sphalerite and calcite respectively. Research of fluid inclusions in sphalerite and calcite indicate that there are differences in homogenization teperature, salinity, density and composition of fluid inclusion. *a. homogenization teperature*. The homogenization temperature of fluid inclusions in sphalerite range from 100.2°C to 344.5°C, for the average homogenization temperature of 179.5°C, which have two change temperature sectors obviously, 150°C~200°C and 250°C~350°C. Whereas, homogenization temperature of fluid inclusions in calcite range from 160°C to 220°C, and few can reach to 250°C. *b. salinity*. Salinity of fluid inclusions in sphalerite is similar to homogenization temperature, which range form 1.05wt% $NaCl_{eq}$ to 18.04 $wt\%NaCl_{eq}$, for the average salinity of 11.56 $wt\%NaCl_{eq}$, and have two change sectors, 1~13 $wt\%NaCl_{eq}$ and 13~20 $wt\%NaCl_{eq}$. Fluid inclusions in calcite are of low salinity, with a range from 0.18 $wt\%NaCl_{eq}$ to 10.8 $wt\%NaCl_{eq}$, and the average sallinity of calcite is 7.29 $wt\%NaCl_{eq}$. *c. density of fluid inclusion*. The densities of fluid inclusions in sphalerite range from 0.8884$g\cdot cm^{-3}$ to 1.0507 $g\cdot cm^{-3}$, and the average densities is 0.9735 $g\cdot cm^{-3}$, but densities of fluid inclusions in calcite range from 0.8811 $g\cdot cm^{-3}$ to 0.9556$g\cdot cm^{-3}$, with a change sectors of 0.900~0.930 $g\cdot cm^{-3}$. *d. composition of fluid inclusions*. The composition of fluid inclusions in sphalerite and calcite is similar, but composition content of fluid inclusions in calcite is higher than sphalerite. Liquid components of fluid inclusions are mainly Ca^{2+}, Mg^{2+}, Na^{+}, Cl^{-}, with minor amounts of F^{-}, K^{+}, Li^{+}. Gas components of fluid inclusions are mainly H_2O and CO_2, CO and CH_4 are less abundant.

Spatial and seasonal variations of iron species in the Changjiang (Yangtze River) sediment

CHAO LI AND SHOUYE YANG*

State Key Lab. of Marine Geology, Tongji Uni., Shanghai 200092, China (*correspondence: syyang@tongji.edu.cn)

The Changjiang River contributes huge amounts of dissolved and particulate matter to East Asian marginal seas. The complex provenance geology and source-to-sink pattern of terrigenous material into the sea complicate the fluvial flux and river chemistry. Geochemical cycle of key elements in the Changjiang, e.g. iron (Fe), has rarely been investigated. This study aims to investigate the spatial and seasonal variations of different chemical species of iron in the Changjiang sediment, and to reveal the low-temperature iron cycle in this large river.

The upper Changjiang sediment is higher in unreactive Fe (Fe_U) for its strong physical weathering and specific lithology, while the middle and lower reaches is relatively enriched highly reactive Fe (Fe_{HR}) because of hydrodynamic sorting and stronger chemical weathering. Seasonal variation of iron species in the lower mainstream is in consistent with variability of monsoon induced precipitation, with more significant supply from the upper reaches during flood season. Anthropogenic impact, such as the Three Gorge Dam, plays a key role in controlling sediment input, especially in dry season. Environmental magnetic study also suggests complicated and variable compositions of iron-bearing minerals within the river system. Thus, spatial and seasonal variations at different scales should be taken into account in the further study on elemental cycle and estimation of river flux.

Quantitative analysis of late Cenozoic tectonic deformation across the Northern foreland of the Chinese Tian Shan

CHUANXIN LI[1,2]* AND ZHAOJIE GUO[3]

[1]School of Energy Resources, China University of Geosciences, Beijing 100083, China (*correspondence: chuanxin_li@163.com)
[2]Research Institute of Petroleum Exploration & Development-Langfang, PetroChina, Langfang 065007, China
[3]Key Laboratory of Orogenic Belts and Crustal Evolution, Ministry of Education, School of Earth and Space Sciences, Peking University, Beijing 100871, China (zjguo@pku.edu.cn)

The East-West trending Tian Shan range has been reactivated and uplifted in the late Cenozoic in response to the northward propagation of deformation related to the India-Eurasia continental collision [1, 2]. Three paralleled rows of anticlinal belts have developed sequentially from south to north. Precise timing of and magnitude of the Tian Shan uplift are required to understand possible mechanisms of continental lithosphere deformation and interactions between climate, tectonism and erosion. Here, we provide structural analysis of seismic section and magnetostratigraphic and biostratigraphic age control on the stratigraphy of the northern Chinese Tian Shan foreland [3, 4]. In the southernmost row of the anticlinal belts, the magnitude of shortening is ~2.9km (15.1%), and the shortening rate is 0.41mm/yr based on the time of tectonic activity of ~6.0Ma. In the middle row, the magnitude of shortening is ~5.9km (23.7%), and the shortening rate is 2.9mm/yr based on the time of tectonic activity of ~2.0Ma. And the northernmost row, the magnitude of shortening is ~4.3km (15.7%), with a shortening rate of 4.3mm/yr. The results indicate that the intensity of the tectonic activity along the northern margin of the Tian Shan has been increasing since the late Cenozoic.

Transient oxic conditions amid ferruginous deep waters after the Cryogenian Sturtian glaciation evidenced from Fe-C-S proxies

DA LI[1]*, HONGFEI LING[1], GRAHAM A. SHIELDS[2], LAWRENCE OCH[2] AND SIMON W. POULTON[3]

[1]School of Earth Sciences and Engineering, Nanjing University (*correspondence: maillida@gmail.com)
[2]Department of Earth Sciences, University College London
[3]School of Civil Engineering and Geosciences, Newcastle University

The Neoproterozoic ocean was characterized by profound perturbations which helped to trigger biological revolutions. While several lines of geochemical evidence indicate that the Ediacaran deep ocean was dominated by anoxic ferruginous conditions, much less is known about Cryogenian seawater. An iron-rich and sulfate-poor environment has been hypothesised for the post-'Sturtian' or late Cryogenian non-glacial interval, in accordance with the growth of a large organic carbon pool, as implied by decoupling between carbonate and organic carbon-isotopes [1].

Here we report iron speciation data from the basal Datangpo Formation which lies between the glacial deposits of the Tiesi'ao (Sturtian) and Nantuo (Marinoan) formations on the Yangtze Platform, South China. Our aim is to examine deep-water redox conditions after the Sturtian glaciation. Samples were collected from two underground rhodochrosite mines named Yuxin and Changxingpo, respectively.

Iron concentrations in different highly reactive species (Fe_{HR}), including $Fe_{carbonate}$, Fe_{oxide}, $Fe_{magnetite}$, were analyzed using the sequential leaching method outlined in reference [2] and performed at Newcastle University, UK.

Siltstone samples from the latest Tiesi'ao Fm. in the Yuxin section yielded Fe_{HR}/Fe_T above 0.38 and Fe_{py}/Fe_{HR} below 0.8, indicating ferruginous conditions. However, three samples from the uppermost Tiesi'ao Fm. at Changxingpo section have Fe_{HR}/Fe_T below 0.38, indicating oxic bottom waters during the melting of the Sturtian ice cover at c. 665 Ma. Organic- and manganese-rich carbonaceous siltstone samples from the lowermost Datangpo Fm. in both sections have Fe_{HR}/Fe_T above 0.38 and Fe_{py}/Fe_{HR} below 0.8, suggesting ferruginous deeper-waters during early interglacial time. This is consistent with a previous study of carbonate and organic matter C-isotope and pyrite S-isotope data from Yuxin section, which showed that the chemocline was initially close to the sediment-water interface and moved up into the water column during the early interglacial interval, as manganese was oxidized in the water column and then converted to manganese carbonates [3].

This study was co-funded by NSFC 40872025 and the DFG FOR736 program.

Formation of summer hypoxia in the Yangtze River Estuary of China: 'Cold pool' and 'thermal barrier' effects

D.J. LI*, H.X. LIU, L. GAO AND P. WANG

State Key Laboratory of Estuarine and Coastal Research, East China Normal University, 3663 North Zhongshan Road, Shanghai 200062, China
(*correspondence: daojili@sklec.ecnu.edu.cn)

Hypoxia in the Yangtze River Estuary has received increasing attention. It occurs in summer and may last until early autumn, and it has recently become more serious. Based on survey data from October 1958 to September 1959, August 2009, and July 2005, we found that the hypoxia area is located in the trough off the Yangtze River Estuary and affected by many external forcing factors, including water temperature and salinity, runoff from the Yangtze River, the Taiwan Warm Current, upwelling, and the Yellow Sea Coastal Current. These factors promote the formation of hypoxia by influencing the dissolved oxygen saturation level, the strength of stratification, the distribution of temperature and salinity, and water movement. In addition to these factors, there was a cyclonic vortex in the hypoxia area, and the bottom water in the area was much more stable. The vortex was mainly made up of water from the Taiwan Warm Current, which is characterized by low temperature in summer. All these factors promote the formation of a cold pool (isolated, closed, and stable waters with lower temperature under a 15-meter layer of warmer water) in the hypoxia area, and a thermal barrier (water at the periphery of the cold pool with higher temperature that protects the stability of the cold pool and blocks the exchange of dissolved oxygen with surrounding waters) is formed. The existence of the cold pool and thermal barrier greatly increases the residence time of water in the hypoxia zones, restricts the supply of dissolved oxygen, and provides necessary preconditions for the formation of summer hypoxia.

This study was jointly funded by Ministry of Science and Technology of China (2010CR951203), Shanghai Municipality (10JC1404400), and State Key Laboratory of Estuarine and Coastal Research of China (2009KYYW03)

Balance of Cenozoic carbon cycle maintained by basalt weathering

GAOJUN LI

Department of Earth Sciences, Nanjing University, Nanjing 210093, China (ligaojun@nju.edu.cn)

The BLAG model proposed that the Cenozoic decline of atmospheric pCO_2 is primarily dirven by the decrease of CO_2 degassing through the pCO_2-weathering feedbacks [1]. However, the sea floor spreading rate, which is believed as the major control of CO_2 degassing, remained relatively constant [2]. Alternative explanation suggests that the drawdown of pCO_2 is forced by the enhanced silicate weathering in response to the widespread Cenozoic tectonic uplift [3], but the increasing CO_2 consumption would deplete the atmosphere of all its CO_2 within a million years [4].

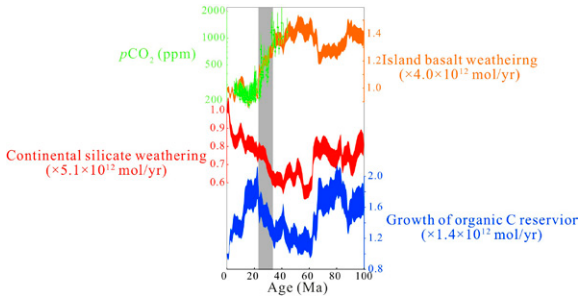

Figure 1: Atmospheric CO_2 sinks and pCO_2 [5] since 100 Ma

Here an reverse calculation coupling the marine isotopic records of C, Sr and Os suggest that the weathering of island basalt is largely controled by pCO_2 (Fig. 1), possibally through the CO_2 fertilization effect on plant weathering. The rate control of pCO_2 on basalt weathering imply that both the BLAG model and the 'uplift driven' hypothesis could stand for the Cenozoic pCO_2 evolution. Tectonic uplift enhanced the atmospheric CO_2 consumption by continental silicate weathering and accumulation of organic carbon during the Oligocene, left the unbalanced carbon cycle compensated by the decreasing island basalt weathering through the pCO_2 controlled basalt weathering rate. Since the Miocene, the increasing CO_2 sink of continental silicate weathering was roughly balanced by the decreasing accumulation rate of organic carbon reservoir, and thus the rate of basalt weathering and pCO_2 kept nearly constant.

Trace elemental geochemistry of black shale from Chengkou district, Chongqing, southwest China and its genetic significances

H. LI, [1,2], Z. ZHU[1,2]*, C. ZHU[1] AND T. LUO[3]

[1]Chongqing Key Laboratory of Exogenic Minerallization and Mine Environment, Chongqing Institute of Geology and Mineral Resources, Chongqing 400042, China (*correspondence: zhuzhjie@163.com)

[2]Chongqing Research Center of State Key Laboratory of Coal Resources and Safe Mining 400042, China

[3]The State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China

The black rock series in Lower Cambrian are well developed in Chengkou district, Chongqing, representing a potentially large multi-metal deposit source in China. Previous study in Chengkou district showed that multi-metals including Ag, V, Se are enriched in black shale. In order to understand the genetic significances of black shale and multi-metal enrichment, ICP-MS techniques was used to analyze trace elemental contents in Lower Cambrian black rock series including cherts, black siltstones and multi-elements concentrated layers. The results indicated that REE is very low relative to other regions such as northern Guizhou, northwestern Hunan, and LREE is relative abundant. δCe shows almost negative anomaly, and δEu shows unconspicuous anomaly. The indicators of δCe, δU, V/Cr, Ni/Cr and V/(V+Ni) demonstrated that black rock series formed in the anoxic environment. REE geochemical characteristics and their diagrams, high enrichments of Cr, Sb, As, Bi and U/Th ratios indicated that black rock series mainly formed by hydrothermal deposition. Meanwhile, the petrogenesis of black rock series was associated with volcanism, and volcanism possibly provided the composition and dynamics to the hydrothermal activity.

Metamorphic fluid activities and their effects on petrological and geochemical characteristics of UHP rocks, Southern Sulu UHP Terrane, China

HONGYAN LI*, DONG WANG AND XIANG CHENG

Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing 100037, China (*correspondence: lihongyan@cags.ac.cn)

Since the 2000s, more and more research work disclosed metamorphic fluid activities during the deep subduction process of the continental materials in many UHP terranes. However, the property, scale and geological significance of the metamorphic fluid activities are still not clear.

Eclogites from the Qinglongshan area in the southern end of the Sulu UHP terrane have acquired celebrity in their unusual oxygen isotope compositions. We take two types of eclogites, an epidote-bearing and an epidote-free for this study in the Qinglongshan area. Four metamorphic stages are identified for the evolution of epidote-bearing eclogite. However, the epidote-free eclogite only records eclogite facies metamorphism. They have distinguished petrological, geochemical and Sr-Nd isotopic characteristics.

In the epidote-bearing eclogite, kyanite-zoisite-paragonite-quartz veins of several to decadal centimeters are developed. These veins were formed from the pre-existed hydrous UHP metamorphic mineral (lawsonite) and give a zircon U-Pb age of 219 ± 9 Ma, which indicate a metamorphic fluid activity in the early stage of the exhumation of the deep subducted continental materials.

U-Pb and Lu-Hf isotope studies of zircon are also carried out for the country gneiss of the epidote-bearing eclogite which develops kyanite-zoisite-paragonite-quartz veins. Zircons from the granitic gneiss have core-rim structure. Although the cores and rims have obviously different Hf isotopic characters, they show no difference in Th/U ratio, REE pattern and U-Pb age. Strongly in contrast with previously published zircon U-Pb ages of the Dabie-Sulu UHP metamorphic rocks where protolith ages of 700–800 Ma are commonly recorded, only metamorphic age of 218 ± 5 Ma, identified either in rim or core of the zircons, are recorded in this granitic gneiss. This result show that, in the locality with strong retrograde metamorphic fluid activities, the U-Pb isotope system of zircon could be reset completely from its magmatic precursor, while the Lu-Hf isotope system could remain relatively close.

Partitioning of chlorine and fluorine between apatite and felsic silicate melts at subduction zone conditions

H.J. LI* AND J. HERMANN

Research School of Earth Sciences, The Australian National University, Canberra, ACT 0200, Australia (*correspondence: huijuan.li@anu.edu.au)

The chemistry of subduction zone fluids has been a primary focus of geological studies in recent years. While the broader nature of the fluid phases remains a matter of debate, the specific role of ligands such as F and Cl are also pooly constrained, even though both elements can exert important controls on fluid chemistry due to their effects on H2O activity, mineral solubility and trace element partitioning, etc.

In this study, piston-cylinder experiments have been conducted to investigate chlorine and fluorine partitioning behaviour in felsic silicate systems at subduction zones conditions. A pelitic starting composition was synthesized with 6-7 wt% H_2O. Initial experiments were conducted over a pressure and temperature range of 25-45 kbar and 650-850°C, with 800 ppm Cl in the starting composition. Apatite was found to be the major mineral carrier of chlorine, with Cl concentrations ranging from ~0.1% at 750°C, 45kbar to 1.2% at 800°C, 25kbar. While an increasing Cl concentration in apatite correlates with increasing temperature, a decrease in Cl occurs with increasing pressure. Chlorine content in the coexisting melt was determined by both analysis and mass balance calculations. Partition coefficients between apatite and melt, $D^{Cl}_{ap\text{-}melt}$, vary from ~1 (e.g. at 750°C, 35kbar, and 800°C, 45kbar) to ~11 (at 800°C, 25kbar), with values rising with increasing temperature and falling with increasing pressure. The preliminary partition coefficient values for aqueous fluids, based on mass balance estimations, are found to be less than 1 at subsolidus conditions.

A further series of experiments was performed at 25 kbar and 800°C with various Cl (~0, 500, 1000, 2000, or 4000 ppm) and F (~0, 1000, or 2000 ppm) fractions in the starting compositions. $D^{Cl}_{ap\text{-}melt}$ values were found to remain relatively constant between experiments with identical F concentrations in the system. Linear regressions show the $D^{Cl}_{ap\text{-}melt}$, to be around 10.6 at 0 ppm F, ~3.5 at 1000 ppm F and ~1.9 at 2000 ppm F. The preliminary $D^{F}_{ap\text{-}melt}$ values range from 15 to 50, with the dominant influence being the F concentration in the system. The obtained results are the first ever reported in the literature, and will provide useful constraints on F and Cl contents in subduction zone fluids.

Geological evolution of Paleotethys: Constraints from Ar-Ar, U-Pb ages of gabbro in Jinshajiang Suture Zone

LI JIE[1,2]*, CHEN WEN[2], YONG YONG[2], SUN JINGBO[2] AND JI HONGWEI[1,2]

[1]China University of Geosciences(Beijing), Beijing, 100029 China (*correspondence: huaer3312@sina.com)

[2]Laboratory of Isotope Geology, Institute of Geology, CAGS, Beijing, 100037 China

Jinshajiang suture zone located in the northern and eastern of Qinghai-Tibet plateau, considered as the boundary of west-north Paleotethys. Therefore it is of significant in the research of the geological evolution of Paleotethys. We collected gabbro samples from ophiolitic melange in the area of Yushu, middle-west of the suture zone, and achieved a number of high-precision Ar-Ar and SHRIMP U-Pb age which with range of 295Ma-233Ma. According to these ages, the gabbro can be divided into three groups: (1) Late Carboniferous gabbro: Outcropped in the middle of Jinshajiang suture zone, with zircon SHRIMP U-Pb age of 295.3±5.2Ma. (2) Middle-late Permian gabbro: Distributing in central and north of the suture zone, with age ranges from 268 to 258Ma. (3) Mid-Triassic gabbro: Distributed in central and south parts of suture zone, the age is about 233Ma.

From above isotope ages of gabbro, we could extract some information for the geological evolution of Paleotethys: (1) The Jinshajiang ocean expansion lasted 60Ma. (2) Along Jinshajiang suture zone, the age of ophiolite from southeast to northwest reduce gradually, which indicate the Paleotethys Ocean opening is earlier in southern part than in northern part, from southeast to northwest, the Ocean basin opened in sharp of shear-like. (3) Considering the existence 362Ma of ophiolite in the south of Jinshajiang suture zone [1], Paleotethys existed more than 130Ma.

Trace elements and REE geochemistry of copper-bearing sandstone in the middle submember of the Liuju Member of the Upper Cretaceous Matoushan Formation, Yunnan,China

JING LI[1], RUNSHENG HAN[2] AND PENG WU[2]*

[1]Kunming University of Science and Technology, Division of Laboratory Administration, Kunming 650093, China (*correspondence: lijing2409@yahoo.com.cn)
[2]Kunming University of Science and Technology, Southwes Institute of Geological Survey, Geological Survey Center for Non-ferrous Mineral Resources, Kunming 650093, China

Liuju sandstone-type copper deposit located in the North Centre of Chuxiong Basin in Yunnan province, China. The main ore-bearing strata is Liuju lower submember of the Upper Cretaceous Matoushan formation (K_2ml_1). The content of Cu is more than 2% recently discovered in Liuju middle submember (K_2ml_2) which has great prospecting futurities.

The metallogenic mechanism of K_2ml_2 is similar to that in the Liuju copper deposit (K_2ml_1). In K_2ml_2, Ta, Sc, Co, Ni, V are deficient, and chalcophile elements Mo, Cd, As, Cu enriched in grey sandstone, which has the feature of ore source rocks. It indicates that the enrichment of Cu is closely related to the water-rock interaction [1]. In terms of n (V)/n (V+Ni) >0.7, the copper ore formed in oxygen-poor environment.

The average contents of rocks $\sum$REE=123.04×10^{-6}, LREE/HREE=8.89, δEu=0.80, δCe=0.92. From the copper ore to gray bed, to purple bed, the average values of Mo、Cd、As and Hg reduced gradually, Nb、Zr、Hf、Th and $\sum$REE increased gradually.

Basis on geochemical research of copper-bearing sandstone in K_2ml_2, it indicates that the copper ore formed by water-rock interaction of ore-forming fluid and wall rocks, Cu is enriched in weak alkaline and reducing property environment.

Granted jointly by the Basic Applied Research Foundation of Yunnan Province (2010ZC013) and the Distinguishing Discipline of KUST (2008).

Diagenetic mobility of Mn and Fe crusts in organic-poor sediments of Lake Superior

J. LI[1]*, S.A. CROWE[2], E.T. BROWN[1], M. DITTRICH[3], D. MIKLESH[1] AND S. KATSEV[1]

[1]Large Lakes Observatory, University of Minnesota Duluth, Duluth, MN 55812 (*correspondence: lixx0590@d.umn.edu, skatsev@d.umn.edu)
[2]NordCEE, Univ. of S. Denmark (sacrowe1@gmail.com)
[3]University of Toronto Scarborough (dimaria@ethz.ch)

Sediment distributions of redox-sensitive metals, such as Fe and Mn, are often used as indicators of paleoceanographic redox conditions. Post-depositional changes in sediment redox conditions, however, may redistribute these metals within the sediment, complicating interpretations of sediment records. The rates and magnitudes of such redistributions in oceanic sediments, as well as their causes, are poorly known. We investigate the redistribution of diagenetically precipitated Fe and Mn phases in organic-poor modern sediments of Lake Superior. These sediments contain prominent (up to 10 wt%) multiple Fe and Mn-rich layers, often visible to a naked eye, and record vertical migrations of the sediment redox boundary in response to varying fluxes of organic carbon and actions of bottom currents. We use scanning XRF and chemical extractions to characterize these layers, and measure the concentrations of oxygen and dissolved metals in sediment porewaters to understand the *in situ* reaction rates and their links to past and present redox conditions. High levels of 0.5M HCl-extractable iron, as well as iron enrichment relative to Ti, within Fe-rich layers suggest that these layers formed diagnetically. Comparison of the porewater distributions of Fe (II), oxygen, and nitrate suggests a significant contribution of iron oxidation coupled to the reduction of nitrate, rather than oxygen. At one of our sampling sites, the depth of oxygen penetration has moved upwards by 4 cm and subsequently re-deepened over the course of ~40 years, as a result of sediment pollution by taconite tailings between 1950s and 1980s. The observed present-day distributions of sediment Fe and Mn and mass balance calculations show that these metals may become re-distributed over time scales as short as decades, even in a system where organic carbon is relatively unreactive (k=0.005 yr^{-1}) and in low quantity (2 wt%). Changes in organic carbon sedimentation within a factor of 2, or variations in the bottom-water oxygen concentrations by ~10% can alter the depth of oxygen penetration in these organic-poor sediments by several centimeters or more.

Magnesite dissolution rates at the column scale: The control of mineral spatial distribution

LI LI[1], FATEMEH SALEHIKHOO[1] AND SUSAN L. BRANTLEY[2]

[1]Department of Energy and Mineral Engineering, Penn State University, University Park, PA 16802

[2]Department of Geosciences, Earth and Environmental Systems Institute, Penn State University, University Park, PA 16802

Mineral dissolution plays a major role in various physical, chemical, and biological processes in nature. The rates of mineral dissolution in the field are often quantified by soil depth profiles and the sharpness of dissolution front within soil columns. Mineral dissolution rates can be affected not only by mineral reactivity, but also by other hydrogeochemical conditions, including flow velocity, inlet flow chemical composition, as well as the spatial distribution of minerals. Although potentially an important factor that determines the kinetics of mineral dissolution, the effects of mineral spatial distribution are often ignored. The objective of this work is to understand and quantify the effects of mineral spatial distribution on the overall dissolution rate at the column scale. Both column experiments and reactive transport modeling are used to investigate the dissolution of a reactive mineral (magnesite) imbedded in a sand column in different spatial patterns. The total mass ratios of the two minerals were kept constant. The variables include flow velocity, column length, and sub-column scale mineral spatial distribution. The results show that mineral spatial distribution is important under conditions where the flow velocities are relatively fast comparing to the reaction rates, and when the columns are relatively short. Under conditions where the small-scale heterogeneities are important, the column scale overall dissolution rates are larger when magnesite is spatially distributed evenly, compared to the case where all magnesite is clustered.

Distribution and release of strontium in rivers around mine: An indicator for the oxidation of sulfide minerals in carbonate area

LING LI[1], GUOPING ZHANG[1,*], HONG LIU[1], MENG XIANG[1,2] AND XIAOFEI WEI[1,2]

[1]State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (*correspondence: Guoping.zhang@tom.com) (lynnfirst@gmail.com)

[2]Graduate School, Chinese Academy of Sciences, Beijing 100049, China

Water samples from two mine areas were collected and analyzed for trace elements by ICP-MS. River water showed average Strontium concentration of 630 $\mu g \cdot L^{-1}$ in the Dachang multi-metalliferous mine area and of 790 $\mu g \cdot L^{-1}$ in the Yata gold mine area, were 4 and 5 times higher than the background values (Dachang mean: 155 $\mu g \cdot L^{-1}$; Yata mean: 160 $\mu g \cdot L^{-1}$), respectively. Especially, content of Sr was up to 1704 $\mu g \cdot L^{-1}$ in the adit water of the Dachang mine area.

Sr is abundant in carbonate rocks resulting from its similar ion radius with Ca. Actually, Dachang and Yata mine areas, as the carbonate rocks area, the former has one of the largest antimony deposit in China, and the latter has a significant gold deposit associated with As, Hg, Sb and Tl mineralisation in China. Although acid generated in the oxidation of sulfide minerals in mine tailings, the surface waters in the both of two mine areas are still circumneutral to slightly alkaline because of the neutralization of the carbonate rocks. However, when sulfide minerals such as antimony and arsenious sulphide are oxided, the sulfuric acid can react with carbonate rocks, and then can lead to the release of Sr from carbonate rocks. As a consequence, Sr shows a good correlation with Sb and As in the Pingcun river ($r = 0.99$ and 0.90, $n = 8$) and the downstream river ($r = 0.99$ and 0.94, $n = 6$) of Dachang mine area. Sr only shows a good correlation with As and but a poor correlation with Sb in the Yata mina area ($r = 0.94$ and 0.28, $n = 8$) [1]. Moreover, Sr in river water also shows a good correlation with SO_4^{2-} ($r = 0.96$, $n = 8$) in the Yata mine area. Therefore, it could be concluded that a strong release of Sr in water of mine area can be resulted from the neutralization of acid drainage. Furthermore, Sr can also be regarded as an indicator of the oxidation of sulfide minerals in the mining environment enriched in carbonates.

Archean sulfur may power modern microbial life in the deep subsurface in the Canadian Shield

LONG LI[1], BOSWELL WING[2], THI H. BUI[2], GREG F. SLATER[3], GEORGES LACRAMPE-COULOUME[1] AND BARBARA SHERWOOD LOLLAR[1]

[1]Department of Geology, University of Toronto, Toronto, ON, Cananda M5S 3B1

[2]Department of Earth and Planetary Sciences, McGill University, Montreal, QC, Canada H3A 2A7

[3]School of Geography and Earth Sciences, McMaster University, Hamilton, ON, Canada L8S 4K1

Saline fracture water in Archean rocks in the Canadian Shield and South Africa have been found to host microbes (mainly sulfate reducers) as deep as 3 km. This provides an important analog for the study of life on the early Earth and for search for life on other planets (e.g. Mars). In order to understand the source and sustainability of the sulfate that supports these deep microbial ecosystems, we carried out multiple sulfur (S) isotope analyses for dissolved sulfate and sulfide in the saline waters from up to 2.7 km depth in the Canadian Shield near Timmins, Ontario (ON) and Thompson, Manitoba (MN).

Prevalent S isotope mass independent fractionations (MIF) were observed: dissolved sulfate at the ON sites had $\delta^{34}S$ values from 3.3 to 8.4‰ and $\Delta^{33}S$ from -0.07 to -0.20‰. Dissolved sulfate at the MN sites had $\delta^{34}S$ values from 21.1 to 26.0‰ and $\Delta^{33}S$ from 0.13 to 0.19‰. One dissolved sulfide sample at the MN sites had $\delta^{34}S$ of 4.4‰ and $\Delta^{33}S$ of 0.13‰. The negative $\Delta^{33}S_{sulfate}$ values at ON are comparable to those of local 2.7Ga sulfide deposits. At MN, the S source of the hosting Proterozoic ore deposits has been inferred to be at least partially from recycling of sulfide in local Archean sedimentary rocks. The observed MIF of the saline waters suggests the possibility that the ultimate S sources of sulfate in these deep groundwater systems are the Archean sulfides. The large $\delta^{34}S$ and consistent $\Delta^{33}S$ between dissolved sulfate and sulfide, and the significantly elevated $\delta^{34}S_{sulfate}$ values in the MN samples relative to the reported values for the ore (2-6‰) suggest significant sulfate reduction (SR). The $\delta^{34}S_{sulfate}$ of the ON samples are also elevated by 1-6‰ compared to the published values of local ore deposits (0-2‰), implying SR may be also taking place at this site. Because all of these groundwaters have temperatures less than 30°C, the SR is most likely biological in origin. Our data raise the possibility that present-day elemental cycling by deep microbial communities can be supported by Archean S sources.

Measurement of intramolecular carbon isotopic distribution of acetaldehyde emitted from plant leaves

NA LI[1]*, KEITA YAMADA[1], RYOTA HATTORI[2], HIROKI SHIBATA[2], ALEXIS GILBERT[1], NAOHIRO YOSHIDA[1]

[1]Department of Environmental Science and Technology, Interdisciplinary Graduate School of Science and Engineering, Tokyo Institute of Technology, 4259 Nagatsuta, Yokohama 226-8502, Japan

[2]Central Laboratories for Frontier Technology, Center for Food Safety Science, Kirin Holdings Company Limited, 3 Miyahara, Takasaki Gunma 370-1295, Japan

Stable isotopic signatures within molecules record a wide range of phenomena in the chemical, biological, environmental, and earth sciences.

Here, we focus on acetaldehyde, which is an important metabolic intermediate in biological systems. Until now, there was only one study on intramolecular carbon isotopic composition ($\delta^{13}C$) of acetaldehyde, which derived from pyruvate decarboxylase during yeast incubation experiments [1]. However, in this study, the analytical protocol and the precision of the method, and the brief description made suggests that the technique was cumbersome, since it predated GC-IRMS techniques.

In this study, we examine the applicability of measurements of intramolecular $\delta^{13}C$ in acetaldehyde through GC-C-IRMS approaches. Using GC-C-IRMS combined with an off-line pyrolysis, we determined the certified values of the intramolecular $\delta^{13}C$ in acetaldehyde samples. Then, based on the certified value, we developed GC-Py-GC-C-IRMS combined with headspace solid-phase microextraction (time-saving and more sensitive than off-line pyrolysis) for the accurate determination of $\delta^{13}C$ of acetaldehyde. This method was applied to samples collected form chamber in which plants were grown. The results shown that the intrmolecular $\delta^{13}C$ of acetaldehyde emitted from plants was influenced by environmental factors, such as temperature, sunlight or humidity. These results suggest that environmental factors influence the fluxes related to acetaldehyde metabolism in plants, which gives us new insights into plant metabolic pathways and potentially plant-atmosphere interactions.

A study on volcanic minerals and hosted melt inclusions in newly-erupted Tengchong volcanic rocks, Yunnan Province

N. LI*, Q.C. FAN, L.Y. ZHANG

Institute of Geology, China Earthquake Administration, Chaoyang District, Beijing 100029 , China (*correspondence: nili@ies.ac.cn)

Tengchong volcanic clusters are located at the border area of western Yunnan Province and Myanmar. They consist of Heikong Mountain, Dakong Mountain, Xiaokong Mountain, Daying Mountain and Ma'an Mountain, etc., which are famous Quaternary volcanic clusters in our country and are divided by oldly- and newly-erupted volcanoes. Previous work testified Daying, Ma'an and Heikong Mountains are newly erupted ones, which had eruption activities in late Pleistocene and Holocene epochs [1].

The phenocrysts in these volcanic rocks are pyroxene, olivines and feldspars. The melt inclusions are found in hosted phenocrysts which have different shapes, randomly distributed and have some variations after entrapment. The compositional variation of melt inclusion in newly erupted volcanic rocks is larger than that of matrix glass. The chemical compositions of melt inclusion and matrix glass have covered basaltic trachyandesite, trachyandesite, trachyte and rhyolite etc., which are consistent with those of late Pleistocene and Holocene volcanic rocks in Tengchong. According to EMP analyses of melt inclusions in hosted phenocrysts, microcrystals and matrix glass, the content of volatile chlorine doesn't show large variations in melt inclusions and matrix glass, but those of volatile fluorine and SO_3 do have more variations in melt inclusions than in matrix glass.

In general, the degassing rate of newly-erupted Tengchong volcanic rocks was low and they didn't emitted more gas to the atmosphere, thus had small effect on the climate and environment by speculation. Nevertheless, future disaster shouldn't be ignored.

The work was supported by Special Project for Earthquake- 'Volcanic and Geologic Mapping of Tengchong'.

A type of high Sr/Yb granite in North Qinling: The melting product of a pre-exiting source of arc environment

PING LI, JUN-LU CHEN, XUE-YI XU AND TING LI

Xi'an Center of Geological Survey (Xi'an Institute of Geology and Mineral Resource), CGS, Xi'an, Shaanxi 710054, China

Located in the North Qinling, the Wuguan intrusive rocks intruded into the Danfeng Group.It's rich in LILE and depleted in HFSE, with a high LILE/HFSE ratio. Moreover, the Wuguan intrusive rocks are rich in sodium and aluminum, having a high Sr/Yb and high CaO/Na_2O ratio, with no obvious negative Eu anomaly. Tthese geochemistry features suggest that there are formed by the remelting of the basaltic rocks with amphibole as a stable residual phase. The result of REE analogue calculation suggests that, plagioclase amphibolite which is formed in an island-arc environment in the Danfeng Group could form the Wuguan intrusive rock via partial melting. Besides, the residual mineral assemblage mainly is hornblende and also includes a small amount of plagioclase and clinopyroxene. The Zircon U-Pb isotopic age is later than the period of the subduction of Shangdan Ocean, but its chemical characters is closely related to the island-arc environments. The geochemical characters reflected in the Wuguan intrusive rocks may be some inherited chemical features of its sources in an arc-environment. However, the Wuguan intrusive rocks is formed in a collision orogenic process.

Precise age determination of the Paleozoic kimberlites in North China Craton and Hf isotopic constraint on the evolution of its subcontinental lithospheric mantle

QIU-LI LI*[,1], FU-YUAN WU[1], XIAN-HUA LI[1], ZHI-LI QIU[2], YU LIU[1], YUE-HENG YANG[1] AND GUO-QIANG TANG[1]

[1]State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029, China (*correspondence: liqiuli@mail.igcas.ac.cn)

[2]Department of Earth Sciences, Sun Yat-Sen University, Guangzhou 510275, China

Kimberlite, a kind of deep-sourced igneous rock, carries not only diamond, but also invaluable mantle xenolith and/or xenocryst, which are vital to track the evolution of subcontinental lithospheric mantle (SCLM). However, crustal and/or mantle contamination and post-emplacement alteration bring difficulties to determining the emplacement age of kimberlite and its compositions of primary magma. This paper finely constrains the emplacement age of diamondiferous kimberlites in Mengyin and Fuxian of the North China Craton (NCC) via three different dating methods. For Mengyin kimberlite, single grain phlogopite Rb–Sr dating yields an isochron age of 485 ± 4 Ma, U–Th–Pb analyses on perovskite give a U–Pb age of 480.6 ± 2.9 Ma and a Th–Pb age of 478.9 ±3.9 Ma, and baddeleyite yields a Pb–Pb age of 480.4 ± 3.9 Ma. For Fuxian kimberlite, baddeleyite gives a Pb–Pb age of 479.6 ± 3.9 Ma, indicating that the Paleozoic kimberlites in the NCC were emplaced at ~480 Ma. Numerous lines of evidence indicate that the studied baddeleyites are xenocrysts from the SCLM, and can be used to constrain Hf isotope compositions (~ –6) of the SCLM when kimberlite erupted. Combined with data from Mesozoic–Cenozoic mantle-derived rocks and xenoliths, the Hf isotope evolution trend of the SCLM beneath NCC before destruction was tentatively constructed, which suggested that the Archean SLCM was enriched by metasomatism at ~1.3 Ga. Further Hf isotope investigations on additional SCLM-derived materials could be compared with the constructed Hf isotope evolution trend before destruction to determine when the lithospheric thinning happened.

Late Mesozoic tectonic evolution of the Songliao basin, NE China: Evidence from detrital zircon ages and Sr-Nd isotopes

S.-Q. LI[1], F. CHEN[1]*, X.-Y. ZHU[1,2] AND W. SIEBEL[3]

[1]CAS Key Laboratory of Crust-Mantle Materials and Environments, University of Science and Technology of China, Hefei 230026, China (*correspondence: fkchen@ustc.edu.cn, lsq@mail.ustc.edu.cn)

[2]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China (zhuxiyan@mail.igcas.ac.cn)

[3]Institut für Geowissenschaften, Universität Tübingen, 72074 Tübingen, Germany (wolfgang.siebel@uni-tuebingen.de)

The Songliao basin, located in NE China, is one of the important oil and gas fields in China. The basin is tectonically bounded by the Jiamusi-Khanka, Erguna, Xing'an blocks between the North China and Siberian cratons. It is filled with thick Mesozoic sedimentary and volcanic rocks. This study presents detrital zircon ages and Sr-Nd isotopic compositions of two late Mesozoic sedimentary sequences, and discusses the tectonic evolution of the basin from the sedimentary record.

Dominant zircon populations of the underlying Denglouku Formation are Paleozoic (270-230 Ma) and Mesozoic (190-160 Ma) in age and are of magmatic origin. The overlying Quantou Formation contains older zircon populations of ~1800 Ma and ~2500-2900 Ma. The youngest detrital zircons place the deposition ages of both rock formations at about 110 Ma. The two sequences have distinguishable Sr-Nd isotopic features. The Denglouku Formation is characterized by higher initial ε_{Nd} values (-6.4 to -2.8) and lower initial $^{87}Sr/^{86}Sr$ ratios (0.707 to 0.709), compared to the Quantou Formation (-12.8 and 0.713).

Both rock formations appear to have been derived from different sedimentary sources. Most likely, Paleozoic and Mesozoic magmatic rocks were widespread in the northern periphery of the basin, and served as potential sources of the Denglouku Formation. In the south and in the east, old basement rocks of the North China craton provided major sedimentary material to the Quantou Formation. The south-eastward migration of erosion center(s) and the north-westward movement of the deposition center of the Songliao basin in late Mesozoic were probably related to the subduction of the western Pacific plate.

Oil-source correlation for severely biodegraded oils in Biyang Depression, China

S.F. LI*, S.Z. HU, S. HE AND D.M. ZHANG

Key Laboratory of Tectonics and Petroleum Resources (China University of Geosciences Wuhan), Ministry of Education, China (*correspondence: lishf@cug.edu.cn, hushzh@cug.edu.cn, shenghe@cug.edu.cn, zdm2007@cug.edu.cn)

There are multi-sources and kinds of crude oil types in Biyang Depression, which include normal oils and different-degree biodegraded oils [1]. Normal biomarker parameters, such as regular sterane and gammacerane index, are influenced by biodegradation [2], and the oil-source correlation for the whole area become very difficult. Some compounds with little or no influence should be chosen for oil-source correlation.

According to Peters [3], the 17α21β-norhopane is more resistant than 17α21β-hopane to biodegradation. Based on the analysis of more than three hundred samples which include source rock and crude oil distributed in six different basins, we proposed 2×αβ-norhopane in place of αβ-hopane and used this new gammacerane index (gammacerane/2×C_{29}hopane) to correlate those severely biodegraded oils and normal oils. Moreover, the different oils and source rocks in Biyang Depression can be distinguished clearly by the plate between gammacerane/2×C_{29}hopane and 2×C_{24} tetracyclic terpane/C_{26} tricyclic terpane (Fig. 1). Hence, the oil-source correlation for Biyang Depression has been made successfully.

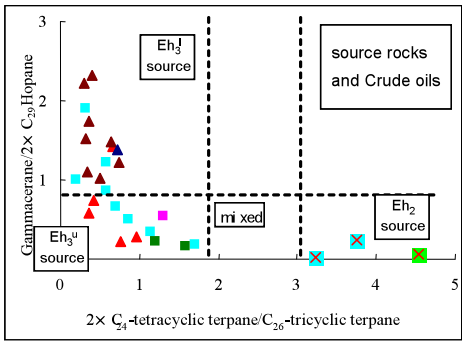

Figure 1: 2×C_{24} tetricyclic terpane / C_{26} tricyclic terpane versus gammacerane / 2×C_{29} hopane for oils and source rocks from Biyang Depression

Carbon isotope composition of DIC in the Yalong Jiang of Changjiang Basin, China

SI-LIANG LI, BENJAMIN CHETELAT, CONG-QIANG LIU, FUJUN YUE AND ZHIQI ZHAO

The State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (lisiliang@vip. skleg. cn)

Concentrations and isotopic compositions of carbon species in water samples are often used in studies of carbon biogeochemistry and rock weathering in rivers. Yalong Jiang is 2nd longest tributary of the Changjiang River in central and southern China. The Yalong rises in the Bayan Har Mountains in southern Qinghai Province at an elevation of nearly 5, 000 metres. The Yalong Jiang basin is covered by mesozoic sediments including low-grade metamorphic rocks and granitoid intrusive rocks. In this study, we surveyed carbon isotopic compositions of dissolved and suspended loads of Yalong Jiang and its main tributaries in August of 2009, with purposes of better understanding carbon sources and processes involved in the riverine carbon cycle.

The concentrations of HCO_3^- are in the range of 0.14 to 3.44 mmol L^{-1} for river waters. The $\delta^{13}C$ values of the dissolved inorganic carbon (DIC) in river waters range from -12.2‰ to -3.5‰ with a mean value of -7.1‰. The water collected from hot spring has high contents of HCO_3^- with 39.3 mmol L^{-1} and high carbon isotopic value of +0.9‰, suggesting dissolved inorganic carbon mainly derived from deep source CO_2. The $\delta^{13}C$ values of POC range from -25.4‰ to -21.9‰ for river waters with a mean value of -24.4‰, which suggests that they are mainly derived from C_3 plants. In the present study, the contents and isotopic composition of carbon species indicated that carbonate mineral and silicate weathering by CO_2 from C_3 plants and equilibration of DIC with atmospheric CO_2 involved riverine carbon cycle in Yalong Jiang of Changjiang Basin, China.

A LA-ICP-MS chronological and tectonic environment study of the ore-bearing volcanics in Baiyin orefield

XIANG-MIN LI, ZHONG-PING MA, JI-MIN SUN AND JI-YUAN YU

Xi'an Center of Geological Survey (Xi'an Institute of Geology and Mineral Resource), CGS, Xi'an, Shaanxi 710054, China

The Northern Qilian orogenic zone is one of the most important massive sulfide deposit provinces in our country and the world, especially, the Baiyin mine field which located at its east is a representative massive sulfide deposit. After the porphyroclastic lava extruding and the quartz albitophyre intruding which belong to the later acidic volcanic, The Baiyin mine field began mineralization, and ends at a relatively quiet period before a large-scale basic volcanism. Therefore, there is an important meaning to research the age and tectonic environment about the acid volcanic and the basic volcanic. In this paper, by using LA-ICP- MS zircon U-Pb isotope dating techniques we were determine the age of the basic volcanic in Baiyin orefield, the formation time of the basic volcanic in Baiyin orefield is 465.0±3.7Ma, this age should be belonging to Middle Ordovician ; Researched by predecessors and with the same method, the age of acid volcanic in Baiyin orefield is 467.3±2.9 Ma, So we think the age of the rocks and the mineralization of the Baiyin orefield shoud be appertaining the later Middle Ordovician. All the discovered industrial deposits were produced in marine bimodal volcanic rocks, the marine bimodal volcanic rocks are composition of quartz keratophyre、spilite and a small amount of keratophyre, Chondrite-normalized trace element distribution patterns display that there is a negative anomalies for the Nb, Ta and Ti, combined with tectonic evolution of the North Qilian Mountains, and the ore-bearing volcanic rocks of the Baiyin mine should be formed in the island arc--rift environment in the later Middle Ordovician. The results of the study has a very important significance for tectono-magmatic evolution of the Qilian orogenic belt and also for the guiding the regional geological prospecting.

This study is supported by National scientific and technological support projects (No. 2006BAB07B03-02) and China Geological Survey survey project (No. 1212010818090).

Sources and fate of nitrate in a dam-controlled subtropical river, Southwest China

X.D. LI[1]*, C.Q. LIU[1], Z.Y. YIN[1], X.Y. LIU[1] AND L.R. BAO[1,2]

[1]Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou, PR China (*correspondence: lixiaodong@mails.gyig.ac.cn)

[2]Graduate University of Chinese Academy of Sciences, Beijing, PR China

The concentrations and dual isotopic ($\delta^{15}N$ and $\delta^{18}O$) values in NO_3^- were analyzed from 23 samples collected along the Jialing River, a major tributary of upper Yangtze. Unlike other ions, the concentrations of NO_3^- were higher in rainy season than in dry season. Heavy use of nitrogen fertilizer with low use efficiency is responsible for nitrogen loss and high NO_3^- content in the river water during rainy season. The dammed river may provide preconditions for algal growth that would assimilate NO_3^-, which led to concentration of NO_3^- decreasing, $\delta^{15}N_{NO3}$ and $\delta^{18}O_{NO3}$ values increasing during rainy season. There was no obvious trend of $\delta^{15}N_{NO3}$ and $\delta^{18}O_{NO3}$ in dam area during dry season. To interpret the sources of nitrate, the co-variation of $\delta^{15}N_{NO3}$ and $\delta^{18}O_{NO3}$ was examined (Figure 1).

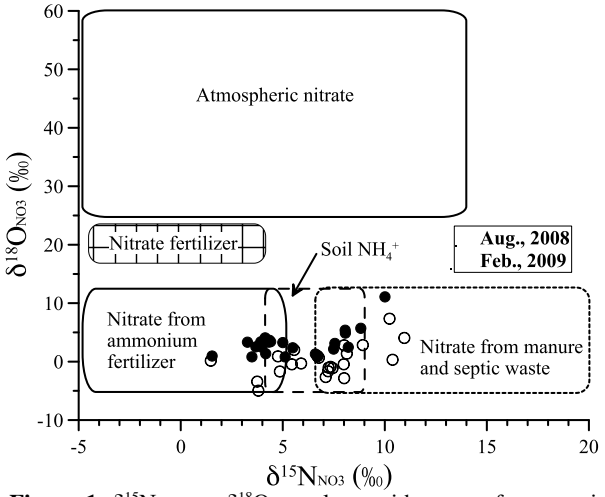

Figure 1: $\delta^{15}N_{NO3}$ *vs.* $\delta^{18}O_{NO3}$, along with ranges for potential sources. (Aug., 2008-rainy season; Feb., 2009-dry season)

The sources of NO_3^- are mainly resulted from the nitrification of ammonium fertilizer and demostic sewage during rainy season while the sewage is the major source during dry season in the Jialing River catchment.

This work was supported by the National Natural Science Foundation of China (Grant No. 40703004 and 40721002).

Combining concentration-area method with indicator kriging analysis for geochemical anomaly identification of the typical deposit

X.H. LI, F. YUAN*, M.M. ZHANG AND T.F. ZHOU

School of Resources and Environmental Engineering, Hefei University of Technology, Hefei, China (*correspondence: yf_hfut@163.com)

Geochemical datasets always include outliers and potentially have skewed distributed data. Althought normal transformation can enhance the robustness of the kriging method, it can smooth the data more seriously. Indicator kriging method does not rely on the stationarity of the datasets, can make more robust and feasible against a series of outliers. The threshold is the most important factor of indicator kriging analysis. The concentration-area method [1] which baesd on the fractal and multifractal theory can provide great help for the threshold calculation.

When we carried out the anomaly identification analysis of Cu concentration in the typical deposit of China, we used the concentration-area method (ACAF) [2] to obtaine the threshold for the indicator kriging. The results of the indicator Kriging interpolation are shown in the figure below.

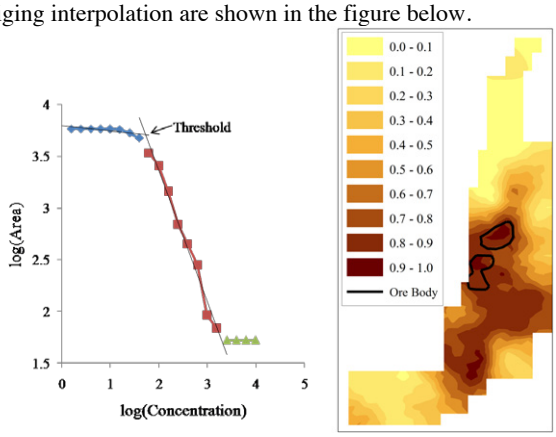

Figure 1: Indicator kriging interpolation results of Cu concentration

Discussion

Combining concentration-area method with indicator kriging analysis can highlight the known ore bodies and delineate mineralization centre more effectively, indicating that it is very suitable for the ore-hunting prognosis which is based on non-stationarity datasets and outliers.

Equilibrium Se isotope fractionation parameters: A first-principles study

XUEFANG LI AND YUN LIU*

State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (*correspondence: Liuyun@vip.gyig.ac.cn)

Introduction

Se belongs to one of the most redox-sensitive elements, so Se isotopes might be used to trace some redox and biointerference processes. But there are just a few pioneering studies [1, 2] that provided equilibrium Se isotope fractionation factors.

Based on the Urey model or the Bigeleisen–Mayer equation method, several important equilibrium Se isotope fractionation parameters are investigated by first-principles calculations. All the frequencies are obtained at B3LYP/6-311+G (d, p) level, with a frequency scaling factor of 1.05. Table 1 shows some of the calculated fractionation factors [3].

Table 1: The formula for Se isotope fractionations at different temperatures (see [3] for details).

Discussion of Results

Our results suggest that the magnitude of isotope fractionation is depended on Se valence states, and there is a trend of heavy Se isotopes enrichment as SeO_4^{2-} > SeO_3^{2-} > $HSeO_3^-$ > SeO_2 > selenoamino acids > alkylselenides > Se (0) or H_2Se > HSe^-. The equilibrium Se isotope fractionation factors provided here might be useful to explain Se isotope distributions in the biogeochemical cycle and also important to the study of Se global cycling.

Geochemistry and metasomatic processes of spinel peridotite suite from mantle wedge of subduction zone, Western Tianshan

XU-PING LI[1]*, LI-FEI ZHANG[2] AND FAN-MEI KONG[1]

[1]College of Geological Science and Engineering, Shandong University of Science and Technology, Qingdao, 266510, China (*correspondence: lixuping@sdust.edu.cn)

[2]The Key Laboratory of Orogenic Belt and Crustal Evolution, MOE, School of Earth and Space Sciences, Peking University, Beijing 100871, China (lfzhang@pku.edu.cn)

Spinel peridotite and olivine amphibolite of the Western Tianshan orogenic belt are enclosed in micaschist and derive from an orogenic wedge environment, showing evidence of melt extraction and metasomatic enrichment and documenting a complex history of the shallow mantle. Al–spinel is closely intergrown with secondary hornblende, diopside and serpentine, indicating that it grows at the expense of former Cr-spinel. Compositions of orthopyroxene, olivine and spinel indicate equilibration within the spinel–peridotite facies of the upper mantle, at depths about 45–65 km and temperatures around 676–735 °C.

High Cr/Al ratio of relict primary spinel and no detected primary clinopyroxene indicate that the ultramafite of the Western Tianshan represents a high degree melting and highly depleted residual mantle. The spinel peridotites derive from a depleted mantle that became enriched in some large ion lithophile element (LILE) and light rare earth element (LREE). Whole-rock trace element patterns from the most spinel peridotite suite show distinct negative anomalies for Nd, Ti and positive anomalies for Pb and Sr. Early amphiboles generated in the mantle wedge above subduction zones are depleted in heavy rare earth element (HREE) with subchondritic Ti/Nb and Zr/Nb ratios, whiles late developed amphiboles are even more depleted in HREE, showing heavily effected by subduction-related fluid. The changing pattern of early edenite to late hornblende in peridotites and amphibolites indicate that the mantle rocks took place within the mantle wedge where a suprasubduction metasomatic event overprinted a probably early mantle metasomatic episode.

Geochemical characteristics of minerals and rocks indicate that the ultramafic rocks from subduction mantle wedge in the western Tianshan represent an island arc environment.

Atmospheric aerosol as the source of nitrate deposits in Turpan-Hami Basin, China: Evidence from oxygen and nitrogen isotopic compositions

LI YANHE *, QIN YAN, LIU FENG, HOU KEJUN AND WAN DEFANG

MLR Key Laboratory of Metallogeny and Mineral Assessment, Institute of Mineral Resource, Chinese Academy of Geological Sciences, Beijing, 100037, China (*correspondence: lyh@mx.cei.gov.cn)

The Turpan-Hami Basin, which located in eastern Xinjiang, China, is a closed inland basin and one of the driest regions on the Earth. Recently, a super-scale nitrate ore field was found in this basin. The total amount of nitrate resources in Turpan-Hami Basin is about 2.5 billion tons, as much as the amount in Atacama Desert of Chile. The Turpan-Hami nitrate deposits can be mainly divided into two types: (1) Quaternary alluvial-pluvial sediment fissures-filling sodium nitrate deposits, (2) Modern saline type niter deposit.

The N and O isotopic compositions are different in the two types of nitrate deposits. The $\delta^{15}N_{Air}$ values of sodium nitrate vary from 0.7‰ to 6.0‰, which are similar to atmospheric NO_3^-; The $\delta^{18}O_{V\text{-}SMOW}$ values are very high, range from 34.4‰ to 45.0‰, which are different from microbial nitrification nitrate, and similar to atmospheric NO_3^-; The $\Delta^{17}O$ values range from 12.20‰ to 20.70‰, mass-independent fractionation (MIF) of oxygen isotope is obviously. With these proofs of oxygen and nitrogen isotopic compositions of nitrate, we can conclude that sodium nitrate deposits in Turpan-Hami Basin were products of long term atmospheric deposition of nitrate aerosol particles, which produced by photochemical reactions. The niter deposits character with high $\delta^{15}N_{Air}$ (15.0‰ ~ 27.6‰), low $\delta^{18}O_{V\text{-}SMOW}$ (30.2‰ ~ 36.3‰) and $\Delta^{17}O$ (3.93‰ ~ 12.39‰) values.

The sodium nitrate and niter deposits in Turpan-Hami Basin are from the same source, and niter deposits experienced strong microbial denitrification during the formation.

Veterinary antibiotics in pig feces

Y.X. LI, W. LI, M. YANG AND C. LIN

School of Environment, Beijing Normal University, Beijing 100875, China (liyxbnu@bnu.edu.cn)

The intense livestock farming in China engenders a significant volume of manures with no other solution for farmers than land disposal. Continued land application of antibiotics-containing manure could detrimental to soil and water quality in the long term. 14 veterinary antibiotics (VAs) in pig feces were quantitatively determined using HPLC.

antibiotics	Appearance (%)	Mean value	Lowest value	Highest value	S.D.
TC	50.0	5.29	0.32	30.55	9.07
OTC	50.0	11.81	0.73	56.81	18.60
CTC	61.1	3.19	0.68	22.34	6.41
SG	22.2	0.63	0.15	1.90	0.85
SA	11.1	0.11	0.10	0.12	0.01
SMR	11.1	0.14	0.13	0.15	0.01
SMZ	27.8	1.07	0.21	2.16	0.85
SMM	27.8	1.14	0.12	4.84	2.07
SCP	16.7	0.85	0.13	2.13	1.11
NOR	27.8	1.10	0.41	3.18	1.18
CIP	27.8	0.49	0.31	0.96	0.27
ENR	44.4	0.87	0.36	2.22	0.75
DIF	5.6	0.14	0.14	0.14	0
TYL	22.2	0.69	0.23	1.88	0.80

Table 1: The residues of antibiotics in pig feces ($mg \cdot kg^{-1}$) (TC:tetracycline, OTC:oxytetracycline, CTC:chlortetracycline, SG:sulfaguanidine, SA:sulfanilamide, SMZ:sulfamethoxazole, SMM:sulfamonomethoxine, SMR:sulfamerazine, SCP:sulfachlorpyridazine, NOR:norfloxacin, CIP:ciprofloxacin, ENR: enrofloxacin, DIF:difloxacin, TYL: tylosin).

Result shows that 5.6-61.1% of four types of VAs could be detected in pig feces. The risk quotients (RQ) indicate a certain probability for adverse effects of VAs on soil microbial activity [1]. The largest RQ of OTC suggested that it should be the priority control of Vas in the study area.

Relationship between the longevous population and trace element in the soils of Xiayi County, China

Y.H. LI*, X.Y. ZOU AND W.Y. WANG

Institute of Geographical Sciences and Natural Resources Research, CAS, Beijing 100101, China (*correspondence: yhli@igsnrr.ac.cn)

Effects of environment on the longevous population

Health and longevity can be considered as the product of interactions between environment, heredity and lifestyle [1, 2]. A case study on Scandinavian twins concludes that the effect of heredity on life expectancy accounts for 20–30%, whereas that of environmental change accounts for at least 70% [3]. Most recently, soil, drinking water and climate were reported to be leading environmental factors influencing regional population longevity [4]. Based on field investigation and laboratory analysis, trace elements in the soils of Xiayi County, a Chinese longevous area, were investigated, and the key elements closely linked to health and longevity were evaluated.

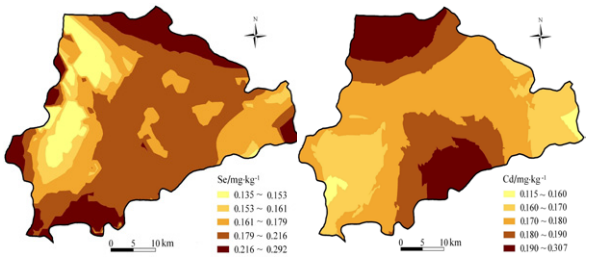

Figure 1: Spatial distribution of Se, Cd in the soil of Xiayi

Discussion of Results

The longevous population was distributed in a belt running across Xiayi County from northeast (NE) to southwest (SW). The longevity rate (number of population aged 95 or older per million) reached 83 in the NW region. Interestedly, it dramatically increased to 187 in the NE region, where the soils contained higher Se and Zn but lower Cd (Figure 1). The findings indicate that sufficient Zn and Se as well as low exposure to heavy metal pollution contribute to human longevity.

Nitrogen speciation in mantle fluids

YUAN LI*, HANS KEPPLER AND ANDREAS AUDÉTAT

Bayerisches Geoinstitut, Universität Bayreuth, D-95440, Bayreuth, Germany
(*correspondence: Yuan.Li@uni-bayreuth.de)

Nitrogen speciation in N-H-O fluids at mantle conditions was studied by means of synthetic fluid inclusions trapped in HF etched quartz and pre-cracked San Carlos olivine. Experiments were performed at 600 - 1300 °C and 15 - 30 kbar using a piston cylinder apparatus, starting with a ~11 mol/L NH_3 solution. A modified double capsule technique was used to attain redox states of various oxygen buffers (Fe-FeO, Co-CoO, Ni-NiO). The recovered fluid inclusions were studied by Raman spectroscopy. The results show that NH_3 and N_2 are the two major nitrogen-bearing species, which stabilities strongly depend on the temperature, pressure, and oxygen fugacity. At conditions relevant to subduction zones, nitrogen occurs mainly as NH_3 and thus behaves similar to the lithophile element K; whereas in the overlying asthenospheric mantle it partially decomposes into N_2 and H_2. The ascent of the mantle fluids into the shallow crust results in complete transform of NH_3 into N_2. In the deep mantle along the geothermal profile, where oxygen fugacity is reduced and pressure is decreased, we expect nitrogen to be present significantly as NH_3 in the fluids, thus there could be much more nitrogen present in the bulk silicate Earth than the value estimated based on N/noble gas ratios in MORB [1].

Ecological stoichiometry of plant nutrients: A case study of degraded grassland in western Jilin Province, NE China

Y.F. LI, D.Y. WANG, C. SUN, D.Y. GUO, Y.Y. YANG AND X. SHI

College of Earth Sciences, Jilin University, Changchun 130061, China (yfli@jlu.edu.cn, wang_dy@jlu.edu.cn, scwutong@163.com, jluguodongyan@163.com, yyyang10@mails.jlu.edu.cn, awenxian@126.com)

Plant growth should be expected to be limited by nitrogen (N) and phosphorus (P) availability in most terrestrial ecosystems. The previous studies indicate that the N/P ratios be usually used to indicate N or P limitation on plant growth. However, how does N/P ratio influence vegetation composition and species richness? It has been one of the hotly discussed issues in the ecological stoichiometry. However, the N and P stoichiometry in the leaves of different plants from the Jiangjiadian grassland in Da'an city in western Jilin Province, NE China, provides insights for the above issue. The results indicate that N and P stoichiometry in the leaves of *Leymus chinensis, Phragmites australis, Chloris virgata, Puccinellia distans, Suaeda glauca* from the grassland are 1.09-3.4%, 0.68-2.94%, 1.69-2.76%, 1.47-2.35% and 1.88-8.7% for N and 0.056-0.254%, 0.082-0.184%, 0.105-0.122%, 0.057-0.107% and 0.067-0.072% for P, respectively. Their corresponding N/P ratios are 9.06-23.53, 8.31-18.12, 16.11-22.64, 22.02-25.88 and 28-28.06 respectively. The arithmetic means for the five species are 1.96%, 1.75%, 2.23%, 1.91% and 5.29 % for N, 0.119%, 0.120%, 0.113%, 0.082% and 0.069% for P, and 17.7, 13.83, 19.38, 23.95 and 28.03 for N/P ratios, respectively. The N and P contents as well as N/P ratios are high in the early stage of plant growth owing to small biomass, and then greatly decrease with leaf expansion during their fast growth period. With the increase of degree of grassland degradation, the *Leymus chinense, Phragmites australis, Chloris virgata, Puccinellia tenuiflora,* and *Suaeda glauca* subsequently appear. Taken together, it is suggested that the N and P contents as well as N/P ratios in plants differ greatly at different degredation stages because of the difference of components of the plant communities at the different degraded stages. Therefore, we conclude that stoichiometry ratios (N/P) in dominant plant species can serve as indicators of direction of plant succession in the degraded grassland.

The genetic feature and reservoir forming model of cracked gas in China

ZHENGWEN LI*, JUN LI AND SHIGUO LIN

Research Institute of Petroleum Exploration and Development-Langfang Branch, PetroChina Ltd, Langfang, Hebei, 065007, China (*correspondence: li-zhengwen@petrochina.com.cn)

Comprehensive research the domestic and foreign research fruit on cracked gas, further analyze the genetic features and reservoir forming differences of cracked gas among crude oil, marine facies source rock, lake facies sapropel type source rock and lake facies humic source rock.

Crude oil crack is the break of long chain fatty structure carbon. It begin to crack when the earth temperatures go beyond 180°C, the crack depth is deep, so its reservoir forming mainly controlled by palaeohigh. Source rock crack is the break of aromatics methyl and terminal methyl in kerogen structure. The gas generation potential of marine sapropel type would dry up when Ro near to 3%, but the gas generation potential of lake facies sapropel type source rock would generate about 201m^3/ton TOC when Ro near 3% to 5%. From simulate experiment, the gas-generating amount is about twenty percents of total [1]. Evolutionary trend of kerogen H/C atomic radtio may reflects that the coal still have large gas generation potential although it is in post-mature stage (Figure 1). The crack potential of lake faces sapropel type is between them and is controlled by the degree of sapropel type. as a whole, it is one of most important cracked gas source rock type. Source rock crack is controlled by the centre of generate hydrocarbon. transforming and reservoir condition are very important.

Divide cracked gas into four reservoir forming model, crude oil cracked gas palaeotectonic control reservoir, marine source rock cracked gas carbonate reef flat-unconformity control reservoir, lake facies source rock conventional and cracked mixed gas structure control reservoir and lake facies source rock cracked gas special lithology control reservoir.

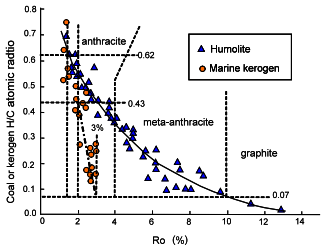

Figure 1: Relation of Coal or kerogen H/C atomic ratio with Ro

Carbon dioxide sequestration within Jinchuan copper-nickel mine tailing, China

ZIBO LI, LIANWEN LIU* AND JUNFENG JI

Institute of Surficial Geochemistry, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093 (*correspondence: Liulw@nju.eu.cn)

Anthropogenic greenhouse gas emissions may be offset by carbon dioxide mineral sequestration, which through the carbonation of magnesium silicate minerals to form magnesium carbonate minerals, and the ultramafic-hosted mine tailings are the ideal raw material for carbon dioxide mineral sequestration. Tailings that can be used to sequestrate carbon dioxide include copper-nickel mine tailings, chrysotile mine tailings, serpentine mine tailings, and V-Ti-magnetite mine tailings in China. We emphasis on particle size, mineral composition, major elements and trace elements, and the potential and capability of natural weathering for carbon dioxide sequestration in Jinchuan copper-nickel mine tailing. Jinchuan is located in central section of Gansu, China (38° 29' N, 102° 10' E) at elevation of 1563. To examine the capability of carbon dioxide fixed in Jinchuan copper-nickel mine tailing, a tailing profile was dug in NO. 1 tailing dam and 9 samples were collected at 10 cm intervals, and 5 other samples were collected from NO. 2 tailing dam. Analyses included particle size, XRF, FT-IR, XRD, and selective leaching, and we find that lansfordite content in NO. 1 and NO. 2 tailing dam is 4.19 wt% and 1.95wt% respectively. According to our preliminary estimate, 706.8 Kt CO_2 were sequestrated during the period of natural weathering in the Jinchuan copper-nickel mine tailing. Our study also indicate that the natural weathering of Jinchuan copper-nickel mine tailing are in abiotic environment, for lansfordite is formed in abiotic environment, and the main reasons may be drought condition, low temperature in Jinchuan, and the microenvironment of serpentine tailing have a high magnesium concentration, which will restrain the metastasis of bacteria. On the basis of tailing reserves and concentration of magnesium, it is about 40 Mt of carbon dioxide that could be fixed in Jinchuan copper-nickel mine tailing. Therefore, the potential of carbon dioxide that could be sequestrated in Jinchuan copper-nickel mine tailing is considerable. And the concentration of Ni, Cr and Cu are 2494 μg/g, 3094 μg/g and 1731 μg/g, hence comprehensive utilization of Ni, Cr and Cu would greatly cut down the investment of carbon dioxide sequestration.

This work was funded by the NSF of China through Grants 40773056.

Two types of gold mineralization from one ore district: Constraints on the genetic model of Yangshan gold deposit in western Qinling, China

J.L. LIANG[1]*AND W.D. SUN[2]

[1]Department of Geochemistry, Chengdu Univ. of Technology, No. 1, Roa. 3 of Eastern Erxianqiao, Chenghua District, Chengdu 610059, China (*correspondence: richardljl04@yahoo.com.cn)

[2]Guangzhou Institute of Geochemistry, the Chinese Academy of Sciences, 511 St. Kehua, Wushan, Tianhe District, Guangzhou 510640, China

Yangshan gold deposit, located in western Qinling orogenic belt, was classified by most previous researchers as Carlin-type mineralization, similar to those in Nevada [1, 2]. The host rocks are middle Devonian greenschist facies siliciclastic metasediments intercalated with carbonate. The distributions of orebodies are strictly controlled by a nearly west-east-striking fault system, Anchanghe Fault. Fine-grained (10s to 100s μm in size) arsenian pyrites and arsenopyrites are the major Au carriers, visible gold was not identified under scan electronic microscope.

Here we report coarse grained pyrite-bearing quartz ore veins through the tunnel of PD051 in Anba district, one of the major district in Yangshan. Significant amount of CO_2-rich fluid inclusions were found in quartz vein. Microthermometric analyses showed that the total homogenization temperature ranges from 221 °C to 310 °C, the salinity from 2.0 to 7.2 wt.% NaCl equivalent.

The new observations suggest that Yangshan gold deposit is actually an orogenic gold deposit in deep segments, and displayed as Carlin-type mineralization in shallow parts. This supports that those Carlin-type gold deposits in western Qinling displayed the charicteristics both epizonal orogenic and Carlin-type deposits [3].

Waves, channels, and diffusive porous flow: Geochemical implications for melt migration in an upwelling heterogeneous mantle

Y. LIANG[1] AND A. SCHIEMENZ[2]

[1]Department of Geological Sciences, Brown University, Providence, RI 02912, USA (yan_liang@brown.edu)

[2]Department of Earth and Environmental Sciences, Munich University, Theresienstr. 41, 80333 Munich, Germany

The style and mode of melt migration in the mantle are important to the interpretation of basalts erupted on the surface. Both grain-scale porous flow and channelized melt migration have been proposed to explain various geochemical observations of basalts. To better understand the mechanisms and consequences of melt migration in a heterogeneous mantle, we have undertaken a high-order numerical study of reactive dissolution in an upwelling mantle column where solubility of orthopyroxene increases upwards. Our setup is similar to that described in [1], except we use a larger domain size and longer simulation time. We show that strong nonlinear interactions among compaction, dissolution, and upwelling give rise to porosity waves and high-porosity melt channels, which may play an important role for melt migration in the upper part of the mantle directly beneath mid-ocean ridges. These compaction-dissolution waves have well organized but time-dependent structures in the lower part of the simulation domain. High-porosity melt channels nucleate along nodal lines of the porosity waves, growing downwards. The upper part of the melt channel is pyroxene-free dunite, whereas the lower part is harzburgite.

Transient melt flow in the wave regime results in significant lateral mixing and chromatographic fractionation of elements of different incompatibility during melt migration in the mantle even when mantle source compositions are independent of time. In one simulation with time-independent sources, we observe strong time-dependent variations in isotopic ratios in melts both within and at top of the domain: Fields of isotopically labelled melts are quickly distorted by differential flows upon entering the column from below, resulting in expansion, contraction, stretching, folding, and mixing in the mid to upper part of the column. Caution therefore must be exercised when inferring the geometry and spatial distribution of mantle heterogeneity based on spatial and temporal variations in isotopic ratios recorded in basalts.

Molybdenum isotopic studies of mantle reservoirs

Y.-H. LIANG*, C. SIEBERT, J. YANG AND A.N. HALLIDAY

Department of Earth Sciences, University of Oxford, South Parks Road, Oxford, OX1 3AN, UK (*correspondence: Yu-Hsuan.Liang@earth.ox.ac.uk)

Mass dependent isotope fractionation of (for example) silicon isotopes between meteorites and planetary materials has been used to assess processes that occurred during formation of Earth and its core (e.g. [1, 2]).

Thus far little is known about the mass dependent isotope fractionation of Mo in the solar system. Molybdenum is a refractory and moderately siderophile element. The processes that might have fractionated Mo in the early solar system include condensation and evaporation of dust grains, metal-silicate segregation, core crystallization, and aqueous alteration. To make comparisons with the silicate Earth it is first necessary to assess how much fractionation takes place during mantle melting.

Although we know much about the behavior of Mo in low temperature environments, little is known of Mo isotope behavior during high temperature processes. In this study we analyzed mafic and ultramafic rocks from a variety of settings. The $\delta^{95/98}$Mo values of mid-ocean ridge basalts (MORB) range from -0.18 to +0.10, and the $\delta^{95/98}$Mo values of oceanic island basalts (OIB) vary from -0.04 to +0.25 (+-<0.1permil (2s. d.) on $^{98/95}$Mo by double spike and MC-ICP-MS, this study; [3]). There is no significant variation in Mo isotope composition in a differentiation sequence from Ketla on Iceland over a range of Si contents. The mean isotope composition of OIB is slightly higher than MORB, but withinuncertainty the same. According to these preliminary results, it seems unlikely that there could exist any significant isotopic variability between these mantle Mo reservoirs. Our results also make Mo isotope fractionation during fractional crystallization unlikely.

Geochemical characteristics and genetic types of natural gas in the Yinggehai Basin, China

FENGRONG LIAO

PetroChina Research Institute of Petroleum Exploration and Development, Beijing 100083, China (liao_xiaoke@163.com)

The genetic types of natural gas in the Yinggehai Basin are complex and dominated by thermogenic gas, with a small quantity of microbial gas and microbial-thermogenic mixed gas. The $\delta^{13}C_1$ values of natural gas in this area range from -28.6‰ to -74.7‰, and the $\delta^{13}C_2$ values range from -21.8‰ to -27‰, showing humic characteristics. In the C_1/C_{2+3}-$\delta^{13}C_1$ diagram (Fig.1), proportion of samples locate in the range of kerogen type III, and the others out of the range for mixing or migration. This phenomenon may be induced by episodic fluid flow in the Yinggehai Basin. The $\delta^{13}C_1$ values of microbial gas range from -74.4‰ to -62.5‰ and the δD values are heavy, ranging from -172.1‰ to -108.5‰. The previous studies suggested that the δD values were influenced by the sedimentary environment and the δD values of microbial gas in this area indicated that the microbial gas was generated in marine environment. Compared to the microbial-thermogenic mixed gas, the thermogenic gas and microbial gas are mixed in proportion and the results indicate that in the microbial-thermogenic mixed gas, the contents of the microbial gas range from 10% to 30%, and those of the thermogenic gas range from 70% to 90%.

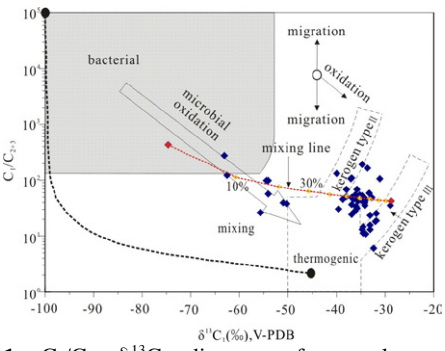

Figure 1: C_1/C_{2+3}-$\delta^{13}C_1$ diagram of natural gas in the Yinggehai Basin(the base map is according to Whiticar [1], the data are according to previous authors [2-6]).

Indoor seismology

ROBERT C. LIEBERMANN, BAOSHENG LI, JENNIFER KUNG, IAN JACKSON, GABRIEL GWANMESIA, SYTLE ANTAO AND JOHN B. PARISE

Mineral Physics Institute, Stony Brook University, Stony Brook, NY USA Robert.Liebermann@stonybrook.edu

In the last decade, considerable progress has been made in our laboratory in conducting acoustic velocity measurements of the elasticity of materials at high pressures and temperatures using ultrasonic interferometric techniques in multi-anvil, high-pressure apparatus. By combining these ultrasonic measurements with synchrotron X-radiation, we have extended the experimental capabilities in multi-dimensions, thereby enabling more complete characterization of solid and liquid materials to pressures of P>25 GPa and temperatures T>1600K. These expanded facilities now allow us to conduct simultaneous measurements of sound velocities using ultrasonic interferometry, crystal structure and unit cell parameters using X-ray diffraction, and sample length using X-radiographic imaging, all *in situ* at high P & T.

Experiments using these new techniques have been conducted on many minerals of the Earth's mantle in the form of polycrystalline and single crystal specimens, including San Carlos olivine [$(Mg, Fe)_2SiO_4$], ortho- and high-pressure clino-pyroxene [$MgSiO_3$], pyrope [$Mg_3Al_2Si_3O_{12}$]-garnet, wadsleyite and ringwoodite [Mg_2SiO_4], magnesium silicate perovskite [$MgSiO_3$] and ferropericlase [(Mg, Fe)O]. We report here new data from our laboratory for pyrope-majorite garnets and high-temperature elasticity of orthoenstatite ($MgSiO_3$) and magnesioferrite spinel ($MgFe_2O_4$).

Paired Sr isotope ($^{87}Sr/^{86}Sr$, $\delta^{88/86}Sr$) systematic of pore water profiles: A new perspective in marine weathering and seepage studies

V. LIEBETRAU*, M. HAECKEL, A. EISENHAUER, F. SCHOLZ, C. HENSEN AND A. REITZ

Leibniz Institute of Marine Sciences, IFM-GEOMAR, Kiel, 24148, Germany
(*correspondence: vliebetrau@ifm-geomar.de)

The simultaneous and independent determination of the radiogenic ($^{87}Sr/^{86}Sr$) and the fractionation reflecting stable ($\delta^{88/86}Sr$) Sr isotope ratio on pore waters, sediments and precipitates (e.g. carbonates and sulfates) opens a new perspective in the field of submarine weathering and Sr contribution to the ocean chemistry.

Four initial case studies covering (1.) CO_2 seeps of the Okinawa Trough (OT), (2.) mud volcanoes (MV) and mounds in the Gulf of Cadiz (GoC) and the (3.) Central American Fore Arc as well as first results from the (4.) Black Sea are conducted and reflect a stable Sr perspective on seeps from a broad range of geological settings.

Referred to NIST-SRM-987, in this study the IAPSO seawater (SW) standard has a $\delta^{88/86}Sr$ of 0.39 ‰ (±0.03, 2SD). As a prominent systematic deviation the OT pore water (PW) data from a site with CO_2 hydrate and liquid CO_2 occurence show values ranging from 0.27 to 0.59 ‰ (286 to 64 cm sediment depth), accompanied by a weak inversely correlated trend from 0.2 to 0.15 ‰ for the corresponding bulk sediment (286 to 36 cm).

In contradiction to a simple fluid/SW-mixing approach as driving mechanism for the PW stable Sr trend the $^{87}Sr/^{86}Sr$ signature stays within analytical uncertainty constant with depth (0.70980 (1)) and differs significantly from SW (0.70917 (1)) and the more radiogenic, slightly heterogeneous sediment (0.71892-0.71731).

Potential explanation for the observed $\delta^{88/86}Sr$ trend and PW signatures heavier than SW are (a) strong fractionation processes enriching light isotopes in secondary precipitates and remineralisation products and heavier signatures in the remaining fluid and/or (b) preferential dissolution of heavier mineral phases.

Examples for the latter kind of sediment component are determined in a detailed study of the Mercator MV (GoC) by high $\delta^{88/86}Sr$ ratios of 0.72 for authigenic and 0.92 ‰ for potentially extruded gypsum crystals.

Combined with PW data from the other seep settings (0.2 to 0.52 ‰) a broad range of Sr contribution and fractionation processes becomes evident.

Precambrian P-T-t history of the Yenisey Ridge as a consequence of contrasting tectonic settings in the western margin of the Siberian craton

I.I. LIKHANOV* AND V.V. REVERDATTO

Sobolev Institute of Geology and Mineralogy, Novosibirsk, Russia (*correspondence: likh@uiggm.nsc.ru)

The Riphean evolution of the Yenisey Ridge was not marked by the prominent tectonic events except for the rift-related bimodal magmatism at ~1380 Ma. The closure of this basin was accompanied by the orogeny with deformation and metamorphism. The early stage is marked by the formation of low-pressure (LP) metamorphic complexes of the And-Sil type (T=400-650°C at P=3.3-5.2 kbar), indicating a normal metamorphic field gradient with dT/dH of about 25-35 °C/km. The relationship between this process and the Grenville-age orogeny was supported by the U-Pb and ^{40}Ar-^{39}Ar dating of metapelites from the Teya complex (~970 Ma). These LP/HT assemblages structurally overlie mid-crustal rocks of the Garevka complex that underwent medium-pressure (MP) metamorphism in the range from amphibolite- to granulite facies conditions of T=582-631ºC at P=7.72-8.64 kbar at depths of ca. 27-28 km.

Rocks closest to the thrusts underwent the MP metamorphism of the Ky-Sil type. A number of specific features and low metamorphic field gradient with dT/dH from 5-7 to 14°C/km are typical of collisional metamorphism during overthrusting of continental blocks, and are evidence of near-isothermal loading in accordance with the transient emplacement of thrust sheets and subsequent rapid exhumation. The proposed model suggests that, given an estimated exhumation rate of 0.368 mm/yr, the peak of collision-related metamorphic conditions occurred at 849-862 and 798-802 Ma.

The 849-862 Ma collisional evens are contemporaneous with the emplacement of low-alkali granite plutons responsible for the heating of rocks at a P=2.5-3.5 kbar, indicating a high gradient with dT/dH >100°C/km. Approximately at the same time (900-880 Ma) the mid-crustal amphibolite-facies rocks have experienced exhumation to a 14-16 km depth of upper-crustal structural levels. D_2-blastomylonites, which localized in narrow strike-slip fault zones, were re-equilibrated under LP conditions at 3.9-4.9 kbar associated with a low metamorphic field gradient with dT/dH ≤10°C/km.

The first occurrence of Siberian equivalents of the mid-Mesoproterozoic event, coupled with evidence of the Grenville-age orogenic events in the Yenisey Ridge, provide the basis for any paleoreconstructions showing a tight connection between Laurentia and Siberia in Rodinia configuration.

Developing models to assess fine scale energy change in soil organic matter under different forest managements

GARRETT C. LILES* AND WILLIAM R. HORWATH

Univ. of California, Davis – Dept of Land, Air and Water Resources (gcliles@ucdavis.edu, wrhorwath@ucdavis.edu)

The energy captured by primary productivity drives the biosphere but we do not view soil and SOM from an energetic perspective. SOM represents a complex thermochemical continuum from ordered energy rich macromolecules and assemblages through less ordered energy 'poor' aromatics and microbial byproducts. This complexity has been reduced conceptually and analytically into a 'black box' where biophysical parameters are summed into pools describing biological function and stability or turnover dynamics.

Simple conceptual models are useful for characterizing gross processes and rates such as ecosystem scale N cycling but fail to provide insight into long-term stability of C and energy dynamics. There is a dearth of information on the effect of simple or mixed litter inputs on SOM stability. Development of quantitative relationships between energy rich inputs and their transformation into a continuum of meta-stable SOM constituents is needed to support mechanistic understanding of ecosystem resilience related to disturbance, management and climate change. Differential Scanning Calorimetry- Thermogravimetry (DSC-TG) provides the flexibility, resolution and reproducibility to quantify distributions of thermochemical stability in soils and SOM across biophysical and management gradients to construct a mechanistic biophysical basis of SOM dynamics and stability.

We present results and models from long-term forestry experiments that manipulated N availability and litter inputs across varying soil mineralogy sequences. Our dataset (field replicated sample) supports robust DSC and TG models for statistical analyses on fine scale temperature subdivision bins (5-20°C). Thermal regions of significant energetic enrichment (associated with fertilization) or reduced litter diversity were detected. In both cases, the differences are apparent at the fine scale temperature subdivision but loose their clarity at coarse scales (150°C exothermic approach) or changes in soil C mass alone. In addition, we developed ratios and relationships between DSC-TG quantities and rates to detangle exotherm SOM signals from varying mineral constituents. These results illustrate the varying capacity of short-range order minerals to support the stability of new inputs or the release of existing SOM related to treatment. Our results illustrate the potential of numerical and modelling approaches to move from coarse aggregated metrics to process based relationships. This is a logical step towards developing a continuous and mechanistic understanding of the complex thermochemical nature of SOM.

Microbial controls on CH_4 cycling in water-saturated mineral soils

K.L.H. LIM[1], P.J. MAXFIELD[1], E.R.C. HORNIBROOK[2], R.D. PANCOST[1], R.P. EVERSHED[1]*

[1]Organic Geochemistry Unit, School of Chemistry, University of Bristol, Cantock's Close, Bristol BS8 1TS, UK (*correspondence: R.P.Eversheed@bristol.ac.uk)
[2]School of Earth Sciences, University of Bristol, Wills Memorial Building, Queen's Road, Bristol, BS8 1RJ, UK

Mineral soils are generally regarded as methane (CH_4) sinks however those which experience regular water saturation, although not always fully anoxic, may host significant methanogenic communities and even act as CH_4 sources [1]. It is evident that the balance between methanogenesis and methanotrophy in such soils, termed 'transitional soils', may be disrupted by marginal increases in water-content. Hence, internal CH_4 production may be underestimated, potentially causing a 'tipping-point' to occur which may increase the capacity of the soil to act as a net CH_4 source.

CH_4 cycling in soils susceptible to frequent seasonal water-logging was investigated using a combination of CH_4 flux measurements, ^{13}C-stable isotope probing and biomarker analyses [2]. In particular the use of archaeol as a potential proxy to assess methanogenic archaeal communities, determined using gas chromatography/mass spectrometry (GC/MS), was explored. The results indicate for the first time in UK mineral soils an increased population of methanogenic archaea at depth due to the anoxic conditions induced by increased water content. Significantly, >90% of the total archaeol was present in 'bound' glycolipid and phospholipid forms, indicating an origin from living archaeal biomass. We are now using these techniques to assess the true 'sink'/'source' capacity of mineral soils subjected to frequent water saturation.

Multipurpose geochemistry project of CPRM in the Pernambuco State, Brazil – Current stage of work

E.A. M. LIMA*, M. FRANZEN, R. CAVALCANTE AND F.G. CUNHA

CPRM – Geological Survey of Brazil (*correspondence: enjolras.lima@cprm.gov.br, melissa.franzen@cprm.gov.br, rogerio.cavalcante@cprm.gov.br, fernanda.cunha@cprm.gov.br)

The work of environmental geochemical mapping and prospective low density are being developed in Pernambuco State, includes Fernando de Noronha Archipelago. We completed work to collect samples of soil, drainage and public water supply as well as stream sediment, with the aim of generating data that can configure the geochemistry of the physical landscape and explain the areas of chemical species impoverished or enriched relative to normal background values of global and regional. Aimed at diagnosing the quality of soils, sediments and water and identify metallogenetic areas looking targets that will be consequential studies involving greater detail.

Results

The phase of interpretation and evaluation of analytical data was started, having achieved the following results of colected samples: 1178 stream sediment samples, 212 soil samples, 338 samples of drinking water, 209 samples of drainage water. Through this regional geochemical mapping of low density at the drainage of the Pernambuco State, is being demonstrated knowledge of the distribution of trace elements. It is being made a database from the results of chemical analysis of collected samples and analytical information. Will also be provided some additional information such as the extent of the contamination plume in surface waters, and indications of anomalous concentrations of metals, indicative of possible mineral deposits.

Thus, the Project was set up not only by geochemical evidence, which could target prospective metallogenic investigations of greater accuracy, but mainly to be used as an efficient tool to diagnose the quality of the environment sampled, and their relationship to public health and the surrounding biota.

[2]Geological Survey of Brazil (enjolras.lima@cprm.gov.br)
[3]Universidade de A Coruña, España (teresat@udc.es)

The Jaboatão river estuary is located in the southern coastal area of the Pernambuco state (Northeastern Brazil). A continuous sediment record measuring 50cm in length was collected 4 km from the river mouth. Sediments were sampled at 5cm intervals and the geochemical sub recent evolution registered from this estuary was investigated by chemical analysis and Magnetic Susceptibility.

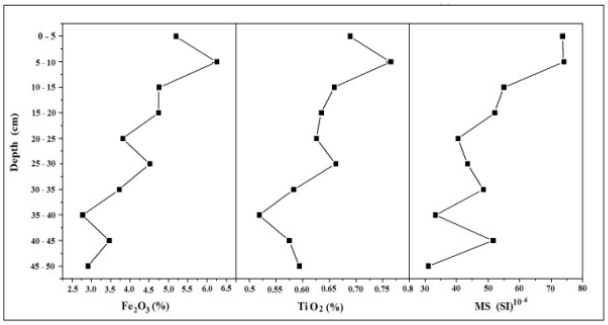

Figure 1: Evolution contents of Fe_2O_3, TiO_2 and MS in core profile.

Discussion of Results

Magnetic susceptibility measured in these samples showed relation to the Fe and Ti content and a sympathetic increase to the top of the core. Similar results have also been found in other parts of the world in industrialized areas [1].

The Enrichment Factor (EF), based in local and global reference values, showed the possible impacts in the considered ecosystem. Presented values below the USEPA´s (ERL, ERM) [2], except for As and Cr. Based on the EF found for the studied sediment core samples the estuarine sediment environment can be classified as below the geochemical contamination level.

Arsenic partition in the native and As-sorbed sediment

C. LIN, M.C. HE, Y.X. LI AND X.T. LIU

School of Environment, Beijing Normal University, Beijing 100875, China (c.lin@bnu.edu.cn)

Arsenic in the native and As-sorbed sediment samples was fractionized to understand how sorbed As partioned into various solid mineral phases with a selective dissolution method [1] (Fig. 1).

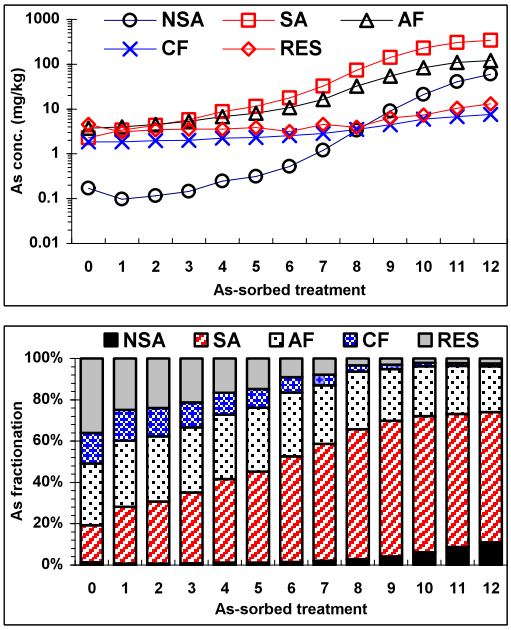

Figure 1: Contents and proportions of As in the native and As-sorbed sediment (0: native sediment, NSA: non-specific adsorption, SA: specific adsorption, AF: amorphos iron oxides, CF: crystalline iron oxides, RES: residual) .

Results showed As in the NSA, SA, AF greatly increased with gradual increasment of sorbed As, while As in CF and RES only slightly increased. On other hand, sorbed As was mostly bound to SA. Whereas Han and Banin observed that metal-added soils tend to return to the fractional quasi-equilibrium state of the non-amended soil [2], this process may take long time scale.

Microbial communities in shallow-sea hydrothermal environment of the Kueishantao Island, Taiwan

LI-HUNG LIN[1], WEN-YU TSAI[1], GUNG-HSIN LU[1], PEI-LING WANG[2], TING-WEN CHENG[1] AND ROY E. PRICE[3]

[1]Department of Geosciences, National Taiwan University
[2]Institute of Oceanography, National Taiwan University
[3]Earth and Planetary Sciences, Washington University in St. Louis

Shallow-sea hydrothermal systems provide easy access to investigating the extent of microbial communities residing in oceanic crustal environments, and the biotic and abiotic interactions along steep physiochemical gradients. This study analyzed venting fluids, pore fluids, surface biofilms and sediments collected from the yellow and white vent areas of the Kueishantao hydrothermal field offshore northeastern Taiwan. Molecular screening of 16S rRNA genes revealed that bacteria and archaea existed ubiquitously in nearly all samples (except for the absence of archaea in biofilms). Of all sequences detected, the bacterial members were affiliated with *Proteobacteria, Bacteroidetes, Cyanobacteria, Chloroflexi, Verrucomicrobia,* and *Firmicutes,* whereas the archaeal members were related to *Thermococci, Thermoplasmata*, and *Thermoprotei*. Communities in the yellow vent area were composed of all phyla and classes described above. In contrast, only ε-*Proteobacteria, Firmicutes, Thermococci,* and *Thermo-plasmata* were detected in the white vent area. The ε-*Proteobacteria* related sequences generally constituted a significant proportion of bacterial libraries, and were more abundant in the white vent area. Thirty strains were isolated from enrichments incubated at 40 ºC. Theses strains were phylogenetically affiliated with α- and γ-*Proteobacteria*, and grew autotrophically or organotrophically by using H_2/O_2, S^o/O_2, As^{3+}/O_2, or complex organic carbon for energy acquisition at acidic or neutral pH. Sequences related to these strains only constituted a small proportion of bacterial libraries in some samples. Overall, the prevalence of potential sulfur-respiring microorganisms, such as ε-*Proteobacteria* and *Thermococci* suggests elemental sulfur as an important energy source, and is consistent with the enriched content of elemental sulfur observed during sampling. The contrasting diversities in different areas and highly similar structures within individual areas further indicate that hydrothermal fluids might entrain variable fractions of seawater along different circulation pathways, enabling the proliferation of microbial communities sustained by distinct energy sources and geochemical characteristics.

'Biogenic natural gas' formation in a pressurized lab scale reactor

R.E.F. LINDEBOOM[1]*, J. WEIJMA[1], K. ZAGT[2] AND J.B. VAN LIER[3]

[1]Environmental Technology, Wageningen University, 6700 EV The Netherlands (*correspondence: ralph.lindeboom@wur.nl)
[2]Bareau Sustainable Technology BV, Heerenveen, The Netherlands (www.bareau.nl; kirsten.zagt@bareau.nl)
[3]Section Sanitary Engineering, Dep. of Water Management, CITG, Delft University of Technology, The Netherlands

It is known that methanogenic micro-organisms produce biogenic natural gas by degrading organic matter in natural gas fields. Methanogens also produce biogas in anaerobic digestion technology [1]. However, biogas generally consists of 55-65% CH_4, ~35% CO_2, and some H_2O, H_2S and NH_3. Our aim was to simulate biogenic natural gas formation in a lab scale pressurized reactor vessel, to see whether natural gas quality could be obtained in a single step reactor system. To do so, pressure reactors were used to simulate CH_4 and CO_2 production from organic matter by mixed culture methanogenic biomass under varying reactor conditions. Temperature, pressure and pH were monitored online with pressure resistant sensors. The lab-scale setup allowed sampling at short time intervals under varying environmental conditions. To determine microbiological organic intermediates, CH_4 and CO_2 production, HPLC and GC were used. Cryo-SEM EDX, FT-IR and TGA-MS were used to acquire information on carbonate precipitates.

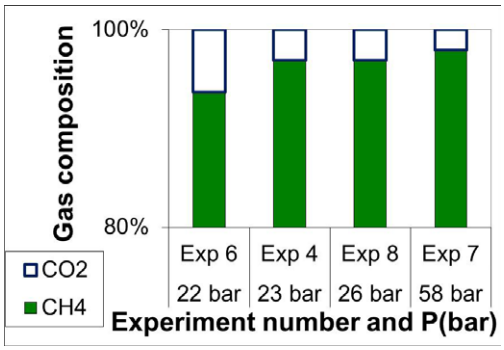

Figure 1: Overview of some experimental gas compositions

Discussion of results

The combination of analytical results highlighted the influence of microbe-mineral interactions on lab-scale biogenic natural gas formation. As a consequence, we found a way to biologically generate pressures up to 90 bar, with 80-97% CH_4-content within a week [2], only limited by the reactor safety limitations.

Phase transformation in simulated acid mine drainage precipitates

MALIN LINDEGREN* AND LARS LÖVGREN

Department of Chemistry, Umeå University, SE-901 87 Umeå, Sweden (*correspondence: malin.lindegren@chem.umu.se)

Metal ions released by oxidation of sulfide minerals in mine tailings may be immobilized from mine drainage by natural attenuation processes involving association to mineral phases. Secondary iron precipitates formed when the discharging drainage is exposed to the atmosphere have the potential to play a particularly important role in this context. However, the mineralogy of these precipitates changes over time, possibly affecting the attenuation.

The phase transformation of a mixture of schwertmannite and goethite, likely to be found in precipitates from acid mine drainage, was monitored over time. In order to investigate the possible influence of metal adsorbed to the mineral surfaces on this process, the precipitates were partially coated with copper or lead ions and compared to un-coated blanks run in parallel. As the formation of goethite from schwertmannite produces sulfuric acid, the amount of OH^- required to maintain suspension pH at 6 and the release of sulfate ions into solution can be used to quantify the phase transformation. To further verify the phase transformation over time, we used the relative intensities of the peaks originating from goethite and schwertmannite in FT-IR spectra of the dried solids. X-ray powder diffractograms of the solids were used to confirm the mineralogy of the original material and reacted samples.

No copper or lead could be detected in the aqueous phase of the samples, suggesting fully adsorbed metal ions. However, in terms of rate of phase transformation, no significant distinction could be made between the coated and un-coated samples, which suggests that the transformation of schwertmannite into goethite is unaffected by adsorbed metal ions.

Origin of hydrothermal fluids of uranium deposits hosted in granite: Constraints from redox conditions

HONG-FEI LING*

State Key Lab for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China (*correspondence: hfling@nju.edu.cn)

Based on experimental data and theoretic calculation results from the literatures, this paper has summarized the valences and geochemical behaviors of uranium in melts and redox and other conditions of uranium being dissolved into fluids. Then the cause for the large difference in ages of uranium deposits and host granites, the source of uranium and the origin of hydrothermal fluids have been elucidated in this paper.

The oxygen fugacity of either mantle-derived melts or granitic magma is below that of the magnetite-hematite (MH) buffer, while the oxygen fugacity for uranyl ion (U (VI)) stable in fluids is much higher than MH. This implies that neither mantle-derived melts nor granitic magma could reach the oxygen fugacity for U (VI). Uranium in magmas occurs predominately as uranous ion (U (IV)) which enters crystals of uraninite and/or other accessory minerals in late stage of magma evolution and hardly enters magma-derived fluids unless under F-rich alkaline magma condition. This is why there is almost no uranium deposit formed by granitic magma-derived fluids. As uranium in fluids occurs as uranyl complexes, it is the key process for forming granite-hosted hydrothermal uranium deposits that high oxygen fugacity fluids ultimately originated from meteoric water leach uranium from uranium-rich granitic rocks. As for the granite-hosted uranium deposits in South China, Indosinian uranium -rich prealuminous leucogranites were the uranium source rocks, and late Yanshanian tectonic extension and dike magmatism provided the heat and the fissure system in granites for meteoric water infiltrating and cycling to leach uranium from the granites. Such fluids became uranium -rich hydrothermal fluids and finally formed the uranium deposits hosted in granties, South China.

Recognition of the Archean high-grade terrain in the South Qinglin orogen and its conection with the South China Block tectonics

W.L. LING[1,2], S.S. LU[1], Z.W. CHEN[1], X.M. LIU[2] AND R.C. DUAN[1]

[1]State Key Laboratory of Geological Processes and Mineral Resources, China Univ. of Geosciences, Wuhan 430074, China (wlling@cug.edu.cn, xiaomingliu@263.com)
[2]State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi'an 710069, China

The South- and North China blocks were welded by the late Paleozoic to early Mesozoic Qinling-Dabie-Sulu orogen. However, timing of some isolated Precambrian terrains within the South Qinling unit and their correlation with the South China Block (SCB) are still poorly understood. The Yudongzi terrain in western South Qinling comprises crystalline basement gneisses and cover layers of banded iron formations (BIF). The basement rocks are dominated by trondhjemite with subordinate tonalite and granodiorite and show upper amphibolite- to granulite facies metamorphism. High precision zircon dating by the present work reveals that the gneisses were formed at 2650-2680Ma, whereas the BIF inherited zircons give an age cluster at 2.1-2.0 Ga with scattered Neoarchean grains, suggesting an early-mid Paleoproterozoic dominated provenance.

In the SCB, the Kongling area is the only terrain where the 2.9-2.7 Ga Archean high grade basement is well proved, whereas the unique early-mid Paleoproterozoic arc-related igneous suites (2150-2120 Ma), the Houhe intrusive rocks, occur at the northwestern SCB. Integrating with our documented works, we suggest that Yudongzi and Kongling terrains were two independent subordinate continents, which likely were welded during 2.0-1.9 Ga along the northwestern Yangtze margin, and were re-separated at ~755 Ma during the break-up of Rodinia.

This work was supported by the NSFC (Grant Nos. 40873017, 40673025).

Plant uptake of metals of economic importance: Laboratory studies

M.J. LINTERN[1]*, R.M. HOUGH[1], R.R. ANAND[1] AND C.G. RYAN[2]

[1]CSIRO Minerals Downunder Flagship, Kensington, WA 6152, Australia (*correspondence: lin082@csiro.au)
[2]CSIRO School of Geosciences, Monash University, Clayton, Vic. 3168, Australia

Biogeochemistry for mineral exploration has been undergoing a renaissance in recent years particularly in Australia. However, fundamental research into uptake of metals of economic importance by plants that are sampled for mineral exploration purposes has been lacking. Previous studies have taken place on crops of agricultural interest or for those pertaining to animal health or environmental monitoring. In this study we examine the uptake of several metals (Au, Cu, Ni, Pb and Zn) at variable concentrations in a series of trials using a sand-based, ebb and flow hydroponic system. Metal concentrations are analysed and the siting of these metals is investigated to understand if, how and where metals are located in biogeochemical sampling media..

Several trays containing several hundred plants were tested during each trial to quantify natural variability. Initially a large selection of Australian native plants were used but this was later reduced to two principal species, both of which are frequently used in mineral exploration, namely Mulga *Acacia aneura* (F.Muell. ex Benth.) and River Red Gum *Eucalyptus camuldulensis* (Dehnh.). In our experiments plant uptake of metal concentrations over three orders of magnitude were examined to test whether there were any barrier mechanisms to uptake at or near concentrations commonly observed in natural ecosystems. Competitive and enhanced interactions between metal uptake were also investigated to see whether certain metals were restricted or enhanced by the presence of others. The effect of pH and salinity variability was examined to emulate the range of natural groundwater conditions on which these plants grow. We used SEM, PIXE and SXRF to determine the location of metals in plant tissues (collected during sampling and from the hydroponic experiments) and establish if dust or anthropogenic contamination had occurred or whether the metals are truly absorbed in the plants. This is important when mineral exploration sampling is done in polluted mining environments.

We will discuss our results and show that they are encouraging for those using biogeochemistry for mineral exploration purposes as well as phytoremediation and phytomining.

We analysed shallow (to ~1 km) and deep fracture waters (to > 3 km) from the Witwatersrand Basin, South Africa for their noble gas isotopic composition. Their neon signature clearly differentiates a group of typical crustal fluids from another one with a significantly enriched nucleogenic neon signal with the highest $^{21}Ne/^{22}Ne$ ratios (0.160 ± 0.003) ever reported in groundwater [1]. Fluid inclusions in adjacent rocks yield even higher $^{21}Ne/^{22}Ne$ ratios between 0.219 and 0.515, consistent with an extrapolated $^{21}Ne/^{22}Ne$ value of 3.3 ± 0.2 at $^{20}Ne/^{22}Ne = 0$. We show that this enriched nucleogenic neon end-member represents a fluid component that was produced in the fluorine-depleted Archaean formations and trapped in fluid inclusions > 2 Ga ago [1]. The observation of enriched nucleogenic neon signatures in deep fracture water implies the release of this billion-year-old neon component from the fluid inclusions and its accumulation in exceptionally isolated fracture water systems. The observed association of this Archaean neon signature with H_2-hydrocarbon-rich geogases of proposed abiogenic origin [2] dissolved in the same deep groundwater suggests that the fracture systems have also allowed for the accumulation of various products of water-rock reactions throughout geologic times. One of these fracture systems contained a chemolithotrophic, single species ecosystem surviving on radiolytically produced H_2 and sulfate completely independent of the surface photosphere [3, 4].

The Atlantic Ocean circulation is an important contributor to Earth's meridional heat flux and much effort has been devoted to reconstructing its past variability. In particular, downcore records of the ratio of ^{231}Pa and ^{230}Th from marine sediments are increasingly used to infer past changes in the strength and structure of the Atlantic meridional overturning circulation (AMOC) [1, 2]. Modelling studies support the use of this tracer [3, 4], but they also indicate that an extensive database is required to apply the method to its full potential [5, 6]. A given strength and geometry of AMOC generates a unique distribution pattern of $^{231}Pa/^{230}Th$ in the water column and sediments. Documenting past changes in this pattern requires systematic sampling on bathymetric profiles at different latitudes to fully capture the vertical and horizontal gradients in sediment $^{231}Pa/^{230}Th$ generated by the AMOC. At any single location, the same $^{231}Pa/^{230}Th$ ratio can be generated by various combinations of AMOC strength and geometry and cannot be uniquely interpreted. Likewise, the pattern generated by an overturning circulation, particularly the vertical gradient, is quite distinct from that generated by changes in opal flux. Here we present a compilation of Atlantic Ocean $^{231}Pa/^{230}Th$ from the literature and new measurements for the Holocene and the Last Glacial Maximum (LGM). Comparing the data to the outputs of a 2D scavenging model [6] indicates that the Holocene $^{231}Pa/^{230}Th$ pattern is consistent with the strength and geometry of the modern AMOC, while the LGM $^{231}Pa/^{230}Th$ distribution pattern points to a different mode of AMOC with a stronger but shallower North Atlantic overturning cell, consistent with paleonutrient proxies [7].

Paleoredox changes of the Yangtze Sea during the Ordovician-Silurian transition and its deposition of black shales, south China

ZHANG LIQIN

Key Laboratory of Geospace Environment and Geodesy of Ministry of Education, Wuhan University, Wuhan 430079, China (lqzhang@sgg.whu.edu.cn)

The redox chemistry of Paleozoic oceans has important implications for understanding the processes of deposition and organic matter preservation of black shale, but empirical constraints on competing environmental models are scarce [1, 2]. To investigate the redox condition changes in the Ordovician-Silurian transition series of the Yangtze Sea, we examine the organic carbon content (TOC), pyrite sulphur content, pyrite sulphur isotope, and Fe species–including dithionite-extractable Fe (FeD), pyrite Fe (FeP), HCL-extractable Fe (FeH), and total Fe (FeT)–in black shale. Fe-TOC-S relationship and several ratios, that C/S ratio, the ratio between highly reactive Fe (FeHR=FeD+FeP) and FeT, and the ratio FeP/(Fep+FeH), known as the degree of pyritization (DOP), are used to evaluate the redox state of Yangtze Sea and the processes that led to the accumulation of organic matter-rich black shale deposits. These redox indices through three intervals, the mid Ashgill, Hirnantian, and early Rhuddanian, indicate that the anoxic–sulfidic marine water occupy most of the Yangtze Sea during the mid Ashgill and early Rhuddanian, while the Hirnantian possesses oxic marine water [3, 4]. Sulfate reduction occurs in euxinic water column and results in characteristic C/S ratio, FeHR/ FeT ratio, DOP, and Fe–TOC–S relationships. Elevated productivity, anoxia and high sedimentation rates support the formation of black shale deposits. For Hirnantian interval, organic matter sedimentation takes place through an oxygenated water column. We suggest that the Hirnantian oxic marine water is the integrative result of glacioeustatic sea-level fall and the influx of cold and oxygen-laden Boreal waters, however, the abrupt transition from oxic to anoxic marine water occurs in the early Rhuddanian resulting from the post-glacial rise in sea level and corresponding increase in surface-water nutrient availability [5].

Pervasive reactive melt migration though the lower oceanic crust: Implications for the evolution of mid-ocean ridge basalt

C. JOHAN LISSENBERG[1]*, CHRISTOPHER J MACLEOD[1], KERRY A HOWARD[1] AND MARGUERITE GODARD[2]

[1]School of Earth and Ocean Sciences, Cardiff University, Park Place, Cardiff CF10 3AT, United Kingdom (*correspondence: lissenbergcj@cardiff.ac.uk)

[2]Géosciences Montpellier, UMR CNRS-UM2 5243, Universite Montpellier 2 - cc60 Place Eugène Bataillon, 34095 Montpellier cedex 5, France

Mid-ocean ridge basalt (MORB) is the most abundant magma on Earth. It is generated beneath mid-ocean ridges by decompression melting of upwelling mantle, and, following processing in lower crustal magma chambers, erupted onto the seafloor. For more then four decades igneous petrologists and geochemists have relied upon MORB as their major window into the mantle, deriving its composition, melting processes and melt migration mechanisms from the erupted lavas. However, this approach assumes that modification of melts in crustal magma chambers occurs exclusively by fractional crystallisation, and can thus be easily corrected for.

Data from an extensive suite of lower crustal rocks from Hess Deep (equatorial Pacific Ocean) demonstrate that melts do not simply evolve by fractional crystallisation. The gabbros crystallised from melts that underwent extensive reactive porous flow, which modified both their major- and trace element composition. The degree to which this reactive signature is present increases up section throughout the lower crust, suggesting that it occurs on a crustal scale. Thus, magma in the lower oceanic crust evolves by a combination of fractional crystallisation and melt-rock reaction. If a reactive signature is present in MORB, this requires a reassessment of its use as a messenger from the mantle.

High degradation efficiency of deicing chemicals affects the natural redox system in airfield soils

H. LISSNER*, M. WEHRER AND K.U. TOTSCHE

University of Jena, Institute of Geosciences, Burgweg 11, 07749 Jena (*correspondence: heidi.lissner@uni-jena.de)

Large amounts of the deicing chemicals (DIC) propylene glycol (PG) and formate are spread for removal of snow and ice on the aircrafts and airfields every winter. A considerable amount of these chemicals are carried into surrounding areas, where they mix with snow and infiltrate in the soil during snowmelt. Even though DIC are easily degradable, the high mobility and the high biological oxygen demand of PG in particular can influence the hydrogeochemistry of the unsaturated and saturated zone. The aims of the study were to evaluate and quantify transport of deicing chemicals during snowmelt under field conditions, and to study effects of DIC degradation on the hydrogeochemistry of the unsaturated zone. Eight undisturbed soil cores (0.3 m x 1 m, 0.071 m^3) were retrieved at the Gardermoen Airport, Norway, and installed as non-weighable small scale lysimeters at a nearby field site. Before snowmelt in March 2010, a mix of snow containing 350 g/m^2 PG, 71 g/m^2 formate, and 17 g/m^2 of bromide were added to the lysimeters. To determine the fate and transport of PG we monitored PG and its metabolites, bromide, manganese, and iron in the seepage water.

High cumulative infiltration and marginal degradation of PG during the snowmelt period allowed up to 50 % of the PG to leave the upper, microbially most active, region of the soil. Only marginal concentrations of formate were analysed in all lysimeters, indicating fast degradation and favoured metabolism by soil bacteria compared to PG. Low contents of metabolites and the concurrent breakthrough of PG and Br in the seepage water even imply that PG was not significantly degraded before June. Redox values down to 200 mV in April, the detection of propionate and manganese, as well as a rise in pH, suggest partially anearobic localities in the soil, not only during high soil water saturation in April and May but also during summer when PG degradation was very efficient. In the longterm, the intense depletion of secondary electron acceptors such as Mn (hydr)oxides lowers the potential of the unsaturated zone to buffer high loads of DIC. Therefore, it is necessary to carefully assess the buffering capacity of the soil and to develop suitable remediation techniques to sustain the natural redox buffer system.

Melting in the peridotite and eclogite, coexisting with reduced C-O-H fluid at 3-16 GPa

K.D. LITASOV[1,2]*, A. SHATSKIY[1,2] AND E. OHTANI[1]

[1]Tohoku University, Sendai, 9808578, Japan (*correspondence: klitasov@m.tohoku.ac.jp)

[2]Institute of Geology and Mineralogy SB RAS, Novosibirsk, 630090, Russia

Melting phase relations of peridotite and eclogite systems coexisting with reduced C-O-H fluid has been studied at 3-16 GPa and 1200-1600ºC. In order to perform these experiments the double-capsule technique with fO_2 control by outer Mo- or Fe-buffer capsule was designed and developed for multianvil experiments at pressures above 3 GPa. The inner capsule contained silicate starting material with an addition of 8-10 wt% stearic acid, which served as a fluid source, whereas outer capsule contained talc, which served as a hydrogen transmitting medium to maximize fH_2 in the inner capsule.

Silicate phase assemblages resemble those in volatile-free lithologies. Melting was detected by appearance of quenched crystals of pyroxene, feldspar and glassy silica. Abundant voids indicate presence of fluid in all runs. The fluid composition was not measured, but should correspond to CH_4-H_2O-bearing one, according to estimations from equations of state. The compositions of partial melt were estimated from mass-balances. The partial melt from peridotite runs has CaO-poor (6-9 wt%) basaltic composition with 44-47 wt% SiO_2 and 1.1-1.6 wt% Na_2O (recalculated to 100% of dry residue). Eclogitic melts contain more SiO_2 (47-49 wt%) and are enriched in CaO (9-15 wt%), Na_2O (9-14 wt%), and K_2O (1.3-2.2 wt%). All runs contained graphite or diamond crystals along with porous carbon aggregate with microinclusions of silicate phases.

The solidi have relatively steep slope in the pressure range between 3 and 16 GPa. Estimated solidus temperatures for peridotite+C-O-H-fluid with fO_2 control by Fe-FeO buffer are 1200ºC at 3 GPa and 1700ºC at 16 GPa. The solidus of the system with fO_2 control by Mo-MoO_2 buffer was about 100ºC lower. Solidi in the eclogite systems are located at another 100ºC lower than peridotitic ones for both buffers. The obtained solidi are much higher (300-500ºC) then those for peridotite/eclogite systems with H_2O and CO_2. However, they are still about 300ºC lower than solidi of volatile-free peridotite and eclogite at 12-16 GPa. Thus, we provide new direct evidences for redox melting by change of oxidation state across a mantle section.

Abiotic and biotic control of the $\delta^{65}Cu$ and $\delta^{66}Zn$ composition of seawater

S.H. LITTLE*, D. VANCE AND D.M. SHERMAN

Bristol Isotope Group, School of Earth Sciences, University of Bristol, Bristol BS8 1RJ UK
(*correspondence: s.little@bristol.ac.uk)

Dissolved copper in seawater is isotopically heavy (1.1‰) relative to both rocks (0‰) and the riverine input (0.7‰). Particulate Cu in the oceans is adsorbed to ferromanganese crusts and is isotopically lighter than seawater, at 0.1-0.4‰. EXAFS and μ-XRF indicate that Cu in the crusts is predominantly associated with the Mn-oxide, δ-MnO_2. Consistent with these observations, the experimental $\Delta^{65}Cu_{solid\text{-}soln}$ on inorganic sorption of Cu to δ-MnO_2 is -0.5‰. Thus, abiotic fractionation of Cu in large part explains the heavy isotopic composition of seawater.

The additional control can be sought in the dissolved Cu fraction, the speciation of which is dominated by complexation to siderophore-like ligands, likely exuded by phytoplankton. We have cultured cyanobacteria, and show that there is indeed a small positive $\Delta^{65}Cu_{ligand\text{-}soln}$ associated with this complexation. Similarly, Cu sorbs to deprotonated surfaces of dissolved organic matter with an isotopic fractionation of +0.27‰ [1], and several species of bacteria preferentially take up ^{63}Cu [2]. All of the above provide mechanisms to enrich the dissolved fraction in heavy ^{65}Cu.

$\delta^{65}Cu$ in the oceans is hence a balance of both inorganic and organic complexation, and our observations contribute to an internally consistent picture. This is not yet the case for zinc, however. Lab experiments [3] and our synchrotron-based study indicate that Zn behaves similarly to Cu in terms of its crystal chemistry and abiotic fractionation. Unlike Cu, however, Zn in ferromanganese crusts is isotopically heavier than the $\delta^{66}Zn$ of seawater. Further work is required to understand this discrepancy.

Origin and evolution of carbonatite magma parental for diamond and syngenetic inclusions

YU.A. LITVIN

Institute of Experimental Mineralogy, Russian Acad. Sci., Chernogolovka, Moscow Dstr. 142432, Russia
(litvin@iem.ac.ru)

Introductory remarks

Mantle-carbonatite model of diamond genesis [1], genetic classification of primary inclusions in mantle-derived diamond [2] and generalized composition diagram for multi-component heterogeneous parental medium for diamond and syngenetic inclusions [3] are the key findings based on integration of mineralogical and experimental data.

Origin of diamond-parent carbonatite magma

In the making stationary chamber of diamond-parent carbonatite magma, two episodes are of a significant part: (1) Mg-Ca-carbonatite primary melts can result from mantle peridotite in response to chemical attack of high-temperature "metasomatic agents" rich in CO_2, K-Na-alkaline carbonates and silicates, minor incompatible and REE elements;

(2) primary carbonatite melts dissolve peridotite minerals, solid and dispersed carbon, minor soluble phases and involve xenogenetic ones. Diamond-forming activity of mantle carbonatite chamber begins when diamond solubility concentration in the magma is attained. During cooling, carbon oversaturation in respect to diamond is reached producing nucleation and growth of diamond.

Evolution of diamond-parent carbonatite magma

In compositional evolution of the fractionated parental magma during cooling, two physicochemical mechanisms which control magmatic ultrabasic-to-basic and peridotite-to-eclogite paragenetic transitions have a dominant role: (1) carbonatization of olivine and orthopyroxene; (2) garnetization of olivine due to reaction between olivine and jadeite components [4]. The both reaction mechanisms control continuous transition from formation of peridotite mineral paragenesis to the eclogite one in diamond-parent carbonatite magma.

Syngenesis diagrams for diamond, paragenetic and xenogenetic inclusions

Syngenesis melting relations of the eclogite-carbonatite-sulfide-diamond system are studied at 7 GPa. Syngenesis diagrams offer a clearer view of how diamond and paragenetic phases have formed. These reveal physicochemical mechanism of origin of natural diamond, PT-conditions of formation of paragenetic silicate and carbonate minerals and their coexistence with xenogenetic minerals and melts. Thus physicochemical conditions of primary caption of paragenetic and xenogenetic phases by growing diamond are revealed. Support: RFBR 1105/00401.

Cr^{6+} reduction by sulfate-reducing bacteria in salt marsh sediments

C.H. LIU*, C. TANG, S.P. YAO AND Y.R. XUE

Nanjing University, 22 Hankou Road, Nanjing 210093 (*correspondence: chliu@nju.edu.cn)

Chromium is one of the most toxic and carcinogenic heavy metals. Cr^{2+} and Cr^{3+} species are the most stable and least toxic species, while Cr^{6+} is highly toxic to eukaryote and prokaryote. Recently, many bacteria have been proved to be an efficient Cr^{6+} removal in the chromium-contaminated sediment. In this study, 34 culturable sulfate-reducing bacteria (SRB) isolated from salt marsh along Yellow Sea of China were evaluated for their potential in Cr^{6+} removal. All procedures regarding bacterial manipulations were performed under aerobic condition with addition of 5mM of ethanol as carbon source and 100mg/L of Cr^{6+} in the medium (pH 7.3). Cells were grown in an shaker at 37 °C, 110 rpm for 6d. Cr^{6+} was quantified by the colorimetric diphenylcarbazide method at 540 nm, while the cell growth was measured at 600nm. Ten of the test SRB showed tolerant to high concentration of Cr^{6+} and 6 were able to reduce Cr^{6+} to Cr^{3+}, which were identified to be *Pseudomonas* sp.(3 isolates), *Bacillus sphaericus*, *Rhiodococcus erythropolis* and *Oceanimonas* sp.. The highest reduction of Cr^{6+} (82.6%) was by *Oceanimonas* sp., while 66.4%-79.7% were reduced by the others. However, the highest reduction rate per cell was by one of the *Pseudomonas* species. Except for *Pseudomonas* and *R. erythropolis* that were confirmed to be able to reduce Cr^{6+} to Cr^{3+}, *Bacillus sphaericus* and *Oceanimonas* were demonstrated at the first time to have a potential ecological role in soil or water bioremediation due to their tolerance or reduction of Cr^{6+} the removal of Cr^{6+}.

Geothermal gradient and heat flow distributions of Northeastern Taiwan and its implication

CHIA-MEI LIU[1]*, SHENG-RONG SONG[1], FU-SHU JENG[2], EN-CHAO YEH[3], TAI-TIEN WANG[4] AND YI-CHIA LU[1]

[1]Institute of Geosciences, National Taiwan University, Taiwan (*correspondence: pollynismo@gmail.com, srsong@ntu.edu.tw, yichialu@ntu.edu.tw)

[2]Depart/ment of Civil Engineer, National Taiwan University, Taiwan (fsjeng@ntu.edu.tw)

[3]Department of Earth Sciences, National Taiwan Normal University, Taiwan (ecyeh@ntnu.edu.tw)

[4]Institute of Mineral Resources Engineering, National Taipei University of Technology, Taiwan (ttwang@ntut.edu.tw)

The continental heat flow map shows the characteristics of regional thermal structures and displays the phenomena of geology and geophysics. Taiwan Island is located in the boundary of Philippine Sea plate obliquely colliding with the Eurasia plate to form an orogenic belt. Meantime, the Philippine Sea plate also subducts northwardly under the Eurasian plate to produce the Ryukyu Trench-Okinawa Trough system in northern Taiwan. Based on the collision maturity in terms of geological and geophysical data, the tectonic of northeastern Taiwan belongs to the arc collapse/subduction zone. In this study, we apply the hydro-geochemical data to gain geothermal gradient and heat flow distributions of northeastern Taiwan, and discuss the possible mechanism inducing the thermal anomaly in this region.

The thermal profile across northeastern Taiwan indicates that the peak with a silica heat flow value about 150 mW/m^2 is located at the Chingshui area, and decreases northeastwardly to Ilan Plain and southwestwardly to Lushan area. According to the results of geodetic monitoring and micro-earthquakes, it has shown the extending southwestwardly from the southwest of the Okinawa Trough into the Ilan Plain, which induced widely the normal faulting and magmatic intrusion. Thus, the origin of the abnormally high silica heat flow in the Chingshui area is likely due to the southwestward propagation of hot fluids from the Okinawa Trough into the Ilan Plain.

Pore-scale process coupling and its effect on the apparent rates of uranyl surface complexation

CHONGXUAN LIU[1]*, SEBASTIEN KERISIT[1], ROBERT EWING[2], JIANYING SHANG[1] AND JOHN ZACHARA[1]

[1]Pacific Northwest National Laboratory, Richland, WA 99354 (*correspondence: Chongxuan.liu@pnl.gov)
[2]Iowa State University, Ames, IA 50011 (ewing@iastate.edu)

Surface complexation is a major process that affects uranyl [U (VI)] fate and reactive transport in subsurface sediments. Surface complexation reactions occur at the pore-scale in coupling with other processes including aqueous speciation reactions, diffusion, and advection. Extensive characterization of U (VI)-contaminated sediments collected from US DOE Hanford site has revealed that U (VI) preferentially associates with certain types of porous domains including intragranular fractures, grain-coating regions, and grain-aggregates. This presentation discusses the nature and complexity of process coupling at the scales of single pore, intragranular domain, and pore-network in flow media that fundamentally control the apparent rates of U (VI) surface complexation reactions and reactive transport in subsurface porous media. Experiments and modeling studies at various scales revealed that the molecular rate of U (VI) surface complexation reactions in a single pore domain was fast with a first-order rate constant of 10^2 - 10^4 s^{-1}. The apparent rate of U (VI) surface complexation, however, decreased to 10^{-3} s^{-1} at the grain scale as a result of coupling of intragranular diffusion and reactions, and further decreased to 10^{-5} - 10^{-6} s^{-1} in flow domains where complex pore-scale coupling of flow, diffusion and reactions occurred in both inter-granular and intragranular domains in field-textured sediments. The scale-dependent reaction rates present a significant challenge to apply laboratory-determined reactions and parameters to predict field-scale reactive transport, and indicate that conceptual and numerical upscaling approaches to scale reaction rates are critically needed. This presentation will also discuss pore-network-based upscaling concepts and theories to scale reactions from the intragranular pore-network to the grain-scale, and from the grain-scale to the flow media. These upscaling approaches explicitly considered pore size and connectivity variability in porous media that affect pore-scale flow and diffusion, and their coupling with intrinsic reactions.

Fragments of hot and metasomatized mantle lithosphere sampled by mid-Miocene ultrapotassic lavas, Southern Tibet

CHUAN-ZHOU LIU[1], FU-YUAN WU[1], SUN-LIN CHUNG[2] AND ZHI-DAN ZHAO[3]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029
[2]Department of Geosciences National Taiwan University, Taipei, 10699
[3]China University of Geosciences, Beijing, 100083

The first suite of mantle peridotite xenoliths have been discovered in mid-Miocene (~ 17 Ma) ultrapotassic lavas from Salipu, southern Tibet [1]. The Sailipu mantle xenoliths are very tiny with diameters of less than 1 cm, and characterized by presence of abundant phlogopite. Olivines of Salipu xenoliths have Fo [100×Mg/ (Mg+Fe)] content of 83~89, lower than typical upper mantle olivines. Both orthopyroxene and clinopyroxene in Salipu xenoliths also became iron-rich with Mg# [Mg/(Mg+Fe)] values of 0.83~0.91 and 0.84~0.89, respectively. Equilibrium temperatures of 1050~1250 ºC have been obtained for the Salipu mantle xenoliths by two-pyroxene geothermometer gives. Spinels reacted with phlogopites became Al-rich with a Cr# [Al/(Cr+Al)] of 0.1~0.2, whereas spinels that are not surrounded by phlogopites have higher Cr# values (0.32 vs. 0.36, respectively). Phlogopites in Salipu xenoliths with Mg# values of 0.82~0.94 are F-rich (2.64~8.1 %), Ti-rich (0.92~4.48 %) and contain variable contents of H_2O (0.5-5 %). Clinopyroxenes in Salipu xenoliths display convex upward rare earth element (REE) patterns, with enrichment of light rare earth elements (LREE) over heavy rare earth elements (HREE). They also mimic some trace element characteristics shown by ultrapotassic lavas in southern Tibet, especially the negative Sr, Nb, Ta, Zr, Hf and Ti anomalies. These features suggest that the metasomatic melts should be subduction-related rather than asthenosphere-derived.

Results of the Sailipu mantle xenoliths indicate the existence of hot, highly metasomatized lithospheric mantle beneath southern Tibet during the mid-Miocene, and thus support the idea that convective thinning of the lithosphere was responsible for the uplift of the plateau. The relict mantle was later removed or squeezed northward by the underthrusting Indian continental lithosphere, which terminated magmatism in southern Tibet and played a role in creating the entire plateau.

Erosion rate estimated from surface and profile of cosmogenic ^{36}Cl in carbonates in China

C.Q. LIU[1], S. XU[2]*, S.P.H.T. FREEMAN[2], Y.C. LANG[1], R. PHILLIPS[3], C.L. TU[1] AND K. WILCKEN[2]

[1]Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou 550002, China
[2]Scottish Universities Environmental Research Centre, East Kilbride, G75 0QF, UK
(*correspondence: s.xu@suerc.gla.ac.uk)
[3]University of Leeds, Leeds, LS2 9LT, UK

This study attempted to quantify long-term subaerial erosion of bare carbonate rock surfaces by using in situ-produced cosmogenic ^{36}Cl in carbonates. Carbonate samples were collected from the topmost 5 cm of exposed pinnacles at several non-glaciated karst or carbonate areas in modern monsoon (Guizhou), arid (Gansu) and transition (Beijing) regions in China. Samples from a 30m-depth profile were also collected in Guizhou karst area. Concentrations of natural Cl and ^{36}Cl in carbonates were determined by accelerator mass spectrometry with isotope dilution with ^{35}Cl-enriched carrier spike. Local ^{36}Cl production rates are calculated on the basis of geomorphological locations and chemical compositions of carbonates. The total Cl concentrations in carbonates were in range of 10-200 ppm. The ^{36}Cl nuclide concentrations were of the order of 10^5–10^7 atom g^{-1}, and converted to total erosion rates averaged over a 10^5 yr-timescale of chemical and physical processes acting on the karst surfaces. The erosion rates were 20–50 mm kyr^{-1} in Guizhou. Variations and mechanisms of the local erosion rates are discussed and the results are compared with the existing observations obtained by other measurement techniques.

U-Pb dating, and Lu-Hf property of zircon from granitic leucosome within orthogneiss from Sulu UHP terrane, Eastern China

F.L. LIU[1]* AND A. GERDES[2]

[1]Institute of Geology, Chinese Academy of Geological Sciences, Beijing, 100037, China
[2]Institute of Geosciences, Mineralogy, J.W. Goethe University, Frankfurt, 60054, Germany

Granitic leucosomes as thin veins are widely distributed within orthogneiss in the Sulu UHP terrane, eastern China. A combined study of mineral inclusions, cathodoluminescence (CL) images, U-Pb SHRIMP dates, and *in situ* trace element and Lu-Hf isotope analyses of zircons provided insight into the nature and timing of partial melting in these rocks. Zircons from orthogneisses have three distinct domains: (1) inherited magmatic cores with Coe + Phe + Ap inclusions, which record a Neoproterozoic protolith age of 790-750 Ma, (2) mantles with Coe + Phe + Ap inclusions that record Triassic UHP age of 230-225 Ma, and (3) rims with Qtz inclusions that record retrograde metamorphism at 215-210 Ma. In contrast, zircons from granitic leucosomes have only two distinct domains: (1) the central UHP domains with Coe + Phe + Ap iclusions record Triassic UHP age of 230-225 Ma, and outmost rims with Qtz + Kfs + Ab + Ap inclusions record partial melting time of 214-210 Ma. Theses data indicate that partial melting in the Sulu UHP orthogneisses took place during late retrograde amphibolite-facies metamorphism. Inherited magmatic zircon cores from orthogneisses give uniform $^{176}Hf/^{177}Hf$ of 0.28187 ± 0.00003 corresponding to εHf (t) and Hf model ages of about -16.3 and 2.41 Ga, respectively. This is consistent with the generation of its protolith by reworking of Paleoproterozoic to late Archean crust. In contrast, UHP zircon domains from orthogneisses and granitic leucosomes are characterized by low Lu/Hf (<0.006), low Th/U (<0.1) and significantly higher $^{176}Hf/^{177}Hf$ (0.28233 ± 0.00002) than the inherited magmatic cores. The uniform but significantly different Hf isotope composition between the UHP and inherited zircon domains indicates equilibrium of the Lu-Hf isotope system only within the UHP metamorphic mineral assemblage. Zircon domains crystallized during partial melting at 214-210 Ma in granitic leucosomes have a Hf isotope composition indistinguishable from that of the UHP zircon domains. This suggests that only Hf (and Zr) equilibrated during UHP metamorphism was remobiliazed during partial melting while inherited magmatic zircons remained stable or was not accessible.

High pressure diffraction tomography technique for mineral physics reseraches

HAOZHE LIU, LUHONG WANG, ZHENHAI YU, LINGPING KONG, JINGGENG ZHAO, DAWEI DONG AND CHUNYU LI

Natural Science Research Center, Harbin Institute of Technology, Harbin 150080, China

The high-pressure behaviors for Olivine and selenium will be presented using synchrotron x-ray diffraction and micro-tomography techniques. The novel development for the combination of synchrotron x-ray microtomography and diffraction techniques in diamond anvil cell high-pressure conditions, which provides new insight for many mineral physics research, will be introduced. The phase transition procedure of iron was studied, and the 3-D distribution of low pressure and high-pressure phases at about 11 GPa was obtain. The deviatoric stress between the parent and new phases in the iron sample, as well as the phase transition mechanism will be discussed based on the 3 dimensional data. The potential application for the diffraction tomography development in diamond anvil cell to the mineral materials will be emphasized.

Comparative Sr-Nd-Pb-Hf-Os isotopic systematics of xenolithic peridotites from Yangyuan, North China Craton

JINGAO LIU[1]*, RICHARD W. CARLSON[2], ROBERTA L. RUDNICK[1], RICHARD J. WALKER[1], FU-YUAN WU[3] AND SHAN GAO[4]

[1]Department of Geology, University of Maryland, College Park, MD20742 USA (*correspondence: gobyliu@umd.edu)
[2]DTM, Carnegie Institution, Washington, DC 20015 USA
[3]IGG/CAS, P.O. Box 9825, Beijing 100029 China
[4]China University of Geosciences, Wuhan 430074 China

Trace element concentrations and Sr, Nd, Pb and Hf isotopic compositions were determined for clinopyroxenes separated from 11 well-characterized spinel peridotites, carried in the ~30 Ma Yangyuan alkali basalts from the central region of the North China Craton. Our objective was to use these isotope tracers to determine the history of initial melt depletion and later metasomatic enrichment of incompatible trace elements in the mantle. Clinopyroxenes were selected from samples for which whole-rock Re-Os isotopic compositions were previously determined, and to span a wide range of rare earth element (REE) patterns (chondrite-normalized $(La/Yb)_N$ = 0.13 to 13.5). Present-day isotopic ratios are $^{87}Sr/^{86}Sr$ = 0.70229-0.70443, ε_{Nd} = -0.6 to +24, $^{206}Pb/^{204}Pb$ = 15.74-19.08, and ε_{Hf} = +13.5 to +167). Some peridotites retain original ancient melt depletion signatures characterized by prominent depletions of light REE (LREE) relative to heavy REE and highly radiogenic Nd (ε_{Nd} up to +24) and Hf (ε_{Hf} up to +167) isotopic compositions, and very non-radiogenic Pb isotopic compositions ($^{206}Pb/^{204}Pb$ as low as 15.74). Ancient metasomatism may have occurred in a few samples, given their elevated LREE, Paleoproterozoic Nd model ages and non-radiogenic Pb isotopic compositions that, on a $^{206}Pb/^{204}Pb$ vs. $^{207}Pb/^{204}Pb$ diagram, plot just to the right of the 1.8 Ga geochron. The remaining samples with LREE-enriched patterns were likely affected by incompatible element re-enrichment more recently, as evidenced by a limited range of $^{143}Nd/^{144}Nd$ (0.5128 to 0.5132), but a large range of $^{147}Sm/^{144}Nd$ (0.13 to 0.28), as well as Pb isotopic compositions that plot along a mixing line between the host basalt and the least radiogenic samples in a plot of $^{206}Pb/^{204}Pb$ vs. 1/Pb. In spite of these re-enrichment events, both the clinopyroxene Lu-Hf isotope and whole-rock Re-Os isotope systems appear to provide robust chronologic information regarding melt depletion in these peridotites. A Lu-Hf 'errorchron' (1.66 ± 0.10 Ga) and Os model ages (1.8 ± 0.2 Ga) are both consistent with Paleoproterozoic (~1.8 Ga) melt depletion in the Yangyuan peridotites. This age is consistent with the oldest (Paleoproterozoic) Nd model ages and non-radiogenic Pb isotopic compositions observed in some samples. The younger age of the lithospheric mantle compared to the overlying Archean crust suggests the removal and replacement of original underlying lithospheric mantle during a ~1.8 Ga collision in this region of the North China Craton.

Apatite from eclogite and veins from Sulu-Dabie eclogite-bearing belt

JINGBO LIU*, LINGMIN ZHANG, KAI YE, YI CHEN AND SHUN GUO

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China (*correspondence: jingboliu@mail.igcas.ac.cn)

We analysed apatites of eclogites and veins hosted in eclogite bodies in Chizhuang, Qinlongshan, Maobei from the Sulu ultrahigh-pressure (UHP) belt, and Bixiling, Maowu, Hualiangtin, Zhujiachong from the Dabie Mountains in order to unravel whether or not saline as a predominant fluid type was involved in high-pressure (HP) or UHP metamorphic process.

The apatites in eclogites have the Cl contents of 0.01-2.0 wt % from Chizhuang, 0.04-0.36 wt % from Qinlongshan, 0.04-0.6 wt % from Maobei, 0.2-1.5 wt % from Bixiling, 0.01-7.0 wt % from Maowu, and 0-0.05 wt % from Hualiangtin and Zhujiachong. The results suggest that the fluids equilibrated with apatites were from very low salinity (Hualiangtin and Zhujiachong) to very high salinity (Chizhuang, Bixiling and Maowu). At the same time, for one sample or outcrop of eclogite, large variability of Cl content in apatites also indicates that the salinity of fluids was greatly changed during HP or UHP metamorphic process.

The apatites in veins from Chizhuang, Maobei, Bixiling, Hualiangtin and Zhujiachong were also analysed. The apatites of kyanite (Ky)-zoisite (Zo)-quartz (Qtz) vein from Chizhuang have Cl content of 0-1.7 wt %, whereas the apatites from other three types of vein (Qtz vein, omphacite (Omp)-rich-Qtz vein and phengite (Phn)-rich-Qtz vein) show less 0.20 wt % Cl content. The apatites of three types of veins from Maobei (Omp, Ky-Qtz and Zo-Qtz) display 0-0.36 wt % Cl contnets. Two types of veins from Bixiling (Omp and Ky-Phn-Qtz) have the apatites with 0.2-1.0 wt % Cl contents. The apatites of epidote-talc-Ky-Qtz vein from Hualiangtin show 0.02-0.30 wt % Cl content, and of Phn-Qtz and Zo-Ky-Qtz veins from Zhujiachong have less 0.05 wt % Cl content. These analytical data indicate that the fluids equilibrated with apatites were also from very low salinity (Zhujiachong) to very high salinity (Chizhuang, Bixiling). Meanwhile, for one vein, significant variability of Cl content in apatites also indicates that the salinity of fluids was greatly variable during the formation process of vein.

Adsorption of thallium(I) onto geological materials: Effect of pH and humic matter

J. LIU[1,2]*, H. LIPPOLD[2], J. WANG[1], J. LIPPMANN-PIPKE[2] AND Y.H. CHEN[1]

[1]School of Environmental Science and Engineering, Guangzhou University, Guangzhou 510006, China (*correspondence: liujuan858585@163.com)

[2]Institute of Radiochemistry, Helmholtz-Zentrum Dresden-Rossendorf, Research Site Leipzigmailto:, 04318 Leipzig, Germany

Thallium (Tl) is a typical toxic heavy metal, with higher toxicity than Hg, Cd, Pb. Anthropogenic sources such as coal combustion or mining/smelting activities generated high enrichments of Tl in some areas. For long-term risk assessments, the mobility in geochemical systems is a topic of major interest. Adsorption onto mineral surfaces can be considerably affected by dissolved humic acids (HAs), which are ubiquitous in natural waters. By using radioactive tracers, we were able to investigate co-adsorption of Tl and HAs at low concentration levels to be considered in real scenarios [1].

Two natural HAs were extracted from river sediments collected in a contaminated mining area in South China (regions of Guangzhou and Yunfu City). They were radiolabeled by an azo-coupling reaction with ^{14}C-aniline. ^{204}Tl (I) was employed as a radiotracer for Tl (I). The geological materials used in this study were goethite, pyrolusite and a natural sediment sample taken from Yunfu City.

For all these substrates, metal adsorption was found to be promoted with increasing pH since more binding sites are provided by deprotonation of surface hydroxyl groups. In contrast, adsorption of HAs was counteracted with increasing pH, which is explained by increasing electrostatic repulsion as a consequence of deprotonation. As expected, the extent of Tl (I)-HA complexation turned out to be very low, with a slight increase at higher pH.

Based on these data, a combined distribution model (Linear Additive Model) was tested for suitability in predicting the pH-dependent influence of HAs on Tl (I) adsorption. Our experimental results could not be reproduced in this way. In view of the fact that the approach worked well in other studies, criteria for its applicability need to be identified. Selectivities within the multicomponent system of humic material, regarding adsorption as well as complexation, are one possible reason for a failure of the model.

^{40}Ar-^{39}Ar isotopic dating of muscovite from the Hukeng tungsten deposit, Jiangxi Province, South China

JUN LIU, MAOYAN MA, GUODONG SHI, HAIJIAO YOU, YONG ZHAN AND YOUFEI GUAN

The Civil Engineering School, Anhui University of Architecture, P.R. China (fzel@tom.com)

Hukeng tungsten deposit, located in central part of Jiangxi Province, South China, is one large-scale quartz vein type wolframite deposit, which is in the south margin of Hukeng granite intrusion, covering the area of 6 km^2. The deposit can be divided into quartz-wolframite, quartz-fluorite-wolframite and quartz-pyrite-sphalerite-wolframite three metallogenic stages [1].

The muscovite for ^{40}Ar-^{39}Ar dating has eminent cleavage, weak pleochroism and high interference color, coexisted with wolframite in ore veins at depth of -60m of the Hukeng tungsten deposit. The variation of apparent age in low temperature (600-800℃) released stage of muscovite is large, varying between 92.0±15.0Ma and 132.7±1.4Ma, and ^{39}Ar only accounts for about 5.4% of the total ^{39}Ar released, which may be caused by lattice defect of mineral of minor argon loss in the periphery of mineral. Five high temperature released stages (1100-1400℃, ^{39}Ar occupies 94.6% of the total ^{39}Ar released) form a plateau age of 147.2 ± 1.4 Ma and an isochron age of 148.0± 2.8 Ma with MSWD of 0.51. The intercept of isochron ((^{40}Ar/^{36}Ar)$_0$) is 280, suggesting certain argon loss may exist in the lattice of muscovite. However, in the fitting process of plateau age, 94.6% ^{39}Ar conforms to plateau-forming conditions, and isoshron is adapted to compare and just the age, which can correct the influence of argon loss efficiently. Therefore, the plateau age of muscovite has geological significance and can represent the cooling age for the formation of muscovite.

In the deposit, homogenization temperatures for quartz from three mineralization stages range from 200 to 300°C [1], obviously lower than the closure temperatures of the ^{40}Ar-^{39}Ar mica chronometers. The closure temperature for the K-Ar isotope system in muscovite is 350–640°C [2]. Therefore, we can assume that the K-Ar system for muscovite remained closed after mineral precipitation, and thus, the ^{40}Ar-^{39}Ar date reported in this study is taken as the age of ore formation in the Hukeng tungsten deposit. Therefore, the absolute timing of tungsten mineralization in Hukeng is about 150 Ma.

This research was financially supported by the Doctoral Fund of Anhui University of Architecture of China (No.K02415).

The inclusions of carbonates in UHP eclogite from the South Altyn Tagh, Northwest China: A new constraint for its peak metamorphic pressure

L. LIU*, Y.T. CAO, C. WANG, D.L. CHEN, L. KANG AND W.Q. YANG

State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi'an 710069, P R China (*correspondence: liuliang@nwu.edu.cn)

Previous studies have revealed that eclogites from the South Altyn Tagh have been underwent UHPM according to coesite pseudomorphs in garnet and omphacite [1, 2], and the P-T conditions of the eclogites were estimated to be about 3GPa and 800°C. But the peak metamorphic pressure of the eclogite remains uncertain due to the absence of confident mineralogical constraints.

Recently, abundant inclusions of carbonations are recognized in garnet and omphacite in the eclogite by detailed petrography observations, Raman spectrum and eclectron probe analyses. Two most remarkable textures of the inclusions are as follow: 1) magnesite was found as relict, rounded inclusions with reaction rims of dolomite within garnet and omphacite. The transition from magnisite to dolomite is by means of the reaction of magnesite + aragonite = dolomite [3]; 2) inclusions of calcite aggregates have well developed radial fractures in garnet and omphacite, and have very similar textures to quartz pseudomorphs after coesite inclusions in garnet and omphacite in other UHP eclogites, which are interpreted as the aragonite pseudomorph. These textures reflect that the peak mineral assemblage of the eclogite is Grt+Omp+Mgs+Arg±Coe.

The reaction of dolomite = magnesite + aragonite has been experimentally and extensively investigated to be stable at mantle conditions (>5-20GPa) [4], and identified in many mantle xenoliths and UHP metamorphic rocks [3, 5]. The assemblage of Grt + Omp + Mgs + Arg ± Coe is observed at >6 GPa in recent experiment of cabonated eclogite [6]. According to the experimental data above, we estimate the peak metamorphic pressure of the eclogite is to be >6GPa, and the subducted depth should be at least 180 km.

Catalytic spectrophotometric determination of iodine in vegetable matter digested by pyrohydrolysis

L. LIU, D. WU*AND P. LI

College of Environmental and Chemical Engineering, Nanchang University, Nanchang 330031, PR China (*correspondence: dswu@ncu.edu.cn)

Revolutionary New Method

The low I contents, complexity of the matrix, chemical interferences, possibility of contamination, and loss during sample dissolution are some of the potential limiting factors for the determination of I in vegetable matter [1]. The reported analytical methods (except RNAA) have the lower detection limit ranging from 5μg/kg to 3 mg/kg [2-6]. Thus few methods can be adapted to determine I in the inland vegetable matter, which usually has I content of a few μg/kg. We have developed a method that combines pyrohydrolysis digestion with catalytic spectrophotometry (CS) to determine I in vegetable matter. The pretreatment program of pyrohydrolysis was designed to decompose the vegetable matter steadily and completely. The conditions of CS were optimized to enhance the sensitivity of iodine determination. Excellent limit of detection has been achieved and meet the analytical requirements.

Discussion of Results

The conditions of pyrohydrolysis optimized through orthogonal experiment are as follows: 0.5 g vegetable matter sample, a temperature of 1100 °C, 20 minutes for pyrohydrolysis, 100 mL/min of oxygen flux and 15 mL 0.2 M NaOH of absorption solution. The conditions of CS are optimized as follows: reaction temperature of 45 °C and reaction time of 35 minutes. The limit of detection and quantification are 0.3 ng/g and 0.9 ng/g, respectively. Hence it can be applied to determine trace I in vegetable matter. Precision and accuracy were evaluated by the analysis of Chinese vegetable matter reference materials.

Owing to the low cost of instruments and analysis, low limit of detection, high accuracy and precision, pyrohydrolysis-CS method is very suitable for the daily analysis of the iodine contents in vegetable matter.

Accumulation of organic carbon in typical hillslope soils in karst area, Southwest China

T.Z. LIU*, C.Q. LIU, X.D. LI AND C.L. TU

State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (*correspondence: liutaoze@mails.gyig.ac.cn)

The content of soil organic carbon (SOC) has long been recognized as a key characteristic of soil quality. During an earlier survey, we observed that a lot of SOC stocked in a hillslope under natural conditions for 10 years of revegetation in karst area, Southwest China. Here, we analyzed the content and ^{13}C isotope of SOC in size-fractionated particles (mainly as sand 53μm~2000μm, silt 2μm~53μm, clay <2μm) of soils in this hillslope, to elucidate the generation and stability of organic carbon.

The results showed that the content of SOC in the upper hillslope was higher than that in down hillslope area. Though the larger SOC accumulation was found in the sand fraction in the upper hillslope, the organic carbon pool was unstable. Oppositely, in down hillslope area, the organic carbon was mainly stored in the slit and clay fraction and has been in relatively stable state (Fig.1). Comparing the $\delta^{13}C$ values of SOC in soil and its three fractions (sand, silt, clay) with $\delta^{13}C$ values of litters, we found that $\delta^{13}C$ values of SOC in sand fraction were strongly correlated with the values of litters, which implying sand fraction was more sensitive to the change of vegetation types in the hillslope.

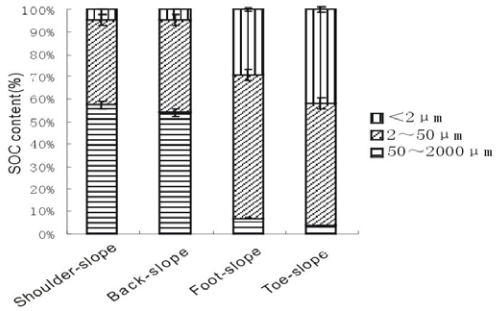

Figure 1: Proportion of organic carbon of different fraction in soil profiles

Our findings indicate that revegetation on hillslope can increase SOC stocks, but distribution has significant difference. And $\delta^{13}C$ value of SOC should be a good tracer for assessing the formation and stability of organic carbon.

A synthetic silica glass reference material for determination of Ti in zircon by LA-ICP-MS

XIAOMING LIU[1], SHAN GAO[2] AND JOHN.C. AYERS[3]

[1]State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi'an 710069, China
[2]Faculty of Earth Sciences, China University of Geosciences, Wuhan 430074, China
[3]Department of Earth and Environmental Science, College of Arts and Science, Vanderbilt University, Nashville TN, USA

The proper use of Ti-in-zircon thermometer mostly depends on the accurate determination of Ti content in zircon. Because of lacking homogeneous matrix-matched mineral standards available, a silica glass (LCD-1) was fused at 1680°C. The major element contents of the glass, SiO_2 (73.89±0.29)%, Al_2O_3 (8.22±0.14)%, ZrO_2 (5.96±0.09)%, K_2O (5.53±0.04)% and Na_2O (7.35±0.11)% (all in1σ), were determined by electron microprobe. The Ti content in the glass is 998±23μg/g (1σ) measured by using solution-ICP-MS method and 1009±22μg/g (1σ) using LA-ICP-MS method calibrated by taking ^{29}Si as an internal standard and NIST SRM 610 as the reference material.

The fractionation index of Ti/Zr is less than Ti/Si in zircon. So, LCD-1 as reference material, Ti contents in zircon 91500, GJ-1 and M257 are determined by LA-ICP-MS. The result for one analysis calibrated using ^{29}Si as an internal standard is lower 16-20% than that using ^{96}Zr. The results calibrated using NIST 610 and LCD-1 as reference material and ^{29}Si as an internal standard are nearly same, their differences are less than 2.3%. All these facts suggested that LCD-1 glass is a better reference material than NIST 610 in determination of Ti in zircon.

Scanning transmission X-ray and atomic force microscopy mapping of exopolymer fractionation in *Bacillus subtilis* biofilms on goethite

X. LIU[1]*, K. EUSTERHUES[1], J. THIEME[2], K. KÜSEL[3] AND K.U. TOTSCHE[1]

[1]Institut für Geowissenschaften, Friedrich–Schiller-Universität Jena, Germany (*correspondence: xinran.liu@uni-jena.com)
[2]NSLS-II, Brookhaven National Laboratory, Upton, NY, USA (jthieme@bnl.gov)
[3]Institut für Ökologie, Friedrich-Schiller-Universität Jena, Germany (kirsten.kuesel@uni-jena.de)

The surface properties of goethite are vital for many environmental processes, such as adsorption and transport of contaminants and nutrients. This study aims at understanding of how biofilm formation changes the mineral surface. Adhesion and mechanical properties (e.g. elastic modulus) were investigated by atomic force microscopy (AFM), while the chemical composition of the biofilm was mapped by scanning transmission X-ray microscopy (STXM).

We investigated single-layered biofilms formed by *Bacillus subtilis* on Lysogeny broth-agar plates in the presence or absence of goethite. Synchrotron-based STXM C K-edge image sequences, recorded at a spatial resolution of ≤ 25 nm, were converted to component maps of proteins, polysaccharides, nucleic acids and lipids by linear combination fitting. STXM revealed that proteins, nucleic acids and lipids were mainly located inside the cells, while polysaccharides dominate in the extracellular polymeric substances (EPS). In the presence of goethite, we found a higher concentration of nucleic acids in the EPS and the goethite needles were covered by nucleic acids. This supports the view that nucleic acids mediate EPS binding to mineral surfaces and are required for establishing biofilms [1].

Quantitative nanomechanical properties measurement by AFM indicated that the DMT modulus (elastic modulus) of the goethite surface decreased from ~40 GPa to ~84 MPa after biofilm formation. The adhesion between the AFM tip and the goethite surface in air increased from ~2 nN to ~12 nN after biofilm formation.

We hypothesize that nucleic acids are intentionally excreted by *B. subtilis* when e.g. goethite surfaces are present. This preferentially adsorbed nucleic acid-rich material is responsible for the observed changes in the mechanical surface properties of goethite.

Introduction

Although *Acidithiobacillus ferrooxidans* (*At. f*) is widely used in mining and metallurgy technologies nearly over thirty countries at present, its application still stay in laboratory and pilot experiments for uranium recovery in China [1]. One of the key problem inhibited its industrialization application is lack of better adaptative strains with strong ferrous-oxidizing activity and stability at very low pH and high conductivity.

Results

A mutant strain of *At. f* was obtained by ultraviolet mutagenesis and directional screening with optimum pH between 1.2-1.8 and iron oxidized rate of 0.2g/L. h^{-1} (Fig.1). Physiological and 16SrDNA

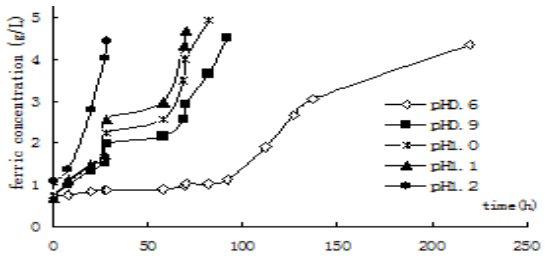

Figure 1: Iron oxidizing capacity with time at extremely low pH sequencing indicated it was *Acidithiobacillus ferrooxidans*.

Compared with the original strain, the characteristics of this mutant strain are as the following: (1) Relatively strong oxidized activity at pH1.2; (2) Relatively Stable in mineral medium after 8 times inoculations; (3) Growing at extremely low pH, even at pH=0.6. It is a promising strain likely being applied in comercial bioleaching.

Studies have shown that exposure to $PM_{2.5}$ (airborne particles less than 2.5 μm in size) may increase the risk of cardiovascular and respiratory diseases. Current $PM_{2.5}$ health effects studies rely on the often sparse ground monitoring networks to provide exposure estimates. We developed a geographically weighted regression (GWR) model to examine the relationship among $PM_{2.5}$, MODIS AOD, meteorological parameters, and land use information. Additionally, Two meteorological datasets: North American Regional Reanalysis (NARR) and North America Land Data Assimilation System (NLDAS), were fitted into the model separately to compare their performances. The root mean squared prediction error (RMSPE) showed that the prediction accuracy was 83.6% and 83.9% for NARR and NLDAS in model fitting, and 69.9% and 72.5% in cross validation. The results indicated that GWR combined with AOD, meteorological parameters, and land use information as the predictor variables could generate a better fit and achieve high accuracy in PM2.5 exposure estimation, and NLDAS could be used as an alternative of the NARR to provide some of the meteorological fields.

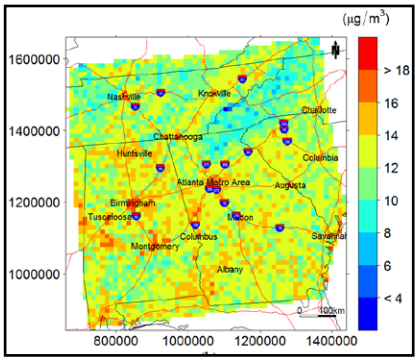

Figure 1: Predicted annual mean PM2.5 concentrations in 2003 using NLDAS meteorological fields.

Constraints of the concentration of the platinum-group elements in Pobei Ni-Cu Sulfide Deposit, Xinjiang Province

YANRONG LIU[1,2], XINBIAO LÜ[1]*, WEI MEI[1] AND YUCHAI DAI[3]

[1]Faculty of Earth Resources, China University of Geosciences, Wuhan 430074, China (*correspondence: lvxb_01@163.com, fwjlyr@ 163.com)
[2]Key Laboratory of Western Mineral Resources and Geological Engineering of Ministry of Education, Chang'an University, Xi'an 710054, China
[3]No.6 Geological Party, Xinjiang Bureau of Geology and Mineral Exploration and Development, Hami 839000, China

Pobei Cu-Ni sulfide deposit hosted in mafic-ultramafic intrusion is located in the Beishan rift valley belts, Northern Talimu plate, Xinjiang Province, NW China. The sulfide ores are mainly disseminated. The disseminated sulfide ores are characterized by variable but generally high Cu, Ni and PGE concentrations:70225-102951ppm Cu, 108691-307454ppm Ni, 175-1637ppb Pt, 214-593ppb Pd, 23.2-80.6ppb Ir, 59-216 ppb Ru, and12-52ppb Rh in 100% sulfides.

All of rocks and ores Pd/Ir ratios (4.34 to 27.75) in Pobei Cu-Ni deposit are less than 100 [1], indicating that the effects of late hydrothermal fluids are weak. The positive correlations between Ir and Pd indicate that sulfide didn't experience fractionation. Pobei deposit has very higher Cu/Pd ratios (90-1626×10^3) than primitive mantle (Cu/Pd=7.5×10^3), which suggest that the sulfide ores formed from the silicate magmas had already experienced prior-sulfide [2].

Assuming a partition coefficient between sulfide liquid and silicate melt for Pd, Pt and Ir of 20000 and for Cu of 1000, for Ni of 500 [3, 4], the primary magma of the Pobei intrusion comes from the primitive mantle.Our calculations indicate that the basaltic magma of melting degree 25% had contained 120ppm Cu, 490ppmNi, 9.4ppb Pt, 16ppb Pd, and 0.48ppb Ir, then 0.02% sulfide removal would result in PGE-depletion in the residual magma with 98ppm Cu, 443ppm Ni, 0.172ppb Pt, 0.293ppb Pd, and 0.009ppb Ir, then sulfer come to saturation again and sulfide segregate from the PGE-depleted magma under silicate/sulfide liquid ratios (R-factor) ranging from 500 to 5000.

Spectral and electrochemical evidence for kinetically separate cytochrome compartments in *Geobacter* biofilms

YING LIU[1], RHONDA R. FRANKLIN[2] AND DANIEL R. BOND[1]*

[1]BioTechnology Institute and Department of Microbiology, University of Minnesota, St. Paul MN 55108 (*correspondence: dbond@umn.edu) (liux0820@umn.edu)
[2]Department of Electrical Engineering and Computer Science University of Minnesota, (drayton@umn.edu)

This work seeks to unite recent reports of the redox potential and putative locations of multiheme c-type cytochromes expressed by *Geobacter* with new electrochemical and spectral data collected during transfer of electrons to electrodes. Spectral monitoring of biofilms revealed that early 40% of *G. sulfurreducens* cytochromes were oxidized at lower potentials (-0.4 V to -0.2 V, the range of extracellular cytochromes OmcS and OmcZ) [1-4], yet sustained electron transfer does not occur at these potentials [5,6]. A second oxidation event was centered at the midpoint potential of the periplasmic cytochrome PpcA (-0.15 V [7]).

The fact that extracellular cytochromes have lower potentials than periplasmic cytochromes is the opposite of how electron transfer chains are typically designed. A hypothesis is that this guarantees the outer surface is in equilibrium with insoluble acceptors, to serve as a sink for the periplasm. If self-exchange and cytochrome-metal transfer rates are rapid, such schemes are possible.

A prediction from this hypothesis is that the periplasmic pool would be slower to respond to changes in electrode potential, as electrons must first travel through extracellular cytochromes. This behavior was observed in scan rate analysis: spectral changes at low potential (-0.4 to -0.2 V) responded immediately to potential steps, while the –0.15 V pool lagged behind. A second prediction is that the redox status of periplasmic cytochromes would kinetically 'gate' electron flow to the exterior, consistent with the -0.15 V midpoint potential observed during catalytic cyclic voltammetry [8]. Further work using mutants lacking key cytochromes are being used to test this model.

Geology and fluid origin of Mohailaheng Pb-Zn deposit in Tibet

YINGCHAO LIU[1], ZENGQIAN HOU[1], ZHUSEN YANG[2] AND SHIHONG TIAN[2]

[1]Institute of Geology, CAGS, Beijing 100037, China (lychappy@126.com)
[2]Institute of Mineral Resources,CAGS,Beijing 100037, China

The Mohailaheng Pb-Zn deposit in south Qinghai, China, is a stratabound epigenetic deposit hosted by Early Carboniferous limestone in the hanging wall of a Cenozoic thrust fault system. Four mineralization stages are recognized in the deposit. During Stage I, xenomorphic grass-green sphalerite, galena, and pyrite precipitated as dissemination with dolomite and calcite. In Stage II, xenomorphic and less colloform brown sphalerite, galena and pyrite precipitated with barite, quartz, fluorite and calcite as cements of limestone breccias. It is followed by calcite-pyrite vein in Stage III and pure calcite vein in Stage IV. Most sulfides in the deposit were produced during Stage II.

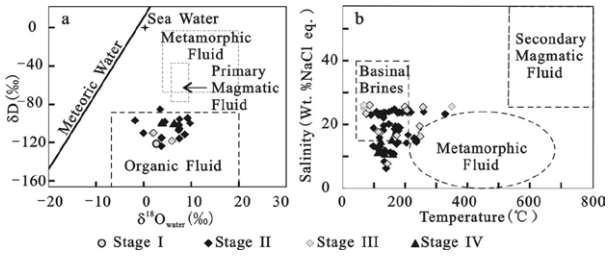

Figure 1: a-Diagram of $\delta D_{v\text{-}snow}$-$\delta^{18}O_{fluid}$ (base diagram after [1]) and b-Diagram of salinity-temperature of fluid inclusions (base diagram after [2])

Raman microprobe analyses indicate that CO_2, CH_4, H_2S and H_2O are common in vapor phases of fluid inclusions in Stage II. The H-O isotopic data of fluid show the character of organic matter or gas (Fig.1a). Most salinity-temperature data of primary fluid inclusions fall into the basinal brine field and some fall near or into the metamorphic fluid field (Fig.1b). The results above give two possible fluid origins which are basinal brine possibly providing CH_4 and metamorphic fluid possibly providing CO_2.

The geology and fluid orogin of this deposit indicate the characters including MVT and fracture controlled Pb-Zn deposit, so it is just considerded as a carbonate hosted Pb-Zn deposit controlled by thrust systerms in the orogenic belt.

Autotrophic denitrification potential: An experimental study on nitrate-N removal from groundwater by pyrite in mining wastes as electron donor

Y. LIU[1]* AND Y.X. LI[2]

[1]School of Biotechnology and Food Engineering, Hefei University of Technology, Hefei 230009, China (liuy99999@163.com)
[2]Hefei University of Technology, Hefei 230009, China

New Method

Groundwater nitrate pollution is a common problem in the world, especially in North China [1-2]. It becomes a serious threat to source of drinking water in fractured media where how to control and remedy it is an open question [3-8]. In addition, there are lots of mining waste including pyrite often causing acid mine drainage. The new method is to use the pyrite as electron donor combining with the *thiobacillus* to remedy nitrate pollution by the experimental study [2].

Discussion of Results

The mixed *denitrogenation thiobacillus* (T.D) is concentrated and separated from the charcoal factory's soil. Then a strain with strong denitrification ability is isolated, which is self-supportive and facultative anaerobic. Based on the analysis of physiological and biochemical measurements, this stain is preliminary judged to Thiobacillus. The mixed T.D is employed to reduce Nitrate nitrogen from the groundwater using pyrite as electron donor. The effect of the ratio by Sulfur and Nitrogen (S/N), iron disulfide quantity and vaccination quantity is investigated experimentally. Results show that: the most suitable S/N is 5/2, the quantity of Sulfur in iron disulfide reach to 250 mg/L is the most suitable iron disulfide quantity, and the best vaccination quantity is 9%. At the condition mentioned above, the nitrate removal rate is 62.17%. The effect of nitrogen removal on chemical synthesis culture medium of pure T.D is better than that using mixed T.D. Conclusions show that the strain isolated can be used to remove the nitrate-N (high concentration) from groundwater using pyrite as electron donor with potential value. (Grant no: 2009HGCX0233)

Crust recycling-induced melt-peridotite interactions in the northern margin of the North China Craton

YONGSHENG LIU, SHAN GAO AND ZHAOCHU HU

State Key Laboratory of Geological Processes and Mineral Resources, Faculty of Earth Sciences, China University of Geosciences, Wuhan 430074, China

Recycling and subsequent melting of crustal rocks (via delamination or subduction) in the upper mantle is thought to be partially responsible for generating mantle heterogeneity and drive evolution of the continental crust to a bulk andesitic composition. It could have induced widely silicate melt-peridotite interaction, and a network of pyroxenite veins in the lithospheric mantle of different ages is then expected. Such pyroxenites have been sampled as garnet/spinel pyroxenite veins hosted in the spinel lherzolite xenoliths carried by the basalts in the northern margin of the North China Craton (NCC). Zircon U-Pb age, single melt inclusions and profile analyses of minerals of peridotite and pyroxenite xenoliths carried by the Neogene basalts are combined to investigate the mantle peridotite-melt interactions in the northern margin of the North China Craton.

Continental crust-derived Precambrian zircon xenocrysts and igneous zircons of 315 ± 3 Ma (2σ), 80 - 170 Ma and 48 - 64 Ma were separated from the pyroxenite veins, which provide evidence for the lower continental crust and oceanic crust recycling-induced multi-episodic melt-peridotite interactions in the central zone of the NCC. The combination of the positive εHf (t) values (2.91-24.6) of the 315 Ma zircons with the rare occurrence of subduction-related diorite-granite plutons of 302 - 324 Ma in the northern margin of the NCC implies that the igneous zircons of 315 Ma could record the melt-peridotite interactions in the lithospheric mantle induced by the Palaeo-Asian oceanic crust subduction. Igneous zircons of 80 - 170 Ma generally co-exist with the Precambrian metamorphic zircons. The 170-110 Ma zircons are generally characterized by negative εHf (t) values, while the 110-100 Ma zircons are featured by positive εHf (t) values. These observations suggest that the melt-peridotite interactions at 80-170 Ma were induced by partial melting of a recycled continental crust. The igneous zircons of 48 - 64 Ma are characterized by negligible Ce anomaly, unusually high REE, U and Th contents and positive εHf (t) values. These features imply that the melt-peridotite interactions at 48 - 64 Ma could be associated with a depleted mantle-derived carbonate melt/fluid.

The 4.2ka BP climate event and its influence on Neolithic Cultures around the middle reaches of Yangtze River, China

YUHUI LIU*, XIA SUN, CHAOYONG HU, JIAOYANG RUAN AND SHUCHENG XIE

China University of Geosciences, Wuhan, 430074, China (*correspondence: yhliu@cug.edu.cn)

A sudden collapse of Neolithic Cultures in China around 4ka BP presents a problem for archaeologists. Recently reported records of the 4.2ka BP event in China [1], raises the possibility of Chinese cultural collapse corresponding to this climate anomaly [2]. However, climate change in China around 4ka BP is not well studied as sites, materials and proxies differ in their sensitivity, response time, duration and temporal resolution. To address this question, information on the 4.2ka BP event at high temporal resolution is required.

A precisely dated stalagmite, HS4, covering the last 9000 years, with clear annual growth banding [3], collected from Heshang Cave in the middle reaches of Yangtze River (30.44°N, 110.42°E), provides an apparent record of 4.2ka BP event. Oxygen isotope data from HS4 with an average resolution of ~16a suggests there is a weak monsoon event between 4.4 ka and 4.1 ka. Following this event, the subsequent 2000 year oxygen isotope average value shows an increase of ~1‰, compared with the previous 3000 year, suggesting the 4.2ka BP event is a marker of the end of the Holocene Climate Optimum. Growth rates of HS4 around 4.2ka BP also show a decrease from 300 μm/yr to 200 μm/yr, extending for 240 years, suggesting less water supply to the cave. Furthermore, Mg/Ca ratios from HS4 at seasonal resolution during this event show a prominent increase by ~40% with large variations, indicating an unstable and severe drought condition.

Consistent climate information from all three proxies from HS4 appears to support the thesis of a severe drought during 4.2ka BP around the middle reaches of Yangtze River. An extensive drought covering a period of over 200 years would devastate rain based agricultural and be a prime cause of the collapse of the flourishing Shijiahe Culture, marking the disappearance of local Neolithic Cultures in the middle reaches of Yangtze River.

Application of remote sensing method for detecting and monitoring water contamination

YUMING LIU[1], JING ZHANG[1]*, XIAOJUAN LI[2] AND HUILI GONG[2]

[1]The Key Laboratory of Resource Environment and GIS of Beijing, Capital Normal University, Beijing 100048, P.R. China (*correspondence: maggie2008zj@yahoo.com)
[2]College of Resource Environment and Tourism, Capital Normal University, Beijing 100048, P.R. China

With the global shortage of fresh water resources and freshwater ecosystems continue to be disrupted, the traditional research based on the objectives and methodology of single-disciplinary, has difficulties to face the complexity of the new challenges of global environmental changes. Beijing as the capital of China, due to continuous years of drought, the amount of available water resources has been greatly attenuated. Two drinking water reservoirs for residents, the Miyun reservoir and Guanting reservoir are only 7.2 billion and 2 billion m3 respectively. In recent years, additionally with water pollution and water quality issues, making available drinking water situation is quite serious. Remote sensing techniques play an important role recently in frequent deterioration of the status of aquatic ecology for drinking water. In this study, landsat imagery was used to detect and monitor water quality in Guanting Reservoir, Beijing, China. This talk will focus on the use of remote sensing technique to determine the nature and extent of water pollution from nitrogen materials which have much more effects on the quality of drinking water in Guanting Reservoir .

Equilibrium isotope fractionation calculation beyond harmonic level

YUN LIU[1]*, QI LIU[1] AND JOHN A. TOSSELL[2,3]

[1]State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (Liuyun@vip.gyig.ac.cn)
[2]Dept. of Chemistry and Institute for Basic Energy Science and Technology, George Washington University, Washington, DC 20052
[3]Dept. of Chemistry and Biochemistry, University of Maryland, College Park, MD 20742

The Bigeleisen-Mayer equation has been the theoretical corner-stone of stable isotope geochemistry for decades. The advantage of using this method is that it largely simplified the calculation procedure by cancelling out as many identical energy terms as possible before the final numerical calculation, concentrating on the vibrational frequency shifts of the different isotopologues. However, Bigeleisen-Mayer equation is purely based on harmonic vibration and rigid rotator approximations. In this study, corrections beyond the harmonic level to the Bigeleisen-Mayer equation have been discussed and compared. The hindered internal rotation correction on isotope effects is found to be significant for H/D exchanges of some organic molecules. Anharmonic correction for ZPE, including the G_0 term, has been found to be very important for all kinds of isotope exchange reactions. For the H/D exchange reactions, almost all the high order corrections discussed in this study are important. The temperature dependences of six higher-order corrections are checked. These higher-order corrections are strongly suggested to be included not only for H/D exchanges but also for several other non-H/D exchange reactions, such as those in B isotope and clumped isotope systems.

Complex tectonic-thermal history of the Red River Shear Zone: Evidence on Zircon SHRIMP and LA-ICP-MS dating of the Yaoshan Group, SE Yunnan, China

LIU Y-P[1], LI Z-X[2], LIAO Z[1], YE L[1], PI D-H[1] AND LI C-Y[1,3]

[1]State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (liuyuping@vip.gyig.ac.cn)

[2]Department of Applied Geology, Curtin University of Sciences and Technology, Bentley, WA6102, Australia (Z.Li@curtin.edu.au)

[3]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China (lcy5736@gig.ac.cn)

The Yaoshan Group is located on the southeastern part of the Ailao Shan-Red River strike-slip fault zone. It has experienced the high-amphibolite facie metamorphism and chorismitization, thus it was thought as one part of the Precambrian basement of the South China Block in the traditional Chinese literatures. According to CL images and optical microscope analysis, the zircons derivered from the Yaoshan Group, which are very complicated with the metamorphosed recrystal and overgrowth, could be divided into inherited, metamorphic, anatectic or magamatic types. In order to probe the history of the Red River Shear Zone, zircons derived from the Yaoshan Group have been dating through SHRIMP and LA-ICP-MS. The inherited zircon yielded the $^{206}Pb/^{238}U$ ages in the range of 235±1.7 Ma and 261±3.6Ma with the weighted mean value of 250.8±9.8Ma (N=4, MSWD=4.1) , suggested that the protoliths of the Yaoshan Group should be a sedimenrary series youger than the Permain period. The $^{206}Pb/^{238}U$ ages of metamorphic, anatectic/magmatic zircons could be divided into five groups, which are ~85 Ma, ~75 Ma, ~43 Ma, ~37 Ma and ~32 Ma, respectively. The five zircon age groups mention above could be taken as important episodes of five intensive activities in Red River fault. The first and second age groups, which related to two magmatic and high-temperature metamorphic episodes, indicated that the Red River Fault acted since the later Cretaceous. The other three age groups, which corresponded with the dating of the Ailaoshan region and North Vietnam, might indicated the three main left-direction activities in the Red River Shear Zone.

[3]University of Glasgow, Glasgow G12 8QQ, UK

[4]SPEME, University of Leeds, Leeds LS2 9JT, UK

[5]Geophysical Laboratory, Washington, DC 20015 USA

Interactions of aqueous organic molecules with the surfaces of metal oxides, such as rutile, are of fundamental interest in a wide range of topics from human implants to the origin of life on Earth. Previous adsorption studies of metals and organic molecules have focused on the {110} form that often dominates macroscopic crystals. However, recent experimental and theoretical studies of glutamate and aspartate adsorption on a synthetic rutile are consistent with attachment to functional groups such as >Ti (OH)2 or >Ti (OH)O which are not present on ideal {110} surfaces but are instead present on the pyramidal {111} or {101} surfaces [1, 2]. The pyramidal forms would have to be sufficiently abundant as steps on {110} to account for the measured adsorption of amino acids. We have used aberration-corrected atomic-resolution scanning transmission electron microscopy high-angle annular dark-field (HAADF) imaging to locate surface Ti atoms and determine the structures present on {110} and {111} faces. HAADF images of {110} prism edges show three structures: Ti-Ti pairs parallel to {110}, {111}, and {11-1} edges. The proportion of these are 4:1:1, respectively, regardless of the roughness of the edges on the μm-scale. This also matches the proportion of crystal prism to pyramidal face lengths. The majority of surface structures consist of only half unit-cell steps. These half steps comprise about 33% of the {110} prism edges. If these extend across the {110} faces, they could account for the sites necessary for amino acid adsorption. Interestingly, odd numbers of Ti pairs between steps requires that bounding steps have different structures not related by symmetry. The calculated energies of the (110) (0.40 J/m2) and (111) (1.41 J/m2) surfaces are also nearly 4:1, suggesting a relationship between growth rate and surface energy. We conclude that: (1) the presence of {111}-type steps on {110} confirms inferences from theoretical and experimental adsorption studies, (2) adsorption models and experiments can be integrated with sub-unit cell surface structures, the detailed nature of which should be characterized with electron microscopy.

Impact of microbial metabolism on radionuclide solubility in natural and engineered environments

J.R. LLOYD[1]*, A. GEISSLER[2], G.T.W. LAW[1], C.L. THORPE[1], V.E. EVANS[1], A.R. BROWN[1], R. KIMBER[1], D.R. BROOKSHAW[1], C. BOOTHMAN[1], F.R. LIVENS[1] AND K. MORRIS[1]

[1]SEAES, WRC and RCRD, University of Manchester, M13 9PL, UK (*correspondence: jon.lloyd@manchester.ac.uk)
[2]Forschungszentrum Dresden Rossendorf, Inst Radiochem, Dresden, Germany

Microbial metabolism can have a controlling influence on the solubility of actinides and fission products in engineered and natural environments. In the 'far field' surrounding a nuclear repository, microbial processes can immobilise redox active radionuclides via respiratory processes that either change directly the oxidation state of the element, or produce new biogenic phases for enhanced sorption. In the 'near field' of the repository, the direct and indirect impacts of microbial metabolism are less well characterised but have the potential to have a significant impact on wasteform evolution and radionuclide mobility, and must be incorporated into the safety case of the repository.

Recent work on the redox cycling of U, Np, Pu and Tc will be discussed, including both reduction and oxidation reactions and their impact on soluble and insoluble radionuclide inventories. The roles of proteins, secreted electron shuttles and other microbial products will be discussed alongside additional controls coupled to bulk element cycles e.g. the production of new mineral phases or significant changes in the geochemical environment such as pH. Studies from a range of contrasting natural and engineered systems will highlight how microbial communities can respond to the radioactive inventory and the extreme (radio)chemistry of some disposed wasteforms, and ultimately control the biogeochemical fate of key radioactive elements.

Laser ablation with the NEPTUNE *Plus* MC-ICP-MS

N.S. LLOYD[1]*, S. SHUTTLEWORTH[2], J.B. SCHWIETERS[1] AND C. BOUMAN[1]

[1]Thermo Fisher Scientific, Hanna-Kunath-Str. 11, 28199 Bremen, Germany (*correspondence: nicholas.lloyd@thermofisher.com)
[2]Photon Machines, 15030 N.E. 95th St., Redmond, WA 98052, USA (shutts@photon-machines.com)

The Thermo Scientific NEPTUNE *Plus* with Jet Interface offers unparalleled MC-ICP-MS sensitivity for all elements across the mass range. An ion yield of > 3 % has previously been reported for uranium solutions [1]. Sensitivity enhancements have been achieved through a combination of a dry high-capacity (up to 130 m^3/h) interface pump, X-cone, Jet cone, and desolvating nebuliser system.

The Thermo Scientific NEPTUNE *Plus* with Jet Interface was coupled with a Photon Machines excimer laser ablation system. This system features a short pulse width (4ns) 193 nm excimer laser and the HELEX 2 volume sample cell. The 193nm wavelength has been shown to reduce the particle size distribution of the aerosol produced by the laser ablation process [2] and this in turn has been shown to help minimize the effects of fractionation by ensuring that particles are in a size range so as to avoid incomplete vaporization and ionization in the plasma [3].

The sensitivity of the Jet Interface for small spot size (< 10 μm diameter) LA-MC-ICP-MS was trialled for natural uraninite and for NBS U-030 certified reference material. The minor uranium isotopes, ^{234}U and ^{236}U, were measured simultaneously on discrete dynode SEMs, with RPQ abundance sensitivity filters, whilst ^{238}U and ^{235}U were measured on Faraday cups with 10^{11} Ω amplifiers. This 'nuclear forensic' application was previously demonstrated with an older generation of MC-ICP-MS instrument, which required larger ablation volumes due to lower analyte sensitivity [4].

Hafnium isotope ratios were measured from zircon reference material 91500 using Faraday cups with 10^{11} Ω amplifiers. Figures of merit are given for precision from decreasing ablation spot sizes (i.e. improved spatial resolution).

Invasion of warm, saline, and well ventilated intermediate water in the cold stadials during the last 30,000 years? Evidence from the middle Okinawa Trough site MD01-2404

LI LO[1], YUAN-PIN CHANG[2]*, CHUAN-CHOU SHEN[1], MIN-TE CHEN[3] AND KUO-YEN WEI[1]

[1]Dept. of Geosciences, Natioal Taiwan Univ., Taipei 106, Taiwan (lo.rogerloli@gmail.com)
[2]Institute of Marine of Geology and Chemistry, National Sun-Yet Sen Univ., Kaohsiung, Taiwan (*correspondence: yuanpin.chang@mail.nsysu.edu.tw)
[3]Institute of Applied Geosciences, National Taiwan Ocean Univ., Keelung 20224, Taiwan (mtchen@ntou.edu.tw)

It has been proposed that the North Pacific may play an important role on the glacial deep water formation during the cold stadials in the last glacial[1]. This deep water formation hypothesis would impact the understanding of deep ocean circulation model and the interpretation of various geochemical proxies. Less evidence, however, could be found in the intermediate water (IW) in the western North Pacific Ocean (NPO). Here we present: 1) benthic foraminiferal (*Uvigerina peregrina*, >250 μm) $\delta^{18}O$[2], Mg/Ca ratios, and calculated $\delta^{18}O_w$ from Site MD01-2404 (24°48'N, 122°30'E, water depth 1397 m) in the middle Okinawa Trough (mid-OT), and 2) composite western NPO IW ventilation ages during the last 30, 000 years.

First, IW temperatures in the mid-OT showed rapid millennial timescale oscillation from 0 to 4 °C, and $\delta^{18}O_w$ were flucutated from -0.8 to 0.3 ‰. Druing the cold stadial periods, e.g. Younger Dryas (YD), Older Dryas, Heinrich events 1 (H1) and 2, and the stadial between Dansgaard-Oeschger interstadials 4 to 5, warm and saline IW could be recognized in the mid-OT region. Second, the ventilation age from the intermediate depth (978-1397 m) in the mid-OT and the western NPO were composited to further identify this warm-saline water mass origin. The age differences could as low as 800-1000 yrs in H1 and YD periods, and as high as ~2000 yrs druing Bølling-Allerød period.

In short, this study proposed a warm, saline and relatively well ventilated IW mass intrusion to the mid-OT during the cold stadial periods through the last 30, 000 years.

Geochemical study of the stone deterioration in a granitic monument of Oporto, Northern Portugal

J. LOBO[1] AND A. ALMEIDA[2]*

[1]ES/3 Daniel Faria – Baltar, Portugal
[2]CGUP, Universidade do Porto, 4169-007 Porto, Portugal (*correspondence: aalmeida@fc.up.pt)

The lighthouse of St Michael the Angel in the mouth of the Douro river, Porto, Portugal, has been selected for a geochemical study of the deterioration of the granite stone. The lighthouse-chapel was built in 1527, under a design by the Italian Francesco de Carmona. It has three entries, contemporary of its foundation. The dome exhibits a purity of Renaissance architecture. It constitutes a single copy in Portugal and the oldest in Europe. It is an emblematic building due to the historical features and also to the stone diseases associated to it.

The recognition of the main deterioration processes was based on the study of the representative granite facies of the Lighthouse of St. Michael the Angel. For this purpose a mineralogical and geochemical study of the granite stone deterioration and of the joint mortars, using various experimental techniques that include stereoscopic binocular microscopy, X-ray diffraction, scanning electron microscopy (SEM- EDS) and the Raman spectroscopy, was carried out. The diagnosis of the deterioration types show granular disintegration, plates, flakes, black crusts, thin black layers, biological colonization and fissuration. The geochemical study of the pathologies puts into evidence the formation of soluble salts and minerals, namely halite, gypsum, barite and calcite. The close proximity to the Atlantic Ocean in the river mouth is an important factor in the composition of rain water and in the formation of marine aerosols, with sodium chloride and sulphate ions.

The stones applied in the lighthouse were extracted from a local quarry of peraluminous two-mica granite, affected by late- to post-magmatic alteration processes well illustrated by the muscovitization of biotite and plagioclase. The potassic feldspar was strongly kaolinized. Hence, during the construction of the building, the stones already exhibited some chemical alteration inherited from the quarry, a fact that is confirmed by the presence of gibbsite and kaolinite that indicate a high degree of mineralogical evolution. The natural deterioration factors, mainly the long exposure to climate conditions and the rock susceptibility to weathering, are aggravated by the reaction of mortars with the rock minerals and by industrial and traffic pollution.

Fluoride complexation of yttrium under hydrothermal conditions

A. LOGES[1]*, A.A. MIGDISOV[2], T. WAGNER[3], A.E. WILLIAMS-JONES[2] AND G. MARKL[1]

[1]Institut für Geowissenschaften, University Tübingen, D-72070 Tübingen, Germany (*correspondence: anselm.loges@uni-tuebingen.de)
[2]Dept. of Earth and Planetary Sciences, McGill University, Montreal, Que., Canada H3A 2A7
[3]Institute of Geochemistry and Petrology, ETH Zurich CH-8902 Zurich, Switzerland

As a result of the recent upsurge in demand for new resources of the REE, there is an urgent need to better understand their behavior in hydrothermal systems. Here we report results of a study designed to determine formation constants for yttrium fluoride species by measuring the solubility of YF_3 in fluoride-bearing solutions. The experiments were performed at 150, 200, and 250°C and saturated water pressure, using the method of Migdisov *et al*. [1]. The pH and fluorine concentration were 0.85 to 3.05 and 3e-4 to 1e-1 mol/kg, respectively. Based on these experiments, Y speciation is dominated by mono-fluoride and di-fluoride complexes.

The elements Y and Ho are geochemical twins, with nearly identical ionic radii (900 pm and 901 pm) and the same oxidation state (3+) in nature. Consequently, they do not fractionate strongly in most geological systems. Important exceptions are fluorine-rich hydrothermal systems, in which their fractionation is pronounced. Our results allow us to assess fluoride-induced fractionation as a function of temperature and fluoride concentration and can be used to quantitatively model Y/Ho ratios in hydrothermal systems. This important geochemical indicator can extend our understanding of the transport processes of the economically important and geochemically interesting Rare Earth Elements.

Geochemical modeling of reactive minerals associated with *in situ* recovery of uranium

P. LONGMIRE, V. LAGNEAU AND M. BOUZID

MINES ParisTech, Centre de Géosciences, 35 rue Saint Honoré, 77305 Fontainebleau, France (patrick.longmire@mines-paristech.fr, vincent.lagneau@mines-paristech.fr)

Dissolution of uraninite and pyrite in the presence of oxidants and SO_4^{2-} derived from H_2SO_4 are important geochemical processes taking place during *in situ* recovery (ISR) of uranium worldwide. During ISR of uranium using H_2SO_4, pH values of 3 or less are typically achieved depending on the buffering capacity of reactive (intermediate kinetic) minerals. Reactions involve significant dissolution of uraninite and primary silicate minerals. Possible precipitation of secondary minerals (gypsum, alunite, and jurbanite) can also occur under localized acidic conditions. Geochemical modeling using PHREEQC and HYTEC was conducted to quantify dissolution and redox reactions. The pre-extraction geochemistry is built, in agreement with observations, by equilibrating groundwater with primary phases (uraninite, pyrite, K-feldspar, hematite, calcite, kaolinite, Mg-montmorillonite, and Ca-nontronite). Acidification results in early-stage dissolution of Fe (III) minerals, which initiates oxidative and irreversible dissolution of uraninite and pyrite. Surface-controlled dissolution of K-feldspar, kaolinite, and Mg-montmorillonite with intermediate kinetics produces an acidic, mixed solute [Al-Ca-Fe (II)-SO_4] composition, enhancing precipitation of alunite and jurbanite. 2D simulations were then performed to study mixing effects, particularly near the production wells. Flow velocities can be much smaller for longer stream-tubes allowing for slower kinetic reactions to be effective. The amount of buffering by calcite increases along these flow paths characterized by increasing pH- buffering capacity.

[4]University of Mato Grosso State, Alta Floresta, MT, Brazil (eignotti@ensp.fiocruz.br)

Every year, biomass burning in Amazonia releases large amounts of aerosols into the atmosphere. The consequent change from low to very high atmospheric concentration of aerosols therefore affects the radiative, cloud physical and chemical properties of the atmosphere over Amazonia. This represents a dramatic perturbation to the local and regional climate, ecology, water and nutrients cycles, and human life. Given the magnitude of biomass burning in Amazonia and the efficiency of the process of atmospheric transport of fire emissions, there perturbations are very likely to affect the climate system even on a global scale. Here, we examine the smoke aerosols simulated by CCATT-BRAMS model (an aerosol and chemistry transport model coupled on-line to a non-hydrostatic and compressible mesoscale model) over South America, aiming to use the model results to assess the local and remote impacts. We will present the current model status, summarizing the efforts made in terms of numerical model development, in order to better represent within the model the atmospheric processes that are the main drivers of the fate of fire emissions and that lead to smoke impacts. Based on a 13-year numerical simulation, we will draw the general pattern of smoke long-range transport over the South American continent and explore local and remote impacts. We will discuss the smoke radiative impacts on the hydrological cycle, surface processes as well as on the troposheric chemistry over the affected areas. Finally, the human dimension of the problem will be visualized throughout correlations between the hospitalization rate of children and elderly people and the level of smoke exposition.

Geochemistry of xenoliths from the Gibeon Kimberlite Province, Namibia

M. LONGO[1], P. NIMIS[1], L. ZIBERNA[1], A. MARZOLI[1], A. ZANETTI[2] AND L. FRANZ[3]

[1]University of Padua, Department of Geosciences, Italy (micaela.longo@unipd.it, paolo.nimis@unipd.it, luca.ziberna@studenti-unipd.it, andrea.marzoli@unipd.it)

[3]University of Basel, Switzerland (leander.franz@unibas.ch)

Mantle xenoliths from the off-craton Gibeon Kimberlite Province (southern Namibia) include garnet peridotites with coarse equant (CE) to mosaic porphyroclastic (MP) textures. The Gibeon mantle is characterized by a perturbed geotherm, with displacement of the most deformed MP-samples to ca. 200°C higher T [1, 2]. We have analysed by LA-ICP-MS the trace element compositions of garnets (Grt) and clinopyroxenes (Cpx) in ten Grt-peridotites from the Gibeon Townsland 1 pipe. The samples included Cpx-bearing and Cpx-free xenoliths showing CE to MP textures and varying estimated equilibrium T. One Grt shows a sinusoidal REE_{CI} profile, with peak at Eu and HREE between 2 and 5xCI, typical of depleted peridotites affected by fluid-metasomatism [3]. The other Grts are richer in HREE (≈10xCI) and show normal or sloped REE_{CI} profiles. The coexisting Cpxs show LREE-enriched profiles with variable La_{CI}/Sm_{CI} ratios (0.6-5.1). Zr vs. HREE (Y) relations are typical of more fertile peridotites affected by variable degrees of melt-metasomatism, possibly involving both PIC- and MARID-type agents [4]. No relationship has been observed between geochemical compositions and xenolith texture or PT conditions. This suggests that the recorded thermal perturbation postdated the above peridotite metasomatism and refertilisation.

Preliminary account of the Silurian carbon isotope record ($\delta^{13}C_{org}$) from the Barrancos region, Ossa Morena Zone, Portugal

G. LOPES[1,3]*, P. FERNANDES[1], R. GOODHUE[2], Z. PEREIRA[3] AND J.M. PIÇARRA[4]

[1]CIMA, University of the Algarve, Campus de Gambelas, 8005-139 Faro, Portugal (*correspondence: gilda.lopes@lneg.pt)
[2]Department of Geology, Trinity College Dublin, Ireland
[3]LNEG, Ap.1089, 4466-956 S. M. Infesta, Portugal
[4]LNEG, Ap. 104, 7801-902 Beja, Portugal

The Barrancos region provides one of the reference sections for the Silurian of the Ossa Morena Zone in Portugal. In this area the Silurian succession is condensed, with a maximum thickness of 50 m and the ages provided by graptolite faunas indicates that all the Silurian system is represented here. The lithologies are fairly homogenous throughout the succession consisting of black carbonaceous shales interbedded with black cherts, that were deposited in marine basins that developed at the northen margins of the Gondwana continent. This study is the first attempt to characterize the variation of $\delta^{13}C_{org}$ in this region, in order to assess well-documented Silurian climatic events.

The studied section is located at Monte do Carreba, near Barrancos village, and consists of a 45 m thick succession of black shales and cherts with graptolite faunas that indicates a Llandovery to lower Ludlow age. The base of the section is faulted against Upper Ordovician greywackes and quartzites. In this section $\delta^{13}C_{org}$ shows a baseline of consistent low values ranging from -25.88 to -25.10‰. This is interrupted by three positive excursions with maximum values of: -22.73‰ at the transition between the Llandovery (Telychian) and Wenlock (Sheinwoodian), -23.33‰ at the Homerian and -23.09‰ at the transition between the Wenlock and Ludlow (Gorstian). The excursions have positive shifts between +2.55 and +3.15‰ and are tentatively related to the three first global climatic events recognized for the Silurian (Ireviken, Mulde and Linde). Although this study is a preliminary account of $\delta^{13}C_{org}$ in this region, it could provide usefull data for the recognition and discussion of climatic global events in high latitude regions as was the OMZ located during Silurian times and for sections with high level of thermal maturation.

This study was sponsored by FCT (PhD grant SFRH/BD/48534/2008).

Isotope geochemistry of São Tomé Island (Cameroon Volcanic Line): Implications for mantle source components

J.M.R. LOPES[1], R. CALDEIRA[2,3]*, U.G. CORDANI[1] AND J.M. MUNHÁ[3]

[1]IGC-USP – Instituto de Geociências - Univ. São Paulo, BR
[2]LNEG – Laboratório Nacional de Energia e Geologia, PT (*correspondence: rita.caldeira@lneg.pt)
[3]CeGUL – Centro de Geologia da Univ. Lisboa, PT

An asthenospheric origin for the Cameroon Volcanic Line (CVL) is today an accepted fact. Its mantle source has been ascribed to a mixture of HIMU with DMM enriched with EM I components. However, in view of the redefined FOZO (Focal Zone) it has been suggested that CVL basalts are generally outside the typical HIMU field and instead encompass de FOZO domain, a component suggested to be common to all OIBs. Here we present new Sr and Nd isotopic data for the previously defined São Tomé Island main volcanic units (CMZ: 6 -8 Ma; CRA: 2.5 - 5 Ma; CST: < 1.5 Ma). São Tomé basalts ($^{87}Sr/^{86}Sr)_i$ = 0.703046 to 0.703530 and εNd = 3.15 to 5.56 isotopic data are similar to values found for other CVL basalts and fit within the projection plane defined by isotopic compositions of the HIMU, DMM and EMI mantle components, displaying a trend between these two. However they also fit, almost perfectly, within the FOZO domain. In addition, already published $^{206}Pb/^{204}Pb$ (19.4 to 20.1) data on São Tomé is consistent with a FOZO contribution, pointing out to FOZO prevalence as the main source component over HIMU. The new data also show an increase in $^{143}Nd/^{144}Nd$ towards the younger volcanic unit, which can be interpreted as a waning of the EMI component with a resulting increase of DMM. Accordingly we propose that the São Tomé magmatism was derived from a deep-seated (FOZO) signature, mixed with DMM and EMI components.

Microbial populations of clay formations and their interactions with uranium

M. López Fernández, O. Fernández Sanfrancisco, M. Martinéz García, P. Ranea Robles, T. Galera Monge, A. Moreno García and M.L. Merroun

Department of Microbiology, University of Granada, Spain (merroun@ugr.es)

Clay formations are considered a very important part of many deep geological repository designs for the final geological disposal of radioactive wastes. The present work describes the culture-dependent bacterial diversity of two different bentonite samples (BI and BII) recovered from clay deposits of 'Cortijo de Archidona' (Almeria, Spain), chosen as potential host rock model for the deep geological disposal of radioactive wastes. The mineralogy of these two samples dominated by smectite phases, slightly differs by the presence of the iron sulphate mineral phase, jarosite (KFe^{3+}_3 $(SO_4)_2$ $(OH)_6$), for the sample BII. The culture dependent microbial diversity studies were performed using media based on clay porewater supplemented with different organic carbon sources, oligotrophic media, etc. The evaluation of aerobic bacterial populations clearly indicated the presence of high numbers of cultivable bacteria in both samples. Bacteria belonging to *Actinobacteria* (*Arthrobacter*, *Micrococcus*, *Amycolotapsis, Kocuria, Isoptericola*), *Gammaproteobacteria* (*Pseudomonas*, *Stenotrophomonas*), *Bacilli* (*Bacillus*), etc. were identified. The interactions of selected isolated bacteria with uranium were studied using a combination of spectroscopic, microscopic and microbiological techniques. A high fraction of the bacterial population (e.g. *Stenotrophomonas* sp.) was able to tolerate high concentrations of uranium up to 10 mM, etc. U precipitation as uranium phosphate mineral phases (e.g. meta-autunite) was involved in the bacterial tolerance to this radionuclide and in the immobilization of this element in the environment.

Geochemical evidence of mud volcano activity in the West Alboran Sea

C. Lopez-Rodriguez[1]*, F. Martinez-Ruiz[1], M.C. Comas[1], C. Hensen[2], E. Piñero[2], M.E. Böttcher[3], O. Dellwig[3] and C. Lenz[3]

[3]Leibniz Institute for Baltic Sea Research (IOW), Seestr. 15, D-18119 Warnemünde, Germany

A broad field of mud volcanoes ('MVs') and pockmarks occur in the West Alboran Sea behind of the Gibraltar Arc. These sea-floor structures appear upon a major sedimentary depocenter encompassing Miocene to Holocene sedimentary sequences more than 7 km thick. The MVs are rooted at diapirs formed by undercompacted units from the older sediments, as demonstrated by geophysical data. Here we provide geochemical results of pore waters obtained with rhizons from two gravity cores drilled in the Southern Mud-volcano Field: the Carmen MV ('CMV') and the Unnamed Pockmark ('UPM'), which locates SW near CMV. In order to estimate their actual activity and determine if fluid composition is influenced by the presence of hydrocarbons, dissolved anions (SO_4^{2-}, Cl^-, I^-, and Br^-) and major and trace cations (Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Mn^{2+}, Fe^{2+}), besides boric acid and silica, were analysed using IC and ICP-OES. CMV fluids are depleted with depth in SO_4^{2-}, Mg^{2+}, K^+ and Br^- and enriched in Li^+ and B. Such dissimilarities evidence that CMV is active. Furthermore, CMV fluids show freshening at depth, similar to results found at active MVs from the Gulf of Cadiz, which suggests that the decrease in chlorinity is related with gas hydrate dissociation. By contrast, the UPM fluids show constant vertical trends for dissolved concentrations of non-metabolites. The profiles of salinity and conservative ions (Na^+ and Cl^-) indicate Mediterranean seawater as the major source at the UPM and therefore no clear evidence for seepage activity at present. Our results point to the close coexistence of active -methane emission- and inactive seepages structures in the Southern Mud-volcano Field of the Alboran Sea.

Tungstate polymerization and its role in sorption on iron and aluminum oxyhydroxides

E.A. LORENZ[1], H. HUR[2] AND R.J. REEDER[1]*

[1]Dept. of Geosciences, Stony Brook Univ., Stony Brook, NY 11794 USA (*correspondence: rjreeder@stonybrook.edu)
[2]Dept. of Chemistry, Stony Brook Univ., Stony Brook, NY 11794 USA

Tungsten, although largely unregulated as an environmental pollutant, is now identified as an emerging contaminant, partly as a consequence of its widespread use in commercial, industrial, and military applications. Interaction with mineral substrates is considered an important process governing the mobility of dissolved tungsten species in aquatic and soil systems. We examined the uptake of tungstate species by iron and aluminum oxyhdroxide phases in model systems. Results indicate that W(VI) uptake is strongly dependent on pH and W concentration. The pH dependence determined from batch studies (pH 4-8) shows sorption behavior typical of anions, with only minor dependence on ionic strength. Sorption isotherms of tungstate on iron and aluminum oxyhydroxide phases show Langmuir-like uptake at low W(VI) concentrations, but increasing uptake at higher concentrations. Solution speciation calculations suggest that a monomeric tungstate species dominates at pH > 7, with formation of polymeric tungstate species favored at lower pH and with increasing W concentration. W L_3-edge EXAFS and W L_1-edge XANES of tungstate solutions are consistent with a monomeric tungstate species at pH 8 and at least one polymeric tungstate species present in solution at pH 4, which is consistent with speciation calculations. EXAFS and XANES of tungstate sorbed on goethite over the pH range 4-8 and at W concentrations 25-1000 uM show spectra that are similar and suggest that tungstate polymerization occurs at the surface, either forming a polytungstate sorption complex or a surface precipitate. This conclusion is supported by differential pair distribution function data, which show correlations extending to 11 Å that are likely attributable to the W-W pair correlations present in polytungstates. EXAFS and XANES spectra of tungstate sorbed onto bohemite over similar pH and W concentrations show differences in uptake mechanism not observed for goethite. Desorption experiments reveal limited reversibility of uptake, consistent with formation of a surface precipitate. These initial findings emphasize the need for additional research to assess the importance of sorption in limiting the mobility of dissolved tungstate in the environment.

Talvivaara Ni deposit and ore potential of Palaeoproterozoic black shale formations in Finland

K. LOUKOLA-RUSKEENIEMI[1]*, E. HYVÖNEN[2], H. ARKIMAA[1], M.-L. AIRO[1], J. VANNE[3], J. LERSSI[3] AND S. VUORIAINEN[1]

[1]Geological Survey of Finland, P.O. Box 96, FI-02151 Espoo, Finland (*correspondence: kirsti.loukola-ruskeeniemi@gtk.fi)
[2]Geological Survey of Finland, P.O. Box 77, FI-96101 Rovaniemi, Finland
[3]Geological Survey of Finland, P.O. Box 1237, FI-70211 Kuopio, Finland

The black-shale-hosted Talvivaara deposit contains more than 1 000 Mt of low-grade Ni-Cu-Co-Zn-Mn ore. The two ore bodies are from 20 m to > 450 m thick, less than 2 km long and almost 0.5 km wide. The textures, mineralogy and geochemistry of the black shales have been studied earlier [e.g. 1, 2].

Talvivaara black shales are characterized by high organic C and S concentrations with median values of 7.6% and 9%, respectively, and the occurrence of horizons with Mn≥0.8%. Nickel precipitated in organic-rich mud from Ni-rich bottom waters in an epicontinental stratified marine basin. The Mn-rich horizons were probably deposited on the margins of the euxinic basin or, alternatively, Mn was derived via upwelling from oxygen-minimum zones.

The ore potential of black shale formations in Finland was first evaluated by nation-wide airborne geophysical surveys, because the geophysical properties of black shales can be used for preliminary classification [3, 4]. Textures, mineralogy, geochemistry and petrophysical properties were studied from altogether 800 black shale samples. Concentrations of organic C and S were as high as at Talvivaara in many localities in eastern and northern Finland, but Ni-Cu-Co-Zn and/or Mn concentrations were lower. High Pd and Pt concentrations were found in some prospects.

A mass extinction for 2 Ga ago has been suggested for the origin of the high C in certain thick (> 50 m) black shale formations in eastern and northern Finland [5].

Magnetic parameters of soils developed on different geologic backgrounds, Central Portugal

A. LOURENÇO[1], H. SANT'OVAIA[2] AND C. GOMES[3]

[1]CGUC, DCT, Universidade de Coimbra, Universidade de Coimbra, Largo Marquês de Pombal, 3000 - 272 Coimbra (*correspondence: ana.lourenco@dct.uc.pt)
[2]Centro de Geologia da U. Porto, DGAOT, FCUP, R Campo Alegre, 4169-007 Porto, Portugal
[3]CGUC, DCT, Universidade de Coimbra, Largo Marquês de Pombal, 3000 - 272 Coimbra, Portugal

Three different types of soils were studied using the environmental magnetism method in the Coimbra region, Central Portugal. Mass specific magnetic susceptibility and isothermal remanent magnetization imparted at 1 tesla (IRM_{1T}) were determined in order to characterize and map the topsoils in an area of 200 km^2. The soils studied are Fluvisols, Cambisols and Leptosols, according to FAO classification. Fluvisols are formed on the alluvial plain of Mondego River (Holocene age). Leptosols and Cambisols are formed on metamorphic rocks of Proterozoic age and red sandstones of Upper Triassic age. Magnetic susceptibility was measured on 48 surface soil samples. This parameter ranges between 0.10 and 1.04 (10^{-6} m^3kg^{-1}) in Fluvisols, between 0.09 and 4.06 (10^{-6} m^3kg^{-1}) in Cambisols and between 0.35 and 6.20 (10^{-6} m^3kg^{-1}) in Leptosols. The IRM_{1T} measured on 32 samples of Cambisols and Leptosols. IRM_{1T} values ranges between 0.60 and 107.40 (10^{-3} Am^2kg^{-1}) in Cambisols and between 4.10 and 49.04 (10^{-3} Am^2kg^{-1}) in Leptosols. The results revealed that the magnetic parameters are higher in soils formed on metamorphic rocks than on sandstones. In this case study the differences obtained are mainly due to the lithological and pedological influences and the role of the geological background is clear. The anthropogenic Fe-particles contribution is only obvious near roads and rivers. Topsoil magnetic parameters can be useful as a proxy to anthropogenic pollution particles and an auxiliary tool for geologic and soil mapping.

Assessing cementation in the El Capitan Reef Complex and Lincolnshire Limestone using ^{13}C-^{18}O bond abundances in carbonates

SEAN J. LOYD[1]*, TONY DICKSON[2], JOHN D. HUDSON[3], JOHN M. EILER[4] AND ARADHNA K. TRIPATI[1]

[1]University of California, Los Angeles, Los Angeles CA USA (*correspondence: seanloyd@ucla.edu)
[2]Univ. of Cambridge, Cambridge, UK
[3]Univ. of Leicester, Leicester, UK
[3]Calif. Inst. Of Tech., Pasadena CA, USA

The Permian El Capitan and Jurassic Lincolnshire limestones have been intensely studied for their stratigraphy, depositional setting and paleoecology. Nevertheless, the diagenetic development of these two units remains controversial, particularly with regard to diagenetic carbonate formation. Calcite cement phases have previously been characterized via $\delta^{18}O$ and $\delta^{13}C$ in order to determine precipitation temperatures and carbon sources, however, these results have lead to conflicting hypotheses.

Here, we present clumped isotope data (values corresponding to of the relative abundance of the ^{13}C-^{18}O bond in carbonates) from cements of the El Capitan and Lincolnshire limestones in an attempt to more robustly characterize precipitation temperatures and directly calculate fluid $\delta^{18}O$ values, a previously elusive measurement. Intriguingly, the resultant data display a fairly tight positive correlation between these two parameters ($R^2 \sim 0.7$ for both units). In El Capitan calcites, cements with elevated fluid $\delta^{18}O$ closer to seawater values (from ~ –2‰ VSMOW) exhibit higher precipitation temperatures (up to 70°C) than those with isotopic compositions more like meteoric fluids (down to ~ –10‰ and 28°C). The Lincolnshire Limestone calcites formed in fluids with $\delta^{18}O$ values and temperatures ranging from ~ –3‰ and 50°C to ~ –6.5‰ and 32°C, respectively.

These results suggest a tight coupling between pore water evolution and cement precipitation temperature, a somewhat intuitive finding. However, the trajectory of the combined fluid $\delta^{18}O$ and temperature trend is intriguing and potentially transformative in our understanding of the cementation of carbonate rock units. In both units, progressive cementation follows a trend toward increasingly meteoric-like fluids potentially suggesting precipitation in mixed-zone settings rather that a strictly marine environment. The nature of cementation, its bearing on the reported geochemical signatures and the implications for standing hypotheses will be discussed further.

Synergistic effects of biocatalysis and mineral photocatalysis

ANHUAI LU AND YAN LI

School of Earth and Space Sciences, Peking University, Beijing 100871, P.R. China (ahlu@pku.edu.cn)

Geophotocatalysis of natural semiconducting minerals play key roles in driving redox reactions on earth surface. Whether it is related to microbial metabolism remains unknown. This study focused on revealing the potential interactions among light, microbes and minerals by studying the relationship between bacterial metabolism and semiconducting mineral photocatalysis. To achieve this goal, a photoelectrochemical approach was employed by using a microbial fuel cell (MFC)-based equipment. To distinguish from traditional MFC, the novel system is named as light fuel cell (LFC), which is specifically used for investigating the biophotochemical reactions participated by microorganisms and semiconducting minerals. When using O_2 as the cathodic electron acceptor, the volumetric power density of a LFC with a microbial anode and a visible light-irradiated rutile-cathode was 12.1 W/m^3, 1.6 times higher than that obtained in the dark (7.5 W/m^3). Electrochemical impedance spectroscopy (EIS) data indicated that the cathodic polarization resistance of the LFC in light was 196 Ω, while that operated in the dark was 2820 Ω. These results manifested the synergistic effect of biocatalysis and semiconductor photocatalysis significantly improved the electron transfer efficiency. Further experiments showed a broad range of pollutants (e.g. hexavalent chromium, azo dyes, landfill leachate) were effectively treated in this system. The finding that microorganisms can donate electrons to photoexcited semiconducting minerals not only indicated a new aspect of microbe-mineral interactive pathway, but also predicted a new environmental remediation strategy. Based on our study, we believe the exploration of LFC will help in discovery of natural solar-driven biogeochemical process and development of interdisciplinary techniques in environmental remediation.

Two contrasting ore-bearing granites: Sn-bearing Qitianling granite and W-bearing Xintianling granite, Hunan province, China

JIANJUN LU, RONGQING ZHANG AND RUCHEN WANG

State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing, 210093, China (lujj@nju.edu.cn)

The Xintianling skarn type scheelite deposit is located to the northern of the Qitianling composite pluton associated with Furong tin deposit and was considered genetically to be relative to the Qitianling granite pluton. The authors had carried out in detail investigations to the age, Hf isotope and geochemical features of the Qitianling granite and the granite spatially associated with the Xintianling tungsten deposit.

The Qitianling composite pluton is mainly composed of hornblende biotite monzogranite with an age of 160~163 Ma, biotite monzogranite with an age of 153~157 Ma and fine-grained granite with an age of 146~150 Ma. These granitic rocks have higher contents of TiO_2, MgO, FeOt, HFSE (Zr+Nb+Y+Ce), total REE and LREE and higher ratio values of 10000×(Ga/Al), Th/U and LREE/HREE. They have an average values of 0.53 wt%, 0.62 wt%, 3.31 wt%, 491.48 ppm, 335.92 ppm, 305.59 ppm, 3.13, 3.51 and 10.87, respectively. The average values of A/CNK and zircon saturation temperature are 0.96 and 818 °C respectively. The ε_{Hf} (t) values of the zircons in the Qitianling granite vary from -8.1 to -3.7. These geochemical features indicate that the Qitianling granite belongs to A_2-type granite.

The granite relating to Xintianling skarn type scheelite deposit (named as Xintianling granite) consists mainly of fine to medium grained biotite granite with an age of 165 Ma and fine-grained biotite granite with an age of 154.5 Ma. The Xintianling granite has lower contents of TiO_2, MgO, FeOt, HFSE (Zr+Nb+Y+Ce), total REE and LREE and lower ratio values of 10000×(Ga/Al), Th/U and LREE/HREE. They have an average values of 0.18 wt%, 0.21 wt%, 1.15 wt%, 164.25 ppm, 87.65 ppm, 75.40 ppm, 2.43, 1.57 and 5.90, respectively. The average values of A/CNK and zircon saturation temperature are 1.03 and 734 °C respectively. The ε_{Hf} (t) values of the zircons vary from -12.7 to -6.1. The Xintianling granite belongs to S-type granite.

The geochemical characters discussed above demonstrate that the W-bearing Xintianling granite is genetically entirely different from the Sn-bearing Qitianling granite.

Environmental protection design of Chinese highway tunnel

LU JUN-FU[1]* AND CUI GUANG-YAO[2]

[1]State Key Laboratory of Geohazard Prevention and Geoenvironment Protection, Chengdu University of Technology, Chengdu, 610059, China (*correspondence: jyyuan521@126.com)
[2]School of Civil Engineering, Southwest Jiaotong University, Chengdu, 610031, China

The environmental protection design of highway tunnel mainly includes 3 aspects: environmental protection design for tunnel portal, water-proof and drainage environment protection design, environmental protection landscape and illumination design in tunnel.

The principle of environmental protection design for tunnel portal is 'natural, concise, harmonious with environment, not exaggerating deliberately and protecting original natural landscape of tunnel'. The content of environmental protection design for tunnel portal is the selection of tunnel portal placement and type. The selection of tunnel portal placement should be a placement that protects the natural status of mountain massif to a largest degree. The selection of tunnel portal placement should avoid high side slope and is good for being compatible with environment. Bamboo-truncating and end wall portal types are recommended because of convenient in construction, handsome appearance, reasonable strength distribution and good seismic behavior.

The principle of water-proof and drainage environment protection design is 'prevention first, blocking and intercepting coordination, and supported by clearing'. The main method to deal with this problem of adopting combined lining to prevent water, improving the anti-permeability of concrete, dealing with the deformation joint and construction joint and so on.

The purpose of environmental protection landscape and illumination design in tunnel is to improve the driving environment and the comfort index. The main methods are: to increase light illumination in tunnel, to arrange artificial green landscape in tunnel, to plant green plants at the tunnel portal and so on.

Elucidating the functions of the active microbial community of Iron Snow in an acidic lake

S. LU[1]*, K. CHOUREY[2], M. REICHE[1], V. CIOBOTĂ[1], S. NIETZSCHE[1], R.L. HETTICH[2] AND K. KÜSEL[1]

[1]Friedrich Schiller University Jena, 07743 Jena, Germany (*correspondence: shipeng.lu@uni-jena.de)
[2]Oak Ridge National Laboratory, Oak Ridge, TN, USA

Lignite mine lakes are characterized by low pH, low nutrient status, and high concentrations of Fe (II) and sulfate. In lignite mine lake 77, located in Brandenburg, Germany, microbial oxidation of Fe (II) at redoxclines with opposing Fe (II) and oxygen gradients leads to the formation of iron-rich macroscopic aggregates (Iron Snow, IS). The IS provides an important input for the reduction of Fe (III) in the anoxic hypolimnion which shows different pH values ranging from 3.3 - 4 to 3.4 - 5.9 in the center basin (CB) or north basin (NB), respectively. Thus, the diversity and function of the IS microbial communities responsible for Fe-cycling may be dissimilar. This study aimed to i) characterize microbial communities from CB and NB and ii) explore active Fe-cycling microorganisms through RNA- and proteomic-based methods. Fe (III) mineral schwertmannite was the dominating iron oxide in CB and NB samples using SEM, EDX and Raman spectroscopy. Metaproteomics analyses was performed using detergent-based cellular lysis for total protein extraction followed by LC-MS/MS interrogation. Spectral matches were accomplished using an artificial metagenome, (assembled using 175 genomes of sequenced reference isolates) and yielded a total of 390 different proteins representing 43 microorganisms in NB samples, and 105 proteins tracing back to 27 genus from CB samples. Proteins of *Chlorobium*, *Acidiphilium*, *Acidovarax*, *Azoarcus*, *Burkhoderia* and *Geobacter* species were detected in both NB and CB samples. *Acidothiobacillus* related proteins were only determined in NB while those related to *Ferroplasma* and *Sulfolobus* were discovered in CB primarily. Detections of cytochrome c class I of *Acidiphilium* JF5 in both NB and CB indicated its active role in Fe (III) reduction among the lake. Carboxysome proteins were found in *Acidimicrobium ferrooxidans* and *Acidithiobacillus* species, suggesting their capacity of CO_2-fixation coupled to Fe (II) oxidation in the upper oxic water epilimnion in Lake 77. 16S rRNA gene libraries and q-PCR for functional proteins will further provide insights into the ecophysiology of the Fe-cycling microorganisms in acidic environments.

The crystal morphology of aragonite and its implications in pumping pipe of hot spring, Taiwan

YI-CHIA LU*, SHENG-RONG SONG, CHIA-MEI LIU AND LIN HUANG

Department of Geosciences, National Taiwan University (*correspondence: yichialu@ntu.edu.tw, srsong@ntu.edu.tw, d91224006@ntu.edu.tw, linhuang@ntu.edu.tw)

This study investigates crystal morphology of sinter and discusses what kinds of factors controlling crystal morphology of aragonite to reconstruct the pumping history of hot spring.

The pipe sinter of this study is collected from Ho-Ya SPA hotel, located in Rui-Shui, Hualien County of Taiwan. Precipitated minerals of it are predominantly composed of aragonite (>99.4%) with preferred orientation by Electron Backscatter Diffraction (EBSD). The sinter displays the rings of gray, white and gray from outside to inside. The white ring of sinter is composed of many strips, but the gray one is not by naked-eyes. Under optical microscope, there are two particle morphologies of aragonite in Ho-Ya SPA white sinter. One is small and rounded crystal gathered to strips, while the other is needle. However, the gray ring almost consists of needle shape of aragonite.

Holcomb *et al*. (2009) [1] simulated the coral's growth and concluded that the small and rounded crystal is owing to high pH and saturation state in the solution. In coral, the gathered small and round crystals are called centres of calcification (COC).

In this case, we propose that the higher pumping rate causes the rapid depressurization to over-saturate quickly, and then crystals nucleate and grow. This process may generate higher porosity and rounded shape of aragonite.

In low season with low pumping rate, the aragonite grows the fine and elongate crystal due to slow supply of hot spring. However, in peak season with high pumping rate causes the quick degassing of CO_2 to occur over-saturated in solutions, then precipitate aragonite rapidly and generate rounded crystals with larger porosity. The crystal morphology, therefore, of the colorful rings implies that the sinter of Ho-Ya hot spring grows at the summer-winter-summer during one and a halfyears.

[6]Earth & Environmental Science, Univ of Illinois at Chicago

The Atom Trap Trace Analysis (ATTA) method has been used to analyze the cosmogenic isotope ^{39}Ar (half-life = 269 yr, isotopic abundance ~ 8×10^{-16}) in the atmosphere [1, 2]. With this demonstration, ATTA has reached a new milestone of detecting isotopes at the abundance level of less than one part per quadrillion. Along with the previously demonstrated analyses of ^{81}Kr (229, 000 yr, ~10^{-12}) and ^{85}Kr (10.8 yr, ~10^{-11}), ATTA can now analyze all three long-lived noble gas radioisotopes covering a wide range of ages and applications in the earth sciences. The detection of ^{39}Ar was made possible by a large improvement (x 100) in both the counting rate and counting efficiency of the ATTA method. We have developed a new apparatus (ATTA-3) to perform ^{81}Kr dating with a required sample size of 10-100 liters of water or ice. This work is supported by DOE, Office of Nuclear Physics, and by NSF, Division of Earth Sciences.

Preliminary high-resolution Ge/Si data in early Archaean BIFs

BEATRICE LUAIS[1]*, PHILIPPE LACH[2], EMILIE THOMASSOT[1], MARC CHAUSSIDON[1] AND MARIE-CHRISTINE BOIRON[2]

[1]CRPG-CNRS, Nancy Université, BP 20, 54501 Vandoeuvre-lès-Nancy, France (*correspondence: luais@crpg.cnrs-nancy.fr)
[2]G2R-CNRS, Nancy Université, Boulevard des Aiguillettes, B.P. 70239, 54506 Vandoeuvre-lès-Nancy, France

Banded iron formations are laminated sediments consisting of alternate banding of Fe-oxides layers and quartz layers which predominate in the Precambrian. Many aspects of their genesis are still controversial, but some observations such as the disappearance of BIFs at the time of atmospheric oxygenation (~2.3Ga), in spite of some recurrences between 0.8-0.6 Ga, indicate that the oceanic and atmospheric conditions have played an important role for their deposition. The Ge/Si ratios have been long used in studies concerning paleochemistry of oceans as a proxy for understanding the geochemical cycle of Si and Si sources in surface environments. It has been shown that Ge/Si ratio is higher in hydrothermal environments than that from continental weathering, and that the solubility of Ge in aqueous fluids varies with temperature [1]. This can suggest that Ge/Si ratios could be a potential tracer of Archaean environmental conditions and sources for BIFs deposition.

BIF samples from Isua-Greenland (≈ 3.7-3.8 Ga) and Nuvvuagittuq-Canada (likely as old as 4.28 Ga [2]) have been studied in order to decipher the chronological evolution of their trace elements, Ge/Si and O, Si isotopic compositions. The main focus is the identification of compositional variations within bands and between bands of quartz and Fe-oxides. High-resolution *in situ* measurements of trace element concentrations have been performed using laser ablation ICP-MS. First results for Isua BIFs indicate that Ge concentrations range from ≈ 7 to ≈ 12 ppm in quartz, with variations of few ppm between large quartz and small quartz bands. The calculated Ge/Si ratios range from ≈ 0.6 to 1* 10^{-5}mole/mole, which is significantly smaller than previously determined data (Ge/Si ≥ 2*10^{-5}mole/mole [2]) on bulk individual mesobands. This discrepancy can be explained by the presence of scarse amphiboles with measured Ge contents of ≈ 100ppm, which bias the Ge budget of individual bands. *In situ* Ge/Si, together with O and Si isotopes will provide insights on BIFs depositional environments.

Alkaline particle size and delivery for settling and dissolution: Optimising ocean-based enhanced weathering geoengineering

A.S. LUBANSKY[1]*, M. TANNENBERGER[2], T. KRUGER[3] AND R.C. DARTON[1]

[1]Department of Engineering Science, University of Oxford, Oxford UK OX1 3PJ (*correspondence: alex.lubansky@eng.ox.ac.uk)
[2]BASF SE, GTE/AB - Q920, 67056 Ludwigshafen, Germany
[3]Oxford Geoengineering Programme, Oxford Martin School, University of Oxford, Oxford UK OX1 3BD

Among the many geoengineering techniques proposed for climate remediation by removing carbon dioxide from the atmosphere, a major benefit of ocean-based enhanced weathering is that it also holds the promise of being able to directly counteract ocean acidification. Operating such a geoengineering scheme successfully involves optimising many fine details. Arguably the most crucial detail is the size and delivery of the alkaline particles into the ocean: if the particle dissolution depth is too high, the particles will leave the mixed layer, underutilising the mineral, while if the particle dissolution depth is too low, there will be high localised concentrations of the alkaline mineral, risking undesirable side-reactions.

In this presentation, we present an analytical model for calculating the settling and dissolution rates for a suspension of multiple particles into ocean water in order to determine the optimum rates for dispersing alkalinity into the ocean. We develop a theoretical framework that can be used to determine the most efficient method for adding multiple alkaline particles, taking into account particle size and concentration as they are being dispersed.

Through our model, extending simple single-particle Stokesian analysis by taking into account average particle spacing as well as flows between and around the particles, the model enables the prediction of local conditions throughout the system to be determined in a straightforward manner. By predicting local conditions, the deleterious effects of side reactions, particularly those on the surface of the particles, can be minimised. By predicting the details of dissolution, such as concentration vs depth and time, our model predicts the efficacy of a given delivery system for adding alkalinity to the ocean.

In this presentation, a discussion will also be provided highlighting some of the applications of the model to geoengineering for removing atmospheric carbon dioxide and for moderating ocean acidification.

Modifying the diffusive gradients in thin films technique for the geochemical exploration of gold

ANDREW LUCAS[1], ANDREW RATE[1], HAO ZHANG[2] AND URSULA SALMON[1]

[1]School of Earth and Environment, University of Western Australia, 35 Stirling Highway, Crawley, WA 6009, Australia

[2]Lancaster Environmental Centre, Lancaster University, Lancaster LA1 4YQ, UK

Using DGT for Gold

Gold is a precious metal that exists in the environment in extremely low concentrations (>1ppb). Any technique which is sensitive enough to usefully determine ultra-low quantities of metals such as gold is of interest to exploration geochemists and mining companies alike. As such, the diffusive gradients in thin films (DGT) technique, which has been used extensively to monitor ultra-low concentrations of metals in soils, sediments and freshwater [1], is likely to be ideally suited for geochemical exploration of gold in the environment.

Methodology and Discussion

This research details the development of a DGT method for the geochemical exploration of gold, and introduces a new binding-layer based on activated carbon. The performance of this new technique was assessed by: 1) determining the diffusion coefficient of gold (as soluble gold (III) chloride); 2) assessing the new binding layer's capacity to uptake gold; 3) determining the elution methodology from the binding layer; 4) assessing possible interference from other environmentally labile metals, and; 5) the effect of ionic strength and pH on performance.

The results of this study show that the technique has significant potential to be used for the geochemical exploration of gold in aqueous environments. Further method development will include assessing the technique's potential with gold species other than the gold (III) chloride used in this study, and further modification to measure gold concentrations in soils and sediments.

Element redistribution during rutile dissolution and titanite precipitation

F. LUCASSEN[1,2], G. FRANZ[1] AND D. RHEDE[2]

[1]Technische Universität Berlin, FG Petrologie, Berlin, Germany (lucassen@gfz-potsdam.de)

[2]Deutsches Geoforschungszentrum, Potsdam, Germany

We investigated the dissolution-precipitation reaction rutile + Ca, Si, Al in fluid = titanite at 400 MPa and 600°C. Solid sources of Ti, rutile (Nb, W bearing natural or Cr doped synthetic rutile) and Ca, Si, Al (wollastonite and Al_2O_3 or grossular) are separated by using a double capsule technique. All element exchange is via an aqueous NaCl fluid. The purpose of the study is to find out what are the rate controlling steps and how are major (Al-Ti) and trace elements distributed.

Titanite growth is very rapid; overgrowth is complete after 1 day. With longer run-time, substantial increase of crystal size and changing crystal habits of the titanite imprint spatially related dissolution patterns on the rutile surface. The reaction progress is controlled by the low solubility of Ti and element transport from and to the dissolution front on rutile along titanite–titanite grain boundaries. Titanium is not transported away from the reaction site, but Al, which is always present in the quench, is perfectly mobile. This contrasting behaviour leads to an irregular 'patchy' Al-Ti distribution in titanite [1]. The Ti/Al is likely dominated by the availability of Ti rather than of Al. We assume quantitative incorporation of dissolved Ti in titanite.

Trace element (Nb, W) contents in titanite around rutile is variable and shows no clear spatial relation to the variable trace element contents of the zoned natural rutile. It is also neither related to core-rim relations in titanite corresponding to the time of the experiment, nor controlled crystallographically. Chromium (source: homogeneous synthetic rutile with 2000 ppm Cr) shows a similar behaviour. It is between ~400 to ~1400 ppm with a few higher values up to ~5000 ppm. From mass balance calculation, ~800 ppm Cr are expected if Cr is quantitatively incorporated and homogeneously distributed in the titanite. Chromium and Ti/Al are not correlated. Decoupling of Cr and Ti, which are released together by rutile dissolution, must origin from randomly different transport of both elements.

Chronological and thermal history of the lithospheric mantle underneath the Gibeon kimberlite field, Namibia

TIMO LUCHS*, GERHARD BREY AND AXEL GERDES

Institut für Geowissenschaften, Goethe Universitaet, Frankfurt am Main (*correspondence: luchs@em.uni-frankfurt.de)

The 70 Ma kimberlite volcanism in the Gibeon Province in Namibia was triggered by the drift of the African continent over the Discovery plume [1]. It brought garnet peridotites, megacrysts and few crustal xenoliths to the surface. The volcanic field is situated in the Rehoboth province which gives crustal basement ages between 1.7 – 2.3 Ga [e.g. 2-3]. The neighbouring Namaqua-Natal belt is charactarised by ages of 0.9 to 1.3 Ga. Rhenium depletion ages of the peridotites range from less than 1 to 2.2 Ga and point towards an early proterozoic depletion event [4].

Major and trace elements of garnets and clinopyroxenes of 19 more or less altered peridotites from Hanaus and Gibeon were analysed by EPMA and LA-SF-ICPMS; the Lu/Hf and Sm/Nd isotope ratios were measured in cpx and grt mineral separates from 12 of these samples by ID-MC-ICPMS.

Garnets from 14 samples have LREE depleted patterns (with corresponding equilibrium patterns in the coexisting clinopyroxenes), five garnets show sigmoidal patterns of the type commonly observed in Archean garnets. The latter show a tendency to higher temperatures (~ 1250 °C) compared to samples with LREE depleted garnet patterns (~ 1100 °C) at same pressures (~ 40 Kbar).

Bulk rock isotopic compositions were calculated from the modal abundances and isotopic composition of the minerals. Three sigmoidal and five LREE depleted peridotites yield two separate Lu-Hf isochrones of 1.88 Ga and 933 Ma respectively. Both isochrones are interpreted as reflecting enrichment events of previously depleted mantle. Timing and extent of depletion must have been very different because the former yield $\varepsilon H = +29$, the latter +5. The younger enrichment age points to an event connected with the Namaqua orogeny, the older to processes connected with the manifestation of the Rehoboth province.

Sm-Nd whole rock isotope systematics indicate a late metasomatic overprint at around 500 Ma during the Damara orogeny.

The significance of Rotliegend brines in mineralizing processes and hydrocarbon systems in the Southern Permian Basin

V. LÜDERS[1]*, B. PLESSEN[1], H.B. VONHOF[2] AND J. SCHNEIDER[3]

[1]Helmholtz Centre Potsdam GFZ, Telegrafenberg, D-14473, Potsdam, Germany (*correspondence: volue@gfz-potsdam.de, birgit.plessen@gfz-potsdam.de)

[2]Vrije Universiteit Amsterdam, De Boelelaan 1085 1081 HV Amsterdam, The Netherlands (vonh@falw.vu.nl)

[3]Badstr. 5-9, D-35792 Löhnberg, Germany (j.schneider@mineral.tu-freiberg.de)

Studies of sedimentary brines from the central part of the Southern Permian Basin (SPB) show that formation water stored in Rotliegend sandstones differs clearly in elemental abundances and isotopic composition from formation waters from the overlying Zechstein and Mesozoic units [1, 2]. The Permian depositional conditions in the central part of the SPB (Rotliegend salt lake) and subsequent Zechstein transgression which caused to the formation of huge evaporite caps led to the preservation of original Rotliegend formation waters that changed their pristine chemical character by water-rock interaction (WRI) during basin subsidence. These 'altered' Rotliegend formation waters are characterized by positive δD and $\delta^{18}O$ values due to evaporation of meteoric water of the Rotliegend salt lake and high radiogenic $^{87}Sr/^{86}Sr$ isotopic ratios due to WRI with surrounding host rocks [1]. Fluid flow of Rotliegend brines is recorded by abundant fracture-fill and vein mineralization within Rotliegend sediments and even in deeper-lying Paleozoic units. Fracture-fill anhydrite shows unusual $\delta^{34}S$ isotopic composition of about +5‰ suggesting that sulphur was derived by WRI between Rotliegend formation waters and Rotliegend sediments of magmatic origin rather than being derived from the overlying Zechstein. Furthermore, Rotliegend brines played a significant role in the formation of nitrogen-rich gas reservoirs in the central and eastern part of the SPB.

Reactive melt transport in the oceanic lithosphere: Implications to MORB thermobarometry

PETER LUFFI* AND CIN-TY A. LEE

Rice University, Houston, TX 77005, USA
(*correspondence: pluffi@rice.edu)

Basalt compositions reflect physico-chemical factors controlling magma generation, transport, and emplacement, and it is widely thought that, if chemical variables are known (e.g. Mg# and fO_2 in source peridotites) or properly corrected for (e.g. olivine fractionation), then the P-T conditions of mantle melting can be reasonably constrained. In this respect, mid-ocean ridge basalts (MORB) are of major interest: they encapsulate information regarding the present thermal state of Earth's mantle. Thermobarometry based on Si and Mg in basalts indicates that fractionation-corrected 'primary' MORB form a narrow P-T array between 1300-1400 °C and 0.7-1.7 GPa, overlapping the 10-15% melting isopleths of dry lherzolite [1]. This P-T array is evident even at short lengthscales, making it difficult to explain the spread by variations in mantle potential temperatures (T_p). More likely, short-lengthscale MORB temperature variability is the result of melt-rock reactions in the oceanic lithosphere, and reflects differences in axial lithosphere thickness [2].

Here we assess to what extent the 'primary' MORB P-T array can be caused by reactive melt transport in oceanic lithosphere. Using Adiabat_1ph [3] with pMELTS [4], we calibrate a synthetic Mg-Si thermobarometer for basalts equilibrated with peridotite at P < 3 GPa, analogous to experiment-based calibrations [1]. We apply this thermobarometer to aggregated melts obtained by simulating polybaric fractional melting of peridotite along relevant T_p and show that, in the absence of low-P melt-rock reaction, MORB P-T values reflect the conditions of mean extent of melting. However, our simulations of percolation of aggregate melts through residual harzburgites at low-P show that reactive melt transport in the oceanic lithosphere decreases Mg and increases Si in melt such that thermobarometry will produce P-T arrays overlapping those observed in MORB. These results render T_p variability unnecessary for explaining most of the global MORB P-T, corroborate the view that short-scale MORB P-T variability is a measure of reactive melt transport, and help constrain geotherms beneath mid-ocean ridge axes.

Re-Os and Lu-Hf dating in Letlhakane peridotite xenoliths (Botswana)

AMBRE LUGUET[1], MELANIE BEHRENS[1], DANIEL HERWARTZ[1] AND D. GRAHAM PEARSON[2]

[1]Steinmann Institute, Poppelsdorfer Schloss, Universitaet Bonn, Germany (Ambre.luguet@uni-bonn.de)
[2]Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada

In order to better understand the lithosphere structure and evolution under the Paleoproterozoic Magondi Belt (NW margin of Zimbabwe craton), 11 peridotites from the Letlhakane diamondiferous kimberlite were studied for HSE, Lu-Hf and Re-Os isotope systematics. These peridotites experienced both high degrees of partial melting and metasomatism as evidenced by the presence of phlogopite and significant enrichments in incompatible trace elements. Their HSE systematics show progressive metasomatic Pt and Pd enrichments, with CI-normalised patterns ranging from those typical of residues of high partial melting degree (PdN/IrN<0.03, PtN/IrN<0.1) to patterns having chondritic to suprachondritic PtN/IrN and PdN/IrN (0.9-1 and 1.06-1.4, respectively). All but 1 sample show Re enrichments (ReN/PdN=0.3-7.6). Re depletion ages range from 2.2 to 2.8 Ga, clearly indicating the presence of Archean mantle beneath this area [1]. Whole-rock Lu-Hf isotope systematics show significant scatter in 176Hf/177Hf vs. 176Lu/177Hf space, but 3 samples yield a ca. 2.1 Ga errorchron age (MSWD = 4.8) with a radiogenic initial 176Hf/177Hf ratio. Apart from 1 peridotite yielding a Lu-Hf model age of 2.5 Ga, the Lu-model ages of Letlhakane peridotites cluster at 0.7-1.1 Ga. Moreover, a clinopyroxene-garnet pair from a single sample defines a 2-point isochron age of 132±38 Ma, within error of the eruption age of the Orapa kimberlite (93 Ma, [2]), which is assumed to be erupted in the same phase of magmatic activity as Letlhakane kimberlite [3].

None of the Lu-Hf isotope systematics is consistent with the Archean depletion event indicated by the Re-Os isotope system. The Lu-Hf isotopic systematics have been highly disturbed by the petrological modifications experienced by the lithospheric mantle under Letlhakane and thus indicate the vulnerability of the Lu-Hf isotopic system in metasomatised peridotites for dating depletion age and formation of the mantle root.

Solubility and species of Zn and Pb in water-chloride fluids at T-P conditions of granite magmas degassing

O.A. LUKANIN, N.A. KUROVSKAYA AND B.N. RYZHENKO

Vernadsky Institute of Geochemistry and Analytical Chemistry, Moscow, Russia (lukanin@geokhi.ru)

Results of thermodynamic modeling of equilibrium relationship of complexes of Zn and Pb in water-chloride solutions as a function of T (600 - 900ºC), P (0.7-5 kbar), the composition and acidity of the fluid (NaCl, KCl, NaCl+HCl), as well as the initial concentration of Zn and Pb in the system in the form of $ZnO_{(c)}$, $PbO_{(c)}$ or $ZnCl_2$, $PbCl_2$ are presented. At 'magmatic' T-P parameters Cl-complexes fraction and total solubility of ore metals in solutions equilibrated with their solid oxides essentially increase with the increase of chloride ion concentration (C_{Cl}) and decrease of pH. The form of prevailing Cl-complexes varies with growth of C_{Cl} towards the increase of quantity of their Cl atoms as follows: $ZnCl^+$, $ZnCl_2^o$ - $ZnCl_4^{2-}$; $PbCl_2^o$ - $PbCl^{3-}$ - $PbCl_4^{2-}$. The increase of pressure and temperature decrease contributes to stability of Zn and Pb Cl-complexes. Zn/Pb (at.) > 1 in solutions equilibrated with $ZnO_{(c)}$ and $PbO_{(c)}$ within wide range of T-P-X parameters. It increases with the increase of C_{Cl} and acidity of the solution.

Results of thermodynamic simulation confirm the assumption about the leading role of Cl-complexes in the distribution of Zn and Pb between water-chloride fluids and granite melts during their degassing and agree with experimental data obtained at 800ºC and 1-5 kbar (Urabe, 1987; etc.) that show: (1) the increase of Zn and Pb distribution coefficients between fluid and granite melt ($D(Zn)^{f/m}$, $D(Pb)^{f/m}$) with the increase of Na and K chloride concentration in a water fluid, (2) the particularly sharp increase of $D(Zn)^{f/m}$ and $D(Pb)^{f/m}$ with addition of HCl to fluid phase (at T, P, C_{Cl} = const), (3) the higher values of $D(Zn)^{f/m}$ in comparison with that of $D(Pb)^{f/m}$ at given T-P-X conditions.

Production of the Cordillera del Paine igneous complex by thermal migration zone refinining

C.C. LUNDSTROM[1], N. GAJOS[1] AND P.J. MICHAEL[2]

[1]Dept of Geology, Univ of Illinois, Urbana IL 61801 (lundstro@uiuc.edu)

[2]Dept. Geosciences, Univ of. Tulsa, Tulsa, OK 74104 (pjm@utulsa.edu)

The Torres del Paine igneous complex consists of a silicic granitoid pluton overlying a contemporaneous mafic gabbro complex that are possibly cogenetic; recent dating studies indicate progressively decreasing age with stratigraphic depth [1, 2]. Descending through the ~1.5 km vertical stratigraphy, the upper 1 km consists of 70-72% SiO2 granite with abundant silicic aplites along the margins including the top. Beneath the granite is a zone of mixed diorite, which is underlain by a few hundred meters of hornblende gabbros. A recent model for graniotid formation by top down sill injection and reaction [3] predicts a similar overall vertical stratigraphy; isotopic measurements of a vertical Torres del Paine transect provides a first order test of this hypothesis.

We have undertaken Fe isotope analyses of previously characterized samples from the studies of Michael (1984, 1991)[4, 5]. We used high resolution MCICPMS techniques and a ^{57}Fe-^{58}Fe double spike method. Analytical precision is ~0.08 permil. Results indicate that 4 granite and evolved granite samples (SiO_2 >71%) have consistently heavy isotopic compositions relative to the IRMM standard (0.23 ± 0.08). Six monzogabbro/diorite samples average 0.09 ± 0.07. Notably, a mafic monzodiorite and two gabbros at the bottom of the Paine mafic complex average -0.80 ± 0.48, representing the lightest Fe isotopic compositions yet observed in igneous rocks. Finally, a dike porphyry sample also has a light isotopic composition of -0.39.

While further analyses are in progress, results thus far are consistent with the prediction that the isotopic variations reflect the role of thermal gradients and thermal diffusion in fractionating Fe isotopes. Specifically, heavier isotopic ratios for granites compared to diorites follows previoius observations of isotopic variations with silica content [6]. However, significantly light isotopic compositions in the bottom of the system provides evidence for a complimentary signature at the hotter part of an igneous body. Trace element modeling using IRIDIUM of top down differentiation will further assess the plausibility of this model.

Impact of parent rocks and diagenetic evolution on sandstone reservoir quality with low to very low permeability

JING-LAN LUO

State Key Laboratory of Continental Dynamics, Northwest University, Xi'an, 710069, China (jlluo@nwu.edu.cn)

Sandstone types, characteristics of fragments and cements, pore types and reservoir quality, and their horizontal distribution of the He 8 and Shan 1 Group, Permian of the Upper Paleozoic from the northern Ordos Basin, China is studied, based upon observation of bore cores, use of multiple analytic measurements. The major factors impacting the reservoir quality is discussed. Results show that feature of parent rocks and diagenetic evolution is the major element which affects the reservoir quality. Parent rocks determined sandstone types and primary pore skeleton, resulting in three types of quartzarenite, lithic quartzarenite and lithicarenite with average primary porosity of 35.1%, 34.2% and 33.6%, respectively. Parent rocks also influenced diagenetic paths and types of cements, which led to diversity pores and pore throats, thus varied reservoir qualities. The sandstones experienced the early (P-T) and late (T_3-K_1) diagentic evolution phases, and three hydrocarbon charging stages during T_3, J_2-J_3 and K_1 as well. Compaction occurred in the early diagenetic phase caused average porosity for quartzarenite, lithic quartzarenite and lithicarenite is 17.4%, 18.3% and 18.5%, respectively. Cementation mainly occurred in the late diagenetic phase resulted in average porosity for quartzarenite, lithic quartzarenite and lithicarenite is 15.0%, 15.8% and 14.8%, respectively. The quartzarenite, with average macro-pores of 3.8%, is the excellent natural-bearing reservoir sandstone type in the studied area.

Migration of toxic elements in biogeochemistry chains in residents and farmlands near a Pb-Zn Mine

L. LUO[1]*, B. CHU[1], T. XU[1], X. WANG[1], Y. LIU[1], Y. BO[2] AND J. SUN[1]

[1]National Research Center of Geoanalysis, Beijing, 100037
[2]Institute of Mineral Resources, CAGS, Beijing, 100037

Biogeochemistry investigation has been conducted in the last five years in the human residents and farmlands near a lead-zinc mine in the suburb of Nanjing city, southeast China. People have lived very close to the mine. Water, soils, plants and animal tissues, as well as human blood, were sampled, and Pb, As, Cd and other minor and trace elements in them were determined by X-ray fluorescence spectrometry, inductively couple plasma atomic emission spectrometry and mass spectrometry.

Pb, As and Cd in the samples of water, soil and dust particles taken from the investigation areas were partly or generally higher than the critical level ruled by Chinese environmental standards. For example, the maximum of Pb concentrations in irrigation water was about four times higher than the standards. The concentrations of Pb, As and Cd in farmland soils were beyond the national quality standards for the edible vegetable soils. Parts of data were shown in Table 1.

Pb and As in leaf vegetable samples were beyond the national quality standards. Parts of Pb, As and Cd in animal tissues displayed the same trends. High concentrations of Pb in human blood and bone were observed.

	Max. in Irrigation Water	Means in Vegetable soils
Pb	13.2	296
As	0.17	59
Cd	0.16	1.4

Table 1: Concentrations of toxic elements

Soil leaf-wax n-alkane δD along altitudinal and latitudinal transects: Implications for paleoelevation and paleohydrology reconstructions

P. LUO[1]*, P.A. PENG[2] AND G. GLEIXNER[3]

[1]Research Institute of Petroleum Exploration & Development, PetroChina, Beijing 100083, China (*correspondence: ipanluo@gmail.com)
[2]Guangzhou Institute of Geochemistry, CAS, Guangzhou 510640, China (pinganp@gig.ac.cn)
[3]Max Planck Institute for Biogeochemistry, 07745 Jena,Germany (ggleix@bgc-jena.mpg.de)

δD values of leaf wax-derived *n*-alkane (δD_{wax}) preserved in soils or sediments could reflect spatial and temporal variations of precipitation δD (δD_p), which develops a way to paleohydrology reconstruction and a proxy for paleoaltimetry.

We find that soil δD_{wax} values track altitudinal variations of δD_p along four altitudinal transects in China that span variable environment conditions and vertical vegetation spectra [1]. An empirical δD_{wax}-altitude relationship, that is the average δD_{wax} lapse rate of -2.27±0.38‰/100m, would be used to estimate paleoelevation change. Additionally, a reversal of altitude effect in the vertical variation of δD_{wax} exists in the alpine zone of the Tianshan Mountains, which might be caused by atmospheric circulation change with altitude. This implies that the paleo-circulation pattern and its changes should be evaluated firstly when stable isotope-based paleoaltimetry is applied.

The apparent fractionation between leaf wax and precipitation ($\varepsilon_{wax\text{-}p}$) in the extreme humid Wuyi Mountains is quite negative (-154‰), compared to the humid Shennongjia (-129‰) and the arid (but with abundant summer precipitation) Tianshan Mountains (-130‰), which suggests aridity or water availability in the growing season is the primary factor controlling soil/sediment $\varepsilon_{wax\text{-}p}$. Moreover, this climatic dependency of soil $\varepsilon_{wax\text{-}p}$ also is present along the N-S latitudinal soil transect. From the wet southeast to the arid northwest of China, values of $\varepsilon_{wax\text{-}p}$ become more positive increasingly. This variation of soil $\varepsilon_{wax\text{-}p}$ might be independent on temperature or elevation change, and could not be interpreted by the vegetation shift. Therefore, we suggest climate-specific $\varepsilon_{wax\text{-}p}$ for δD_p reconstruction: -150‰ for extremely humid climate, -130‰ for moderately wet climate (or no water stress in growing season) and -100‰ for typical arid climate. Also, paleoelevation would be estimated using empirical (observation) or theoretical (Rayleigh model) δD_p-altitude relationship.

New Measuring Method for Fracture

Fluid flow in a single fracture is an important research subject in CO_2 sequestration, hydrogeology, engineering geology and petroleum engineering [1, 2]. Recent years, some authors study mechanism on flow and transport in laboratory [1-5] and situ [6-8]. However, the main question that has still not been answered satisfactorily is: How to correlate fluid flow with fracture geometry and roughness. Therefore, we study a new method to measure and characterize the surface of fractures.

Results and Discussion

As shown in the research, fracture state *in situ* measurement applied in the experimental method is feasible.The fracture was visualized based on coordinate values of fracture Surface by the cross-sectional photographs of samples without separating the fracture surfaces (Fig.1). And New methods can show the view of fracture surface (Fig.2).

Fracture aperture is large around the borehole wall where fracture is thought to occur, and the farther away from the borehole wall, the narrower the fraction opening is.

There are more high opening angles (> 10 degree) around the borehole wall, and more low opening angles far away from the borehole wall. The fractal dimension of profiles of fracture surface is between 1.17 and 1.68.

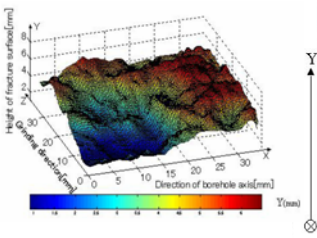

Fig. 1: Image of a single fracture.

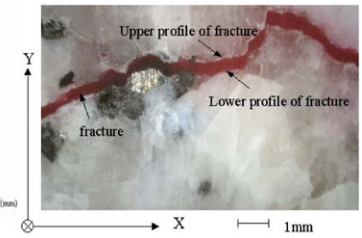

Fig. 2: Lower surface of fracture

Biogas generating simulation from source rock and oil in Jiyang Depression, Bohai bay Basin, China

X. LUO, L.H HOU, C.YANG AND J.H WANG

Research Institute of Petroleum Exploration and Development, Beijing, China (luoxia69@petrochina.com.cn, lhhou@petrochina.com.cn, yangchunzs@petrochina.com.cn, 284174762@qq.com)

Bacterium detection is carried out in rocks, which are different types of formation, lithology and depth in Jiyang depression, Bohai bay Basin in this paper. The results are that *methanococcales* are widely existed in different rocks such as mudstone and sandstone and in different formations such as Es_3, Es_1 and Ed formation and in wide depth from 1297 to 2522 meters (the formation temperatures are about 45°C and 80°C). The above results indicate that the living of *methanococcales* only depends on its survival environment and is independent of formation and lithology of rocks. Similar results were got from the characteristics of biogas generating simulation from source rocks and oils. The results are as follows: all kinds of rocks and oils can and only generate CH_4 and CO_2 during simulation. 45°C and 65°C are biogas generating peaks and the productivities are 20-160m^3/t TOC and 10-15m^3/t oil respectively. Carbon isotope compositions of methane ranging between -80.2‰ and -41.5‰ change lighter with simulation temperature rising while carbon isotope compositions of carbon dioxide change heavier. The hydrogen isotope compositions of methane ranging between -300‰ and -350‰ change little but deviation with biogas ranging between -240‰ and -270‰ from gas filed such as Luliang basin in Yunnan province as affected by the geological environment.

Himalayan weathering evolution from LGM to present

MAARTEN LUPKER[1], CHRISTIAN FRANCE-LANORD[1], VALIER GALY[2], JEROME LAVE[1] AND HERMANN KUDRASS[3]

[1]CRPG - 15 rue Notre Dame des Pauvres, 54501 Vandoeuvre, France

[2]WHOI-Department of Marine Chemistry, Woods Hole, MA, USA

[3]Federal Institute for Geosciences and Natural Resources (BGR), Hannover, Germany

We use the sedimentary record from the Bay of Bengal (BoB) spanning from the Last Glacial Maximum (LGM) to document the weathering intensity in the Himalayan system. These cores record the Himalayan erosion products transported by the Ganga and Brahmaputra (G&B) through their floodplains. The physical setting of the G&B basin remained essentially unchanged over the Quaternary. Therefore, climate change marked by reduced river runoff and lower snowline during the LGM are the main forcing variables in the basin.

We use the classical mobile elements geochemistry but also introduce the less conventional sediment hydration [H_2O^+] and detrital carbonate concentration as weathering tracers. These tracers were first applied to the modern Ganga basin, showing the predominant role of the floodplain in weathering Himalayan sediments. These tracers also highlight that mineral sorting has to be accounted for, to derive a weathering signal from detrital sediments. The BoB sediment record is then compared to the modern system. Source proxies such as Sr and Nd isotopic composition suggest that the G&B balance between both rivers has remained constant since LGM [2]. The evolution of [H_2O^+], [K] and [Carbonates] of the cores, corrected for mineral sorting, shows that the sediments exported by the system during the LGM were significantly less weathered than modern sediments. Reduced monsoon intensity [1, 3] during glacial periods yields lower precipitation, which reduces the overall weathering intensity. Lower discharge and base level likely inhibits river avulsion and limit the reworking of mature, weathered, floodplain sediments. We thus hypothesize that during LGM, river-floodplain interactions were more limited reducing the weathering of Himalayan sediments.

Distinguishing arc, backarc, and hotspot affinities using helium isotope and C/^{3}He ratios

J. LUPTON[1], J. RESING[2], M. LILLEY[3], D. BUTTERFIELD[2], N. KELLER[4], R. ARCULUS[5], E. BAKER[2] AND R. EMBLEY[1]

[1]NOAA/PMEL, Newport, OR, USA
[2]NOAA/PMEL, Seattle, WA, USA
[3]School of Oceanography, Univ. of Washington, Seattle, WA, USA
[4]IES, Univ. of Iceland, Reykjavik, Iceland
[5]RSES, Australian National University, Canberra, ACT, Australia

The northern Lau Basin is host to a complicated pattern of volcanic activity, including the volcanoes of the Tofua Arc and several back-arc spreading centers. Farther west along the NW Lau Spreading Center, elevated ^{3}He/^{4}He ratios in the seafloor lavas suggest that an OIB or mantle plume signature, possibly from Samoa, has influenced this extensional zone. Helium isotope and C/^{3}He ratios have proved useful for differentiating between arc vs. back-arc influences. True back-arc systems are similar to mid-ocean ridge (MOR) systems with ^{3}He/^{4}He of ~ 8 Ra (R = ^{3}He/^{4}He and Ra = Rair) and C/^{3}He of ~10^9. In contrast, arc volcanoes typically have lower ^{3}He/^{4}He ratios and higher C/^{3}He ratios ($\geq 10^{10}$), presumably due to downgoing slab components. For example, the recently erupting West Mata submarine volcano in the NE Lau Basin has 7.3 Ra and C/^{3}He of ~10^{10}, indicating strong arc affinities. In contrast, lavas and hydrothermal fluids from the NELSC have 8.0 – 8.6 Ra and C/^{3}He of 1 – 3 x 10^9, typical MOR or back-arc signatures. Other volcanic centers in the region show varying degrees of arc or downgoing slab influence based on their ^{3}He/^{4}He - C/^{3}He fingerprint. A broader view of the entire northern Lau Basin indicates that elevated ^{3}He/^{4}He ratios indicative of an OIB signature are confined to the Northwest Lau Spreading Center, and that the NE Lau Basin is characterized by both arc and back-arc signatures.

Thermodynamics of one and two electron transfer steps: Implications for iodide oxidation and iodine environmental cycling

GEORGE W. LUTHER, III

School of Marine Science and Policy, College of Earth, Ocean and Environment, University of Delaware, Lewes, DE 19958, USA (luther@udel.edu)

In oxygenated waters, chloride and bromide are the thermodynamically stable halogen species that exist whereas iodate, the thermodynamically stable form of iodine, and iodide can co-exist. The stability and oxidation of halides in the environment is related to the unfavorable thermodynamics for the first electron transfer with oxygen to form X· atoms. However, reactive oxygen species (ROS) such as $^1O_2$, H_2O_2 and O_3 can oxidize the halides to X_2 and HOX in two electron transfer processes; these reactions become less favorable with increasing pH. Fe (III) and Mn (III, IV) solid phases can oxidize halides with similar patterns as ROS.

The best oxidants in aqueous solution appear to be the one electron oxidant, ·OH, and the two electron oxidants, $^1O_2$, H_2O_2 or O_3. However, thermodynamic favorability depends on the halide with iodide being the easiest to oxidize as well as on pH with thermodynamic favorability decreasing with increasing pH. In sediments, Mn (III) (oxy)hydroxides are possible oxidants at near neutral pH for iodide; however, chloride and bromide reactions can only occur at pH values ≤ 2-3. I_2 and HOI form on iodide oxidation and can react with natural organic matter with formation of organo-iodine (R-I) compounds. During the treatment of drinking water, unwanted R-I disinfectant byproducts can form when the oxidant is not capable of quantitatively converting iodide to iodate.

In the atmosphere, halogen oxidation reactions are more likely due to photodecomposition of C-X bonds to X atoms, which react with O_3, NO, XO and other species by O atom transfer, a two electron transfer process. In the case of iodine, iodine oxide species form aerosol nanoparticles leading to cloud condensation nuclei.

How crystalline matter dissolves: Contours of a comprehensive stochastic model

ANDREAS LUTTGE[1]*,[2], ROLF S. ARVIDSON[1], INNA KURGANSKAYA[1] AND CORNELIUS FISCHER[3]

[1]Department of Earth Science MS-126, Rice University, Houston TX 77005, USA (*correspondence: aluttge@rice.edu)
[2]Department of Chemistry MS-60, Rice University, Houston TX 77005, USA
[3]Georg-August-Universität, D-37077 Göttingen, Germany

In the 1950's Burton, Cabrera and Frank developed BCF theory for crystal growth and some specific cases of crystal dissolution, e.g. the formation of etch pits along screw dislocations. Subsequently, we have struggled with attempts to develop a comprehensive theory and model that will describe and correctly predict how crystalline matter dissolves.

Today, we can point to a large pool of experimental and field data and a correspondingly large number of so-called rate laws that mainly attempt to fit these data. At the same time, we have identified a number of obstacles that potentially prevent us from understanding fundamental problems, including the measured discrepancies between field and laboratory data, 'reactive' surface area, and related issues. This situation cripples our ability to quantitatively predict how crystalline matter dissolves, and thus has significant consequences for important decisions involving, e.g. the licensing of repositories for nuclear waste, the treatment of hazardous waste, and regulations to ensure groundwater and aquifer quality during the 'fracing' process used by the energy industry to generate shale gas.

As an alternative we have developed a new approach that treats the dissolution and growth of crystalline matter stochastically as a many-body problem. Laboratory studies using vertical scanning interferometry and atomic force microscopy demonstrate that computer simulations of reaction kinetics based on parameterized Monte Carlo simulations are increasingly capable of correctly predicting how a specific surface or an entire crystal dissolves.

Our study shows that variations of up to 2.5 orders of magnitude in dissolution rates are likely real and not an experimental artifact. Thus, the concept of an intrinsic dissolution rate, i.e. the 'rate constant' as a material constant, is indeed fiction. Even if we postulate that the development of a steady-state surface is possible for dissolving crystals, this scenario would not be realistic for most natural processes under ambient conditions.

^{17}O anomaly of dissolved O_2 in the deep Atlantic Ocean

BOAZ LUZ[1]*, EUGENI BARKAN[1], GIDEON HENDERSON[2], WILLIAM SMETHIE[3]

[1]The Institute of Earth Sciences, The Hebrew University of Jerusalem, Jerusalem 91904, Israel (*correspondence: boaz.luz@huji.ac.il)
[2]Department of Earth Sciences, Oxford University, Oxford OX1 3AN, UK (gideonh@earth.ox.ac.uk)
[3]Lamont-Doherty Earth Observatory, Palisades NY 10964-8000, USA (bsmeth@ldeo.columbia.edu)

It is well established that oceanic dissolved O_2 contains an excess of ^{17}O ($^{17}\Delta$) with respect to atmospheric oxygen [1, 2]. This excess originates from newly produced O_2 by marine photosynthesis. $^{17}\Delta$ is unaffected by respiration and therefore behaves conservatively in the deep sea. In contrast, air-sea gas exchange drives $^{17}\Delta$ towards zero in surface water. As a result, $^{17}\Delta$ is low (20-40 per meg) in the oceanic mixed layer, but high values (up to ~200 per meg) are typical in the seasonal thermocline, where exchange with air is slow and new production of O_2 by photosynthesis is the main factor affecting $^{17}\Delta$. Below the seasonal thermocline, in layers that originate in winter at high latitudes, $^{17}\Delta$ tends again toward low values indicating the dominance of gas exchange over photosynthesis in the source areas. Yet, there is no information on $^{17}\Delta$ below 300 m.

Here we report results of the first measurements in the deep sea. In the Sargasso Sea, $^{17}\Delta$ is ~50 per meg at 500 m and gradually declines to ~30 per meg at 4700 m. These values are expected according to the explanation above and the high latitude origin of the water in this depth range. In contrast, high $^{17}\Delta$ values (79 to 97 per meg) were measured over the depth range of 1250 to 5000 m in two stations in the S. Atlantic (~35º and ~39ºS). Such high values in both NADW and AABW are unexpected and we will discuss possible explanations for their origin.

Research on hyperspectral remote sensing estimation model of heavy metal pollution in vegetation

LV KAIYUN[1,2] AND ZHANG MING[1,2]

[1]Key Laboratory of Nuclear Resources and Environment (East China Institute of Technology), Ministry of Education,Nanchang 330013, P.R. China
[2]East China Institute of Technology, Fuzhou in Jiangxi, 344000, P.R. China

Hyperspectral remote sensing, which can provide higher spectrum resolution and super multi-band image spectrum data, and can well reflect the inherent spectral characteristics and differences of various vegetation in nature, has a wide range of applications in the vegetation monitoring. After the heavy metals getting into the interior of vegetation, they will cause changes in various physical and chemical parameters of vegetation, so that they will lead to the changes of spectral characteristics. This paper will take the corn in heavy metal copper pollution as an example, through analyzing the main spectrum features under hyperspectral remote sensing, and extracting the feature parameters of the red edge from the spectral, analyze the movement rules of the red edge of the corn in different pollution degrees and the relationships between the physiological index of the corn under the heavy metal pollution and them. According to multiple statistical analysis technique, regarded the red edge feature parameters as independent variable, establish the multiple regression estimation model of physiological index, and invert various physical and chemical parameters of vegetation polluted by heavy metals, which is helpful for the pollution degrees of vegetation to diagnose and evaluate. By analyzing the test data, based on the regression model of the red edge feature parameters with the character of simple and practical and high accuracy, it will be able to well reflect the pollution degrees of vegetation polluted by heavy metals, so it is worth doing and applying in practice.

Photochemistry and the observed enrichment of O, C, N, and H isotopes in meteorite IOM

J.R. LYONS

Institute of Geophysics & Planetary Physics, UCLA, Los Angeles, CA 90095-1567 USA (jimlyons@ucla.edu)

Recently measured large isotope excursions in IOM

The remarkable O MIF signatures seen in acid-insoluble organic matter (IOM) from a CR2 meteorite [1] show some correlation with enhanced $\delta^{13}C$ values, suggesting that both enrichments may be a result of CO photochemistry. ^{2}H and ^{15}N enrichments in the same IOM do not correlate with $^{17,18}O$ and/or ^{13}C enrichments, but do show some correlation with each other [1]. Both N and H isotopes have been shown to be strongly fractionated by ion-molecule reactions in molecular clouds [2, 3]. The question I address here is are these results, particularly those for meteorite IOM [1], consistent with expected photochemical and ion-molecule processes.

Photochemical models of clouds and the solar nebula

It is well established that CO self-shielding produces large enrichment in product ^{17}O and ^{18}O, which are then stored in H_2O. Product C is similarly enriched in ^{13}C, although by a factor of ~2 less than the enrichment in ^{17}O and ^{18}O [4]. Self-shielding enrichment of ^{13}C is predicted by photochemical models of disks [5], but CO exchange with C^+ and CO condensation [6, 7], are also important. Disk model calculations, including ^{13}C at temperatures well above CO condensation, are in progress. As with CO, N_2 also undergoes self-shielding, producing enriched N and N (^2D), with the N stored in HCN. The N (^2D) rapidly forms NH, leading to reformation of N_2 by reaction of N and NH. Large ^{15}N enrichments are possible by N_2 self-shielding, but the total amount of enriched material produced is small [8]. Finally, H_2 also has a line-type absorption spectrum, and so also undergoes self-shielding at the edges of clouds and high surface of disks. At greater depths into these objects, where CO and N_2 self-shielding become important, H_2 lines are very broadened and will shield HD lines, thus reducing D enrichment. These results are consistent with a photochemical origin for O and (possibly) C isotopes signatures in IOM, and ion-molecule origin for H and N isotopes signatures in IOM.

Concentrations and isotope trends of molybdenum in organic-rich shales are among the favored tracers for euxinia in the ancient ocean on local and global scales. With the successes, however, has also come increasing awareness of the complexity.

The purpose of this talk is to synthesize the broad range of refining and defining proxy developments and applications over the past several years, as a progress report and roadmap for future applications. Among the key topics are (1) our new and refined models for Mo uptake and burial under euxinic conditions, including a rigorous mechanistic understanding of the apparent coupling between Mo and organic matter sinks; (2) our comprehensive view of how Mo is taken up, fractionated isotopically, and buried [or recycled] beneath oxic bottom waters, particularly as coupled to Mn and Fe cycles; (3) our improved perspective on how and when Mo isotopes can be fractionated under permanent or transient euxinia, leading to a more effective use of the global redox proxy and to novel estimates of dissolved sulfide concentrations and their variability within ancient euxinic settings; and (4) our new, all-inclusive understanding of the cycling and mass balance of Mo in the ocean. We are encouraged by emerging consistency with the very latest models for the redox structure of the Proterozoic ocean; inferrences about Mo-limited early eukaryotic and prokaryotic life; and our ability to use Mo isotopes, with caution, to estimate global redox conditions.

Structural phase transition of ammonia hydrate under high pressure

CHUNLI MA, QIANG ZHOU, FANGFEI LI, JIAN HAO, JINGSHU WANG, FENGXIAN HUANG AND QILIANG CUI*

State key Laboratory of Superhard Materials, Jilin University, Changchun, 130012, P.R.China
(*correspondence: cql@jlu.edu.cn)

High pressure Raman scattering studies and angle-dispersive synchrotron x-ray diffraction measurements have performed on water-ammonia binary system up to 29.92GPa and 45.11GPa, respectively. Moreover, with pressure increased slowly, it was found from microscope that the appearance of lozenge blocked solid in the sample chamber at 3.48GPa. Compared with the Raman spectrum of ice and solid ammonia, we observed that the new appeared solid was ammonia hydrate. Hence, Raman spectrum of water-ammonia binary system and ammonia hydrate would be obtained at same pressure, respectively. Therefore, it was observed that the water-ammonia binary system transformed from liquid to solid phase at 3.8GPa but the ammonia hydrate had no phase transition up to 20.34GPa because of the disappearance of Raman spectrum. However, high pressure angle-dispersive synchrotron x-ray diffraction measurements showed that there was a solid to solid phase transition of ammonia hydrate at about 20GPa. And the mechanism of this phase transition is in processing.

Characteristic of mineral component in carlin-type gold deposit in Qinling area

MA GUANG[1], GONG LI[1]*, DONG YUN FENG[2], CHEN KUIKUI[1] AND ZHANG GUIPING[3]

[1]Henan Polytechnic University, Heana 454001, China (*correspondence: gongli5678@163.com)
[2]Liaoning Geological environment monitor station, Liaoning 100032, China
[3]China Geological Library, Beijing, 100083

Introduction

The intergrowth combination of ore mineral in different Carlin-type gold deposits in the Qinling area are roughly consistent, and, the gold mainly forms in the first stage of the hydrothermal period—arsenic-rich sulfide phase, Gold existed mainly in the form of native gold with irregular granular shape, secondly, it assumes the sub-microscopic gold existing in the arsenic sulfide.

Experiment and Results

Gold minerals output mainly in the form of native gold and have irregular granular primarily, also show the shape of flake, clavate, arborization and so on. Particle size are generally small and mostly exists as the form of microscopic gold - sub-microscopic gold, a few may be visible to the naked eye. Most of the sub-micro golden are located within the arsenic-sulfide mineral (80.4%~85.2%). The major minerals are the arsenical pyrites and arsenopyrite, in the next place are the tennantite, the realgar, the orpiment, the stibnite and so on, sometimes associated with the few chalcopyrite, the galena and the sphalerite. It has the characteristic of proliferation annulus in crystal grain interior of the arsenical pyrites, according this, may determine the ore deposit type and the provide effective prospecting method.

In the metallogenesis hydrothermal stage of ore deposit, arsenic pyrite and arsenopyrite is the gold-bearing mineral crystallized earliest and distributed widely in most deposits, however, the arsenopyrite content change large in the different ore deposit. Minerals above constituent uppermost stage of gold mineralization—rich-arsenic sulfide stage, this stage has formed the stable Au-As element combination and the mineral association, the stibnite, the cinnabar, the realgar and the orpiment forms late and fill in opening space with vein shape. After rich-arsenic sulfide hydrothermal stage, appear the vein with intense silicification, calcilized and the barite arteries, the veins forms in the late stages of metallogenesis under oxidation.In this stage, gold-bearing arsenic sulfide has suffered intense oxidation and hydrolysis, submicroscopic gold dissociating has obvious enrichment in the surface.

Mine hydrochemistry evolution and water-inrush discrimination based on GIS: A case in Panyi

L. MA[1]*, X.M. WANG[2] AND X.P. ZHOU[1]

[1]School of Resources and Environmental Engineering, Hefei University of Technology, Hefei 230009, China (Lei8505@gmail.com)
[2]Public Geological Survey Management Center of Anhui Province 230001, China

New Method

With the increase of the coal exploitation depth, intensity, rate and scale, coal mining has been under the serious threat of fracture-karst groundwater [1-2]. Many studies show that groundwater flows in fractures are nonlinear and difficult to identify [3-8]. An alternative mothod is to make use of groundwater hydrochemical characteristics and groundwater temperature for discriminating the source of water-inrush. Based on ArcSDE and Microsoft SQL Server, the spatial database for discrimination of water-inrush source of Panyi Coal mine was designed and established. Spatial data mining technology was introduced and applied to the analysis of mine groundwater. Based on Voronoi diagram and DEM methods, the distribution rules of the hydrochemical types and the spatial association rules of groundwater chemistry and structure were mined from the above spatial database. The models for water-inrush source discrimination were studied and coupled with GIS.

Results and Discussion

Spatial data mining technology was applied to analyze the groundwater of mine, and based on Voronoi diagram and DEM methods the distribution rules of the chemical types of groundwater were mined.

A GIS-based identification method of mine water-inrush source with comprehensive information which integrated water level, water chemical and water temperature was proposed, and the application in Panyi Mine showed that the method can improve the precision of discrimination.

A simple, rapid and practical GIS-based system for mine water-inrush source rapid discrimination with comprehensive information was developed. (Grant no: 2009HGCX0233)

Olympic Dam U-Cu-Au deposit, Australia: New age constraints

R. MAAS[1], V. KAMENETSKY[2], K. EHRIG[3], S. MEFFRE[2], J. MCPHIE[2] AND G. DIEMAR[3]

[1]University of Melbourne, Australia, maasr@unimelb.edu.au
[2]CODES, University of Tasmania, Hobart, Australia
[3]BHP-Billiton, Adelaide, Australia

The Olympic Dam supergiant U-Cu-Au-REE deposit is located in the Olympic Dam IOCG province of the mid-Archean-Proterozoic Gawler Craton, South Australia. Mineralization is hosted in hematite-rich breccia within the 1590 Ma Roxby Downs Granite, part of the strongly mineralized Gawler Range Volcanic LIP. Initially linked to the GRV event, recent work supports a post-GRV, late-Mesoproteroic age of mineralization. Our Sm-Nd data for step-leached ores are similar to published whole rock data and define an (imprecise) ~1300 Ma apparent age. This is broadly supported by Rb-Sr isochrons for the same step-leach fractions. ε_{Nd} and $^{87}Sr/^{86}Sr$ (at 1300 Ma) are ~-7.5 and ~0.708. Pb isotopes in isotopically zoned pyrite from mineralized clastic sediments and galena in the ore have common Pb model ages which suggest sediment deposition/diagenesis and U introduction no earlier than 1.3-1.1 Ga. These age constraints are consistent with earlier work (ionprobe U-Pb ages in uraninite no older than 1.4 Ga, ReOs dating of chalcopyrite ~1.26 Ga). Evidence for post-ore disturbance is preserved in the form of 450-550 Ma apparent ages for a step-leached sericite-rich ore (Rb-Sr) and a texturally late fluorite-rich vein (Sm-Nd); the ~500 Ma apparent ages are associated with $^{87}Sr/^{86}Sr = 0.715$-0.722.

Extraction of unequivocal age evidence for this very complex deposit is difficult, and all ages – previously published and new – need to be treated with caution. For example, Sm-Nd isotope systematics are easily modified by local REE redistribution involving Nd-rich 'nuggets' of bastnaesite and florencite. Nevertheless, the balance of evidence now indicates a post-1590 Ma age for much of the mineralization in the period 1.4-1.1 Ga. Metal deposition in several stages, from the magmatic GRV event to renewed crustal-scale fluid flow during amalgamation of Rodinia at 1.2-1.1 Ga may explain the enormous size of the deposit.

Variations in atmospheric helium isotopes

J.C. MABRY*, B. MARTY, P. BURNARD

CRPG-CNRS, 54501 Nancy, France
(*correspondence: jmabry@crpg.cnrs-nancy.fr)

The purpose of this work is to look for variations in the isotopic helium composition in the atmosphere. Anthropogenic activities such as oil and gas exploitation release crustal helium, which has excess ^{4}He compared to atmospheric helium. This may give rise to detectable spatial and temporal variations in the atmospheric ^{3}He/^{4}He [1].

These differences, if they exist, would be very small [2], and thus require very high precision measurements. However, high precision measurements of atmospheric helium presents a significant analytical challenge because helium is only present in trace quantities in the air (5.24 ppm) and there are are many of orders of magnitude difference in the abundance of the two isotopes (^{3}He/^{4}He$_{air}$ = 1.38 x10^{-6}). We are designing a method to reliably measure ^{3}He/^{4}He with 2‰ or better precision.

Air samples are collected in copper tubes which are then sealed manually at the sample site with steel clamps. Each tube holds a volume of approximately 20 cm^3. Samples collected cover a wide range of longitudes and latitudes, with a particular emphasis on sampling across many latitudes since the largest spatial variation is expected to be seen in latitude.

For each measurement we purify a relatively large amount of gas (~5-15 cm^3) so that we can make many repeat analyses of the same sample gas. We have constructed an automated extraction line which can rapidly switch between measuring aliquots of sample with standards. A major component of our method features an adjustable bellows on the sample aliquot volume that enables us to adjust the size of a sample aliquot to precisely match the standard, eliminating biases arising from nonlinear pressure effects in the mass spectrometer. The measurements are made using a Helix split flight tube multi-collector mass spectrometer.

At present, the measured ratios of a sample have a 1σ reproducibility of 2-3‰, which is still too large to detect variations. We have planned several changes to further improve the next round of measurements including installing a quadrupole mass spectrometer to monitor the gas purification process and the addition of a cold trap to the mass spectrometer volume.

On the origins of dissolved natural organic matter (DNOM) in rivers and lakes

DONALD L. MACALADY[1]
AND KATHERINE WALTON-DAY[2]

[1]Colorado School of Mines, Golden, CO, USA
(dmacalad@mines.edu)
[2]U.S. Geological Survey, Denver, CO USA
(kwaltond@usgs.gov)

One of the most important characteristics of DNOM, at least with respect to reversible chemical reactivity, is its aromatic carbon content. The DNOM (measured as dissolved organic carbon, DOC) that dominates most rivers and lakes is derived primarily from land plants, including various species of woody trees and shrubs, grasses, fungi and mosses. The specific ultraviolet absorbance (SUVA, absorbance at 254 nm in a 1.0 cm cell divided by DOC in mgL^{-1}) of DNOM provides a simple, widely applicable indication of a sample's aromatic content. Examination of SUVA values of water samples from rivers and lakes, then comparison of these to SUVA values for DNOM samples derived from precursor materials, shows little apparent commonality. These precursor materials consist of senescent materials from plant species common to the catchment basins of the rivers and lakes. This paper examines the effects of geochemical processes on the SUVA values of natural waters and associated precursor materials in order to develop an understanding of the primary factors affecting the origins and aromatic content of DNOM in natural waters.

Proterozoic analog ecosystem and organic biomarkers in a Florida sinkhole

J.L. MACALADY[1]*, H.L. ALBRECHT[1], P.V. WELANDER[2], J.M. FULTON[1], I. SCHAPERDOTH[1], T.S. WHITE[1], K.H. FREEMAN[1], D.K. NEWMAN[3] AND R.E. SUMMONS[2]

[1]Geosciences Dept., Penn State Univ., University Park, PA 16802 USA (*correspondence: jlm80@psu.edu)
[2]Dept. EAPS, MIT, Cambridge, MA 02139 USA
[3]California Inst. Technology, Pasadena, CA 91125 USA

Competition between oxygenic and anoxygenic phototrophs has been proposed as a mechanism that delayed the oxygenation of the Earth's oceans and atmosphere in the Proterozoic [1]. Factors affecting competition among modern phototrophs are not well understood, especially under low oxygen conditions thought to have been prevalent in Precambrian oceans. Little Salt Spring (Sarasota County, FL, USA) is a brackish, sulfidic sinkhole hosting a mixed community of oxygenic and anoxygenic phototrophs. Groundwater vents discharge into the bottom water at 73 m depth, and thick, purple microbial mats cover sediment surfaces in the sunlit upper basin. 16S rRNA clones from the mat were affiliated with *Cyanobacteria* and *Chlorobi*, with smaller numbers of *Deltaproteobacteria* in sulfate-reducing clades. Six bacteriochlorophyll e homologues and isorenieratene reflect contributions from *Chlorobi,* and abundant chlorophyll a and pheophytin a likely derive from *Cyanobacteria*. Hopanoid content of the mat is high (29% of total membrane lipids). The relative abundances of polar hopanoids in the mat are preserved in organic-rich surface sediments accumulating in the deep portion of the sink. Remarkably, more than half of the hopanoids in the mat and surface sediments have 2-methyl structures, which are preserved in the geologic record as 2-methyl hopanes and have been interpreted as biomarkers for *Cyanobacteria*. PCR amplification of the hopanol 2-methylase (*hpnP*) from mat DNA retrieved a sequence affiliated with other cyanobacterial HpnP homologs. Ongoing work at the site is aimed at: (1) a quantitative model of anoxygenic and oxygenic contributions to net primary productivity and biomarker production; (2) understanding the ecological factors that promote the co-existence of oxygenic and anoxygenic phototrophs in the mat; and (3) describing the timescale and chemical changes associated with diagenesis of organic biomarkers.

Combined SIMS U-Pb ages and Ti-in-zircon geothermometry fingerprints long deep crustal residence in the Archaean

JOHN MACDONALD[1], JOHN WHEELER[1], KATHRYN GOODENOUGH[2], SIMON HARLEY[3], QUENTIN CROWLEY[4] AND ELISABETTA MARIANI[1]

[1]School of Environmental Sciences, University of Liverpool, Liverpool, L69 3GP jmacd@liv.ac.uk
[2]British Geological Survey, Edinburgh EH9 3LA
[3]School of GeoSciences, University of Edinburgh, Edinburgh EH9 3JW
[4]School of Natural Sciences, Trinity College, Dublin

Combined SIMS U-Pb ages and Ti-in-zircon geothermometer temperatures for a population of zircons from Archaean gneisses indicate long deep crustal residence at >780°C for >350Ma. This technique of having both an age and minimum temperature for each analytical spot is a new and direct way of showing that heat flux from the mantle to the base of the crust was higher in the Archaean than the present day.

The rocks are TTG gneisses from the polymetamorphic Archaean-Palaeoproterozoic Lewisian Gneiss Complex of NW Scotland. The analysed zircon population comprises a small number of primary magmatic cores and a range of metamorphic domains; CL imaging showed that the metamorphic domains were either rims or whole crystals of uniform CL. The metamorphic domains comprised a mix of anatectic growth and recrystallisation textures. U-Pb data produced a spread of ages from 2.5-2.8Ga with some ages older than this. Tight discordance limits (+5/-2%) were applied so only the best, most concordant age data were used. Ti analyses were filtered to exclude those from plastically-deformed (EBSD data) and contaminated (Ba >1ppm) zircons.

We interpret the data as TTG protolith formation around 2.8-3.0Ga followed by granulite-facies metamorphism at 2.8Ga. The studied part of the Lewisian Complex remained at >780°C up until 2.5Ga when it was cooled, possibly by uplift and erosion. This 300 My period of elevated temperature contrasts with Phanerozoic crustal behaviour, in which such high grade rocks are cooled over much shorter timescales.

Assessment of heavy metal contamination in soils around Chinnaeru river sub-basin, Nalgonda District, India

G. MACHENDER[2], S. YASHODA[1], M.N. REDDY[2] AND P.K. GOVIL[1]

[1]National Geophysical Research Institute (Council of Scientific and Industrial Research) Uppal Road, Hyderabad-500007, A.P., India
[2]Dept. of Geology, Osmania University, Hyderabad-500007, A.P., India

The concentration of heavy metals such as As, Ba, Co, Cr, Cu, Ni, Pb, Rb, Sr, V, Y, Zn and Zr were studied in soils to understand metal contamination due to agriculture and geogenic activities in Chinnaeru river basin, Nalgonda district, India. This area is affected by the geogenic fluoride contamination. The contamination of the soils was assessed on the basis of geoaccumulation index, enrichment factor (EF), contamination factor and degree of contamination. Forty four soil samples were collected from the agricultural field from the study area from top 10-50 cm layer of soil. Soil samples were analyzed for heavy metals by using X-ray fluorescence spectrometer. Data revealed that, soils in the study area are significantly contaminated, showing high level of toxic elements than normal distribution. The ranges of concentration of Ba (370-1710 mg/kg), Cr (8.7-543 mg/kg), Cu (7.7-96.6 mg/kg), Ni (5.4-168 mg/kg), Rb (29.6-223 mg/kg), Sr (134-438 mg/kg), Zr (141.2-8232 mg/kg) and Zn (29-478 mg/kg). The concentration of other elements was similar to the levels in the earth's crust or pointed to metal depletion in the soil (EF<1). The high EFs for some heavy metals obtained in soil samples show that there is a considerable heavy metal pollution, which could be due to excessive use of fertilizers and pesticides used for agricultural or may be due to geogenic activities in the area. A contamination site poses significant environmental hazards for terrestrial and aquatic ecosystems. They are important sources of pollution and may results in ecotoxicological effects on terrestrial, groundwater and aquatic ecosystems.

Influence of interfacial water structure on surface protonation and ion adsorption at metal oxide surfaces

The overall goal of our research is to quantitatively link experimental and computational results to elucidate the atomic scale structure and dynamics of aqueous solutions at metal oxide surfaces and to link these atomistic interfacial properties with their macroscopic manifestations. Most of our efforts have been directed toward the isostructural oxides rutile (TiO_2) and cassitertite (SnO_2). The surfaces of these oxides (primarily the 110 face) have been probed by X-ray and neutron scattering, second harmonic generation, pH and zeta potential titrations, and ab initio and classical MD. In total, these techniques reveal a fairly consistent picture of interfacial water structure and cation binding. Directly bound water molecules are more tightly held at the cassiterite 110 surface than rutile 110 surface, and this difference helps account for the observed differences in surface protonation and ion binding exhibited by these oxides.

This research has been largely supported by the Division of Chemical Sciences, Geosciences and Biosciences, Office of Basic Energy Sciences, U.S. Deparment of Energy.

[5]National Oceanography Centre, University of Southampton
[6]Graduate School of Engineering, the University of Tokyo

A type of distal ridge-hotspot interaction is observed between the Central Indian Ridge (CIR) and the Réunion hotspot. The Rodrigues, Three Magi, and Gasitao Ridges clearly indicate topographic connection of CIR at 20°S and the Réunion hotspot track. However, northward geochemical enrichment of MORB along a segment of CIR at 18-20°S still remains a contentious issue, and is explained by an inflow of plume materials from the Réunion hotspot [1, 2] or ancient recycling process [3]. In order to define what factor regulates melt production along hotspot-influenced CIR, it is important to clarify extensive distribution of the plume-related or -unrelated MORB. We thus report Sr, Nd, and Pb isotopic compositions, with geochemical data set [4] and H_2O content, of fresh quenched glasses and basalts along CIR at 15-20°S.

Variation of isotopic compositions, Ba/Nb (Ba/La, Nb/Zr), and H_2O content are interpreted by mixing of three mantle endmembers: depleted MORB mantle (DMM); enriched source mantle for the Rodrigues Ridge [5] and intermediate series of the Mauritius Island [e.g. 6]; and enriched source mantle for the Gasitao Ridge [3]. These two enriched components are geochemically distinct from the Réunion plume. In fact, geochemical variation of MORB doesn't relate to the pollution of the upper mantle by the Réunion plume. Melting of the ancient recycled plate materials with a low melting point by the heat brought from the Réunion hotspot regulates voluminous magma production along CIR around 19°S. These results strongly support that small-scale plume-unrelated heterogeneity widespread in upper mantle [7].

A field method for the *in situ* determination of excess air and oxygen consumption in groundwater

L. MÄCHLER[1]*,[2], M.S. BRENNWALD[1] AND R. KIPFER[1,3]

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland. (*correspondence lars.maechler@eawag.ch)
[2]Institute of Geochemistry and Petrology, ETH Zürich, Switzerland
[3]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zürich, Switzerland

Measurements of dissolved gases play a crucial role in studying aquatic systems in the environment. An important example is the study of oxygen consumption in groundwater. For its determination, the input of oxygen into the water body must be estimated. This input not only depends on the temperature at recharge, but also on a common phenomenon called "excess air", i.e. the entrapment and dissolution of air bubbles into the water, caused by water-table fluctuations, that lead to an excess of dissolved gases in water relative to solubility equilibration.

Noble gases are chemically inert and therefore ideal tracers to study gas transport in groundwater and gas-exchange mechanism at the air-water boundary. The light noble gases (He, Ne) are sensitive indicators for excess air formation, while the heavy noble gases (Kr, Xe) are good proxies to reconstruct the physical conditions (i.e. temperature and salinity) of the water body during the last gas exchange with atmosphere. Furthermore, Ar has similar physical properties as O_2 and can be used to estimate the O_2-input into groundwater.

Common methods to measure noble-gas concentrations are all based on sampling the water in the field and transporting the sample to the laboratory, where the analysis is performed. However, changes in dissolved-gas concentration, in river-groundwater interactions, can occur within minutes/hours and cannot be studied using the conventional approaches for noble-gas analysis.

Therefore, we developed a membrane-inlet mass-spectrometric system to analyse *in situ* O_2, He, Ar, Kr, and CO_2 concentrations in groundwater in the field. The system is based on a commercially available quadrupole mass-spectrometer connected to a membrane-contactor module. We optimized the system to a measurement cycle of about 15 minutes in order to measure gas-concentration changes in groundwater occurring in response to river table fluctuations.

Natural Fe-Oxidizing Lagoon as a pretreatment in AMD remediation

FRANCISCO MACÍAS[1], CARLOS AYORA[2], MANUEL A. CARABALLO[1], JOSÉ MIGUEL NIETO[1] AND TOBIAS S. RÖTTING[3]

[1]Department of Geology, University of Huelva. Avda Fuerzas Armadas s/n 21071 Huelva, Spain
[2]Institute of Environmental Assessment and Water Research, CSIC, Jordi Girona 18, E-08034 Barcelona, Spain
[3]Department of Geotechnical Engineering and Geosciences, Technical University of Catalonia UPC-Barcelona Tech, Jordi Girona 1-3, D2-005b, E-08034 Barcelona, Spain

A concept called Natural Fe-Oxidizing Lagoon (NFOL) has been developed as an AMD pretreatment to enhance the iron oxidation and remotion processes involved in the natural attenuation of the AMD pollution, by the recreation, at a larger scale, of the iron terraces and pools observed in the Fe-rich AMD systems tipically found in the Iberian Pyrite Belt, SW Spain.

The NFOL comprises a first section formed by several preexisting iron terraces followed by a lagoon with a capacity of 100 m^3. The AMD pretreated in the NFOL, mean flow of 1.5 L/s, displayed a pH near 3 and contains 275 mg/L Fe (99% Fe (II)), 440 mg/L Zn, 3, 400 mg/L SO_4, 250 mg/L Ca, 100 mg/L Al, 18 mg/L Mn, 5 mg/L Cu and 0.1-1 mg/L As, Pb, Cr, Cd, Co and Ni. The NFOL was built following the recommendations offered by Piramid Consortium (2003) [1] according to surface area (m^2) and inflow (L/s) for lagoons and aerobic wetlands, but facing an inflow Fe concentration 5 times higher.

During the 6 months period of study, the NFOL pretreatment oxidized an average of 65% of the inflowing Fe (II) and precipitated a mean of 38% of total inflowing Fe. Additionally, over 80% of As in the inflow water was retained. Schwertmannite, subsequently aged to goethite, are the minerals responsible for the Fe (III) and As removal. The NFOL showed a mean Fe removal rate as high as 100 $g/m^2/day$, this value is one order of magnitude higher than the common standards for the efficient operation of a lagoon or an aerobic wetland in AMD environments.

NFOL pretreatment can be considered an efficient option to oxide and remove Fe and As prior to the treatment in the alkaline-based passive remediation system dispersed alkaline substrate (DAS) [2].

Skarn bearing clintonite from Kuhe-Dor, Shirkuh, Yazd Province, Iran

MOHAMMAD ALI MACKIZADEH[1] AND BATOUL TAGHIPOUR[2]

[1]Department of geology, faculty of sciences, Isfahan University, Isfahan, Iran (ma_mackizadeh@yahoo.com)
[2]Department of earth sciences, faculty of sciences, Shiraz University, Shiraz, Iran (taghipour@shirazu.ac.ir)

Shirkuh skarns (Kuhe Dor) are located in Cenozoic magmatic belt of Central Iran. There is a diorite intrusion in lower Cretaceous limestone's are detected:

Pyroxene – spinel – clintonite – phligopite – garnet – vesuvianite – calcite

Kuhe Dor skarn, is characteristic with rare mineral clintonite. Clintonite shows the transition processes from mg – skarn to ca – skarn and is formed in geologic environment with high X H_2O, low X CO_2 and depletion in SiO_2. Content mineral texture evidences show unstable boundaries when clintonite is in contact with spinel. Such petrographic evidence suggests the formation of clintonites at the expense of aluminum rich phase (spinel) is taken place. Skarn formation is started in peak temperature about 800°C.

Due to post Cretaceous intrusions, various marble-skarn mineralization are formed in eastern Shirkuh fault zone. Marbles are made the last zone in contact metamorphic aureole. Marbles are characterized by following mineral assemblages:

brucite+serpentine+forstrite+hydromagnesite+calcite+dolomite.

The marbles are undergone to pyroxene hornfels facies with temperature between 450°C to 600°C (p<2kb). There is three different stages in the formation of marbles; decarbonation, hydration and carbonation which revealed by mineral paragenes is and textures.

Adsorption of Cr(VI) on hydrous manganese oxide

A. MACLEOD* AND C.M. KORETSKY

Department of Geosciences, Western Michigan University, Kalamazoo, MI 49008, USA
(*correspondence: andrew.k.macleod@wmich.edu)

Hexavalent chromium is used in a variety of industrial processes. When released into the environment, it can be quite mobile and is highly toxic. Understanding and accurately predicting Cr(VI) speciation and transport is key to remediating contaminated sites. Cr(VI) forms chromate (CrO_4^{-2}) and bichromate ($HCrO_4^-$) anions in natural systems, which adsorb to various substrates at low pH and desorb at high pH. The goal of this study is to investigate sorption of Cr(VI) on hydrous manganese oxide (HMO) as a function of ionic strength, pH and pCO_2.

Hydrous manganese oxide was synthesized by alkametric titation and subsequently stored under 0 pCO_2 conditions. HMO was confirmed by XRD, and N_2-BET indicated a surface area of ~230 m^2/g. Experiments were conducted by adding 20 g/L HMO to a solution of $NaNO_3$ (0.001, 0.01 or 0.1 M) containing 10^{-5} M Cr(VI). The batch solution was titrated to an initial pH of 3, and by small additions of NaOH was titrated upwards to pH 10 with ~10 mL aliquots drawn off at ~0.8 pH intervals. These aliquots were further equilibrated for 24 hrs under varying pCO_2 (0, atmospheric or 2.5%), then centrifuged and the supernatant filtered and tested for Cr(VI) concentrations using UV-vis spectrophotometry or total Cr by ICP-OES.

Cr(VI) sorption decreases as pH increases, from nearly 95% (0.1 M $NaNO_3$) or 75% (0.001 M $NaNO_3$) sorbed at pH 3 to 0% sorbed at pH > 7. Cr(VI) sorption depends strongly on ionic strength, with ~50% of the Cr(VI) sorbed at pH~6 in 0.1 M $NaNO_3$, compared to ~4 in 0.001 M $NaNO_3$ experiments. In contrast, Cr(VI) sorption on HMO was nearly identical for a given ionic strength under atmospheric compared to elevated (2.5%) pCO_2 conditions.

Future work will focus on investigating possible competitive sorption interactions between carbonate and chromate at pCO_2 levels $\geq$5%, and on Cr(VI) adsorption under other Cr(VI) loadings and ionic strength conditions. The data will be used to parameterize a surface complexation model, so that results can be readily incorporated into reactive transport models. This will further advance our predictive understanding of Cr(VI) mobility and speciation in natural environments.

Fractionation of HSE in the Tonga arc: Flux melting of a depleted source

C.G. MACPHERSON[1]*, C.W. DALE[1], D.G. PEARSON[1,2], S.J. HAMMOND[3] AND R.J. ARCULUS[4]

[1]Dept. of Earth Sciences, Durham University, DH1 3LE, UK (*correspondence: colin.macpherson@durham.ac.uk)
[2]Dept. for Earth & Atmos Sci, University of Alberta, Edmonton, Canada
[3]Dept. of Earth & Environ. Sciences, Open University, UK
[4]Dept. of Earth & Marine Sciences, ANU, Australia

Highly siderophile element concentrations (Os, Ir, Ru, Pt, Pd, Re) have been determined for a suite of fresh, submarine mafic lavas from the Tonga arc front and the nascent Fonualei backarc spreading centre (FSC). The highly depleted Tongan mantle wedge combined with a high fluid flux is thought to have produced boninitic magmas at several arc and FSC locations. As such, this arc system provides an opportunity to assess the fluid mobility of PGE and to investigate the effects of fluid-induced melting and prior melt depletion on PGE behaviour during both mantle melting and magma evolution.

Tongan lavas display extreme fractionation of the platinum-group PGE (P-PGE) from the iridium-group PGE (I-PGE) which is inherited at source and is significantly greater than MORB. All of the PGE display low bulk compatibility during magma evolution, reflecting sulphide undersaturation. Rather than source PPGE enrichment by slab fluids, the fractionation of the PPGE from the IPGE can be explained by relatively low-temperature yet high-degree melting of fluid-fluxed depleted mantle. Prior melt depletion increases the likelihood of complete consumption of sulphide in the source during melting, which typically produces melts with high concentrations of all the PGE. In the Tonga arc, however, the high PPGE contents can be explained by the exhaustion of sulphide liquid in the source [e.g. 1], while the retention of the IPGE requires residual monosulphide solid solution (mss) or platinum-group minerals. Complete sulphide exhaustion is likely given high aggregate degrees of partial melting (≥25%) of a DMM source which is sufficiently hot to melt mss. If so, the presence of laurite (Ru-Os-(Ir) sulphide) or IPGE alloys may explain the retention of IPGE in the source residue.

Flux-melting investigated here and a previously proposed PGE flux from the slab indicate that subduction zones are undoubtedly an environment where significant fractionation of Re and Pt from Os occurs, further indicating that the core contribution hypothesis to explain the coupled enrichments of ^{186}Os and ^{187}Os may be non-unique.

New insights into San Carlos mantle xenoliths using iron isotopes

C.A. MACRIS[1]*, E.D.YOUNG[1,2], C.E. MANNING[1] AND E.A. SCHAUBLE[1]

[1]Department of Earth and Space Sciences, UCLA, CA (*correspondence: cmacris@ucla.edu)
[2]Institute of Geophysics and Planetary Physics, UCLA, CA

Iron isotopic compositions of mantle minerals can provide powerful tracers for geochemical processes in the mantle, such as partial melting, metasomatism, and oxidation. Predictions of equilibrium fractionation from theory and Mössbauer data conflict, making the meaning of Fe isotope fractionation in the mantle uncertain. To address this, we studied inter-mineral iron isotopic fractionation of minerals from five distinct mantle-xenolith lithologies from San Carlos, Arizona. The samples represent a broad range of mineral modes and include a clinopyroxenite, a websterite, a lherzolite, a harzburgite, and a dunite. All samples except for the websterite are Group I inclusions, which are typically rich in Mg and Cr, and consist of mainly olivine-rich rocks. Group II inclusions, represented here by the websterite, are enriched in Al and Ti, and commonly contain more clinopyroxene than orthopyroxene [1]. Each xenolith exhibits Fe-isotopic variation between minerals in a single sample, and between samples. In all cases where spinel and olivine coexist in a sample, the $^{57}Fe/^{54}Fe$ of spinel is greater than that of the corresponding olivine, agreeing with predictions of equilibrium fractionation from theory. $^{57}Fe/^{54}Fe$ values of clinopyroxenes and orthopyroxenes from the xenoliths show no clear systematic differences. Plots of $\delta^{57}Fe$ of the pyroxenes versus $\delta^{57}Fe$ of the other minerals show that the pyroxenes underwent some open-system processes and are not in equilibrium with the coexisting olivine and spinel. We interpret this as a result of varying degrees of disequilibration in the samples due to late stage open-system processes, such as metasomatism or partial melting, affecting the pyroxenes only. A strongly linear reverse correlation between olivine content and bulk rock $^{57}Fe/^{54}Fe$ was found for all samples except the websterite (the only type II xenolith measured). The strong linear relationship among Group I samples, and deviation from the trend in websterite, suggests Fe isotope systematics can be added to the list of differences used to distinguish between Group I and Group II xenoliths.

Soluble Mn(III), Mn(II) and total Mn in sediment porewaters: Soluble Mn(III) is ubiquitous

ANDREW S. MADISON[1], ALFONSO MUCCI[2], BJØRN SUNDBY[2], BRADLEY M. TEBO[3] AND GEORGE W. LUTHER, III[1]*

[1]School of Marine Science and Policy, College of Earth, Ocean and Environment, University of Delaware, Lewes, DE 19958, USA (*correspondence: luther@udel.edu) (amadison@udel.edu)
[2]Department of Earth and Planetary Sciences, McGill University, Montreal, QC., Canada H3A 2A7 (alfonso.mucci@mcgill.ca, bjorn_sundby@uqar.ca)
[3]Division of Environmental and Biomolecular Systems, Oregon Health and Science University, Beaverton, OR 97006, USA (tebo@ebs.ogi.edu)

Recent research shows that soluble manganese(III) or $[Mn(III)]_{aq}$, that material which passes through a 0.2 μm filter, exists in natural waters such as the Black Sea, the Baltic Sea and Chesapeake Bay and can constitute a large fraction of the dissolved Mn pool at the oxic/anoxic interface. Recently Madison *et al*. [1] have reported a direct and accurate spectrophotometric method to measure $[Mn(III)]_{aq}$ in sediment porewaters. The method is capable of rapid and simultaneous determination of $[Mn(III)]_{aq}$, $[Mn(II)]_{aq}$, and total soluble Mn. This method was successfully applied to the determination of all soluble Mn species in sediment porewaters of the Lower St. Lawrence Estuary collected during cruises in 2009 and 2010 and in Delaware salt marsh sediments. In all samples, $[Mn(III)]_{aq}$ accounts for up to 80% of the total dissolved Mn pool in the upper oxic and suboxic sediments with concentrations ranging from the detection limit of 50 nM to 80 μM. Data will be presented that highlight the role $[Mn(III)]_{aq}$ plays in Mn cycling and how it can impact several important geochemical cycles.

We present He and Ne isotopic data from subaerial and submarine samples collected along the Terceira Rift. Graciosa Island as well as the western end of S. Miguel Island and D. João de Castro Bank display $^4He/^3He$ ratios similar to those observed along the MAR segments located to the north of the Azores Triple Junction area. Conversely, samples from the south Hirondelle Basin display a $^4He/^3He$ ratio similar to that of the MAR segments located to the south of the Azores Plateau. The Terceira Rift is thus characterized by the mingling of two different mantle domains referred as 'Eurasia' and 'Nubia' type. He and Ne systematics shows that the influence of the relatively primitive source sampled by the Azores plume can be followed along the Terceira Rift from the Graciosa Island towards the south Hirondelle Basin. Moreover, samples from the south Hirondelle Basin, D. João de Castro Bank and Graciosa Island cannot be explained by the same hyperbolic mixing model that encloses Terceira data.

SHRIMP studies of the uranium oxide-based U/Pb SIMS calibration

C.W. MAGEE

Australian Scientific Instruments 111/113 Gladstone St. Fyshwick ACT 2609 Australia (cwmagee@gmail.com)

Since the earliest days of SIMS U/Pb geochronology, it has been necessary to correct for variations in the relative ionization efficiency of Pb and U. Extensive research during the twentieth century has resulted in the empirical derivation of calibration cures based on observed relationships between Pb/U and UO_x/U, where x is equal to 1 or 2. This calibration is the precision-limiting step in SIMS U-Pb data reduction.

Both oxygen activity and secondary ion energy have been proposed asmachanisms for measured Pb/U variation. For example, the extreme sensitivity of Pb ionization to oxygen flooding in some SIMS instruments suggests that oxygen activity at the sample surface may important to relative Pb and U ionization. As is shown in figure 1, this is consistent with the ability to use a variety of Zr, Hf, Th, or U oxide pairs as a rough calibration, with about ~3% accuracy and precision.

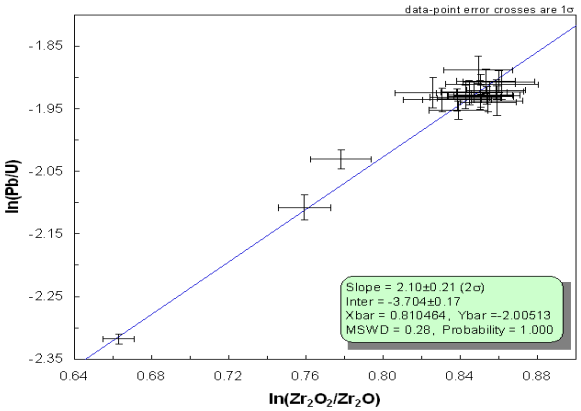

Figure 1: Arbitrary oxide calibration of SHRIMP U/Pb data. This and similar Hf and Th-based calibrations yield less scatter than raw Pb/U or Pb/UO_2.

Additional effects beyond fO_2 must be responsible for the superior performance of UO_x based calibrations compared to randomly selected metal oxide pairs. While the effect of secondary ion energy has been discussed previously, the effect of primary ion energy is less well studied. Primary energies as low is 2.5kV have been investigated to determine the change in calibration due to changes in Pb ionization efficiency, secondary ion energy dispersion, and uranium oxide speciation.

Reconstructing ancient landscapes: Molecular insights to spatial patterns in ecosystems and water

CLAYTON R. MAGILL[1]*, GAIL M ASHLEY[2] AND KATHERINE H. FREEMAN[1]

[1]Pennsylvania State University, University Park PA 16802 (*correspondence: clayton.magill@psu.edu)
[2]Rutgers University, Piscataway NJ 08854

Water shapes vegetation and natural landscapes at different spatial and temporal scales – defining habitats, selective pressures and the evolution of fauna. Hydroclimate may have catalyzed morphologic and behavioural adaptations in early humans through changing spatial patterns in ecosystem structure. These can be evaluated using molecular and isotopic 'landscape biomarkers' lending insights to ancient habitats and providing means to test links between evolution and environment. We apply these to landscapes at spatial scales of human habitation (~1 km^2) from paleosol and lake deposits at Olduvai Gorge (*ca*. 1.845 million years ago).

Biomarker signatures reveal heterogeneity in sources and composition of sedimentary organic matter. Near to a freshwater spring (tufa) deposit, algae (heptadecane [nC_{17}]) and sedge (*n*-alkylresorcinol [*n*AR]) biomarkers are associated with positive ratios between the lignin monomers syringic acid/vanillic acid (S/V) and *p*-coumaric acid/vanillic acid (C/V). In contrast, sediments associated with early human remains contain nominal nC_{17}, *n*AR and C/V, instead showing high plant-wax (hentriacontane [nC_{31}]) abundances. Plant-wax biomarkers $\delta^{13}C$ values range nearly 14‰ across the 1 km paleosol transect, between sediments associated with early human remains (-33.0‰) and grass phytoliths (-19.3‰).

Our data indicate pronounced heterogeneity in this early human habitat, consistent with geochemical and faunal data.[1] Near the spring deposit, biomarkers suggest a shallow wetland environment with emergent vegetation. Nearby, depleted $\delta^{13}C_{31}$ values and nominal C/V indicate a shrubby or wooded environment. This area is proximal to sites with $\delta^{13}C_{31}$ and C/V ratios that indicate grassland. This study focuses on a time slice with dominant grassland (C_4) signals captured in lake sediments. In this dry time, woody and wetland vegetation drew early humans[2] to their resources.

Lithium – Light metallic traveller through crusts of the Earth and beyond

TOMÁŠ MAGNA[1,2]

[1]Universität Münster, Germany (tomas.magna@uni-muenster.de)
[2]Czech Geological Survey, Prague, Czech Republic (tomas.magna@geology.cz)

Lithium isotopes have become an increasingly used tool for unraveling metasomatic processes in the mantle, extent and duration of fluid transfer in subduction settings or alteration of oceanic crust, for example. Only recently have Li isotopes been employed to study the magmatic evolution, metamorphism, alteration and weathering of continental crust. This is rather surprising considering the large economic potential of Li deposited in the crust and its utility in modern technologies. Available data suggest a dominant control of protolith heterogeneities and modal mineralogy for bulk terrestrial crust, superimposed on long-term secular evolution of Li in the continental crust as a response to weathering and recycling through subduction zones.

For the Moon, the limited dataset for highland crust shows a dramatic difference between mafic lower crust and calcic plagioclase-dominated rocks of the upper anorthositic layer, with the latter showing extreme net Li depletions coupled with high δ^7Li that extends far beyond the range of mare basalts. Whether plagioclase segregation from lunar magma ocean exerts a major control on crust–mantle Li isotope fractionation remains to be investigated.

That as yet unsampled evolved (crustal?) reservoirs may exist on Mars can be deduced from the nakhlite lava sequence as well as from two distinctive lithologies found in Zagami and having different Li (and also Ca) systematics. Yet, this finding is still consistent with linear Li-δ^7Li relationship recorded for the enriched shergotittes, thought to contain larger proportion of evolved crustal material among shergottites. These data point toward a low-Li high-δ^7Li reservoir that may have once existed early in Martian history. On the contrary, bulk Martian crust appears basalt-andesitic in composition, leaving granitic rocks subordinate although, on Earth, granitic rocks develop distinctive Li fingerprints as a consequence of complete geological cycles. This applies perhaps to 4 Vesta too despite local exposures of highly evolved terrains.

It may well be that juvenile crust in general develops a uniform Li isotope signature as observed in Iceland, for example, with invariant δ^7Li over a large range of chemical compositions. Only with ample time would Li become enriched and fractionated in the crust relative to the mantle on a planetary scale.

Lunar crust consists of ferroan anorthosites (~80%) and Mg-rich suite lithologies (~20%). It represents products from the most ancient lunar magmatic events (>4.1 Gyr [1]) and is accepted to have formed through plagioclase flotation on the lunar magma ocean (LMO) [2], from which significant amounts of incompatible elements (e.g. K, Th and U) were concentrated in the residual LMO melt (KREEP). Lithium has received little attention [3–6] despite its utility in tracking the history of the terrestrial crust [7–9].

New Li data show that anorthosites are the most Li-depleted lunar material known to date with <1 ppm in pristine samples. This is consistent with [6] and opposite to Earth's continental crust [7, 8] and may in part be explained by limited Li partitioning into plagioclase ($K_d^{plg\text{-}melt}$ ~0.2, [10]) from progressively crystallizing LMO for which ~3–4 ppm Li would thus be estimated. This appears higher than Li content of the Earth's mantle [3, 4]; the nature of such a difference is currently unclear but it could perhaps reflect a lack of net Li depletion before the accretion of the Moon [11]. Anorthosites show uniformly high δ^7Li>5.7‰ (up to 9.4‰), distinct from mare basalts [3–5] as well as the Earth's continental crust [7, 8]. δ^7Li of norite 77215 with a KREEP affinity is resolved from other KREEP-rich lithologies [5]. The tight positive correlation of δ^7Li with Na across the whole suite may reflect fractional crystallization of clinopyroxene appearing on the liquidus shortly after plagioclase during LMO crystallization. Overall, the Li data suggest (i) rapid plagioclase segregation without further re-equilibration with remaining LMO (through equilibrium Li isotope fractionation) and (ii) little subsequent modification of the lunar crust without an influence from younger magmatic events.

Surface and subsurface geochemical monitoring of an EOR-CO_2 field: Buracica, Brazil

C. MAGNIER[1], V. ROUCHON[1], C. BANDEIRA[2], R. GONÇALVES[2], D. MILLER[2] AND R. DINO[2]

[1]IFP Énergies nouvelles,1-4 avenue du bois Préau, 92852 Rueil Malmaison, France (caroline.magnier@ifpen.fr)
[2]PETROBRAS-CENPES/PDEXP Rua Horácio Macedo n.950, Cidade Universitária, Ilha do Fundão, Rio de Janeiro, Brasil, 21941-915

We present a surface and subsurface geochemical survey of the Buracica EOR-CO_2 field on-shore Brazil. A methodology coupling the stable isotopes of carbon with the noble gases was adopted to investigate the adequacy of a geochemical monitoring to track deep fluid leakage at the surface, with a scope of future application in the developping CCS industry. Three campaigns of CO_2 flux and concentration in soils were performed to understand the CO_2 variability across the field. The distribution of the CO_2 soil contents between 0.8 to 14 % is correlated with the proprieties of the soil, with a first order topographic control. These results, together with a $\delta^{13}C_{CO2}$ between -15 and -23 ‰, suggest that the bulk of the soil CO_2 flux at Buracica is biological.

The gas injected and produced at numerous wells across the field showed a great spatial and somewhat temporal heterogeneity with respect to molecular, $\delta^{13}C_{CO2}$ and noble gas compositions. The injected CO_2 is characterized by $\delta^{13}C_{CO2}$ near -31 ‰ and a peculiar noble gas composition enriched in Kr with respect to atmospheric values, while being depleted in the lighter noble gases. The heterogeneity of the gas produced from the reservoir is a consequence of the EOR-induced sweeping of the indigenous fluids by the injected CO_2, producing a heterogeneous mixing controlled by 1) the production scheme and 2) the distribution in reservoir permeability. In the light of the $\delta^{13}C_{CO2}$ found in the reservoir (from -36 to +6 ‰), the stable isotopic composition of carbon revealed insufficient to track CO_2 leaks at the surface. We demonstrate how noble gases may be powerful leak discriminators, even for CO_2 abundances in soils in the bottom range of the biological baseline (~1 %). The results presented in this study show the potentiality of geochemical monitoring techniques, involving stable isotopes and noble gases at the reservoir and soil levels, for tracing CO_2 in CCS and EOR projects.

Geology and mineralogy of Bidakhavid indusrial soil

A. MAHDAVI AND B. TAGHIPOUR

Department of earth sciences, student of sciences, shiraz university, shiraz, Iran (amirmahdavi1984@yahoo.com, taghipour@shirazu.ac.ir)

Bidakhavid industrial soil is located 70 km southwester of ayzd city, central Iran. this area is a part of Cenozoeic magmatic belt. According the geological map of geology survey of Iran (1:250000 map of Yazd, Iran).

Bidakhavide feldspar mine is near the Shir-Kuh massive intrusion and Jamal limestone formation with Jurassic age, Darreh-Zereshk is the main fault in this area.

Petrologicaly, predominant rock is sandstone in this area. with attention the Folk classification this sandstones are including: litarenite, arkosic arenite, arenite and sublitarenite. Quartz, alkali-feldspar and jarosite are the main minerals and biotite, muscovite and hematite are minor minerals.

X-ray diffractometery results show, quartz, albite, orthoclase, jarosite and clay minerals are the main minerals in the Biakhavid sandstones (Fig. 1).

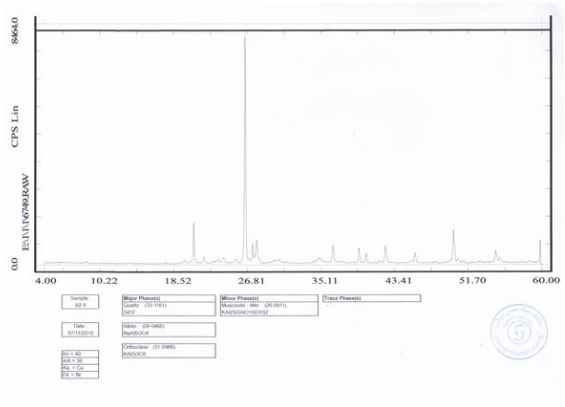

Figure 1: sample figures of XRD diagram

Because of weak roundness structure and poorly sorted of sandstones grain it is obvious that, parent rock is near the Biakhavid mine. According to fild evidence, petrography and mineralogy studies sandstones composition is similar to the Shir-Kuh granite. So we can conclude that Shi-kuh intrusion has an important role for the providing of primary material for the industrial soil in the Biakhavid area. Also it must be noted that Darreh-Zereshk fault movements may have supported fluids for alteration of Shir-Kuh granite.

The role of fluid residence times in controlling the chemical fluxes and isotopic compositions of rivers

K. MAHER*, A. SCHNEIDER-MOR AND J.L. OSTER

Dept. of Geological and Environmental Sciences, Stanford University, Stanford, CA, 94305, USA (*correspondence: kmaher@stanford.edu)

The role of fluid residence times and catchment length scales in controlling the chemical composition of rivers is evaluated by comparing numerical simulations and scaling arguments to concentration-discharge data from small catchments and global rivers. The analysis suggests that the actual residence time of fluid relative to the residence time required to approach chemical equilibrium is likely a dominant control on solute fluxes. Catchments that show little variability in concentration with discharge (or 'chemostatic behavior') likely have average fluid residence times that exceed the time required to reach chemical equilibrium. Conversely, decreases in concentration with increasing discharge are explained by average residence times shorter than required to approach equilibrium, resulting in dilution. Increases in runoff associated with climate change can result in either a proportional increase in weathering fluxes, or a plateau in weathering fluxes if the fluid residence times become shorter than the time required for equilibrium. The same theoretical considerations can be applied to interpret the behavior of Sr and U isotopes in rivers. The extent of isotopic equilibrium and the final isotopic composition reflected by river waters will also depend on the ratio of the fluid residence time to the time required to reach isotopic equilibrium, where the later varies widely across isotopic systems and weathering environments.

This framework also has implications for weathering rates in the past. As a consequence of the thermodynamic and hydrologic restrictions on the amount of weathering outlined above, global solute fluxes may depend more strongly on the geometry, relief, runoff and permeability of basins then on temperature and rates of erosion. If fluid residence times and catchment length scales are a dominant control on weathering fluxes, the chemistry and isotopic composition of different rivers could vary entirely as a function of the nature subsurface flow paths and the composition of the system at chemical equilibrium, which is complex to predict and strongly coupled to biological processes.

Latitudinal changes in sea surface temperature and salinity over the Eastern Arabian Sea during the Last Glacial Maximum through Holocene

B.S. MAHESH* AND V.K. BANAKAR

National Institute of Oceanography (CSIR), Goa, India.
(*correspondence: maheshsbadanal@gmail.com)

Three sediment cores dated by radiocarbon spanning the last ~35 kyr have been utilized to reconstruct the past hydrography in the Eastern Arabian Sea (EAS). These three sediment cores were collected in a North-South transect where significant hydrographic differences occur between their locations. The EAS receives significant amount of overhead precipitation as it borders the orographic barrier all along the western margin of peninsular India due to Deccan Mountains. As a result the sea surface temperature (SST) and surface salinity (salinity) in the EAS respond to subtle changes in the intensity of the monsoons. Here we reconstruct the SST and salinity from by the paired measurement of $\delta^{18}O$ and SST utilizing *Globigerinoides sacculifer*, an upper mixed layer dwelling foraminifera. The last glacial maximum (LGM) could be defined as the heaviest $\delta^{18}O_{G.sacculifer}$ (-0.07±0.08‰) and is evident between 23 – 15 ka BP. The $\delta^{18}O_{G.sacculifer}$ shift between the LGM and Holocene in all the three sediment cores is ~ 2‰. The SSTs show an overall warming of 2°C from the LGM to Holocene (28°C to 30°C). However, coldest SSTs are observed prior to LGM (~27 ka BP) in all the three records. The salinity is higher (~ 38 psu) throughout most of the last glacial period (32.5 – 15 ka BP) compared to the salinity during the Holocene (~36 psu). During the LGM, the North-South salinity gradient was higher than that of modern gradient. The increased North-South salinity gradient during LGM may suggest not only reduced summer monsoons but also relatively intensified winter monsoons. The higher salinity together with generally lower SSTs indicates sustained weaker summer or stronger winter monsoons. The deglacial warming is associated with rapid reorganization of monsoons and is reflected in decreased salinity to a modern level of ~ 36.5 psu within a period of ~ 5 kyr, which indicates process of intensification of summer monsoons during cold to warm climate transition.

Adsorption behaviour of copper in natural composite sedimentary materials

FLÁVIA MAIA* AND MÁRIO A. GONÇALVES

Dep. Geologia and CREMINER/LA-ISR, Fac. Ciências da Universidade de Lisboa, Campo Grande, 1749-016, Lisboa, Portugal,
(*correspondence: flavia.maia@amphos21.com)

The understanding of adsorption processes is important both to evaluate the potential hazard related to contaminants as well as to minimize their impact on the environment. The aim of this work is to carry out comprehensive adsorption experiments using composite natural materials corresponding to matrices of continental alluvial deposits (so called raña deposits) from Macedo de Cavaleiros in the NE of Portugal. These materials were considered to evaluate their capacity for the attenuation of metal dispersion, as well as for the retention of low to intermediate level radioactive waste. The main minerals present in the matrices include quartz, montmorillonite, illite and kaolinite, with abundant poorly crystallized iron oxyhydroxides. The matrices also contain substantial amounts of organic matter.

A protocol was developed to characterise the adsorption behaviour of copper onto the main constituents of the natural matrices (clay minerals, organic matter, and iron oxyhydroxides). They were designed as to reflect the removal efficiency of copper by the various constituents while maintaining the structural integrity of the clay minerals.

The adsorption behaviour of copper has been evaluated by carrying out batch experiments with Cu^{2+} on a series of samples without previous treatment, removal of organic matter, removal of Fe oxyhydroxides, and removal of both organic matter and Fe oxyhydroxides in a range of pH between 4 and 6.

The results show that the adsorption capacity of these materials is rather limitted but slightly enhanced as the pH gets higher. However, the pre-treatments had some influence on the enhancement of the adsorption results, especially Fe oxyhydroxides and organic matter. The low equilibrium pH of these samples was shown to be derived from the presence of organic matter which on itself is also likely to alter the adsorption capacity of these matrices.

Ptychography: A powerful X-ray imaging tool

A.M. MAIDEN[1]*, G.R. MORRISON[2], B. KAULICH[3], A. GIANONCELLI[3], G. KAKONYI[1] AND J.M. RODENBURG[1]

[1]Kroto Research Institute, University of Sheffield, Broad Lane, Sheffield, S3 7HQ, UK (*correspondence: a.maiden@sheffield.ac.uk)
[2]King's College London, Dept. of Physics, Strand, London, WC2R 2LS, UK (graeme.morrison@kcl.ac.uk)
[3]ELETTRA, S.S. 14, km 163.5 in Area Science Park, I-34012 Trieste, Italy (burkhard.kaulich / alessandra.gianoncelli@elettra.trieste.it)

Ptychography is a form of diffractive imaging in which overlapping regions of a specimen are illuminated by coherent radiation, the resulting scatter patterns recorded, and an image formed using iterative algorithms [1, 2]. The method is currently undergoing a renaissance as a tool for X-ray imaging [3, 4], since its genesis as an electron microscopy technique in the late 1960s.

The principal benefit of ptychography is its experimental simplicity: no focussing optics are required in a ptychographic experiment, with resolution being limited only by the angular width of the recorded scatter patterns. Despite being successfully demonstrated only recently in the X-ray regime, ptychographic imaging has advanced to a stage where sub 50nm resolution is obtainable using hard X-rays [5]. Ptychography also produces quantitative phase images that in the x-ray regime can be used to measure electron densities accurately. By varying the beam energy ptychography can provide chemical contrast and it can be combined very effectively with tomography to produce three-dimensional images [6].

Here we will introduce the ptychographic method and describe how it works. We will discuss the merits and drawbacks of the technique relative to more established methods such as Scanning Transmission X-ray Microscopy (STXM), and we will present results from recent soft X-ray experiments at the ELETTRA synchrotron in Trieste, where ptychography was used to image iron nanoparticles within cells.

Detailed field relations of pre-3.85 Ga zircon bearing metasediments from southern Montana (USA)

A.C. MAIER*, N.L. CATES AND S.J. MOJZSIS

University of Colorado, Department of Geological Sciences, 2200 Colorado Avenue, Boulder, CO 80309-0399 USA (*correspondence: analisa.maier@colorado.edu)

Paleoarchean fuchsitic detrital quartzites in the Bearthtooth Mountains (Wyoming craton, southern Montana, USA) are one of the few documented localities that host Hadean (>3.85 Ga) detrital zircons [1]. Our high-resolution mapping (1:250) revealed several other rock-types in the area that include intrusive granitoids and mafic dikes, banded iron-formation (BIF), paragneisses, and a possible meta-conglomerate. Zircon geochronology from quartzites and paragneisses [1; this study] reveals several age populations: >3.6-4.0 Ga; 3.4-3.6 Ga; 3.2-3.3 Ga; 3.0-3.1 Ga; and 2.7-2.8 Ga. Some of these are coincident with known metamorphic events [2] responsible for discordant ages seen in much of the data. We find that there is no obvious correlation between degree of discordance and zircon-bearing lithology.

Zirconiferous quartzites are Cr- (40-360 ppm) and SiO_2-(93-95 wt.%) rich with low Zr (37-81 ppm). Paragneisses resemble the quartzites (Cr: 230 ppm), but with less SiO_2 (75 wt.%) and more Al_2O_3 (14 wt.%) and high Zr (348 ppm); paragneisses and quartzites follow expected weathering trends for a mixed granitoid + mafic source [3]. A candidate conglomerate (SiO_2 77 wt.%; Al_2O_3 14 wt.%) and (intrusive) granitoids (SiO_2 73 wt.%; Al_2O_3 15 wt.%) resemble the paragneisses, but the conglomerate has 70 ppm Cr and 49 ppm Zr, whereas the intrusive felsite body is Cr-poor (<D.L.), with typical orthogneissic Zr (167 ppm). The BIF is Fe_2O_3-rich (51 wt.%) with low SiO_2 (44 wt.%) and minor Al_2O_3 (3 wt.%), Cr (50 ppm) and Zr (26 ppm) pointing to a detrital component; multi-element plots compared to other BIFs and normalized to NASC shows a similar positive slope, but with no Eu anomaly and low (but still superchondritic) Y/Ho (28.7). In PM-normalized spider diagrams, detrital and igneous 'felsic' lithologies show enriched LILE, negative Nb anomalies, with depletions in Sr and Ti.

Ancient detrital/xenocrystic zircons confirm that older crustal components existed in the area, suggestive of a genetic link between the Beartooth quartzites and the geology of the Western Slave Province [1] and perhaps the Thelon Basin in Nunavut [3] and the Assean Lake Complex (Manitoba; [4]).

Gold contents of the cratonic sub-continental lithospheric mantle: Implications for orogenic gold deposits

W.D. MAIER[1]*, A KONTINEN[2] AND I. MCDONALD[3]

[1]University of Oulu, Oulu, 90014, Finland (*correspondence: wolfgang.maier@oulu.fi)
[2]Geological Survey of Finland, Kuopio, 70211, Finland
[3]Cardiff University, Cardiff, CF10 3YE, Uk

The occurence of many orogenic gold deposits within Archaean cratons suggests that the gold could be sourced from the sub-cratonic lithospheric mantle. The model has been difficult to test because the available cratonic mantle samples consist almost entirely of kimberlite-borne xenoliths, few of which have been analysed for Au. Furthermore, Au levels in mantle rocks tend to be close to the detection limit of current analytical methods. In the present study we have determined Au contents in 81 kimberlite borne peridotite and MARID mantle samples from the southern Africa, using ICP-MS after Ni-sulfide fire assay and Te co-precipitation at Cardiff University. The blank contained 0.11±0.03Au, resulting in a procedural detection limit of 0.1 ppb Au and a quantification limit of 0.33 ppb Au. On average, the Kaapvaal xenoliths contain 1.09 ppb Au, broadly in the range of primitive upper mantle estimates. In order to exclude the possibility that the xenoliths could be non-representative of the SCLM we have also analysed Au in 24 samples of the Jormua massif in Finland, interpreted to represent Archean cratonic SCLM that was obducted onto the Karelian craton margin at ca 1.95 Ga. The average Au content of 23 Jormua samples is 1.01 ppb, with one additional highly talc-carbonate replaced sample containing more than 100 ppb Au.

Our samples, as well as many other samples from non-cratonic lithospheric mantle, show high primitive-mantle normalized Au/Pd ratios, due to pervasive Pd depletion.

We infer that introduction of Au during contamination with host kimberlite is unlikely to account for the observed positive anomalies. One could alternatively suggest that Au is stabilized in refractory alloys during mantle melting, based on the observation that Au does not enter into mantle sulfides. However, the Au enrichment in magmatic sulfide ores clearly indicates that Au behaves incompatible during mantle melting, consistent with the high D values of Au with regard to sulphide liquid (D ~ 1000, Barnes and Lightfoot, 2005). The formation of distinct Au-rich phases associated with sulfides can be explained by the fact that the ionic radius of Au is too large to fit into the structure of mss or iss. As the solubility of Au in basaltic magmas is >10 ppm, Au will be released to the magma during partial melting of the mantle. In conclusion, our preferred model is that the relative Au enrichment in the cratonic SCLM formed through metasomatic introduction of Au, implying mobility of Au in the mantle. This is consistent with derivation of at least some orogenic gold from the SCLM.

Local structure of poorly ordered nanosized iron oxides. Implications for contaminants scavenging

F. MAILLOT[1], G. MORIN[1], C. CASIOT[2], Y. WANG[1], D. BONNIN[3], C. CHANEAC[4] AND G. CALAS[1]

[1]IMPMC, CNRS – UPMC, Paris, France
[2]Hydrosciences, CNRS-Universités Montpellier I and II-IRD, Montpellier, France
[3]Laboratoire de Physique et d'Etude des Matériaux, ESPCI ParisTech, Paris, France
[4]CMCP, CNRS – UPMC, Paris, France

Iron (oxyhydr)oxides nanoparticles are ubiquitous in natural environments (soils, rivers, sediments…), as well as in impacted systems such as acid mine drainage, where they strongly impact the mobility of most trace elements. Among these (oxyhydr)oxides, the poorly crystalline minerals ferrihydrite and schwertmannite are the most efficient in the scavenging of toxic solutes such as arsenic, either via sorption or coprecipitation mechanisms. The knowledge of the structure of these compounds is a prerequisite to the understanding of their surface reactivity. However, due to their nanoparticulate nature and to the lack of well-crystallized isomorph compounds, their structure remains poorly constrained. Recent X-ray scattering studies [1, 2] have yield unique information on the medium-range order in these materials. However, for such disordered nanomaterials, scattering techniques that yield average periodic structural models may fail at accurately describing the local coordination sphere of cations. To overcome this difficulty, we have used Extended X-ray absorption fine structure (EXAFS) spectroscopy to determine the local coordination and arrangement of cations in these poorly ordered solids. Using EXAFS data recorded at liquid helium temperature over a wide energy range, we will particularly discuss the presence of tetrahedral iron in ferrihydrite [3], and the structural specificities of natural and synthetic schwertmannites coprecipitated in the presence of arsenic. The structural information derived from these data will be compared with existing structural models, and yield clues for better understanding the reactivity of these materials.

Inverse estimates of the air-sea flux of carbon using surface pCO_2 measurements

JOSEPH MAJKUT AND JORGE L. SARMIENTO

Princeton University, Princeton, NJ, USA 08544
(*correspondence: jmajkut@princeton.edu)

A new method of estimating the historical pCO_2 at the sea-surface is used to estimate the air-sea CO_2 flux and the time rate of change of ΔpCO_2 from 1980 through 2010. Using a large surface pCO_2 measurement database [1], which despite its size sparsely represents much of the ocean over the past 40 years, we find optimal estimates of the pCO_2 using information from global circulation models and a simplified model of pCO_2 in the surface water. The simplified model describes the time evolution of surface pCO_2 on a 5x4 ° grid according to

$$pCO_2(t) = At + B + C \cdot pCO_2'(t).$$

The third term, pCO_2' (t), represents the interannually-varying seasonal cycle and other interannual variations in pCO_2 diagnosed from a series of simulations using the GFDL MOM4.1 ocean general circulation model and the BLING biogeochemistry model (OGCM). For each grid box, we estimate the model parameters A, B and C by evaluating likelihood against the data using a bayesian markov chain monte carlo technique (MCMC) [2].

The resulting pCO_2 trends and diagnosed fluxes are provocative. The method indicates an ocean sink for anthropogenic carbon of 2.7 $\pm$.15 Pg C for the year 2000. The estimated annual rate of change of the ΔpCO_2, used as an indicator of flux trends, shows where the ocean is changing at a rate significantly different than the atmosphere. The implied air-sea carbon flux is increasing over much of the ocean, with exceptions in the Northern Atlantic and Pacific basins.

Projections and hindcasts of the ocean carbon sink that are based on OGCM simulations rely on the response of the OGCM to climate change. The framework proposed here allows us to evaluate that modeled response, of the carbon cycle to climate change, against the observations. We present regional analysis indicating whether or not modeled trends and feedbacks are occuring in the real earth system.

Distinguish the mineralized factors in anomaly data

In the current research, the abilities of the discriminant analysis in distinguishing anomaly from background [1, 2, 3] for soil lithogeochemical samples in porphyry Cu-Au- Dalli area (Iran) was shown. A group of 163 samples with sample space of 50*50 m^2 were used. According to the results (Fig. 1), three populations were separated in data set (Fig. 1a). The second group (code 2) is related to the anomalous sub-population, the first group (code 1) is considered as mixture of background and anomalous sub-population and the zero group (code 0) is shown the background sub-population. In the anomalous sub-population, the elements of Au and Cu (Fig. 1b) are introduced as mineralized factors, the elements of V, Fe, P, Y, Ba, and Sc are important in the mixed sub-population.

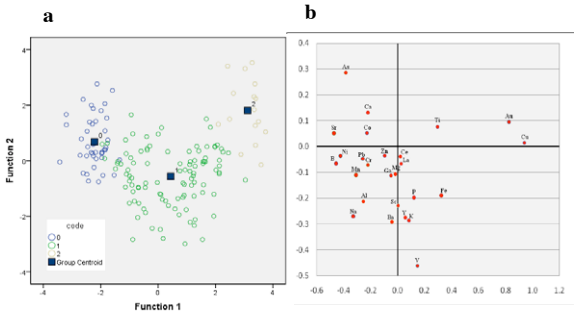

Figure 1: Discrimination analysis, anomly separation (a) and mineralized factor (b).

Conclusion

One of the charactristic of the discrimination analysis as anomaly separation method in compare with the other methods is the identification of the mineralized factors or elements.

Thermodynamics of crystalline iron(III) arsenates scorodite, kaňkite, and bukovskýite

J. MAJZLAN[1], P. DRAHOTA[2], M. FILIPPI[3], M. NOVÁK[4], J. LOUN[4] AND K.-D. GREVEL[1]

[1]Institute of Geosciences, Friedrich-Schiller University, Jena, Germany (*correspondence: Juraj.Majzlan@uni-jena.de)
[2]Institute of Geochemistry, Mineralogy and Mineral Resources, Charles University, Prague, Czech Republic
[3]Institute of Geology AS CR, Prague, Czech Republic
[4]Department of Geological Sciences, Masaryk University, Brno, Czech Republic

The crystalline ferric arsenates are candidates for arsenic storage at sites contaminated by this metalloid. The remediation technologies today usually involve precipitation of poorly crystalline hydrous ferric oxide which is capable of adsorbing As(V) or crystalline scorodite ($FeAsO_4 \cdot 2H_2O$). We seek alternatives which could be used for such processes, if found to be advantageous. To this end, we study the mineralogy and geochemistry of various sites polluted with arsenic and measure the solubility of the arsenate minerals by calorimetric techniques.

In this work, we present the formation enthalpies ($\Delta_f H^o$) of three arsenates, scorodite, kaňkite ($FeAsO_4 \cdot 3.5H_2O$), and bukovskýite ($Fe_2(AsO_4)(SO_4)(OH) \cdot 9H_2O$). The $\Delta_f H^o$ values were determined by acid-solution calorimetry at T = 298 K in 5 N HCl as the solvent, using $HCl \cdot 9.96H_2O$, γ-FeOOH, α-$MgSO_4$, MgO, KCl, and KH_2AsO_4 as the reference compounds. The resulting values for scorodite, kaňkite, and bukovskýite are –1508.9±2.9, –1940.2±2.8, and –4742.2±3.8 kJ/mol, respectively. We have also determined the $\Delta_f H^o$ value for anhydrous $FeAsO_4$ (not known as a mineral) as –899.0 ±3.0 kJ/mol.

Scorodite served as a test of our approach as many studies have been conducted on this phase (e.g. [1]). Using our $\Delta_f H^o$ value and a Kopp rule estimate of entropy of 180.3 J/mol·K, we arrive at a solubility product of –25.4, in good agreement with –25.8 in [1] or –25.4 in [2]. Our data also predict kaňkite to be unstable with respect to scorodite, in line with the rare occurrence of kaňkite in nature.

The results presented here will be soon complemented by heat capacity measurements and entropy calculations. Once these data are secured, calculations of phase diagrams for the title and related phases will be done and presented.

Sr and Nd isotope disequilibrium in migmatites and leucogranites, the Higo metamorphic terrane, Japan

K. MAKI[1,2]*, J.G. SHELLNUTT[2], T.W. WU[3], Y. MORI[4], K. MIYAZAKI[5], T.F. YUI[2] AND B.M. JAHN[2,6]

[1]Kyoto University, Kyoto 606-8502, Japan (*correspondence: k-maki@kueps.kyoto-u.ac.jp)

Sr and Nd isotope compositions of migmatites and leucogranites in the highest grade zone of the Higo low-*P*/high-*T* (andalusite-sillimanite type) metamorphic terrane, central Kyushu, Japan, suggest that the nebulitic migmatites (diatexite) formed due to melt infiltration into the pelitic gneisses, and the stromatic migmatites (metatexite) due to *in situ* partial melting of the pelitic gneisses. The nebulitic migmatites occur as a 3 m-thick layer and is sandwiched between 2 m-thick layers of storomatic migmatites within pelitic gneisses. Both types of migmatites are parallel to the foliation of the gneisses. The leucogranites occur as a few to ten cm-thick layer or lens within the gneisses. The nebulitic migmatites preserve a record of large magnitude Sr and Nd isotope disequilibrium with the pelitic gneisses, which show the isotope equilibrium with the stromatic migmatites. The nebulitic migmatites have higher epsilon Nd (T) values of -0.6 and P_2O_5 contents of 0.42 wt.% than those of the pelitic gneisses (-2.1 and 0.18 wt.%) and stromatic migmatites (-3.1 and 0.10 wt.%). The initial $^{87}Sr/^{86}Sr$ ratio, I_{Sr}, of the nubulitic migmatite, 0.70572, is lower than that of the pelitic gneisses and stromatic migmatites ranging from 0.70792 to 0.70857. Some leucogranites with high P_2O_5 contens of 0.91 wt.% have the higher epsilon Nd (T) values of +3.4 than, and similar I_{Sr} value of 0.70800 to that of the pelitic gneiss and stromatic migmatites. Based on the Sr and Nd isotope characteristics and P_2O_5 contents, *in situ* partial melting of the pelitic gneisses could form the stromatic migmatites, but could not produce the nebulitic migmatites with the higher epsilon Nd (T) value and P_2O_5 contents. The higher epsilon Nd (T) value and P_2O_5 contents may imply the participation of externally derived melt during the formation of nebulitic migmatites. Dissolution of apatite into the melt under dry and high-temperature conditions might produce such a high degree of Nd isotope disequilibrium and high P_2O_5 contents.

Adsorption of organophosphorous compounds on well-characterized iron mineral nanoparticles

PETER MÄKIE[1], PER PERSSON[1] AND LARS ÖSTERLUND[2,3]

[1]Dep. of Chemistry, Umeå Univ., SE-901 87 Umeå, Sweden (peter.makie@chem.umu.se, per.persson@chem.umu.se)

Particles of iron (hydr)oxides in the eartht's crust are highly reactive towards phosphates, and sorption of organophosphorous (OP) compounds constitutes an important part of the anthropogenic phosphor cycle [1]. In this study, three different polymorphs of well-characterized nanoparticles were chosen as model systems for iron minerals, i.e. hematite (α-Fe_2O_3), maghemite (γ-Fe_2O_3) and and goethite (α-FeOOH). Comparative studies of structure-specific sorption processes were performed using three OP compounds, namely trimethyl phosphate (TMP), triethyl phosphate (TEP) and dimethyl-methyl phosphonate (DMMP). Using *in situ* infrared vibrational spectroscopy, calibrated OP adsorption measurements were performed in a temperature controlled system under different conditions: Dry sorption with and without irradiation by simulated sunlight, and sorption under controlled humidity with and without sunlight.

The surface reactivity was shown to be strongly dependent on detailed bonding coordination of the central P atom, the structre of iron mineral surface, and environmental parameters (humidity and sunlight). All OPs were found to adsorb through the phosphoryl O atom on unsaturated iron cation surface sites (Lewis acids) on hematite and maghemite. In contrast, on goethite hydrogen bonding to surface OH (Brønstedt acid sites) dominates. On the iron oxides dissociative adsorption is facile yielding predominantly methoxy and formate reaction intermediates (oxidative pathway), and predominantly methoxy and phosphoric acid on the hydroxide (hydrolysis). The reactivity increases in the order goethite < maghemite < hematite. Addition of water blocks reactive adsorption sites, whereas sunlight strongly promotes OP dissociation on all minerals. Absence of water favours oxidation on hematite and maghemite, whereas presence of water during sunlight irradiation yields a combined oxidation/hydrolysis pathway.

It is believed that most important energy source in ocean crust or subseafloor is vastly abundant iron. Therefore, it is suggested that the iron-oxidizing chemolithoautotrophic microbe is a key player for the microbial ecosystem. However, there were no direct evidences because cultivation of iron oxidizer was difficult.

Recently, '*Mariprofundus ferrooxidans*' belong to the ζ (zeta)-proteobacteria [1] was isolated. This microbe can oxidize ferrous iron as the elctron donor and can be widely observed in various deep-sea low-temperature hydrothermal fields [2].

However, the diversity, distribution and role of these iron-oxidizing ζ-proteobacteria are still unknown. In addition, it is still unclear how these microbes cope with iron predominantly from oceanic basalts.

Therefore, to clarify these questions, we have investigated several iron-containing flocculent mats from deep-sea hydrothermal fields in the Mariana Vocanic Arc and the Okinawa Trough. Culture independent analysis of these mats demostrated that ζ-proteobacteria was the most dominant phylotypes. The X-ray analysis (XANES and EXAFS) revealed that the abundance of potentially biogenic Fe-oxides-species would be relevant with the abundance of ζ-proteobacteria population in the iron-containing flocculent mats. These results strongly supported that iron-oxidizing chemolithoautotrophs have significant ecological roles for iron and carbon cycles in deep-sea low-temperature hydrothermal systems.

Recycled crust in the source of Deccan flood basalts

K. MALAMOUD[1]*, A.V. SOBOLEV[1,2], D.V.KUZMIN[2], S. VILADKAR[3] AND A.W. HOFMANN[2]

[1]ISTerre, University J. Fourier BP 53, 38041 Grenoble Cedex 9, France (*correspondence: karim.malamoud@gmail.com)
[2]Max Planck Institute for Chemistry, Postfach 3060, 55020 Mainz, Germany
[3]Carbonatite Research Centre, Amba Dongar, Kadipani, District Vadodara 390117, India

The Deccan Flood Basalts (DFB), Seychelles plateau and Mascarene Islands (e.g. Réunion) are thought to trace the evolution of a single mantle plume from its initial stage under thick continental lithosphere to a hot-spot stage under thinner oceanic lithosphere. DFB may also have contributed to the Cretaceous-Tertiary-boundary mass extinction [1].

We intend to reconstruct the source compositions of lavas from the DFB and the Mascarene Islands using the compositions of melt inclusions and host olivine phenocrysts following [2]. Preliminary results on samples from the Kutch district (Gujarat state, India) indicate significant Ni excess and Mn deficiency in the composition of olivine phenocrysts similar to Hawaiian magmas (see Fig). This suggests a large contribution of pyroxenite-derived melt (recycled oceanic crust). Furthermore, this component appears compatible with that of lavas from the Réunion Island.

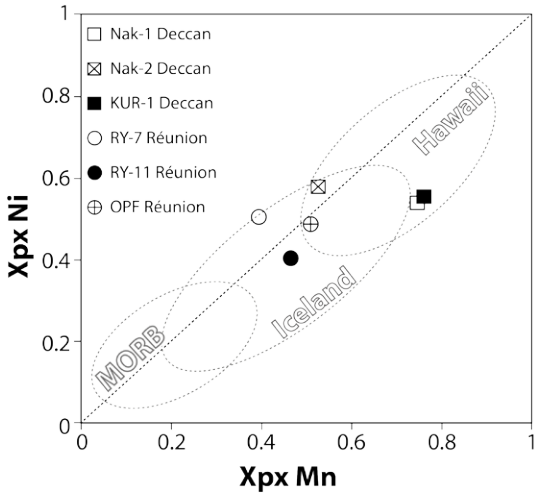

Figure 1: Proportion of pyroxenite derived melt from Ni excess and Mn deficiency in averaged (per sample) olivine compositions [2].

Serpentinite channel and the role of serpentinite buoyancy for exhumation of HP rocks (Voltri Massif, Western Alps)

C. MALATESTA[1], T. GERYA[2], M. SCAMBELLURI[1], L. FEDERICO[1], L. CRISPINI[1], G. CAPPONI[1]

[1]Dipartimento per lo studio del territorio e delle sue Risorse, Università di Genova, Corso Europa 26, Genova - Italy
[2]Institute of Geophysics, ETH Zentrum, Sonneggstrasse 5, 8092 Zürich (Switzerland)

The high-pressure (HP) Voltri Massif (at the eastern end of the Western Alps) consists of meta-ophiolites and metasediments recording peak blueschist (Palmaro-Caffarella Unit) to eclogite (Voltri Unit) facies. Eclogite and blueschist metagabbro lenses within highly sheared serpentinite or metasediments reveal strain heterogeneity within the lenses and between lenses and host-rocks. P-T pseudosections of these rocks indicate clockwise P-T paths for subduction and exhumation. Peak conditions range from 10-15 kbar and 450-500°C (Palmaro-Caffarella), to 21 kbar and 450-490°C, and to 22-28 kbar, 460-500°C (Voltri). To constrain exhumation of these rocks, we performed 2D numerical models simulating intraoceanic subduction in a basin surrounded by continental margins, same as the Mesozoic Ligurian Tethys. We reproduced a non-layered lithosphere typical of slow and ultra-slow spreading ridges, where serpentinized lithospheric mantle hosts discrete gabbro intrusions and is discontinuously covered by basalts. As the result of slab dehydration, a viscous serpentinite channel forms in the mantle wedge, whose evolution is strongly controlled by rheology of serpentine. Ductile deformation of serpentine within the channel enhances mixing of parts of the overriding plate with slab-derived sediments, oceanic crust and mantle. The simulations show that serpentinites decreased the bulk density of HP terrains below the mantle value, causing exhumation of part of the serpentinite channel. They also provide P-T paths of selected rock volumes with close correspondence with the P-T paths of the Voltri gabbroic lenses. The dominance of highly sheared serpentinite, the strong strain-partitioning, the metamorphic peaks attained by the various rock volumes within the Massif, and the similarity of natural and simulated P-T paths, suggest that the Voltri Massif may represent a ‘fossil’ serpentinite channel.

Sr and Nd isotope studies on sediment core samples from Cauvery delta, South India: Evidence for monsoon induced changes in provenance

MALIK ZUBAIR AHMAD, S. BALAKRISHNAN AND P. SINGH*

Department of Earth Sciences, Pondicherry University, Pondicherry 605014, India
(*correspondence: pramods@yahoo.com)

Sr and Nd isotope composition of sediments are useful to trace their provenance and past changes in climate [1]. Here, we present $^{87}Sr/^{86}Sr$ ratios of four different leachate fractions and Sr and Nd isotopic composition of the residual detrital phase of the sediments from a 25 m core obtained from the distal part of the Cauvery River delta. The $^{87}Sr/^{86}Sr$ ratios of exchangeable, carbonate, Fe-Mn and organic phases of the sediments exhibit similar trends falling between seawater and river water values (Fig.1). All these phases exhibit a sharp positive excursion at 3.8 m depth. This could be due to stabilization of vadoze zone for a long period, permitting greater microbial assisted weathering of minerals to release more radiogenic Sr.

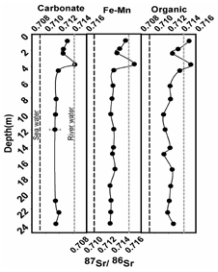

Figure 1.

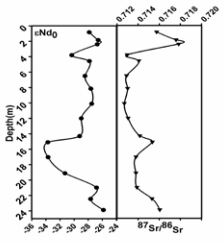

Figure 2.

Comparison of trends of εNd_o and $^{87}Sr/^{86}Sr$ ratios in the detrital phase of the sediments shows five excursions (Fig. 2). Comparing the isotope ratios of rocks exposed from the catchment of Cauvery river suggest that the dominant source of sediments varied from (1) granitic gneisses and basalts of Dharwar craton exposed along northern westcoast, receiving rains during southwest monsoon (2) enderbites and granulites of Nilgiri mountains that receive rainfall during both southwest and northeast monsoon and (3) gneisses and granulites found along Moyar, Bhavani and Cauvery shear zones and Southern Granulite Terrain receiving rains during NE monsoon. Evidence for intensification of SW monsoon is observed at a depth of 4 m upward (~7800 years B.P.) to 1.85m (upto ~5990 years B.P.).

Redox conditions of formation of osmium-rich alloys from dunite and chromitite of the Guli massif (Maimecha-Kotui Province, Russia)

K.N. MALITCH[1]*, A.A. KADIK[2], BADANINA I.YU.[1] AND E.V. ZHARKOVA[2]

[1]Russian Geological Research Institute, St. Petersburg, 199106, Russia (*correspondence: dunite@yandex.ru)
[2]Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, Moscow, 119991, Russia (kadik@geokhi.ru)

This study presents the new data on mineral composition and physico-chemical conditions of formation of Os-rich alloy grains derived from dunite and chromitite of the Guli clinopyroxenite-dunite massif (Maimecha-Kotui Province, Russia). The study employed a multitechnique approach that utilized electron microprobe analysis and experimental determination of the intrinsic oxygen fugacity (fO_2) of Os-rich alloys using solid electromechanical cells.

Measured fO_2 values of native osmium ($Os_{84}Ir_{11}Ru_5$) and iridian osmium ($Os_{66}Ir_{28}Ru_5$) are plotted (Fig. 1) between standard equilibrium buffers of wustite – magnetite (WM) and quartz – fayalite – iron (QFI). The similarity of fO2 for Os-rich alloys from dunite and chromitite indicates that formation of these minerals occurred in compatible redox conditions, characteristic of the region of generation of mantle peridotites.

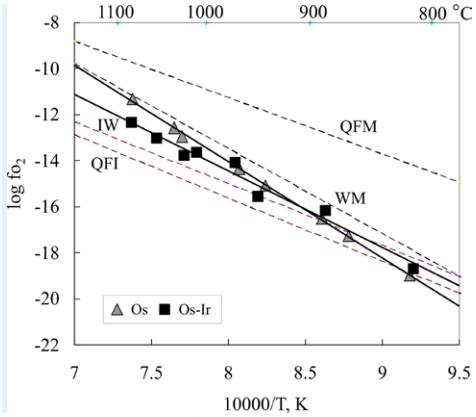

Figure 1: Plot log fO_2 - 10^4/T (K) for the measured samples of native osmium from dunite and iridium osmium from chromitite.

The study was supported by Russian Foundation for Basic Research (grant № 09-05-01242).

Late metasomatic addition of garnet to the SCLM: Os-isotope evidence

V.G. MALKOVETS[1]*, W.L. GRIFFIN[2], N.J. PEARSON[2], D.I. REZVUKHIN[1], S.Y. O'REILLY[2], N.P. POKHILENKO[1], V.K. GARANIN[3], Z.V. SPETSIUS[4] AND K.D. LITASOV[1]

[1]V.S. Sobolev Institute of Geology and Mineralogy, Novosibirsk, 630090, Russia (*correspondence: vladimir.malkovets@gmail.com)
[2]GEMOC National Key Centre, Macquarie University, Sydney, 2109, Australia (wgriffin@els.mq.edu.au)
[3]Moscow State University, Moscow, Russia
[4]ALROSA Ltd., Mirny, Russia

Archean cratons are underlain by highly depleted subcontinental lithospheric mantle (SCLM). However, xenolith and xenocryst data [1; references therein] suggest that Archean SCLM has been extensively refertilized by metasomatic processes, with the addition of Fe, Ca, and Al to depleted protoliths. The distribution of sub-calcic garnets in the SCLM beneath the Siberian craton suggests (1) sub-calcic garnets and diamonds are metasomatic phases in the cratonic SCLM; (2) the distribution of both phases is laterally heterogeneous on relatively small scales and related to ancient structural controls [2].

Re-Os isotopic compositions of sulfide inclusions in lherzolitic Cr-pyropes from four Siberian middle Paleozoic diamond mines have been determined by laser ablation MC-ICP-MS: Mir (n=17) and Internationalnaya (n=109), Malobotuobiya field, Udachnaya (n=17), Daldyn field, and Nyurbinskaya (n=12), Nakyn field.

Most analysed sulfides (~84%) have very low Re/Os ratios (<0.07), and their Re-depletion ages (T_{RD}) fall between 2.2 and 3.0 Ga (±0.03 Ga, mean 2s analytical uncertainty). 10 to 15% of the sulfides give younger T_{RD} down to 600 Ma.

Our previous study [3] of sulfide inclusions in megacrystic olivines from the Udachnaya pipe suggests that most of the SCLM beneath the Daldyn kimberlite field formed at 3-3.5 Ga, and that lithosphere formation culminated at ca 2.9 Ga. Our new data suggest that refertilization of the highly depleted SCLM and the introduction of Cr-pyrope garnet occurred between 2.2 and 3.0 Ga; little garnet was present before 3 Ga. Pyropes with young sulfides (between ~1.9 and ~2.2 Ga) may have crystallised during the amalgamation of the Siberian craton in Paleoproterozoic time.

On dating of groundwater with a high $^{234}U/^{238}U$ and Eh> 100mV

A.I. MALOV

Institute of the Ecologic Problems of the Northern Region, Naberezhnaya Severnoi Dviny, Arkhangelsk, 163061, Russia (malovai@yandex.ru)

In this report, on the basis of geological dating and developed PI Chalov method for determining the age of surface water for non-equilibrium uranium, attempted to assess the possibility of using isotopes U to determine the age of groundwater. In alpha-decay of ^{238}U atoms in an unbroken part of the mineral species appears disorders (disordered) region (*d. r.*) formed by atom recoil ^{234}Th. Among disordered may be the atom itself and the impact that formed this region. The probability of this event, p: $0 < p < 1$. If the groundwater is constantly supplied nonequilibrium uranium $^{234}U/^{238}U > 1$ ($\gamma_{d.\,r.}$) within a certain time t, then the following expression:

$$\gamma_{d.r.} = \left(\gamma_{t.water} - 1\right)\frac{\lambda_2 t}{1 - ?^{-\lambda_2 t}} + 1.$$

Therefore, asking a few randomly chosen values of t, we can define the corresponding values $\gamma_{d.\,r.}$. Then get some corresponding values N_{1rocks} / p:

$$\frac{N_{1rocks}}{?} = \frac{\lambda_2}{\lambda_1\left(\gamma_{dr} - \gamma_{rocks}\right)}.,$$

where N_{1rocks} - the number of atoms of ^{238}U, $\lambda_1 = 1.55 \cdot 10^{-10}$ years^{-1} and $\lambda_2 = 2.75 \cdot 10^{-6}$ years^{-1} - decay constant of ^{238}U and ^{234}U. Knowing the number of atoms of ^{238}U, located in the water contained in a unit volume of rock V_{unit} is currently $N_{1unit..\,water}$, and the activity of ^{238}U of the mineral species in the same volume $A_{1unit.\,rocks}$, you can roughly estimate the average number of atoms N_{1rocks} goes into the water from a disordered region:

$$N_{1rocks} \approx \frac{N_{1unit.water}}{?_{1unit.rocks} \cdot t}.$$

Having obtained the values N_{1rocks}/p and N_{1rocks}, we define p. As a result, for each of several arbitrarily chosen values of t we obtain the corresponding value of probability p. The values of t and p are related by a power dependence. Therefore, defining p, for several values of t, we can derive an equation of type $t = ap^{-0.971}$, where a - the age of groundwater at p=1%, and construct the corresponding diagram. The key point of the proposed method is the choice for charting the calculated value of p, on which is t, age-appropriate groundwater. On the example of North Dvina basin (northwest Russia) have shown that for aquifers with a high $^{234}U/^{238}U$ and Eh> 100 mV in increments homogeneous sandy rocks, p value is 0.35%. It is important to note that the chemical dissolution of equilibrium uranium contained in areas of undisturbed radioactive decay of rocks, as well as sorption to the results of calculations by the proposed method is not influenced.

Progress in understanding of sulfur in subduction zone magmas

C. MANDEVILLE[1]*, N. SHIMIZU[2], K. KELLEY[3], N. METRICH[4], A. FIEGE[5] AND H. BEHRENS[5]

[1]US Geological Survey (cmandeville@usgs.gov)
[2]Woods Hole Oceanographic Institution (nshimizu@whoi.edu)
[3]University of Rhode Island (kelley@gso.uri.edu)
[4]Institut de Physique du Globe de Paris (metrich@ipgp.fr)
[5]Univ. of Hannover (a.fiege@mineralogie.uni-hannover.de)

Progress in developing a better understanding of sulfur's behavior and origin in subduction zone magmas has now been facilitated through new *in situ* analytical techniques and recent conduction of high pressure and temperature (P-T) partitioning and isotopic fractionation experiments. Development of an *in situ* secondary ionization mass spectrometry (SIMS) technique for measurement of $^{34}S/^{32}S$ ratios in silicate glasses now allows for direct measurements of experimental glasses and melt inclusions from mafic arc magmas. Complementary SIMS calibrations for sulfur isotope ratio measurements of pyrrhotite and anhydrite now allow for investigation of S isotopic fractionation between sulfur-bearing melt and condensed sulfur phases at magmatic temperatures. Conventional and SIMS analysis of run products from high (P-T) decompression experiments investigating S partitioning between vapor and melt (Fiege *et al*. [1]) provide direct measurement of isotopic fractionations that can now be compared to estimates derived from previous extrapolations of data from lower temperature experiments, analogue materials and/or theoretical models [2]. Advances in S and Fe micro-X-ray Absorption Near Edge Structure Spectroscopy (XANES) has allowed for determination of the oxidation state of S and Fe in both natural and experimental samples.

Measured $^{34}S/^{32}S$ ratios via SIMS in olivine-hosted basaltic melt inclusions (MI's) from Krakatau and Galunggung volcanoes in Indonesia and Augustine volcano, Alaska yield $\delta^{34}S$ values from -2.8‰ to 17.2‰. Highest $\delta^{34}S$ values of 9.6‰ to 17.2‰ were measured in MI's from a Pleistocene basalt from Augustine volcano that have high disolved volatiles of 8.0 wt.% H_2O, 2624 to 5100 ppm S, 3900 ppm Cl, and sulfur XANES spectra with prominent peaks at 2482 eV indicating 100% SO_4^{2-} species in melt. Melt inclusions from the 1982 eruption of Galunggung yield $\delta^{34}S$ of -2.8‰ to 9.6‰. Melt inclusions from Krakatau pre-1883 basaltic scoria yield $\delta^{34}S$ values of 1.6‰ to 8.7‰. $A^{34}S$-enriched material is present in these magma source regions.

Mn-crusts record deep ocean ventilation changes

AUGUSTO MANGINI

Heidelberger Akademie der Wissenschaften, INF 229, D-69120 Heidelberg (amangini@iup.uni-heidelberg.de)

The end of glacial stages is accompanied by an increase of atmospheric CO_2. During the last Termination this increase goes along with a drastic drop of atmospheric ^{14}C by about 190‰. The probable explanation assumes the release of old carbon stored from a poorly ventilated glacial Ocean. This period was addressed by Broecker as the 'Mystery Interval' due to lacking higher glacial Benthic-Planktic foraminifera ages. However, the mystery could be an artefact of the tool applied, as benthic foraminifera cannot survive in an anoxic ocean.

More than 20 years ago we had measured profiles of ^{230}Th in the top mm of two Mn-crusts from the Central Pacific, from 4, 400 m and 1, 500 m water depth at a resolution of 20μm. In both samples growth rates during the past 300, 000 years were faster in Interglacials than in Glacials. We attributed the extremely slow growth rate during stage 2, and, especially, stops of growth during glacial stages 6 and 8 to periods of anoxia of the deep ocean, impeding formation of Mn-oxides. However, these conclusions were ignored, arguing that the occurrence of benthic forams and the lack of peaks of uranium in sediments contradicted periods of anoxia. In the meantime, however, there are a number of indications that the deep glacial Pacific Ocean was less ventilated than at present and that the shut down of N. Atlantic deep water formation during Heinrich 1 could have led to a short anoxic period in the deep Pacific. Reconsidering the data from the Mn crusts may help to solve the mystery.

Geochemical implications of iodine distribution in Indian soils

DEVLEENA MANI*, D.J. PATIL AND A.M. DAYAL

Petroleum Geochemistry Group, National Geophysical Research Institute(CSIR), Hyderabad-500007 (*correspondence: devleenatiwari@ngri.res.in)

Iodine plays a pivotal role in many of the geological, chemical and biological processes because of its litho-, bio-, atmo-, hydro- and chalco-philic nature. Speciation of iodine as inorganic iodine (iodides and iodates), molecular iodine and organically bound iodine provides its chemical signature in diverse forms in the earth crust. Contrasting distributions of iodine are observed in the Indian soils; wherein iodine lows below the permissible limits of WHO are observed in several parts of India, especially in the northern region [1], and on the other side, elevated iodine concentrations in hydrocarbon prospective/petroliferous sedimentary basins of India have been documented [2].

Soil iodine studies have been carried out in Saurashtra and Deccan Syneclise basins, which are potentially prospective hydrocarbon realms in the western and west central India, respectively. Results show the concentration (in mg/kg) of iodine to be in the range of 1.5-68.5 and 1.1-19.3 in the surficial soils of Saurashtra and Deccan Syneclise, respectively. The values are quite high compared to average distribution of iodine in soils (0.01-6mg/kg) [3]. The iodine highs in these regions appear to be associated with the hydrocarbon prone organic matter of the sedimentary basins.

The geological and geophysical variations occurring in different regions and sedimentary basins of India corroborate the concentration distribution pattern of iodine in the soils and the related geochemical anomalies.

HIMU-EMI type OIBs from the Neoarchean Penakacherla greenstone belt, Dharwar craton, India: Implications on Recycling of Mesoarchean crust

C. MANIKYAMBA[1] AND R. KERRICH[2]

[1]National Geophysical Research Institute (CSIR), Hyderabad-606, India; (cmaningri@yahoo.com)

[2]Univeristy of Saskatchewan, Skatoon, Canada S7N 5E2, (rbkerrich@shaw.ca)

Alkaline basalts, having relict aegirine, leucite and nepheline mineralogy, are associated with high-Mg and island arc basalts in the Neoarchean Penakacherla greenstone belt, eastern Dharwar craton, India. These are compositionally uniform, where SiO_2 = 43 to 46 wt%, Mg# = 0.70 to 0.58, and Ni = 183-85 ppm, enriched in alkalies (K_2O+Na_2O ~7 wt.%), TiO_2 (2.3-2.1 wt.%), and exhibit fractionated REE patterns with $(La/Yb)_N$ ranging from 23 to 29. On the Ni-Zr diagram, alkaline basalts plot with counterparts from the ocean island of Tubuai, Cook-Austral volcanic chain. On paired REE and primitive mantle normalized multi-element diagrams these basalts are characterized by coherent patterns: (1) smoothly fractionated REE [(La/Sm)N 4.08-5.00, (Gd/Yb)N 3.09-4.27]; (2) uniform Th/U ratios (4.1-5.4); (3) no Ce or Eu anomalies; (4) depletions of Th relative to Nb and La, yielding small negative anomalies of Nb relative to La (Nb/La = 0.78-1.01 vs.1.04 the primitive mantle ratio, in common with compositional characteristics of Phanerozoic alkaline ocean island basalts (OIB). These basalts plot with Recent counterparts from Aitutaki and Heard OIB on SiO_2 vs Nb/Y plot. High-μ, EM1 and EM2 OIB have distinct to overlapping trace element characteristics, of which HIMU OIB alone are characterized by positive Nb-anomalies. Comparison of PT-alkaline basalts with average trace elements ratios of OIB end members of Greenough *et al*. (2005) exhibit resemblance with some features of HIMU and EM1. Ratios of Zr/Nb (2.7-3.61), and La/Yb (32 - 41) compared to respective values in HIMU (3.4, 30), EM1 (5.4, 36), and EM2 (6.3, 21). Ti/Y (559) and Y/Yb (14) compare to respective values in HIMU (598, 13), EM1 (680, 15) and EM2 (638, 16). Consequently, PT alkaline basalts have trace element ratios intermediate between HIMU and EM endmembers. This occurrence of alkaline basalts indicates subduction, recycling, and incubation of Mesoarchaean oceanic and continental crust in the mantle, and generation of a mantle plume at 2.7 Ga.

Nutrient uptake at the fungi-mineral interface

UTRA MANKASINGH[1]*, SALVATORE A. GAZZE[2], LOREDANA SACCONE[2], ADELE L. DURAN[3], JONATHAN R. LEAKE[3] AND KRISTIN VALA RAGNARSDOTTIR[1]

[1]Faculty of Earth Sciences, School of Engineering and Natural Sciences, University of Iceland, Askja, Sturlugata 7, Reykjavik 107, Iceland (*correspondence: utra@hi.is)
[2]H.H. Wills Physics Laboratory, University of Bristol, Tyndall Avenue., Bristol, BS8 1TL, UK
[3]Department of Animal and Plant Sciences, University of Sheffield, Western Bank, Sheffield, S10 2TN, UK

This study focuses on the central role of soil fungi to acquire mineral nutrients from rocks and minerals, and thus participate in the weathering of bedrock to soil. We investigate fungal uptake of nutrient elements from minerals via direct contact and transport across the organism membrane.

Plant seedlings (*Pinus sylvestris*) in symbiosis with ectomycorhyzal fungi were grown directly on mineral surfaces in a controlled microcosm environment with regulated light, nutrients, moisture and carbon dioxide. The seedlings were grown in mixed mineral microcosms that were starved of a single essential nutrient. Initial chemical analysis of foliage and roots from microcosms starved of the major nutrients K and Mg showed lower concentrations of these elements in plant tissue compared to plants from microcosms that were not starved of these elements. However, despite systems being starved of K, an appreciably greater K concentration was observed in the shoots vs roots, suggestive of K storage in the foliage. Ca was also higher in shoots than roots. This trend is perhaps indicative of water efflux in the plants. Similarly, the essential nutrients P, Mg, Mn and Zn were higher in the foliage than in the roots,

Conversely, Fe and Al concentrations are higher in the roots than the shoots. Similar trends have been observed in the literature, suggesting low mobility of Al and Fe in plants [1]. Al, which is a non-essential element to plants, is toxic to fungi and they excrete it. The ready supply of Al to the roots system and the selective uptake to the shoots could imply that fungi may act as a filter for Al uptake by the seedlings. Fe uptake needs to be further investigated through comparison of systems with varying Fe nutrient supply.

The role of North Atlantic asthenosphere in the genesis of Icelandic lavas: Evidence from Heimaey

C.J. MANNING* AND M.F. THIRLWALL

Royal Holloway University of London, Egham Hill, Egham Surrey TW20 0EX
(*correspondence: c.manning@es.rhul.ac.uk)

Recent work on Iceland has indicated minimal involvement of North Atlantic asthenosphere (NAA) in the genesis of Icelandic lavas [1, 2]. Whilst the variation in isotopic and trace element compositions of Icelandic lavas requires several distinct mantle sources, these are all suggested to be derived from the Iceland plume rather than the surrounding asthenosphere [2, 3, 4]. It follows that areas remote from the current plume position are more likely to exhibit evidence for interation with NAA. We present new high-precision isotopic and elemental data for samples from the island of Heimaey which is proposed to be the tip of the propagating Eastern Rift Zone in South East Iceland.

In contrast to the incompatible element enrichment expected in the small degree melts produced at off-rift zones, the Heimaey samples exhibit lower concentrations (up to 21%) at a given MgO% than the South Iceland central volcanoes. Despite this the Heimaey lavas still plot in the alkali field on a TAS diagram which is a consequence of enrichment in Na that is not coupled with enrichment in other incompatible elements.

Relationships between K/Nb, Na_2O/TiO_2, and radiogenic isotopes indicate mixing between an enriched component with an 'Icelandic' signature and a depleted component similar to NAA. Na_2O/TiO_2 has been shown to vary as a function of melting depth [5] and polybaric melting models for Na_2O/TiO_2 indicate that the high values seen within the Heimaey samples can be generated by mixing between <40% of an 'Icelandic' source melting in the garnet facies (~45kbar) and <72% of a North Atlantic MORB source melting in the spinel facies (~10kbar).

New roles for rutile in tracing petrogenetic processes

C.E. MANNING

Department of Earth and Space Sciences, University of California Los Angeles, Los Angeles, CA 90095-1567 (manning@ess.ucla.edu)

Rutile is common in a wide range of igneous and metamorphic systems. Its wide stability and mechanical durability make it an important addition to the petrologist's accessory-phase toolkit. And, for at least two jobs, it may be a better tool than its more commonly deployed partner, zircon. First, rutile is nominally anhydrous but can contain up to 3000 ppm H_2O, significantly more than zircon [1]. Thus, OH in rutile can help evaluate the role of hydrous components during petrogenesis. Colasanti *et al*. [2] determined OH solubility in pure synthetic rutile at 0.5-2.0 GPa, 500-900 °C and four fO_2 buffers using FTIR spectroscopy. OH solubility increases with decreasing fO_2 at fixed *P*-*T*, and with *T* or *P* at isobarically or isothermally buffered fO_2. Data support OH substitution via $Ti^{4+}O_2 + {}^1/_2H_2O = Ti^{3+}O(OH) + {}^1/_4O_2$, and yield nearly ideal, multi-site mixing of the TiO_2-TiOOH solid solution along with $\Delta V_r°$, $\Delta H_r°$ and $\Delta S_r°$ of 1.90±0.48 cm^3/mol, 219.3±1.3 kJ/mol, and 19.9±1.4 J/molK (1σ). OH in rutile can be deployed as a thermobarometer and/or oxybarometer. Elevated OH in rutile may imply unexpectedly high Ti^{3+} in some terrestrial settings.

A second role for rutile arises from its participation in net-transfer reactions, which is rare for zircon [3]. This makes it especially useful in thermobarometry [4]. Kapp *et al*. [5] showed that solid solution in titanite leads to titanite-rutile coexistence over a range of *P* and *T*, in turn permitting titanite-rutile barometry. Evaluation of 2 zoisite/clinozoisite + rutile + quartz = 3 anorthite + titanite + water (TZARS) and anorthite + 2 titanite = grossular + 2 rutile + quartz (GRATiS) reveals that using appropriate solution models both return *P* within 0.5 kbar of independent constraints for a range of lithologies and cotexts. Moreover, crustal rocks possess nearly constant titanite activity, so accurate *P* is recorded even if only one Ti-phase is present, greatly expanding the range of assemblages on which TZARS and GRATiS can be deployed. These two examples show that rutile may provide key insights into conditions attending igneous and metamorphic processes.

Aqueous complexing and element recycling by subduction-zone fluids

C.E. MANNING

Department of Earth and Space Sciences, University of California Los Angeles, Los Angeles, CA 90095-1567 (manning@ess.ucla.edu)

Mineral solubility in pure H_2O is a poor guide to assessing minor-element transfer by subduction-zone fluids. This is because all such fluids exist in a soluble rock matrix, and it is the interactions with the major solutes derived from host lithologies that exert the dominant controls on element mobility. This can be seen with three examples. First, low rutile solubility in pure H_2O at subduction zone conditions [1] fails to explain occurrence of this phase in veins in high *P* rocks. However, TiO_2 solubility is greatly enhanced dissolved Na-Al silicates, via incorporation in Na-Ti complexes or Na-Al-Si oligomers [1, 2]. Experimentally constrained solubility data indicate that at 600 °C along model slab geotherms, rutile solubility in H_2O is 2 ppm Ti, whereas in H_2O equilibrated with cpx+mica+quartz the high dissolved Na-Al-Si [3] yield 88 ppm Ti. If albite-H_2O fluids are supercritical, even greater Ti transport is possible [4]. Alkali halides are also important complexing agents. Tropper *et al*. [5] showed that at 800°C, 1 GPa, $CePO_4$ monazite and YPO_4 xenotime solubilities are very low in pure H_2O but are significantly enhanced by NaCl via REE/Y-chloride and Na-phosphate complexing. This may promote REE mobility; for example, H_2O/Ce inferred for subduction-zone melts and silicate-rich fluids [6] can also be produced by a $CePO_4$-saturated fluid with $X_{NaCl} = 0.1$. Finally, mineral-solute interactions fix pH in a given lithology and set of conditions. The pH controls the solubility of amphoteric metal oxides. It also governs volatile transfers, e.g. carbon. Molecular CO_2 from carbonate minerals is low along slab geotherms. Most carbon is dissolved instead as carbonate. The strong dependence of aragonite solubility on pH translates to important controls by buffering mineral assemblages. Changes in pH with *P*, *T* and bulk composition must be the primary factors governing loss of carbon from slabs before they reach sub-arc depths. In general, the strong influence of aqueous complexing on element solubility highlights that the role of fluids in element recycling can vary widely.

Chemical fractionation of Pb and Zn and determination of Pb isotopes in deposited blast-furnace sludge

TIM MANSFELDT, HENNING SCHIEDUNG AND STEPHAN SCHUTH

Department of Geosciences, Soil Geography/Soil Science, University of Köln, Germany (tim.mansfeldt@uni-koeln.de)

Blast-furnace sludge is a waste of pig iron production and was deposited in large surface landfills. Since it contains high amounts of Zn and Pb it is of environmental concern. The first aim of this study was to investigate the solubility and binding forms of Zn and Pb in this industrial waste.

We performed a five step sequential chemical fractionation on 32 samples: (A) 1 M NH_4NO_3; (B) 1 M NH_4OAc, buffered at pH 5.4; (C) 0.2 M NH_4-oxalate-buffer, pH 3.25; (D) 0.1 M ascorbic acid + 0.2 M NH_4-oxalate-buffer, pH 3.25; (E) aqua regia.

The second aim was to determine the Pb isotope ratios of representative bulk samples (n = 10) and related fractions (n = 3) with MC-ICP-MS.

Total contents of Zn ranged from 15, 720 to 86, 400 mg kg^{-1} (median 30, 360 mg kg^{-1}) and from 1, 420 to 19, 510 mg kg^{-1} (median 9, 835 mg kg^{-1}) for Pb. The proportion of the mobile fraction (A) ranged from 0.09 to 2.11% (median 0.26%) for Zn and from 0 to 0.3% (median 0.04%) for Pb. For the easily mobilized fraction (B) we obtained a range from 2 to 23% (median 7%) for Zn and from 5 to 68% (median 19%) for Pb. In contrast to Zn, which is largely associated (63 to 96%, median 85%) to fraction C, i.e. poorly crystalline iron oxides, Pb is much more distributed over the fractions D (4 to 26%, median 18%), i.e. crystalline iron oxides, and E (9 to 64%, median 39%). Sequential fractionation indicates that Zn and Pb are bonded differently in blast-furnace sludge, resulting in a contrasting mobility of these two elements.

The Pb isotope ratios of the bulk samples are clearly distinguishable and ranged from 18.088 to 18.634 ($^{206}Pb/^{204}Pb$), 15.595 to 15.670 ($Pb^{207}/^{204}Pb$) and 37.709 to 38.402 ($^{208}Pb/^{204}Pb$). In contrast, the isotope ratios of the different fractions show little variation, especially the ^{207}Pb-^{204}Pb ratios overlap within analytical uncertainty. No mass-dependent fractionation was observed between the different fractions, because variation is higher for $^{207}Pb/^{204}Pb$ and $^{206}Pb/^{204}Pb$ than for $^{208}Pb/^{204}Pb$.

Seasonal variation in the clay mineral and Sr-Nd isotopic compositions of the suspended sediments of the lower Changjiang River at Nanjing, China

CHANGPING MAO[1,2]*, JUN CHEN[1] AND JUNFENG JI[1]

[1]Institute of Surficial Geochemistry, School of Earth Sciences and Engineering, Nanjing University

[2]State Key Laboratory of Pollution Control and Resource Reuse, School of Environment, Nanjing University, Nanjing 210093, China (*correspondence: chpmao@nju.edu.cn)

The clay minerals and Sr-Nd isotope signatures have been extensively used to characterise the provenance of detrital sediments and wheathering processes. The Changjiang (CR) River is one of the largest rivers in the world. The CR originates on the Tibetan Plateau and enters the East China Sea. A large part of the CR Basin has a subtropical monsoon climate. To examine seasonal changes in clay minerals and Sr-Nd isotopic compositions of the CR, suspended sediment (SS) samples were collected monthly for two hydrological cycles in Nanjing city.

The results indicate that the concentration of CR SS ranges from 11.3 to 152 mg/L and is highly correlated to the rate of water discharge with a higher concentration in flood season. Illite dominates the clay minerals of the CR SS, followed by chlorite, kaolinite and smectite. Illite and kaolinite show distinctly seasonal variations; SS has more illite and less kaolinite contents during flood season than the dry seasons. The illite chemistry index and crystallinity as well as kaolinite/illite ratio all indicate intense physical erosion in the upper CR basin during the flood season.

The Sr-Nd isotopic compositions (silicate fraction) also show distinctly seasonal variations. The results indicate that the $^{87}Sr/^{86}Sr$ ratios of CR SS ranges from 0.725352 to 0.738128, and the εNd (0) values ranges from −10.55 to −12.29. The relative decrease in $^{87}Sr/^{86}Sr$ ratios and increase in εNd (0) values during the flood season can be interpreted to reflect an increasing in the mechanical erosion rate in the upper basin and contribution of more radiogenic Nd and non-radiogenic Sr to the suspended load in flood season.

The Sr-Nd isotopic compositions correlate well with the clay mineral associations, indicating that the seasonal variations primarily reflect the controls of provenance rocks and erosion between different sub-catchments. Furthermore, these signatures can be now used to decipher past discharge and flow regimes of the rivers from sediment cores offshore.

^{230}Th inventories in new sediment cores from the eastern equatorial Pacific: Constraints on the ^{230}Th constant-flux proxy

FRANCO MARCANTONIO[1], RAMI IBRAHIM[1], AJAY K. SINGH[1] AND MITCHELL LYLE[2]

[1]Department of Geology & Geophysics, Texas A&M University, College Station, TX 77843, USA (*correspondence: marcantonio@tamu.edu)
[2]Department of Oceanography, Texas A&M University, College Station, TX 77843, USA

We have conducted an oceanographic survey in the eastern equatorial Pacific Ocean to assess the water and sedimentary budget of ^{230}Th along water flow paths into the Panama Basin. Our survey, along ~85°W, included bathymetric mapping, sub-bottom profiling, seismic reflection data acquisition, and collection of water and new sediment cores. Our goal is to address the controversy concerning the use of ^{230}Th activities as a constant-flux proxy in the Pacific Ocean. Proponents of the ^{230}Th technique maintain that sediment redistribution is widespread in the eastern equatorial Pacific and that the flux of laterally advected sediment can surpass the vertically rained flux by up to 2-4 times. Others suggest that there may be a discrepancy between the ^{230}Th flux and its rate of production which, in turn, causes accumulation rates to be underestimated due to potential lateral transport of ^{230}Th in the water column. The crux of the disagreement amounts to how one explains the larger-than-expected inventories of sedimentary ^{230}Th along the equator in the Pacific, inventories above those expected from a constant water column production rate.

The Carnegie gap region, bounding the southern border of the Panama Basin, is the main deep water flow path into the basin, and provides an ideal testing ground for investigating sediment advection. Our seismic and sub-bottom profiling surveys determined 'end-member' areas within this region with both thick and thin sediment cover, and several of these sites were multi- and piston-cored. The cores have been dated via radiocarbon and XRF-major-element correlation, which has enabled us to construct common stratigraphies in each survey region. A high-resolution assessment of a ^{230}Th deficit or excess from each end-member region (bathymetric highs versus lows; thin versus thick sediment piles) will be presented. The processes that control this distribution will be assessed in relation to the present-day ^{230}Th water column systematics, which we present elsewhere at this conference (Singh *et al*.).

Geochemistry of antigorite serpentinite and chlorite harzburgite from the Cerro del Almirez (S. Spain): Compositional constraints on fluids released by dehydration of mantle serpentinites

C. MARCHESI[1]*, C.J. GARRIDO[1], J.A. PADRÓN-NAVARTA[2], M.T. GÓMEZ-PUGNAIRE[2] AND V. LÓPEZ SÁNCHEZ-VIZCAÍNO[3]

[1]Instituto Andaluz de Ciencias de la Tierra, Granada, Spain (*correspondence: claudio@iact.ugr-csic.es) (garrido@iact.ugr-csic.es)
[2]Dpt. of Mineralogy and Petrology, UGR, Granada, Spain (padron@ugr.es, teresa@ugr.es)
[3]Dpt. of Geology, University of Jaén, Jaén, Spain (vlopez@ujaen.es)

In the Cerro del Almirez massif (Betic cordillera, S. Spain) hydrous antigorite (Atg)- serpentinite exceptionally records prograde dehydration to chlorite (Chl)- harzburgite under eclogite facies conditions (680-710°C and 1.6-1.9 GPa). Al_2O_3 contents of Atg-serpentinites and Chl-harzburgites match those of variable fertile mantle peridotites. SiO_2 is rather higher in some Atg-serpentinites than the values usually reported for oceanic peridotites, probably owing to normalization of the whole rock compositions after partial MgO loss during seafloor weathering.

The REE patterns of Atg-serpentinites are flat or LREE-depleted and show a negative anomaly in Eu. On the other hand, Chl-harzburgites have 'U-shaped' patterns enriched in LREE and HREE relative to MREE, or are depleted in LREE. Chl-harzburgites also show negative anomalies in Eu and their REE concentrations generally coincide with those of Atg-serpentinites except for lower abundances in MREE. The concentrations of lithophile trace elements are usually above 0.1 the values of the primitive mantle and well overlap those of abyssal peridotites from ocean ridges.

Chl-harzburgites have significantly higher Nb/La, Ta/La, Zr/Sm and Hf/Sm than precursor Atg-serpentinites. This indicates that fluids released during the formation of prograde Chl-harzburgites had complementary low Nb-Ta/LREE and Zr-Hf/MREE ratios. Zr and HREE concentrations of most Chl-harzburgites are similar to those of Atg-serpentinites, and these elements were hence effectively immobile during deserpentinization. The high Zr/Sm and Hf/Sm ratios of Chl-harzburgites are therefore due primarily to the preferential mobility of MREE into fluids. Additionally, Chl-harzburgites have also lower Ba/Th than Atg-serpentinites, consistently with the higher solubility of Ba in fluids compared to Th.

Low latitude surface ocean contribution to the deglacial atmospheric radiocarbon decline

T.M. MARCHITTO[1]*, S.J. LEHMAN[1], C. LINDSAY[1], S.P. BRYAN[2], J.D. ORTIZ[3] AND A. VAN GEEN[4]

[1]University of Colorado, Boulder, CO 80309, USA (*correspondence: tom.marchitto@colorado.edu) (scott.lehman@colorado.edu, colin.lindsay@colorado.edu)
[2]Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA (sbryan@whoi.edu)
[3]Kent State University, Kent, OH 44242, USA (jortiz@kent.edu)
[4]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY 10964, USA (avangeen@ldeo.columbia.edu)

The bulk of the atmospheric radiocarbon decline across the last deglaciation was likely driven by a release of ^{14}C-depleted CO_2 from the deep ocean. Renewed deep mixing in the Southern Ocean is most often cited as the main mechanism of that release. However, observations from the intermediate-depth Indo-Pacific suggest that ^{14}C-depleted waters were also present at low latitudes during deglaciation. If those waters impacted the sea surface via upwelling, then part of the atmospheric Δ^{14}C drop might be attributable to radiocarbon isofluxes across the air-sea interface in the tropics and subtropics.

Here we present new radiocarbon results from two species of shallow-dwelling planktonic foraminifera in Baja California core MV99-PC08 (23.5°N, 111.6°W, 705 m water depth). Calendar ages are estimated by stratigraphic correlation to the GISP2 ice core in Greenland, allowing us to calculate seawater Δ^{14}C through time. We find that the two deglacial Δ^{14}C minima previously seen in intermediate waters at this site are also reflected in the planktonic foraminifera, but in attenuated form. The rate of decline in *Globigerinoides ruber* Δ^{14}C across Heinrich Stadial 1 was slower than in intermediate waters, but faster than in the atmosphere. These observations are consistent with partial upwelling of the Δ^{14}C minima to the sea surface. Additional constraint on the vertical transfer is provided by new benthic Δ^{14}C data from nearby Soledad Basin (290 m sill depth). We diagnose the potential impact of low latitude ^{14}C exchange on the atmosphere using a simple numerical model of the atmospheric radiocarbon balance.

Phases and phase transitions of tropospheric aerosols

C. MARCOLLI[1]*, M. SONG[1], V.G. CIOBANU[1], A. ZUEND[2], G. GANBAVALE[1], B. ZOBRIST[1], B.P. LUO[1], V. SOONSIN[1], U.K. KRIEGER[1] AND T. PETER[1]

[1]ETH Zurich, Institute for Atmospheric and Climate Science, Switzerland (*correspondence: claudia.marcolli@env.ethz.ch)
[2]Department of Chemical Engineering, California Institute of Technology, Pasadena, California, United States

Submicron aerosol particles exert a potentially large but not well constrained effect on the radiative balance of Earth's atmosphere by direct interaction with solar radiation and indirectly by modifying cloud properties. They typically consist of a high variety of organic substances, sulfate and other inorganic ions such as ammonium and nitrate. Knowledge of the physical state and morphology of these particles is needed to predict hygroscopicity and gas/particle partitioning of semivolatile species, to improve knowledge of heterogeneous and multiphase chemistry, and to quantify light scattering and absorption.

However, it is difficult to infer the physical state of atmospheric aerosol particles directly from field measurements. Laboratory experiments on model mixtures and thermodynamic models are thus required to gain insight into the phases and phase transitions of aerosols. The high variety of organic substances impedes crystallization and the organic fraction remains as a liquid or glass even at low relative humidty (RH) and cold temperatures. The way this organic phase interacts with inorganic salts depends on its hydrophilicity. We use Raman microscopy to investigate the phase transitions of micrometer-sized particles during humidity cycles and a high-speed video camera to observe the efflorescence process. For particles consisting of dicarboxylic acids and ammonium sulfate, liquid-liquid phase separation into an organic-rich and an aqueous electrolyte phase occurs for O:C ratios of 0.7 or lower. Using the thermodynamic model AIOMFAC (Aerosol Inorganic-Organic Mixtures Functional groups Activity Coefficients) we can also model liquid-liquid equilibria and gas/particle partitioning of such particles. While crystal growth occurs within milliseconds in the aqueous electrolyte phase, it is drastically slowed in the highly viscous organic-rich phase. Slow diffusion in glassy aerosol particles indeed keeps particles off thermodynamic equilibrium during humidity cycles, as we have shown for sucrose particles levitated in an electrodynamic balance. This highlights the need to also consider deviations from thermodynamic equilibria caused by diffusion limitations especially at cold and dry conditions.

Geoneutrino observations and the Earth energy budget

JEAN-CLAUDE MARESCHAL[1], CATHERINE PHANEUF[1], CLAIRE PERRY[1] AND CLAUDE JAUPART[2]

[1]GEOTOP, Université du Québec à Montréal, PO8888, Station Downtown, Montréal, H3C 3P8, Canada
[2]Institut de Physique du Globe de Paris, 1, rue Jussieu, 75238, Paris Cedex 5, France

The total energy loss of the Earth has been calculated to be 46+/-2TW. The heat loss is balanced by the radio-activity of the Earth's crust and mantle, the core heat flow and the mantle secular cooling. The crustal radioactivity is relatively well constrained (6.5+/1TW), but the uncertainty on all the other components is very large. Estimates of core heat flow vary between 5 and 14TW. Mantle cooling could provide between 6 and 18TW. Bulk silicate earth models predict about 13TW for the heat generation in the mantle, but proposed values of mantle heat production vary between 9 and 20TW.

Underground neutrino observatories now have the capability of detecting geo-neutrinos, anti-neutrinos produced by β decay in radio-elements U and Th series.

It is thus hoped that geoneutrino observations will put constraints on the abundance and distribution of U and Th in the mantle and their contribution to the earth's energy budget.

A small error on the crustal heat generation has a large impact on the estimates of the abundance of U and Th in the mantle, because the contribution of the crust to the geoneutrino flux is 4 to 5 times larger than that of the mantle,. Combining heat flux and heat production data is the most robust method to determine with high precision the crustal radio-activity and to predict the crustal geo-neutrino's contribition.

Rare earth element (REE) quantification in geochemical samples: Can we trust commercially available ICP-MS calibration solutions?

E. MARILLO SIALER AND T. MEISEL*

General and Analytical Chemistry, Montanuniversitaet, 8700 Leoben, Austria
(*correspondence: thomas.meisel@unileoben.ac.at)

The ICP-MS technique allows the analyses of individual REE concentrations in a wide range of matrices relevant for geochemists. However, the quantification of concentrations via in the mass spectrum still faces complications due to the vast potential chemical and spectral interferences, arising from complex sample matrices, when quantification is needed. To overcome these interferences, a number of measures including internal standardization, matrix separation, isotope-dilution, the standard addition method, algebraic correction, among others, are employed.

In this work we report the results from the isotopic analysis of fourteen REE in geological materials by ICP-MS. Three different analytical approaches were studied: 1) ICP-MS using matrix matched reference materials (RM) for calibration and 2) HPLC-ICP-MS after Tm addition 3) Isotope Dilution ICP-MS with and without chemical separation. All approaches involve sample dissolution by sodium peroxide sintering to assure complete dissolutions of refractory minerals. The first analytical procedure for determination by ICP-MS uses external calibration curves generated from certified and well characterized, matrix matched geological RM (CRM, provided and certified by the International Association of Geoanalysts, IAG) which were prepared in the same way as the studied samples. The determination by HPLC-ICP-MS comprises spiking with Tm before sample dissolution and a straightforward chromatographic matrix separation procedure. Oxalic and diglycolic acid were used as complexing agents on a Dionex Ionpac CS5A analytical column. Synthetic standard solutions obtained from Inorganic ventures, High Purity Standards and Spex were used for calibration of the HPLC-ICP-MS.

The findings of this study, and the advantages and disadvantages of all methodologies used are discussed. Significant differences between the three calibration strategies were observed for some of the ICP-MS solutions. Thus the traceability of the so called certified ICP-MS standard solutions is questioned and the reliability of the new CRM is highlighted.

The diagenesis effect on paleo-temperature reconstruction from Precambrian cherts

JOHANNA MARIN-CARBONNE[1,2]*, MARC CHAUSSIDON[1] AND FRANCOIS ROBERT[3]

[1]Universite de Lorraine, CRPG-CNRS 54500 Vandoeuvre les Nancy, France (chocho@crpg.cnrs-nancy.fr)
[2]Department of Earth and Space Sciences, UCLA, CA 90095 USA (*correspondence: jmarin@ess.ucla.edu)
[3]Laboratoire de Mineralogie et Cosmochimie du Museum, Museum d'Histoire Naturelle Paris, France (robert@mnhn.fr)

Cherts are considered as possible proxies of paleo-environmental conditions of the Early Earth. Variations in $\delta^{18}O$ and $\delta^{30}Si$ in Precambrian cherts have been used to reconstruct oceanic temperature [1, 2], and to try to address the Faint Young Sun Paradox. However, these reconstructions did not calculate the diagenesis effect, assumed small, on the isotopic compositions. The *in situ* ion microprobe study $\delta^{18}O$ and $\delta^{30}Si$ of microquartz in cherts of different ages, from 3.50 Ga to 1.88 Ga, allowed better understanding of the origin and the formation of these rocks. These results impact the paleo-temperatures reconstruction for Precambrian seawater [3].

The correlation between Al_2O_3 content and $\delta^{30}Si$ can discriminate diagenetic cherts from hydrothermal or silicified cherts. The diagenetic cherts are from the Gunflint Iron formation (1.88 Ga). These cherts show a typical 2-14 ‰ range for $\delta^{18}O$ and 2-5 ‰ range for $\delta^{30}Si$ at the scale of microquartz grains (~ 2 μm). We interpret this heterogeneity as inherited from the diagenesis. Hence, these variations could be explained by a simple model of dissolution-precipitation of an amorphous silica precursor.

The calculated temperatures from this model ranges from +37° to +52 °C, suggesting an hot ocean during the Precambrian Era if Gunflint cherts are representative of global environment conditions [3]. Taking the diagenesis account decrease the seawater temperatures found by bulk analysis previously.

The Manicouagan impact crater: A site for testing the accuracy of revisions to the K-Ar system

DARREN F. MARK[1] AND LEAH E. MORGAN[2]

[1]Scottish Universities Environmental Research Centre, East Kilbride, Scotland, G75 0QF, UK
[2]Dept. of Petrology, Vrije Universitiet, De Bolelaan 1085, 1081HV Amsterdam, Netherlands

Compared with the U-Pb geochronometer the K-Ar system still retains relatively large systematic uncertainties. Recent studies have attempted to improve the accuracy of the Ar/Ar method by determination of an accurate age for Fish Canyon sanidine (FCs) [2, 4] and the K-Ar decay constants [3]. The results vary by 1%, beyond what is expected from analytical precision. Although the magnitude of this uncertainty is difficult to assess in single experiments, one can examine whether the amount of dispersion in the three latest revisions represent true external reproducibility and thus reflect geological uncertainties?

Inter-comparison of one Ar/Ar (sanidine) age with one U-Pb (zircon) age is problematic (e.g. zircon magma residence time). Sanidine and zircon have markedly different closure temperatures for the retention of daughter products so we are commonly faced with the question: what are these minerals dating and at what level can we assume equivalence?

Melt rocks from large terrestrial impact events are an ideal target for an Ar/Ar – U-Pb inter-comparison study as they have a somewhat simple crystallization and cooling history and do not suffer the protracted crystallization histories that typify magma-chamber process. Ramezani *et al*. [1] determined a high-precision ID-TIMS ^{206}U-^{238}Pb age for zircon from the Manicouagan impact crater. Here we present a high-precision Ar/Ar age for the coeval sanidine. We will discuss revisions to the age of FCs and the K-Ar decay constants, and show that the latest proposed age for FCs (Channell *et al*. 2010) is not consistent with our data. The approach allows us to get beyond the question of 'what are we dating?' and assess the inter-calibration of the Ar/Ar and U-Pb chronometers at a level approaching analytical precision.

Mineralizations monitor depth and composition variations of paleohydrothermal fluid systems

G. MARKL* AND S. STAUDE

Eberhard Karls Universität Tübingen, Wilhelmstrasse 56, 72072 Tübingen, Germany
(*correspondence: markl@uni-tuebingen.de)

More than 1000 hydrothermal mineralizations in the Schwarzwald ore district of SW Germany formed discontinuously over the last 300 Ma [1]. Fluid inclusions, structural and mineralogical specifics allow to distinguish six different mineralizing fluid systems [2]. Most mineralizations formed by mixing of a deep-seated and a near-surface fluid. Interestingly, ore mineral compositions (especially fahlore [3]) and fluid inclusion systematics appear to reflect the relative importance of the deep and the shallow fluid systems, while e.g. Sr or Pb isotope systematics allow to quantify their contributions more precisely in some cases. Stable sulfur, oxygen and carbon isotope systematics allow to draw conclusions regarding the source of these (and geochemically similar) elements.

Combination of these various methods allows to characterize paleofluid systems with respect to their composition, their timing and their ore-forming potential in great detail on a district-wide scale and thereby help to understand the communication of deep and shallow aquifers over time in a typical crustal block of 100x50 km size.

Volatile elements in apatite: An integrated analytical approach with special focus on bromine

M.A.W. MARKS[1]*, M. WHITEHOUSE[2], T. WENZEL[1], H. STOSNACH[3] AND G. MARKL[1]

[1]Universität Tübingen, 72074 Tübingen, Germany (*correspondence: michael.marks@uni-tuebingen.de)
[2]Swedish Museum of Natural History, Stockholm, Sweden
[3]Bruker Nano GmbH, Schwarzschildstrasse 12, D-12489 Berlin, Germany

We analyzed a Durango apatite crystal and apatites from five plutonic samples from the alkaline Mt. Saint Hilaire Complex (Canada) by means of Electron Microprobe Analysis (EPMA), Laser Ablation ICP-MS (LA-ICP-MS), Secondary Ion Mass Spectrometry (SIMS), pyrohydrolysis combined with ion chromatography, Fourier Transformed Infrared Spectroscopy (FTIR), Instrumental Neutron Activation Analysis (INAA) and Total Reflection X-ray Fluorescence Analysis (TXRF).

The focus of our study are volatile elements (F, Cl, Br, S, C) with a special emphasis on Br, since the analytical possibilities for this element are especially in the low- to sub-μg/g range restricted and thus, reliable concentration data for Br in rock-forming minerals are scarce. We demonstrate here that TXRF, which is barely used in geosciences so far, is suitable for analyzing the bulk content of Br and Cl as well as of a range of important minor and trace elements (e.g. Sr, Ce, Fe, Mn, As) in apatite simultaneously. The TXRF method combines the advantages of low to very low detection limits (μg/g- to sub-μg/g range), small sample amounts needed (mg range) and a relatively fast and inexpensive analytical procedure. In the case of apatite, reliable concentration data for Br can be produced with detection limits in the sub-μg/g range. The analysis of Cl is also possible, if a suitable correction method, which accounts for the observed systematic underestimation, is applied. For investigations, where space-resolved data are needed, a large geometry SIMS machine offers the possibility to analyze F, Cl, Br and S if reliable data for suitable reference materials exist.

Based on our data, we propose an average Br concentration of around 0.1 μg/g as a preliminary reference value for the Durango apatite. However, more data on the Br content of the Durango apatite are needed in order to validate this value.

Endolithic anaerobic methane oxidation at cold seeps

JEFFREY J. MARLOW*, JOSHUA STEELE AND VICTORIA J. ORPHAN

California Institute of Technology, MC 100-23, 1200 E. California Blvd., Pasadena, CA 91125 (*correspondence: jjmarlow@caltech.edu)

The anaerobic oxidation of methane (AOM) at deep sea cold seeps has been the target of much work over the last decade, as researchers have sought to characterize complicated syntrophic relationships [1], identify metabolically relevant chemical species [2], and understand the role of AOM in the broader carbon cycle [3]. However, much of this work has focused on cold seep sediments, and comparatively little is known about the associated authigenic carbonates that are formed as a product of AOM. If biologically active, these rocks would contribute significantly to AOM processes in the global deep ocean environment.

Here we describe a unique microscopy and molecular study of cold seep endolithic environments that compares sediments, protolithic carbonate nodules, carbonate rocks associated with active methane seepage ('active'), and carbonate rocks from dormant seep areas ('inactive'). Image analysis and cell staining with DAPI and domain-specific CARD-FISH probes showed abundant cell aggregates in all environments including the interiors of the 'inactive' carbonates. Carbonate rocks from active seep habitats contained the largest and most abundant cell aggregates, with average diameters around 10 um. 16s rRNA gene sequences and T-RFLP analyses revealed syntrophic methane oxidizing archaea and sulfate reducing bacteria, in keeping with previous studies. X-ray diffraction exposed mineralogical differences between samples; a relative abundance of metal-based minerals in rock interiors could expose cells to additional electron acceptors and accommodate larger, more abundant aggregates.

A quantitative model of methane uptake based on aggregate density, theoretical enzyme kinetics, measured methane concentrations, and carbonate rock porosity will be presented to demonstrate the role of carbonate pavements in overall methane consumption. The finding of active endolithic AOM consortia expands our understanding of where and how AOM occurs, suggesting that a significant – possibly dominant – component of AOM activity in cold seep habitats may occur within lithified carbonates at and within the seabed.

Elastic properties of nano-crystalline MgO to high pressures by Brillouin scattering

HAUKE MARQUARDT[1], ARIANNA GLEASON[2], KATHARINA MARQUARDT[1], SERGIO SPEZIALE[1], LOWELL MIYAGI[3], GREGOR NEUSSER[4], HANS-RUDOLF WENK[2] AND RAYMOND JEANLOZ[2]

Recent Brillouin scattering results on the sound wave velocities of MgO powder compressed under non-hydrostatic conditions show velocities that are around 20% lower than expected from single-crystal data [1]. These results question the reliability of Brillouin scattering of polycrystalline materials and they illustrate that several poorly understood processes might affect the derived sound wave velocities, including a preferred orientation of the crystallites (texturing), non-hydrostatic conditions in the diamond-anvil cell, and grain size effects.

Here, we report the elastic properties of nano-crystalline MgO powder determined by Brillouin scattering to pressures above 30 GPa. We find the acoustic velocities to be significantly lower than reported data on single-crystal MgO. A careful characterization of the crystallite sizes in our sample material by synchrotron x-ray diffraction and high-resolution scanning and transmission electron microscopy shows that the average crystallite size stabilizes at about 7 nm at high pressures. The small crystallite size has a profound effect on the elastic properties and is responsible for the observed low velocities in MgO. We show that this effect prevails at high pressures.

Based on our first data analysis, zero-pressure bulk and shear moduli of the intercrystalline material (mostly grain boundaries) are reduced by about 70 % and 80 %, respectively, as compared to the crystalline material. The effect of grain size on the measured velocities is by far exceeding any effects of non-hydrostaticity and texturing. Our findings imply that a thorough characterisation of the crystallite size distribution is crucial for the interpretation of Brillouin scattering results from polycrystalline materials.

Synchrotron X-ray diffraction of nano-crystalline MgO Powder to 65 GPa

HAUKE MARQUARDT[1], SERGIO SPEZIALE[1], HANS JOSEF REICHMANN[1] AND HANNS-PETER LIERMANN[2]

[1]German Research Center for Geosciences (GFZ), Telegrafenberg, 14473 Potsdam (hama@gfz-potsdam.de)
[2]DESY, PETRA III, Notkestr. 85, 22607 Hamburg

The compression behavior of nano-crystalline materials (crystallite sizes smaller than 100 nm) might significantly differ from the behavior of larger grained materials.

We compressed MgO powder with an average crystallite size of about 20 nm in a diamond-anvil cell. The sample material was loaded either with or without a pressure-transmitting medium. Our results indicate that the crystallite size is preserved in the quasi-hydrostatic experimental run, whereas it reduced to below 10 nm in the non-hydrostatic experiment.

High-pressure synchrotron x-ray diffraction was performed at DESY/PETRA III beamline P02.2 using an energy of about 42.8 keV, a focusing spot of ~2 x 2 μm^2, and a collection time of 30-60 seconds. Up to nine diffraction lines could be detected at high-pressures.

Our results that were collected in hydrostatic conditions indicate that the zero-pressure bulk modulus is slightly decreased as compared to large-grained MgO [1], but both zero-pressure volume and zero-pressure derivative of the bulk modulus are unaffected within the experimental uncertainties. The material that was non-hydrostatically compressed appears to be less compressible compared to the same (starting) material that was quasi-hydrostatically pressurized. The compression behaviour in this run is, however, likely also influenced by a continuous crystallite size reduction and the consequent increase of the volume fraction of intercrystalline material in the sample, that occurs upon compression in non-hydrostatic conditions.

Focused ion beam cutting of large samples for Brillouin spectroscopy

KATHARINA MARQUARDT AND HAUKE MARQUARDT

German Research Center for Geosciences (GFZ), Telegrafenberg, 14473 Potsdam (hama@gfz-potsdam.de)

Brillouin spectroscopy is a major technique for the determination of elastic properties of single-crystals at high-pressures and high-temperatures. Brillouin scattering at extreme conditions is usually carried out in symmetric platelet forward scattering geometry, which allows for a straightforward evaluation of shear and compressional velocities. However, well-polished platelet samples with parallel faces are required. Mechanical polishing is restricted to materials of sufficient size and mechanical stability. This precludes the preparation of a number of compounds with significant geophysical relevance, including both natural samples and candidate Earth materials that are synthesised at high-pressure/high-temperature conditions (for instance ferropericlase, perovskite).

Here, we show that ion cutting and polishing is a very elegant approach to prepare μm-sized samples of well-defined thickness with high surface quality. It does not expose the samples to mechanical forces, thus allows for preparing materials that are brittle, meta-stable, or show a strong cleavage. In addition, it offers the chance to cut more than one sample from a piece of material, for instance two platelets with different orientation from one single-crystal (fig. 1). A transmission electron microscopy (TEM) foil can be produced simultaneously. This allows for a detailed characterization, including chemical composition, crystallographic orientation, defect structure and secondary phases, of the same sample material, i.e. the same single-crystal, that is later used for optical spectroscopy.

We successfully tested this method on different geomaterials, including perovskite, ferropericlase, spinel, and antigorite.

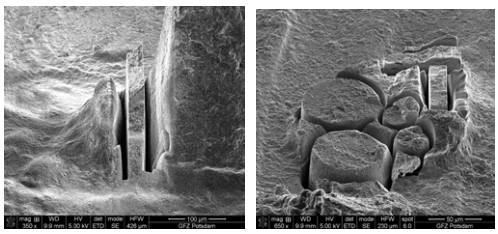

Figure 1: Secondary electron images of a perovskite single-crystal platelet that was cut from an aggregate made up of several single-crystals. The platelet, with approximate dimensions of 180 x 180 x 30 μm^3, was double-side polished (left). The platelet was manually flipped by 90° and again inserted into the dual beam machine (right). Several samples were cut for Brillouin spectroscopy, single-crystal x-ray diffraction and TEM analysis.

[2]Dep. Geociências, Univ. Aveiro, Aveiro, Portugal
[3]GeoBioTec, Univ. Aveiro, Aveiro, Portugal

Introduction

Red paleosols developed on volcanic ashes occur in Fogo island (Cape Verde, semi-arid climate). Four samples were collected in a vertical profile (70 cm depth) of paleoweathered volcanic ashes (Monte Almada, western Fogo) with decreasing grain size upwards and varying in colour: P1-1- dark gray + dark reddish brown; P1-2 – dark yellowish brown + yellowish brown; P1-3 – red; and P-4 – weak red at the top. The paleosol is underlayed by carbonatite and covered by nephelinite lavas. Chemical and mineralogical analyses were done by INAA, Mössbauer spectroscopy and XRD.

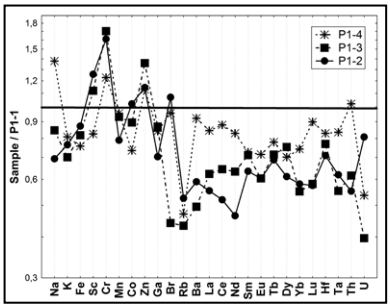

Figure 1: Chemical variations with depth.

Discussion of Results

A general decrease of the analysed chemical elements (rare earth elements included) occur in the upper levels (Fig.1, where sample P1-1, collected at the bottom, was used as reference). Exceptions were found for Cr and Zn. Na is enriched at the top level. Quartz, augite and phyllosilicates are ubiquitous. Magnetite is present in the lower P1-1 and P1-2 levels and gradually oxidizes towards maghemite in P1-3 and P1-4. Hematite is observed in all samples, its content increasing upwards. Fe^{2+} is incorporated in phyllosilicates and augite throughout the profile. The Fe^{2+}/Fe^{3+} ratio is slightly lower in the surface level.

Horozontial and vertical water mass tracing of the SW Pacific Ocean during the last deglaciation

J.P. MARR[1], J.A. BAKER[1], L. CARTER[1], A. ALLAN[1], K. CHRISTENSEN[1] AND H.C. BOSTOCK[2]

[1]Victoria University of Wellington, Wellington, New Zealand (*correspondence: julene.marr@vuw.ac.nz)
[2]National Institute of Water and Atmospheric Research, Wellington, New Zealand

We have measured Mg, Al, Mn, Zn, Sr and Ba/Ca ratios for *Globigerina bulloides* by LA-ICPMS, in a high-resolution marine sediment core (MD97-2121, 40°22.935′S; 177°59.68′E; 25 ka to present) from the SW Pacific Ocean at centennial scale resolution. The core site resides beneath two major, interacting surface water masses (Subtropical Water [STW], Sub-Antarctic Water [SAW]). Mg/Ca ratios record a change in mean ocean temperature of 6°C from the last glacial period to the Holocene, with a maximum regional temperature difference of 11°C. Alkenone paleo-ocean temperatures from the same core record significant differences with an earlier (2 kyr) onset of deglaciation, subdued short-term temperature variability and do not define the Antarctic Cold Reversal, which is clearly visible in the Mg/Ca record. Mg/Ca ratios in the final (*f*) and antepenultimate (*f-2*) chamber of *G. bulloides* appear to reflect its migration through the water column at differing stages of its life cycle. Holocene Mg/Ca values have a 20% difference between chambers f and f-2 compared to 10% during the last glacial period, suggesting a reduction in the glacial surface ocean thermal stratification. Measurement of Mn, Ba and Zn in *G. bulloides* from a regional suite of core-tops potentially discriminates STW and SAW. The down-core results demonstrate a dominance of SAW during the last glaciation when enhanced winds forced northward transport of surface waters, accompanied by increased upwelling, and a prominence of STW during the Holocene.

https://doi.org/10.1180/S0026461X00006502 Published online by Cambridge University Press

Controls on modern and paleo-shell weights of *G. bulloides* in the SW Pacific Ocean

JULENE MARR, ANNETTE BOLTON, KYLIE CHRISTIANSEN, JOEL BAKER* AND LIONEL CARTER

Victoria University of Wellington, P.O. Box 600, Wellington, New Zealand (*correspondence: joel.baker@vuw.ac.nz)

Shell weights of the planktic foraminfera *G. bulloides* have been used to track changes in near-surface ocean carbonate ion concentrations over the past 50 kyr in the Atlantic Ocean [1], and to hypothesize that anthropogenic atmospheric CO_2 increases and ocean acidification resulted in decreases in modern *G. bulloides* shell weights as compared to mean Holocene weights in the Southern Ocean [2]. We have carried out a study of the test sizes and weights, and trace element chemistry of 'modern' *G. bulloides* in sediment core-tops from the SW Pacific Ocean (latitudes 33-53°S; T=7-19°C). Mean size-normalized shell weights (SNW) correlate negatively with near-surface ocean temperature in the SW Pacific Ocean ($T = 31.8 \times e^{-30.5 \times SNW}$) and, unlike the study of [1], shell weights are heaviest in southernmost sites of *lowest* temperatures and *lowest* carbonate ion concentrations. Similar suites of data have been obtained for *G. bulloides* from sites offshore of eastern New Zealand for the past 25 kyr covering the last deglaciaton, and MIS-33 to MIS-29 encompassing the warm MIS-31 interglacial when collapse of the Ross Ice Shelf and substantive ice loss from West Antarctica may have occurred [3]. Hypothetical *G. bulloides* SNW can be calculated for these paleo-records using the modern relationship between ocean temperature and SNW, Mg/Ca paleo-ocean temperatures, and then compared with measured SNW. In the current interglacial (<10 kyr) and the MIS-29 interglacial, measured SNW are in good agreement (within 10%) of predicted values. However, during the last and MIS-30 glacial periods, measured SNW are often more different (up to 30%) than predicted SNW, although the modern ocean temperature-SNW relationship is still the prominent control on SNW. During and prior to MIS-31, measured SNW deviate significantly (up to 100%) from predicted vaues and, in fact, correlate positively with Mg/Ca paleo-ocean temperatures and, presumably, are largely controlled by carbonate ion concentrations. These results demonstrate the complexity in attributing changes in *G. bulloides* SNW to one process both in different ocean settings and also back in time at a single site in the SW Pacific Ocean.

[3]Institut für Anorganische Chemie, Universität Regensburg, 93040 Regensburg, Germany

In the context of underground storage of radioactive waste, investigating water molecules dynamics in swelling clays considered in engineered barriers is of prime importance. In the vicinity of the canisters containing the nuclear waste, the temperature can reach more than 350K. Swelling clay minerals are lamellar alumino-silicates with permanent negative charge compensated by exchangeable cations situated between clay layers. In contact with water, the cations hydrate, leading to the formation of one, two or more layers of water confined between clay surfaces.

We study the translational dynamics of water in clays in low hydrated states by coupling quasi-elastic neutron scattering experiments (Neutron Spin Echo or NSE) and molecular dynamics (MD) on a large scale of temperature range where water remains liquid. As the natural montmorillonite clay of interest is complex to analyze because of interstratification, we chose to model it by a synthetic clay with well-defined states of hydration [1]. The activation energies of the diffusion processes determined by NSE are around 6 kJ/mol higher than for bulk water, for both the hydration states studied. The simulations are found to be in good agreement with experiments for relevant set of conditions [2] and they allow more insight into the origin of the observed dynamics, like the influence of hydrogen bonding and specific interactions with the surfaces.

Competition between lanthanides and Al for humic acid binding

R. MARSAC*, M. DAVRANCHE, G. GRUAU AND A. DIA

Geosciences Rennes, Rennes 1 Univ., UMR 6118 CNRS, France (*correspondence: remi.marsac@univ-rennes1.fr)

Lanthanides or rare earth elements (REE) are commonly studied as analogues of actinides. This group of 14 elements present a unique feature related to their similar and coherent chemical properties. In natural waters, REE aqueous concentrations and transport is strongly affected by dissolved organic matter such as humic acids (HA). However, in organic-rich waters, different REE concentration patterns are observed. A first explanation is the heterogeneity of HA binding sites: REE-HA pattern is the fingerprint of the dominant REE binding HA sites. Previous study showed that light REE (LREE) are more bound to HA carboxylic sites whereas heavy REE (HREE) are more bound to HA phenolic sites. Secondly, in natural waters, various cations are also bound to HA and might therefore affect REE-HA binding and subsequent pattern. Al is one of the major competitor cation for REE regards to its high affinity for HA and it strong concentration in natural waters.

Al-REE competition experiments for HA binding were performed between pH 3 and 6. Results were modelled with Model VI, a specific humic-ion binding model. It appeared that Al^{3+} and $Al(OH)^{2+}$ present the same affinity for HA sites as already assumed in Model VI. However, Al^{3+} and $Al(OH)^{2+}$ are stronger competitors for HREE than LREE, which is not expected in the model and was attributed to Al strong affinity for HA phenolic groups. From pH 5 to 6, Al competitive effect decreases because of $Al(OH)_3$ precipitation. However, Al becomes more competitive for LREE than HREE regards to the $Al(OH)_2^+$ binding to HA carboxylic groups. Model VI parameters were re-evaluated and, for the first time, $Al(OH)_2^+$ was also considered to bind to HA. The new set of Al parameters improved model accuracy for both our REE-Al competitive experiments and Al-HA data from literature.

REE-Al competitive study for HA shows a new Al-HA binding mechanisms which was not observed before. These results highlight the strong impact of competitor cations on the REE-HA binding behaviour in natural organic-rich waters. This study provides a more accurate description of Al-HA binding and, therefore, will indirectly improve REE and actinides speciation modelling in environmental systems.

Recycling agents in subduction zones: Fluids, melts and solids!

HORST R. MARSCHALL[1] AND JOHN C. SCHUMACHER[2]

[1]Dep. of Geology & Geophysics, WHOI, Woods Hole, MA 02543, USA, (hmarschall@whoi.edu)

[2]Dep. of Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK, (j.c.schumacher@bristol.ac.uk)

Sediment melts and hydrous fluids loaded with solutes generated in the subducting slab at elevated *P-T* conditions are thought to transport differing amounts of trace elements and variable isotopic signatures from the subducting slab into the overlying mantle, where they ultimately contribute to the source region of magmas produced at convergent plate margins. Conventional geochemical models of subduction zones consider trace elements to be derived from two distinct sources: hydrous fluids derived from altered oceanic crust during subduction and partial melts derived from the thin sedimentary veneer. However, the physical processes of transport and mixing of these contributors within the subduction factory are largely enigmatic.

Studies on exhumed subduction mélanges suggest that hybrid rocks with newly grown minerals concentrate, sequester and redistribute water and key trace elements [1, 2]. The strong petrologic and chemical contrast at the slab-mantle interface, produces these hybrid rock compositions by metasomatic reactions, diffusion and mechanical mixing: the Al-, Si- and alkali-rich slab that carries crustal isotopic signatures and trace-element abundances is juxtaposed with the Mg-rich ultramafic rocks of the harzburgitic mantle. Mechanical mixing of crustal and mantle rocks will propagate the formation of hybrid rocks, and fluxing by hydrous fluids derived from the dehydrating slab will enhance reactivity and lead to fluid saturation of the newly formed rocks.

The identification of cold plumes in high-resolution numerical experiments [3] provides a mechanism to transport buoyant hybrid rocks from the slab-mantle interface towards the source region of arc magmas. Mélange rocks travelling into the mantle wedge in ‘wet’ diapirs would be subjected to *P-T* conditions dramatically different from those at the slab surface. Partial melting of hybrid rocks may produce the large range of major and trace-element compositions found in modern island arc volcanic rocks.

Erosion monitored by riverine sediment Ti-in-quartz, Southern Alps, New Zealand

C.E. MARTIN*, K.B. MCKERCHER AND J.M. PALIN

Dept. of Geology, Univ. of Otago, P.O. Box 56, Dunedin 9054 NZ (*correspondence: candace.martin@otago.ac.nz)

Quartz is an abundant mineral in the surface environment, and can have as its source a variety of primary and recycled sources. Recent developments have shown that Ti incorporation into quartz is proportional to crystallization temperature, pressure, and *a* (TiO_2) [1, 2]. We have explored the use of Ti and other trace elements as a fingerprint of the source of quartz sediment in rivers draining the actively uplifting and eroding Southern Alps of New Zealand.

The Haast River drains the western side of the Southern Alps and experiences very high rainfall and erosion rates. The bedrock schist within the catchment exhibits a metamorphic field gradient from chlorite through garnet-oligoclase zone. Quartz in these rocks have Ti concentrations that reflect prograde re-equilibration of detrital grains and crystallization of new quartz in the presence of ilmenite or titanite at appropriate pressures [3].

Sediment was collected along the length of the river system and sieved to obtain grain size fractions. Quartz grains from each size fraction were mounted in epoxy, polished and analyzed by LA-ICP-MS. Raw intensity data were normalized via analyses of the NIST 610 standard to obtain trace element concentrations. Ti-in-quartz temperatures [1, 2] were calculated using estimated pressure and *a* (TiO_2) for the schist bedrock.

Quartz sediment shows changes in trace element concentrations and Ti-temperature with location that reflect the metamorphic grade of the upstream bedrock. Several samples exhibit smooth variations with grain size. Bulk chemistry and mineralogy of bedload sediment have previously shown that physical erosion dominates over chemical weathering processes in the Haast River catchment but were unable to discriminate the bedrock sources [4]. Our results for the Haast River indicate that Ti-in-quartz can be a sensitive provenance tracer for sand; we are currently analyzing quartz sediment from other active river systems and sedimentary basins on the South Island in order to assess the robustness of the method.

Contribution of groundwater to chemical weathering fluxes in the Pingtung Plain, Taiwan

CAROLINE MARTIN[1]*, ALBERT GALY[1], NIELS HOVIUS[1], MIKE BICKLE[1], IN-TIAN LIN[2], MING-JAME HORNG[3], DAMIEN CALMELS[4], HAZEL CHAPMAN[1] AND HONGEY CHEN[5]

[1]Dept. Earth Sciences, University of Cambridge (*correspondence: ceam4@cam.ac.uk)
[2]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan
[3]Water Resources Agency, Ministry of Economic Affairs, Hsin-Yi Road, Taipei, Taiwan
[4]Institute de Physique du Globe, Paris, France
[5]Dept. of Geosciences, National Taiwan University

The concentration of dissolved cations in flowing groundwaters of the Pingtung Plain gravel, sand and clay aquifer systems in southwest Taiwan demonstrates that underground circulation is a significant source of major and trace ions to the ocean for Taiwan, comparable in magnitude to the weathering flux measured in the surface runoff of the Pingtung Plain in the Kaoping River. The waters from 33 wells at varying depths through a 280 m window in the plain were analysed for cations: Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, Sr^{2+}, Fe^{2+} and Ba^{2+}, and anions: Cl^{-}, SO_4^{2-} and NO_3^{-}, and compared with a 5-year bi-weekly time series from the Kaoping River. Multi-year hydrological head data gives the direction of groundwater flow through the drilled depth of the basin, and indicates that pumping of the aquifer for irrigation and fish farming has had a limited effect on the hydrological stability of the system. Hydraulic conductivities for each well location show that hydrological connectivity exists throughout the drilled depth of the basin whereas chemical gradients suggest that stratified flow is in operation. At the proximal position of the groundwater flow paths, the concentration of dissolved species in the groundwater ranges from 1.1 to 3.3 times that of the Kaoping River; increasing to 2.3 to 8.5 times the Kaoping River values at the coastal region of the aquifer, indicating that net chemical weathering occurs along subsurface flow pathways. When compared to the 5-year time series for the Kaoping River, the relative contribution of subsurface fluxes is between 40 to 50% for Na, K, Sr, Ca and around 30% for Mg and SO_4. The results suggest submarine groundwater discharges in the Taiwan strait and that the impacts of groundwater from active margins on global ocean geochemcial budgets need to be much better constrained.

Nd and Hf model ages in the Western Gneiss Region, Norway: A new way to better understand mantle-crust evolution

CÉLINE MARTIN[1,2], STÉPHANIE DUCHÊNE[1,3], BÉATRICE LUAIS[1] AND ETIENNE DELOULE[1]

[1]CRPG, Nancy-Université, CNRS, 15 rue Notre Dame des Pauvres 54501 Vandoeuvre les Nancy cedex
[2]present adress: DGLG – WE - Vrije Universiteit Brussel, Pleinlaan, 2 B-1050 Brussels
[3]present adress: LMTG, UMR 5563, CNRS - UPS Toulouse III - IRD, 14 rue Edouard Belin, 31400 Toulouse

The signification of Hf model ages is revisited through the study of metabasites and their gneissic host-rock of Vårdalsneset (Western Gneiss Region, Norway), with the comparison of Nd and Hf model ages, that are assumed to be similar for a given sample.

Three different mantle-crust differentiation models currently exist on the basis of Nd and Hf isotope systematics: (i) the canonical model with chondritic Earth and an unique early step of differentiation, (ii) a model with chondritic Earth and a continual growing crust since 3 Ga and (iii) a model with sub-chondritic Earth and a continual growing crust since 4.56 Ga, and they remain to debate. It is therefore expected that Nd and Hf model ages calculations could allow the validation of one of these models.

Rock protoliths as well as trace-element mobility are characterized by a petrological and geochemical study. Metabasic samples likely came from cumulates and MORB-type basalt whereas gneiss could represent paragneiss and not orthogneiss as usually accepted in the WGR of Norway.

As the trace elements appear slightly mobile, the Nd and Hf isotopic data enable to calculate model ages.

Interestingly, whatever the crust-mantle differentiation model used, Nd model ages are equal within error contrarily to Hf model ages (Table 1).

	Nd (i)	Hf (i)	Nd (ii)	Hf (ii)	Nd (iii)	Hf (iii)
min	1.44±0.35	2.18±0.39	1.16±0.30	1.44±0.38	1.09±0.34	1.22±0.39
max	1.87±0.02	3.21±0.52	1.44±0.06	1.97±0.78	1.31±0.04	1.56±0.38

Table 1: Nd and Hf model ages in Ga calculated on metabasites for the three mantle-crust differentiation model.

We assume that both Nd and Hf model ages should be in agreement with metabasites zircon U-Pb age (1.15 ± 0.20 Ga). Thus, we show that only the third model with sub-chondritic Earth and a continual growing crust since 4.56 Ga allows to obtain significant model ages with both Nd and Hf isotopic systems ranging from 1.09 ± 0.34 to 1.56 ± 0.38 Ga.

Pb isotopic history of weathering on Antarctica during the Eocene-Oligocene transition

ELLEN E. MARTIN[1] AND CHANDRANATH BASAK

Dept. of Geological Sciences, Univ. of Florida, Gainesville, Fl 32611, USA (eemartin@ufl.edu, basakc1@ufl.edu)

The initiation of Antarctic continental glaciation at the end of the Eocene is one of the most dramatic climate events in the Cenozoic. Drawdown of atmospheric CO_2 below a threshold value is considered one of the prerequisites for this glacial transition, suggesting a possible role for silicate weathering. In this study we compare Pb isotopes recorded in Hydroxylamine Hydrochloride extractions (seawater) and residual terrigenous material from two intermediate water, circum-Antarctic sites (ODP Sites 689 and 738) to evaluate the extent of chemical weathering and the composition of weathered material during the Eocene/Oligocene transition (EOT). Prior to the EOT, seawater and residues record similar $^{206}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ values. At the EOT, both sites record increasing seawater and residue $^{207}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ values, with some structure apparent in the higher resolution record of Site 738 that matches the two-step glacial transition defined by $\delta^{18}O$. In contrast, $^{206}Pb/^{204}Pb$ values for seawater become more radiogenic at both sites, while values for residues become less radiogenic.

The similarity between seawater and residue values for all three Pb isotopic systems suggest extensive, congruent chemical weathering that may have started during the warm Eocene, an interpretation supported by other proxies. Variations in residue Pb isotopes starting at the EOT imply intensified mechanical weathering that incorporated multiple silicate source rocks with different chemical compositions. This interpretation is consistent with the idea that the glaciers weathered rocks from a broader region as they grew. The fact that seawater Pb isotopic values track residue values argues that the silicate mechanical weathering products from the glaciers were exposed to active chemical weathering and controlled the local seawater Pb isotopic signal. This silicate weathering could have contributed to the drawdown of atmospheric CO_2. The correlation with the $\delta^{18}O$ two-step also implies that intervals of cooling and ice growth were associated with weathering pulses. The pattern for $^{206}Pb/^{204}Pb$ values is distinct from the other two isotopic systems after the EOT and is interpreted to represent weathering of Phanerozoic carbonates that contribute uranogenic, but not thorogenic, Pb. Weathering inputs from these carbonate source rocks may have contributed to deepening of the carbonate compensation depth.

Experimental determination of CO_2/H_2O in subduction zone fluids by GC-TCD analysis

LAURE A.J. MARTIN[1] AND JOERG HERMANN[2]

[1]Research School of Earth Sciences, The Australian National University, 0200 Canberra (laure.martin@anu.edu.au)
[2]Research School of Earth Sciences, The Australian National University, 0200 Canberra (joerg.hermann@anu.edu.au)

Carbon recycling in subduction zones plays an important role in the evolution of climate through geological time and in the formation of diamonds in the deep mantle. Carbonates formed during seafloor alteration of the oceanic crust are buried into the deep Earth along subduction zones. Experimental studies on the phase stability in H_2O-CO_2-bearing basaltic compositions indicate that the fluid at sub-arc depth is dominated by H_2O [1]. However, experimental studies are hampered by the difficulty to estimate accurately the H_2O/CO_2 of the fluid in the experimental products.

We conducted experiments with a starting material made of a synthetic K_2O, CO_2 and H_2O-bearing basaltic composition between 3.0 and 3.5 GPa, 700 - 775°C in a piston-cylinder apparatus. The experimental results indicate that the solidus occurs between 700 and 750°C at both 3.0 and 3.5 GPa. At T≤750°C, dolomite and magnesite coexist with garnet, omphacite, phengite, epidote, coesite, rutile ± kyanite. At T≥750°C, Mg-calcite±dolomite coexist with melt, garnet, omphacite, epidote, rutile ± coesite and phengite.

The experimental capsules have been pierced under vacuum and the experimental gas, mixed with pure He, has then been directly analysed with an Agilent Technologies 6850 gas chromatograph equipped with a thermal conductivity detector (GC-TCD). The accurate determination (±5%) of small quantities of CO_2 and H_2O in a He mixture by GC-TCD method has been validated in using pure standards of these gas and the elaboration of the calibration lines between their partial pressures in a He mixture versus the peak area read in the chromatograms. P_{CO2}/P_{H2O} of the gas mixture in equilibrium with the sub-solidus assemblages decreases with pressure from 6.3 to 4.0, confirming the previous estimations of low CO_2 contents in such aqueous fluids [1]. The gas mixture released from experiments above the solidus is characterised by P_{CO2}/P_{H2O} ranging from 6.1 to 3.6. This indicates that some H_2O and CO_2 are released from the glass during quenching. Therefore, analyses of the glass and the quench fluid are needed in order to quantify the CO_2 release during partial melting of altered oceanic crust.

Influence of different sources on cloud condensation nuclei numbers in the high Arctic

M. MARTIN[1]*, B. SIERAU[1], C. LECK[2] AND U. LOHMANN[1]

[1]ETH Zurich, Institute for Atmospheric and Climate Science, Universitätsstr. 16, 8092 Zurich, Switzerland (*correspondence: maria.martin@env.ethz.ch)
[2]Department of Meteorology, Stockholm University, Stockholm, Sweden

Introduction

A thin cloud layer is often observed in the high Arctic in summer. The sources of particles in this region that act as cloud condensation nuclei (CCN) can be long-range transport from continental sources, but also primary particles emitted from the Central Arctic Ocean including the pack ice area, and secondary formed from local sources or transported precursors might contribute.

The ASCOS (Arctic Summer Cloud Ocean Study) campaign on board an icebreaker was undertaken into the high Arctic in summer 2008 to investigate aerosol properties. Measurements from two CCN counters are presented.

Results and Discussion

CCN properties were analysed and classified based on different meteorological conditions, and CCN number concentrations were correlated with different air mass source regions. The CCN concentration and the activated fraction was very variable throughout the campaign.

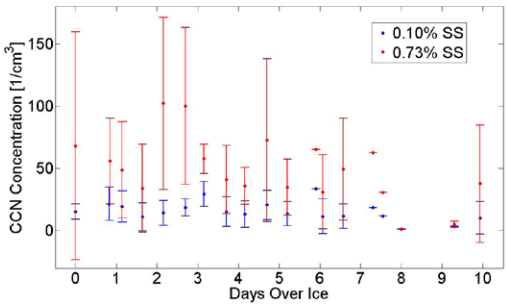

Figure 1. Measured CCN concentration at 0.10 and 0.73% supersaturation as a function of the number of days the air spent over the ice.

The data was also investigated using the time, which the air masses spent over the pack ice before reaching the ship (see Fig. 1). High concentrations after a few days over the ice can be taken as a hint for local particle sources.

Which is more ionic? UO_2 or PuO_2

RICHARD L. MARTIN

Theoretical Division, Los Alamos National Labnoratory, Los Alamos, NM (rlmartin@lanl.gov)

The electronic structure of many of the oxides containing *d*- and *f*-elements has long been a challenge for theory. For example, the traditional workhorses of density functional theory, the local density approximation (LDA) and the generalized gradient approximations (GGA), predict most of these systems to be metallic, when in fact they are insulators with band gaps of several eV. These problems reflect the localization/delocalization dilemma faced in systems with weak overlap and seem to be largely overcome by the new generation of hybrid density functionals developed for molecular studies. Only fairly recently has it been possible to apply these functionals to solids but in the cases studied thus far we find a distinct improvement when comparing with experiment. Hybrid functionals have also made a counterintuitive prediction: that of significant covalency in PuO_2, as opposed to UO_2; a prediction that has now been addressed by experiment. I will review predictions of the theory and recent experimental work on the first single-crystal quality samples of PuO_2.

Covalency in the actinides probed with ligand K-edge X-ray absorption spectroscopy

RICHARD L. MARTIN AND ENRIQUE R. BATISTA

Theoretical Division, Los Alamos National Laboratory, Los Alamos, NM 87544 (rlmartin@lanl.gov, erb@lanl.gov)

I will discuss experimental and theoretical investigations of ligand K-edge X-ray absorption spectroscopy for a number of actinide complexes and solids. Evidence for *f*-orbital – ligand bonding interactions will be presented, and the ramifications of this for actinide electronic structure discussed.

Corals constrain $CaCO_3$ chemistry at the Triassic–Jurassic boundary, a potential ocean acidification event

ROWAN C. MARTINDALE, WILLIAM M. BERELSON, FRANK A. CORSETTI, DAVID J. BOTTJER AND A. JOSHUA WEST

University of Southern California, Los Angeles, USA (rmartind@usc.edu, berelson@usc.edu, fcorsett@usc.edu, dbottjer@usc.edu, joshwest@usc.edu)

Ocean acidification associated with emplacement of the Central Atlantic Magmatic Province (CAMP) has been suggested as a kill mechanism for the Triassic–Jurassic (T–J) mass extinction (~200Ma), but few direct proxies for ocean acidity are available in the Mesozoic. In this work, we show that the presence of corals and reefs in the fossil record can provide a proxy for saturation state, and we use this proxy to determine the plausibility of an acidification event at the T-J.

The new proxy for surface aragonite saturation (Ω_{Arag}) proposed here uses the physiological constraints of modern corals to determine minimum Ω_{Arag} during the intervals when coral are preserved in the fossil record. Corals lose the ability to biomineralise below aragonite saturation (Ω_{Arag}) of 2 and coral reefs are restricted to $\Omega_{Arag} > 3$, so when scleractinians are preserved in the rock record, surface ocean Ω_{Arag} was > 2, and when coral reefs are preserved, $\Omega_{Arag} > 3$. Coral reefs are preserved throughout the latest Triassic but disappear from the fossil record at the T–J boundary, reappearing in the mid Hettangian (~370 kyr coral gap).

We use atmospheric pCO_2 reconstructions from the literature in conjunction with these Ω_{Arag} limitations to calculate the total dissolved inorganic carbon (TCO_2) in the T-J ocean. Our results suggest that the T-J pCO_2 increases recorded by stomatal and pedogenic carbonate proxies would depress saturation state to the point where it would be extremely difficult for corals to biomineralise ($\Omega_{Arag} < 2$), resulting in a coral and reef gap in the fossil record. However, the Jurassic elevation of pCO_2 observed in the proxies does not produce complete carbonate undersaturation in the surface ocean. Models suggest that higher pCO_2 values (between 3000 ppm and 7000 ppm) could be possible, and at these levels, the saturation state would have been low enough for aragonite undersaturation in the surface ocean. This short but extreme acidification in an ocean with low TCO_2 would explain the significant extinction of calcareous organisms and the Early Hettangian coral gap.

Surface $\delta^{11}B$-pH reconstructions and insights into the dynamics of the oceanic carbonate system during the last deglaciation

M.A. MARTÍNEZ-BOTÍ[1]*, G.L. FOSTER[1] AND D. VANCE[2]

[1]School of Ocean and Earth Science, National Oceanography Centre Southampton, University of Southampton, Southampton SO14 3ZH, UK (*correspondence: M.A.Martinez-Boti@noc.soton.ac.uk)

[2]Bristol Isotope Group, Department of Earth Sciences, University of Bristol, Bristol SO8 1RJ, UK

There is a long-standing debate about the role of an isolated deep-ocean carbon-rich reservoir in the rise of atmospheric CO_2 during the last deglaciation. One of the most commonly invoked hypotheses implies that CO_2 is 'stored' in the deep ocean during glacial periods, and that re-communication of this reservoir with the surface ocean and atmosphere at deglaciations (mainly via upwelling in the Southern Ocean) increases atmospheric pCO_2. While several studies in the Southern Ocean, Eastern Equatorial Pacific and Indian Ocean have confirmed the validity of this hypothesis, others have cast doubt on the existence and even the feasibility of such ^{14}C-depleted reservoir [1-5].

Boron isotopes in planktic foraminifera are a proven proxy for surface oceanic pH [6, 7], which has been shown to provide valuable insights into past changes in the ocean carbonate system and ultimately into past atmospheric pCO_2. Here we will present novel results from sediment cores retrieved from the equatorial regions of several ocean basins that provide valuable insights into the causes and mechanisms of deglacial pCO_2 rise.

Preliminary estimation of scavenging rates in the Guadalete estuary (Bay of Cádiz, Spain) based on U-Th disequilibrium series

C. MARTÍNEZ-RAMOS[1], E. CUESTA[2], M. CASAS-RUIZ[1], J.P. BOLÍVAR[2], E.G. SAN MIGUEL[2], L. BARBERO[3], AND M. BASKARAN[4]

[1]Departamento de Física Aplicada, Universidad de Cádiz (celia.martiramos@uca.es)
[2]Departamento de Física Aplicada, Universidad de Huelva, Spain (estefania.cuesta@dfa.uhu.es)
[3]Departamento de Ciencias de la Tierra, Universidad de Cádiz, Spain
[4]Department of Geology, Wayne State University, Detroit, USA

Several samples were taken along salinity gradient in the Guadalete River estuary (SW Spain), with the aim of estimating the scavenging rates and residence times of U and Th. Scavenging processes can be quantified from the measurements of members of the U-Th series, such as ^{234}Th and ^{238}U, based on the differences in the geochemical behaviour with respect to sorption on to particulate matter. We analyzed the dissolved and particulate ^{234}Th in a suite of water samples. Our results show that the dissolved U is conserved in the estuarine mixing zone. Using a simple box model for the particulate and dissolved ^{234}Th, the calculated scavenging rate constant k and the residence time τ in the lower salinity samples are 0.96±0.28 d^{-1} and 1.01±0.28 d, respectively. At intermediate salinity, these values are 0.74±0.11 d^{-1} and 1.30±0.11 d, respectively. Scavenging rates and residence times from samples in the surrounding Bay of Cádiz, are 0.56±0.08 d^{-1} and 1.69±0.08 d, respectively. A comparison of these values indicate that there is active scavenging (lower residence time) at low salinity region compared to high salinity region towards the sea. Furthermore, these results imply high scavenging rates in the Guadalete River estuary as well as short residence times, as is normally the case in estuarine areas.

Biogeochemistry of Devonian shale gas resources of the Midwest USA: Antrim and New Albany Shales

[6]Sandia National Laboratory, Albuquerque, NM 87185

To better understand the role of subsurface microbial communities in natural gas generation in shales, we have pursued comparison of the aqueous geochemistry, gas isotope geochemistry, organic geochemistry, and microbial ecology in two US gas shale formations. Both formations exhibit key geochemical/isotopic indicators of methanogenesis, including high concentrations of HCO_3^-; $\delta^{13}C$ values of HCO_3^- between 10-33 ‰; low concentrations of SO_4^{2-} and CH_3COO^-; and a strong co-variance of H_2O and CH_4 δD values. These indicators reach more extreme values in the Antrim compared to the New Albany, suggesting greater overall microbial gas generation and/or a more active microbial community in the Antrim. Analysis of extractable hydrocarbons from shale core samples also reveal that biodegradation is much less severe in the New Albany compared to the Antrim. 16S rRNA partial gene sequences from production waters of both formations include both Archaea and Bacteria. Phylogenetic analyses suggest different microbial communities occur both between and within the two formations, yet all exhibit broadly similar functions of bacterial fermentation of hydrocarbons accompanied by predominantly hydrogenotrophic methanogenesis.

Assessment of trace element concentration related to the K-Pg event by the use of PXRF

FRANCISCO J. MARTÍN-PEINADO[1]*
AND FRANCISCO J. RODRÍGUEZ-TOVAR[2]

[1]Department of Soil Science, University of Granada, Spain (*correspondence: fjmartin@ugr.es)
[2]Department of Stratigraphy and Paleontology, University of Granada, Spain

The field portable X-ray fluorescence (PXRF) analyser is a useful tool for screening and assessing contaminated areas. This equipment allows *in situ* trace-element concentrations to be determined both rapidly and easily. According to its advantages, the method reveals especially appropriate when sampling is difficult or even forbidden (e.g. scarce sample, difficult access to sampling or protected areas), as is the case of the K-Pg boundary layer in some sections. To check its potential applicability, the K-Pg boundary layer at the Caravaca section (Murcia province, SE Spain), has been analyzed. In this section, the 2-3 mm thick K-Pg rust-red boundary layer has been previously characterized by the presence of Ir and other geochemical anomalies that, together with other evidences, where related to a extraterrestrial origin. Samples were taken to analyse *in situ* the element concentrations in the sediments of the K-Pg boundary interval, from the uppermost Maastrichtian to the lowermost Danian, including the boundary layer, as well as in the infilling material of trace fossils registered at the K-Pg boundary interval. The results indicated statistical significant differences between the different samples analysed for the following elements: Zn, As, Ti, Fe, Sr, Ca and K. Maximum values of these elements (up to 1480 ppm of As, 1272 ppm of Zn and 166 g/kg of Fe) were detected in the K-Pg boundary layer. Cretaceous sediments were characterized by the lowest concentration of these elements but the maximum values of calcium. Tertiary materials statistically differ from the Cretaceous sediments, with significant increase in Sr, Fe, and Ti and strong decrease in Ca content. Finally, trace fossils registered at the K-Pg boundary interval show variable concentrations according to the type of infilling material.

In this study, PXRF has proved to be a useful tool for screening and assessing particular fossil examples as that from the K-Pg boundary for quick and easy *in situ* determination of trace-element concentrations related to this type of events.

Zircon typologies and internal structures as petrogenetic indicators in contrasting Variscan biotite-rich granite plutons from Northern Portugal

H.C.B. MARTINS[1] AND P.P. SIMÕES[2]

[1]Centro de Geologia, Faculdade de Ciências, Universidade do Porto, Rua do Campo Alegre, 4169-007 (hbrites@fc.up.pt)
[2]Centro de Geologia da Universidade do Porto/ Universidade do Minho, Campus de Gualtar (pimenta@dct.uminho.pt)

The aim of the present morphological zircon study is to characterize the sources reservoirs involved in the generation of the different type of granites, testing the classic 'Pupin method' and zircon geochemistry against the petrogenetic indications given by geochemical and isotopic data. In northern Portugal large volumes of granitoids were emplaced during the last stage (D3) of the Variscan orogeny and display a wide range of petrological signatures. We studied the morphologies, internal structures and geochemistry of zircons from (1) Syn-D_3 biotite granitoids: Ucanha–Vilar, Lamego, Felgueiras, Sameiro and Refoios do Lima plutons (2) Late- D_3 biotite-dominant granitoids: Vieira do Minho pluton and (3) post- D_3 biotite granitoids: Vila Pouca de Aguiar pluton. The typological evolutionary trends suggest a crustal or dominantly crustal origin for the syn-D_3 Refois do Lima granite and for the late- D_3 pluton whereas an hibridisation process is proposed for the Ucanha-Vilar, Lamego and Sameiro granites. The zircon population from the post- D_3 granites define a typological evolutionary trend betweeen calc-alkaline and subalkaline granites suggesting a under crustal or mantle source. The petrogenetic model proposed by zircon typological and geochemical study in all plutons is in accordance with geochemical and isotopic data. In fact the Syn-D_3 biotite granitoids display Sr_i ratios and εNd values varying in the range 0.7072-0.7116 and - 4.4 to - 6.3, respectively; the late- D_3 pluton present Sr_i= 0.7089-0.7090 and εNd = - 5.6 to - 5.7 and finally post- D_3 biotite granitoids present weakly evolved isotopic compositions, Sri=0.7044–0.7077 and εNd=–2.0 to –2.6.

Radon risk and their geological controle in the region of Amarante (Northern Portugal)

L. MARTINS[1], M.E.P. GOMES[1], L. NEVES[2] AND A. PEREIRA[2]

[1]Dep. of Geology, UTAD, 5001-801 Vila Real, Centro de Geociências, Portugal
[2]IMAR, Dep. of Earth Sciences, 3000-272 Coimbra, Portugal

Amarante is located in the border of an extensive tardi-tectonic massif, formed by Hercynian granites. Around Amarante city, two types of the granitic rocks occur: AT1 is a coarse-grained, porphyritic, bi>mu (biotite>muscovite) and AT2 is granite with medium-grained, bi>mu, porphyritic. Other units are metamorphic rocks of Silurian and Devonian in Aboim village. Representative samples of granitic rocks unaltered and with different degrees of alteration were studied. The variations of SiO_2, TiO_2, Fe_2O_3t, MgO, V, Zr, Sr, Ba, U, Fe/(Fe+Mg), their subparallel REE of two unaltered granites suggest a relation by crystal fractionation; and AT2 is the most differentiated granite. The average uranium content of the AT2 granite was found to be 18 ppm, higher than the crustal average, subsequently showing a high radon potential. Accessory minerals from granites were studied through SEM suggesting that, U and Th are mainly concentrated in zircon, monazite, uraninite, thorite and thorianite. In three geological units was evaluated a radioactive background with gamma-ray portable spectrometers and in the granitic rock a gamma ray flux of 289 ηGy/h measured in direct contact with the rock was observed; a lower flux of 155 ηGy/h was observed for metamorphic rocks that also outcrop in the area. An important measured system of fractures with tardi-hercynian directions affects the studied area. Some fractures that crosscut the Amarante granite show a moderate degree of uranium enrichment (26 ppm), with gamma ray fluxes up to 420 ηGy/h.

The indoor radon concentrations, during the winter, were measured in 73 dwellings with CR39 passive detectors. The highest radon levels occur in 35 dwellings and built over the granite AT2 (geometric mean of 430 Bq/m^3), which also shows the highest uranium. Buildings from Aboim village show the lowest U contents and consequent lowest radon levels. Fourteen representative samples of groundwater were analysed for Rn, gross α and β. Groundwater related with AT2 has the highest radon (up to 2295 Bq/l) and the highest gross α (up to 0, 83 Bq/l) allowed by Portuguese legislation. Overall, we can conclude that the area of Amarante city presents a moderate to high radon risk and the area of Aboim presents low to moderate radon risk.

Nitrogen fixation through early Earth history

F. JAVIER MARTIN-TORRES* AND ALFONSO DELGADO-BONAL

Centro de Astrobiologia (CSIC-INTA), Carretera de Ajalvir, km.4, 28850, Torrejón de Ardoz, Madrid, Spain (*correspondence: javiermt@cab.inta-csic.es)

Nitrogen is an essential part of many of the chemical compounds, such as proteins and nucleic acids, which are the basis of all life forms. However, N_2 cannot be used directly by biological systems to build the chemicals required for growth and reproduction. Before its incorporation into a living system, N_2 must first be combined with hydrogen. This process of reduction of N_2, commonly referred to as *nitrogen fixation* may be accomplished chemically or biologically. In this paper we present a study of the evolution of nitrogen fixation through Earth history between 3.4 and 0.5 Gyr ago and its effects on the geophysical Earth system.

Metal-rich brown layers in Arctic Ocean sediments: Climate versus diagenesis

C. MÄRZ[1]*,[2], A. STRATMANN[2], S. ECKERT[2], B. SCHNETGER[2], S.W. POULTON[1] AND H.-J. BRUMSACK[2]

[1]CEGS, Newcastle University, NE1 7RU Newcastle upon Tyne, UK (*correspondence: christian.maerz@ncl.ac.uk)
[2]ICBM, Universität Oldenburg, 26111 Oldenburg, Germany

The sediments of the central Arctic Ocean are a unique archive for past climate and environmental changes in this highly sensitive ocean region. Amongst the most prominent and widespread features of Arctic Quaternary deposits are marked cm- to dm-thick brown layers. Their origin is unclear, and might either be related to specific environmental conditions during either deposition, or to diagenesis. To understand the genesis and composition of these layers, we studied sediments cores from the southern Mendeleev Ridge (RV *Polarstern* Expedition ARK-XXIII/3) by inorganic-geochemical methods (XRF, ICP-MS, Fe extraction) at high resolution.

The brown layers are consistently enriched in Mn and Fe (oxyhydr)oxides, but also in various trace metals (As, Co, Cu, Mo, Ni) that most probably adsorbed to Mn and Fe phases and were scavenged from the water column. These metal enrichments are likely related to enhanced riverine input to the Arctic Ocean, as Arctic river waters are known to be metal-rich. Increased fluvial runoff should be related to a more intense hydrological cycle under warmer (interglacial-type) climate conditions.

However, pore water data indicate ongoing Mn (but not Fe) diagenesis in the recovered sediments, questioning the primary nature of the observed metal enrichments. We suggest that relative changes in the enrichment patterns of specific trace metals (especially of Co and Mo) in individual brown layers might be used to determine if the composition of the respective layers was overprinted by diagenetic processes.

In detail, we observe that brown layers currently serving as pore water Mn sources have Co/Mo ratios above 5, while those layers acting as pore water Mn sinks have Co/Mo ratios below 5. This trace metal pattern may be explained by preferential retention of Co in dissolving Mn (oxyhydr)oxide layers. In contrast, Mo is preferentially desorbed, diffuses through the pore space in conjunction with Mn, and re-adsorbs onto freshly precipitating, authigenic Mn (oxyhydr)oxides. However, the wider application of trace metal ratios as 'diagenetic markers' in Arctic sediments requires further investigation.

Nitrate reduction drives distant sulfide oxidation

U. MARZOCCHI[1]*, N. RISGAARD-PETERSEN[2], N.P. REVSBECH[1] AND L.P. NIELSEN[1]

[1]Section for Microbiology, Department of Biological Sciences, Aarhus University, 8000 Aarhus C, Denmark (*correspondence: ugo.marzocchi@biology.au.dk) (revsbech@biology.au.dk) (biolpn@biology.au.dk)
[2]Center for Geomicrobiology, Aarhus University, 8000 Aarhus C, Denmark (nils.risgaard-petersen@biology.au.dk)

Recent observations in marine sediments show that electric currents may couple oxygen reduction at the sediments surface to sulfide oxidation deep within the sediment [1]. In this study we tested if electric currents can couple also nitrate reduction to sulfide oxidation

Sediment collected from Aarhus bay (Denmark) was pre-incubated for 2 months in two different aquaria: one with oxic seawater and another where oxygen was replaced with nitrate. After the pre-incubation, sulfide, oxygen and pH distribution in the sediment were determined with microsensors whilst a biomicrosensor was used to measure nitrate & nitrite.

Our concentration profiles showed a 4 mm separation between nitrate and sulfide in sediments incubated with nitrate in the water column. In sediments incubated with oxygen in the water column, oxygen and sulfide were separated by 25 mm. In both types of incubation, the pH signature indicated the presence of electric currents coupling spatially segregated biogeochemical processes.

These results provide an important indication of the capacity of nitrate to sustain sulfide depletion over distances not coverable by diffusion only. Moreover demonstrating that oxygen is not the only electron acceptor able to sustain such a system, implies that this distant coupling can be more spread in nature than previously expected.

Origin of Cameroon Line basanites from metasomatized lithosphere

A. MARZOLI[1]*, F.T AKA[2], M. CHIARADIA[3], L. REISBERG[4] AND R. MERLE[1]

[1]University of Padua, Italy (renaud.merle@unipd.it) (*correspondence: andrea.marzoli@unipd.it)
[2]IRGM-ARGV, Ekona, Cameroon (akatongwa@yahoo.com)
[3]Université de Genève, Switzerland (Massimo.Chiaradia@unige.ch)
[4]CRPG (CNRS UPR2300), Université de Lorraine, France (reisberg@crpg.cnrs-nancy.fr)

The Cameroon Line is located above a zone where a sharp gradient in lithospheric thickness occurs north of the Congo Craton keel [1]. This zone was the site of magmatic activity since (at least) the beginning of the Cenozoic until the Present. Here we investigate the Miocene basic-ultrabasic magmatism of Mt. Bambouto volcano (Western Cameroon). Its 20 to 15 Ma old basanitic flows and alkali-basaltic dykes are characterized by extreme enrichments in Sr (up to 2200 ppm), Ba, and P and by generally high TiO_2 (up to 4.6 wt%). The other alkali basaltic flows from Mt. Bambouto lack such extreme compositions and resemble other typical continetal and oceanic Cameroon Line basalts. Compared to the alkali basaltic flows, the Mt. Bambouto basanites yield also slightly higher initial $^{87}Sr/^{86}Sr$ (0.7034-0.7036 vs 0.7030-0.7033) and $^{143}Nd/^{144}Nd$ (0.51290-0.51285 vs 0.51285-0.51283) and lower $^{206}Pb/^{204}Pb$ (19.4-19.6 vs 19.6-19.9). Moreover, basanites are characterized by higher initial $^{187}Os/^{188}Os$ (0.191-0.220) than the only analyzed alkali basalt ($^{187}Os/^{188}Os$ = 0.127). The high Os isotopic compositions of basanites would seem to suggest a significant amount of crustal assimilation (ca. 25 or 35% of silicic upper or mafic lower crust, respectively). However such an interpretation is not easy to reconcile with their OIB-like Sr-Nd-Pb isotopic compositions, their little evolved whole-rock compositions (e.g. MgO 9-11 wt%, Cr 350-550 ppm) and their mineralogy (high-Mg olivines: Fo_{80-88}, high pressure clinopyroxenes: crystallized at ca. 10 kbar [2]). Alternatvely, we suggest that basanites derived from mafic material entrapped within the mantle, which would also be compatible with their major and trace element compositions. In particular, we propose that these mafic veins may have metasomatically pervaded the continental lithosphere during the early stages of Cameroon Line magmatism and developed relatively high $^{187}Os/^{188}Os$ prior to the Mt. Bambouto volcanism.

Magnetic anisotropy of artificial deposits

A.V. MASHUKOV*, A.E. MASHUKOVA AND S.A. SIMINCHUK

Siberian Federal Univ., Krashoyarskiy Rabochiy, 95, Krasnoyarsk, 660025, Russia (*correspondence: avmashukov@sfu-kras.ru)

There was studied the influence of the sizes of grains of Fe_3O_4 in the artificial deposits, precipitating in the Earth magnetic field, on magnetic characteristics of the samples. To obtain most of the information, for the same samples, there was used a complex of investigations of research of same samples was used for obtaining more information.

The dependences of uniaxial anisotropy constant (K), maximum losses from the rotator hysteresis (W_m), the value of the alternating magnetic field, half reducing residual magnetization ($\tilde{H}_{1/2}$) on grain size, are shown in table 1.

Grain size Fe_3O_4, mcm	K, Joule /m^3	W_m, Joule /m^3	$\tilde{H}_{1/2}$, Oe	Intensity
0 < d ≤ 8	410,0	1020,0	320,0	1,9
8 < d ≤ 16	305,0	820,0	280,0	1,8
16 < d ≤ 32	180,0	500,0	200,0	1,5
32 < d ≤ 44	130,0	410,0	120,0	1,3
44 < d ≤ 64	115,0	225,0	110,0	1,2
64 < d ≤ 100	105,0	160,0	105,0	1,1
100 < d ≤ 150	105,0	160,0	100,0	1,1

Table 1: Dependences of magnetic characteristics on grain size

The X-ray technique of straight pole figures (intensity in table 1) shows anisotropic distribution of axes for particles d > 40 mcm.

Thus, the magnetic characteristics of rocks are controlled by ferrimagnetic particle size as well as its crystallographic ordering.

Geochemical variation of fracture carbonates in crystalline bedrock

O. MASKENSKAYA*, H. DRAKE, P. PELTOLA AND M. ÅSTRÖM

Geochemistry research group, School of Natural Science, Linnaeus University, SE Sweden (*correspondence: olga.maskenskaya@lnu.se)

The current study is focused on trace and rare earth elements (REE) in carbonates from two fracture mineral generations formed at separate events at very different conditions, but in the same granitoid fracture system. Both generations are well-characterized and separation is based on paragenesis, $\delta^{13}C$, $\delta^{18}O$, $^{87}Sr/^{86}Sr$ and crystal habit [1]. The oldest generation was formed in the Proterozoic era (~1.4 Ga) [2] and the youngest in the Paleozoic era (~440-400 Ma) [2, 3].

In total, 41 calcite samples and 1 dolomite sample from 17 drill cores (up to 1 km depth), originating from the Swedish Nuclear Fuel and Waste Management Co's investigations in the Laxemar-Simpevarp area, SE Sweden, were analysed (with ICP-MS of calcite leachates).

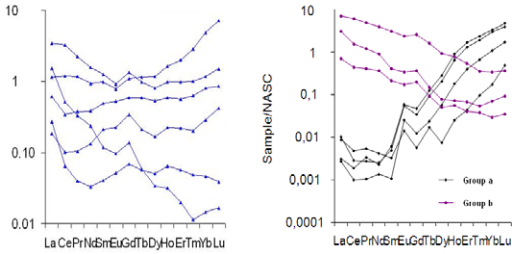

Figure 1: NASC-normalized REE patterns (REE_n) of Proterozoic carbonates (left) and Paleozoic carbonates (right), NASC according to [4].

Proterozoic carbonate shows two groups (a and b) which differ both in REE_n patterns and trace element compositions, accordingly: a) positive Eu_n- and La_n-anomalies, very low light REE concentrations, gradually enriched in REE_n from Gd_n to Lu_n, relatively high amounts of Sr, Mg and Fe; b) no Eu_n- or La_n-anomalies, gradual decrease in REE_n from La_n to Lu_n, depleted in other trace elements.

Paleozoic calcite shows larger REE_n variation including e.g. both slightly enriched heavy or middle REE_n, as well as gradual depletion from La_n to Lu_n. All Paleozoic calcite samples show low trace element concentrations and large Mn and Y variations. Observed trace element variations in different generations are predominantly caused by factors that influenced composition of parental solutions. Intense hydrothermal wall rock alteration in the Proterozoic, and microbial activity and descending organic-rich fluids in the Paleozoic might be these factors.

Microbial sulfur isotope fractionation in littoral sediments: Interpreting $\delta^{34}S$ variability in Archean rocks

PAUL R.D. MASON[1], MARJOLIJN C. STAM[1], ANNIET M. LAVERMAN[2], CELINE PALLUD[3] AND PHILIPPE VAN CAPPELLEN[1,4]

[1]Utrecht University, The Netherlands (mason@geo.uu.nl)
[2]Universite Pierre et Marie Curie, Paris, France
[3]UC Berkeley, Ca, USA
[4]Georgia Institute of Technology, Atlanta, Ga, USA

Sulfur isotope variations in Archean rocks have been used to argue for the presence of sulfate reducing mircoorganisms as one of the earliest forms of life in the early Archean, back to 3.49 Ga [1-3]. Extensive laboratory pure culture and incubation studies with modern sediments have been used to support these interpretations with measured and predicted $\delta^{34}S$ values up to 49 ‰ for a single reduction step of sulfate to sulfide (e.g. [4, 5]). Here we expand the available data for isotope fractionation by natural communities of microorganisms, with an extensive laboratory flow through reactor study, that enables sulfate reduction under close to *in situ* conditions. Sediments were collected from a brackish marine estuary (Sheldt estuary, The Netherlands), a hypersaline soda lake (Mono Lake, California), a freshwater river (Scheldt, Belgium) and a shallow marine hydrothermal system (Vulcano, Italy).

Sulfate reduction rates (SRR) varied between 5 and 180 nmol cm^{-3} h^{-1} with corresponding isotope fractionations (ε), calculated as the difference between inflow sulfate and product sulfide, of 5 to 43 ‰. No overall relationship was found between SRR and ε , but weak correlations were found within the individual sites. Isotope fractionation data fall within the range predicted by standard models with lowest values at highest rates, but do not fall towards the smallest values predicted by the Rees model [5]. Our data indicate that relatively small isotope fractionations (<20 ‰) would be typical for sulfate reducing communities, under optimum growth conditions, and in the absence of competition from other metabolisms. Without an oxidative component in the sulfur cycle, widespread microbial sulfate reduction would result in minor $\delta^{34}S$ variations and may be more widespread in the Archean than previously envisaged.

Catching a collapsing solidification front through thermal gradient experiments

M. MASOTTA[1]*, C. FREDA[2] AND M. GAETA[1,2]

[1]Sapienza - Università di Roma, Italy
(*correspondence: matteo.masotta@uniroma1.it)
[2]Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy

Large explosive eruptions commonly emplace differentiated (i.e. rhyolite, phonolite), crystal-poor juveniles. This is a well-known paradox in volcanology, considering that magmatic differentiation implies crystallization and that crystal-melt separation processes (e.g. crystal settling) are more efficient in high-temperature, primitive magmas. Conversely, differentiated, crystal-poor juveniles are usually associated to shallow, thermally-zoned feeding systems. Here, the generation of differentiated, crystal-poor magmas may be explained throughout the development of a 'solidification front' [1] at the roof of the chamber. Although natural evidences and theoretical models support the solidification front concept, its capability to originate differentiated, crystal-poor magmas remains unconstrained.

By experimentally investigating the formation of a solidification front in a thermally zoned environment we demonstrate its capability to originate glassy belts and pockets phonolitic in composition (figure 1). We recognize in the instability and collapse of rigid crystal frame the driving mechanism producing segregation and upward accumulation of crystal-poor melts and suggest this model may apply to thermally zoned magma chambers.

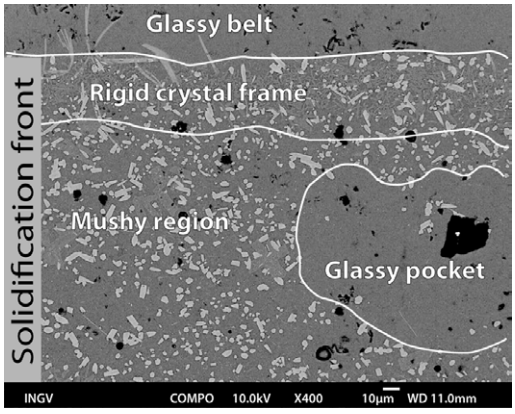

Figure 1: Solidification front obtained in a thermal gradient experiment performed at 300 MPa and T ranging 1000-850°C. The glassy belt (top, cooler zone of the capsule) is phonolitic in composition.

[4]Dep. Eng., Shinshu Univ., Nagano 380-8553, Japan
(nakayas@shinshu-u.ac.jp)

In order to investigate the timing of As release in the Holocene groundwater aquifer, Sonargaon, Bangradesh, age of groundwaters were determined using $^3He/^4He$ ratio. Among the ten well waters collected from the active recharging zone of the Holocene aquifer within 300 m diameters, the lowest $^3He/^4He$ ratio was found in the groundwater containing highest concentration of As >1000 µg/L. Groundwater giving the highest $^3He/^4He$ ratio contained <1µg/L As. Compared with the histrical tritium unit in the air of New Delhi, the former groundwater was recharged after 1980, while, the latter was before 1970. As concentration of the groundwater increases decreasing $^3He/^4He$ ratio, indicating that the As release started after 1980.

In this area, the As conmtaninated Holocene aquifer directly contacts to As-free Pleistocene aquifer due to lack of the Pleistocene impermeable clay layer. Presumably, the As release is triggered by increasing infiltration of groundwater into the Holocene aquifer in association with the increasing withdrawel of groundwaters from the Pleistocene aquifer to cause drastic change of the Holocene aquifer condition.

Fe rich chlorite was found to be a primary source of As, and this mineral was oxidized to precipitate goethite in the aquifer. Thus, the rapid infiltration of aerobic water into the Holocene reducing aquifer is the trigger to cause oxidation-decomposition of the As-bearing chlorite.

Experimental study on As and Cd releases from anoxic sedimentary rock under anoxic and aerobic conditions

S. MASUDA, Y. OGAWA*, K. SUTO AND C. INOUE

Graduate School of Environmental Studies, Tohoku University, Miyagi 980-8579, Japan (*correspondence: ogawa@geo.kankyo.tohoku.ac.jp)

The dissolution behaviors of As and Cd from the anoxic sedimentary rock and subsequent immobilization mechanism were investigated under anoxic and aerobic conditions.

Under aerobic condition, the decrease in pH and concomitant Cd release were attributable to oxidative dissolution of sulfide minerals, and 22 % of Cd in rock sample was dissolved out for 2 months. On the contrary, Cd concentration in the solution reacted under anoxic condition was maintained low level, and the contribution of dissolved Cd was only 0.14 %.

Arsenic was released as arsenite under both conditions. The As concentrations in extracts under both conditions was small, and the maximum contributions of As dissolution were about 1 %. The XANES spectra reveal that samples before the extraction contained the sulfide form As and As(V). Under aerobic condition, the As sulfide completely decomposed within a month and only As(V) existed in the samples after extraction.

The chemical state of As in samples oxidized under 100% humidity was changed to sulphide form to oxide and/or strongly sorbed ones. This experiment shows the change in chemical states of As within rock sample before the contact with water, and the result reveals that the oxidation of As sulfide did not lead to large amounts of As release. On the contrary, under anoxic condition, As and Cd concentrations were maintained low and the sulfate-rich acidic solution was not produced. Furthermore, the sulfide As were still remained in samples extracted for 2 months. These results indicate that the sulfide minerals containing As and Cd in anoxic sedimentary rock almost remained during extraction experiment for 2 months.

The Mesozoic evolution of the West Iberian Margin as witnessed by magma geochemistry

J. MATA[1], C.F. ALVES[1], R. MIRANDA[1,2], L. MARTINS[1], J. MADEIRA[2], P. TERRINHA[2], N. YOUBI[1,3], M.K. BENSALAH[1,3] AND M.R. AZEVEDO[4]

[1]Centro de Geologia da Univ.Lisboa (jmata@fc.ul.pt)
[2]Lattex/IDL
[3]Université Cadi Ayyad Marrakech, Morocco
[4]GeoBioTec, University of Aveiro

The main phases of the onshore West Iberian Margin (WIM) Mesozoic evolution were marked by the occurrence of 3 magmatic cycles separated by time lags of ≈50 Ma. The first cycle (202 - 198Ma) is linked to the initial stages of the Central Atlantic opening, being considered part of an important LIP: the Central Atlantic Magmatic Province. Magmatism produced low-Ti tholeiites characterized by $(La/Yb)n < 4$, $(^{87}Sr/^{86}Sr)_0 > 0.7050$ and $(^{143}Nd/1^{44}Nd)_0$ down to 0.512268 which post-date the beginning of syn-rift sedimentation by ≈ 20-30 Ma. The second cycle (147 - 141Ma) was coeval of the westward rift axis migration from the Lusitanian Basin to the location where oceanization was successfully reached. Preserved rocks are hypabyssal with transitional affinities (moderately alkaline to subalkaline), $6 < (La/Yb)n < 12$, $(^{87}Sr/^{86}Sr)_0 = 0.70403$ to 0.70456 and $(^{143}Nd/^{144}Nd)_0 = 0.512531$ to 0.512664. The third cycle (94 to 72 Ma) was synchronous with the opening of the Bay of Biscay and of the rotation of the Iberia. It was characterized by the formation of abundant alkaline magmatism presenting $(La/Yb)n$ up to 21, $(^{87}Sr/^{86}Sr)_0$ down to 0.702870 and $(^{143}Nd/1^{44}Nd)_0$ up to 0.512897. The geochemical evolution depicted by WIM magmas expresses the diminishing role of lithospheric sources. They prevailed during the first cycle, when magmas present fingerprints of supra-subduction processes probably developed in the lithosphere during the Upper Paleozoic Variscan orogeny.

Molybdate sorption from steel slag eluates by soils

K. MATERN[1]*, T. MANSFELDT.[1] AND T. RENNERT[2]

[1]Department of Geosciences, Soil Geography/Soil Science, University of Cologne, Albertus-Magnus-Platz, 50923 Cologne, Germany (*correspondence: katrin.matern@uni-koeln.de)
[2]Institute of Earth Sciences, Friedrich Schiller University of Jena, Burgweg 11, 07749 Jena, Germany (thilo.rennert@uni-jena.de)

Steel slags are an industrial by-product. The latest statistic of 2009 show a use which amounted to 4.62 mio. t slag in Germany [1]. Over 60 % have been used as construction material (ways, roads, earthworks). Molybdenum is added during steel processing in order to harden the steel. The objective of this study was to evaluate the sorption behavior of molybdate from slag eluates towards different soils to assess the risk that may arise from contamination of ground water by leaching of molybdate.

Molybdate sorption batch experiments were carried out with eluates obtained from (i) steel slag (Linz-Donawitz operation, LD) and (ii) electric furnace slag (EF).

Six different soils and sediments were chosen to provide a wide range of chemical properties (pH 4.0 to 7.6; dithionit-extractable Fe 0.73 to 14.69 mg kg^{-1}). Molybdate sorption experiments were carried out at pH of the steel slag eluates (pH 11 to 12) as well as at pH adjusted to soil pH. The data were evaluated with the Freundlich equation.

Molybdate sorption exhibited a maximum near pH 4 for steel slag eluates which were adjusted to soil pH and decreased rapidly with increasing pH until sorption was virtually zero at pH > 11. Sorption was greater for soils with high amounts of dithionite-extractable iron oxides. Molybdate sorption behavior of both eluates was similar. After reaching equilibrium, the pH of the EF steel slag eluate was lower than the pH of the LD steel slag eluate that was caused by different buffer capacities. Some soils were able to decrease the pH of the EF steel slag eluates by about four pH units enhancing the sorption of molybdate.

The Mo-sorption behavior from steel slag eluates is similar to sorption experiments with commercial Mo standard solutions. The same factors affect Mo-sorption, but Mo-sorption from steel slag eluates is more complex as a result of eluate chemistry.

Brackish marine water intrusion in deep fractured granitic bedrock

F.A. MATHURIN[1]*, B.E. KALINOWSKI[2], M. ÅSTRÖM[1] AND M. LAAKSOHARJU[3]

[1]Department of Natural Sciences, Linnaeus Univ., Kalmar, Sweden (*correspondence: frederic.mathurin@lnu.se)
[2]Swedish Nuclear Fuel and Waste Management Co, Stockholm, Sweden
[3]Geopoint AB, Stockholm, Sweden

Groundwater residing in the fractures of granitic bedrock in a costal environment can be related to the climate changes and seawater stages. The purpose of this study is to hydrogeochemically characterise the different brackish marine water types present at the Äspö Hard Rock Laboratory, an underground bedrock laboratory situated at the Baltic Sea shore, in south-east Sweden [1].

Groundwater samples collected from the different boreholes along the tunnel at 50-560m depth were classified according to their Cl content and $\delta^{18}O$ signature. Groundwater classified as brackish marine component was used to study the Mg/Cl and Mg/K ratios in detail.

For samples with Mg/Cl ratio higher than 0.03, two different trends can be observed both with respect to the Mg and the Cl concentrations. One group of samples is distributed along an evolution line from the present Baltic Sea water (Cl = 3380 mg.L^{-1}). The other group, consisting of fewer samples and higher Cl concentration, appears to gather along an evolution line from the ancient Baltic Sea, also called the Littorina Sea (Cl = 6500mg.L^{-1}; [2]). However, the samples of the second group have lower Mg and Cl concentration than the original Littorina Sea composition. The brackish marine water considered to be influenced by Littorina Sea water is located in relatively shallow fracture sections at 30-180m depth. This suggests storage of Littorina Sea water as pockets in some fractures. Nevertheless the high Mg/K ratio, which is more than four times the ratio of the Littorina Sea water, indicates that a strong water-rock interaction occurred since the Littorina sea water intrusion. The alignment of the samples along different evolution lines of the two different brackish Sea water types shows that mixing processes with other water types [3] take place in the fracture network.

Depth profile of $^{129}I/^{127}I$ ratio in Andisol collected in preserved field of NIAES, Tsukuba, Japan

H. MATSUZAKI[1]*, Y. MAEJIMA[2], T. OHKURA[2], Y.S. TSUCHIYA[1], K. ABE[1], Y. MIYAIRI[3] AND Y. MURAMATSU[4]

[1]The University of Tokyo, Tokyo 113-8656, Japan (*correspondence: hmatsu@n.t.u-tokyo.ac.jp)
[2]NIAES, Tsukuba 305-8604, Japan
[3]AORI, The University of Tokyo, Chiba 277-8564, Japan
[4]Gakushuin University, Tokyo 171-8588, Japan

Depth profile of $^{129}I/^{127}I$ ratio were measured as well as iodine concentration, carbon concentration and $^{14}C/^{12}C$ in Japanese Andisol collected in the well preserved field of National Institute for Agro-Environmental Sciences, Tsukuba, Japan. Today, most of ^{129}I in the surface environment involving soils is originated in the human nuclear activities: atmospheric nuclear bomb testing, spent nuclear fuel reprocessing, and nuclear acceident. To estimate total deposition of ^{129}I in soil precisely and to investigate iodine transfer process correctly, the depth profile information is essential. From the gradient of the profile iodine transfer model can be constructed. If $^{14}C/^{12}C$ profile shows the signal from the bomb testing (110 pMC just below the surface), the sampling field has been undisturbed at least several decades [1]. This study was the case.

Resulting $^{129}I/^{127}I$ depth profile shows steep decreasing trend above 20cm depth. This part can be fitted simple diffusion curve (error function). Below this depth $^{129}I/^{127}I$ come to be rather constant. This observation suggests that there are at least two component of iodine: quick diffusion component (with which most of recent ^{129}I is carried) and rather static component (maybe as old as the mother material of the soil).

The maximum $^{129}I/^{127}I$ ratio in Tsukuba (this study) is 1.67 x 10^{-8} at 1.5cm deep which is as twice as higher than the Shimokita soil (7.29 x 10^{-9}) [1]. This should be due to the influence of a nuclear fuel reprocessing plant at Tokai area located about 60km northern east of Tsukuba. Total deposition density of ^{129}I was calculated using $^{129}I/^{127}I$ ratio profile and iodine concentration of each depth and soil density. That was 0.036 Bq/m^2 corresponding to 2.6 x 10^{13} atoms/m^2. These data should be a reference for the evaluation of the influence of the nuclear power plant acceident like the Fukushima dai-ichi power plant.

Tracking permanent CO_2 storage in basaltic rocks using conservative and reactive tracers at the CarbFix injection site, Iceland

J.M. MATTER, M. STUTE AND W. BROECKER

LDEO, Palisades, NY 10964 (jmatter@ldeo.columbia.edu)

Injection of CO_2 modifies ambient formation waters, inducing fluid-rock reactions that may lead to mineral carbonation of the CO_2. In the CarbFix pilot CO_2 injection project in Iceland, we are investigating *in situ* mineral carbonation of CO_2 in a basaltic aquifer. At the moment, the pilot test involves the injection of 2, 200 tons of CO_2. The CO_2 is injected dissolved in water at a rate of 0.07 kg/s of CO_2 in 2 kg/s of water at 19°C [1].

The success of mineral carbonation in basaltic rocks depends on the ability to monitor and understand the behavior of the injected CO_2. The currently existing monitoring techniques in CO_2 capture and storage are insufficient to characterize mineral carbonation in any storage reservoir. Most geophysical detection methods require that CO_2 is present as a supercritical phase. Dissolved CO_2 and chemically transformed carbon thus avoid detection.

We are using a multi tracer approach, including conservative and reactive tracers to track CO_2 storage in basaltic rocks. Trifluormethylsulphur pentafluoride (SF_5CF_3), a conservative tracer, is injected in pulses into the CO_2 gas stream at a concentration of 2700 pptv. It is used to characterize the physical transport processes of advection and dispersion of the CO_2 solution. Furthermore, the injected CO_2 is tagged with radiocarbon (^{14}C). Radiocarbon is injected as dissolved bicarbonate at a concentration of 1.20x10^1 Bq/kg of injected water. This results in 5x enrichment compared to the 1850 background. The total ^{14}C activity needed for the 2, 200-ton injection is 7.44x10^8 Bq or 20 mCi. We use ^{14}C as a tracer to monitor the CO_2 reactivity in the storage reservoir. Its ratio to carbon in the groundwater of the basaltic aquifer will change as a result of dissolution and precipitation of carbonate minerals. Thus, by measuring the carbon isotopic ratio in water samples collected in monitoring wells, we are able to quantify and verify *in situ* mineral carbonation and therefore long term storage.

Fluid-flow controls of low δ^{57}Fe hydrothermal iron mineralization

A. MATTHEWS[1]*, Y. EREL[1], D. STERN[1], U.RYB[1] AND Y. AVNI[2]

[1]Institute of Earth Sciences, Hebrew University of Jerusalem, Israel (*correspondence: alan@vms.huji.ac.il)
[2]Geological Survey of Israel, Jerusalem 95501, Israel

Low δ^{57}Fe values are characteristic of iron isotope fractionation during bacterial and abiogenic reduction. However, experiments on the Fe isotopic fractionation during sorption-desorption of aqueous Fe on quartz [1, 2] indicate alternative mechanisms for generating isotopically light iron.

We investigate the controls of Fe-isotopic fractionation during low temperature hydrothermal iron mineralization along a 70 km section of a fault (Paran Fault) adjacent to the Dead Sea Transform (DST), which separates the Arabian plate from the Sinai Sub-plate. The MVT type mineralization comprises iron oxide lenses in the fault zone and iron oxide-bearing dolomites in the adjacent Cretaceous host rock limestone. The Mg-Fe rich brines were sourced in evaporite-bearing sandstones (Nubian) underlying the limestone.

Fe isotopic compositions from two 10 km long segments in the west (Haspas) and East (Menuha) parts of the fault show uniformly negative values: Menuha: δ^{57}Fe (Fe-ox) = -1.08±0.4‰ (n=23); (Fe-dol) = -0.87±0.26‰ (n=15); Haspas δ^{57}Fe (Fe-ox) = -0.86±0.26‰ (n=17); (Fe-dol) = -0.61±0.21‰ (n=13). These values represent isotopically light source solutions formed by the dissolution of clastic iron minerals in the sandstone with δ^{57}Fe = 0.34±0.19‰. (n=8).

Both bacterial and abiotic reduction of the clastic iron oxides could have provided isotopically light Fe (II) solutions. However, the highly saline conditions of the sandstone fluids do not necesssarily favour bacterial intervention. An alternative fluid flow model is examined whereby the isotopically light Fe compositions are generated by sorption on sandstone grain surfaces. The uniformity of the Fe isotope composition suggests that fluid flow was generally orthogonal to the E-W trending fault. Northward fluid flow is consistent with the topographic recharge being to the south (present-day Suez Rift) at the Oligocene time of the major pulse of mineralization. Slightly lighter δ^{57}Fe values (≤ -1.0 ‰) in dolomites closer to the DST possibly represent Miocene reactivation related to creation of the transform [3].

Using atomic force microscopy to probe pore surfaces of oil-bearing sandstone

J. MATTHIESEN*, T. HASSENKAM, N. BOVET AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark
(*correspondence: jmatth@nano.ku.dk, tue@nano.ku.dk)

Pore surface properties of oil-bearing sandstone control the oil recovery from sandstone reservoirs. The wettabillity of the pore surface, i.e. the tendency of the surface to cover itself with a fluid, plays a key role in recovery. Pore surface wetting behavior for chalk reservoirs has previously been shown to be inhomogeneous over scales of 10's of nanometers [1]. Here we investigate whether the same applies for sandstone.

Using atomic force microscopy/spectroscopy (AFM/AFS), we have probed the surface wetting properties at the nanoscale of natural oil-bearing sandstones. A self-assembled monolayer of alkane-thiols is formed on the AFM tip surface, creating a hydrophobic layer. Force curves measuring the adhesion between the hydrophobic tip and the sandstone surface were acquired in a 50x50 grid over a 5x5 μm area thereby forming a map of adhesion. Properties such as topography and elasticity were also extracted from these measurements.

We observe that sandstone wettability varies on a sub-micrometer scale. In some areas, the degree of adhesion of the hydrophobic tip decreases with number of scans over the area and the force curves indicate that material is pulled off the surface. Using X-ray photoelectron spectroscopy (XPS) measurements, we saw that the initial surfaces were covered with several layers of carbon containing material. The wetting behavior of the pore surface is thus controlled by adsorbed organic material and not by the actual surface of the mineral. This improved understanding about the wetting behavior of reservoir minerals will hopefully provide clues for increasing oil recovery.

George R. Tilton and the development of U-Pb geochronology

J.M. MATTINSON

Department of Earth Science, Univ. of California, Santa Barbara, CA 93106-9630 USA (mattinson@geol.ucsb.edu)

In the early decades of U-Pb geochronology, following the discovery of radioactivity and the recognition of the decay products of U decay, ages based on U/Pb ratios were determined using classical chemical methods. As a result, age determinations were limited to U ore minerals containing large amounts of U and Pb. The application of mass spectrometry to U-Pb studies, e.g. Nier [1, 2], was a major advance, but did not change the sample requirements -- the early mass spectrometric methods required several milligrams of Pb per determination.

From the late 1940's to the mid-1950's, George Tilton and his fellow graduate student at the University of Chicago, Clair 'Pat' Patterson completely revolutionized U-Pb geochronology. They developed the clean chemistry, isotope dilution, and thermal ionization mass spectrometry techniques to accurately measure the low concentrations and isotopic compositions of U, Th, and Pb in meteorites [3] and in virtually every mineral in a sample of ca. 1 Ga granite [4]. The new techniques reduced the amounts of Pb required for accurate measurements of concentration and isotopic composition by ca. three orders of magnitude, allowing application of $^{207}Pb/^{206}Pb$ dating to meteorites and the Earth [3], and of U-Pb dating to small amounts of zircon, sphene (titanite), apatite [4] and monazite [5], thus setting the stage for the modern era of U-Pb geochronology.

Fe –metasomatism in upper mantle beneath SW Poland

M. MATUSIAK-MAŁEK[1]*, J. PUZIEWICZ[1], M. GREGOIRE[2] AND T. NTAFLOS[3]

[1]Univ. Wroclaw, Poland (*correspondence: magdalena.matusiak@ing.uni.wroc.pl)
[2]CNRS-UMR 5562, Univ. Toulouse, France (michel.gregoire@get.obs-mip.fr)
[3]Univ. Wien, Austria (theodoros.ntaflos@univie.ac.at)

Cenozoic alkaline volcanic rocks from SW Poland make the NE termination of Cenozoic Central European Volcanic Province. The volcanics occur on both sides of the NW-SE trending Intrasudetic Fault Zone (IFZ), a major Variscan dislocation feature separating crustal blocks of different geological record. Two peaks of volcanic activity (30-26 and 23-15 Ma) are recorded in volcanics occurring to the north of IFZ, whereas Cenozoic eruptive rocks located south from the fault zone (Lądek Zdrój volcanic field, Kozákov volcano) are much younger (5 – 3 Ma). All of the mantle xenoliths occurring in alkaline rocks are from the mantle spinel peridotite facies.

The xenoliths occurring in volcanic rocks located N of the IFZ record significant depletion, especially in basaltic components followed by various style of melt-related metasomatism. Significant part of peridotites are enriched in Fe, which is evidenced by low (83-89 %) forsterite content in olivine, and low #mg in orthopyroxene (0.85-0.86) and locally cpx (0.87-0.88). Textures of these peridotites exludes cumulative origin linked to crystal sellting. Some of mineral chemical features (e.g. NiO in Ol 0.30 – 0.44 wt.%) indicate upper mantle origin. We suggest that the Fe – enriched peridotites represent parts of mantle affected by Fe (and Mn) – rich metasomatic agent, which appearts to be alkaline silicate melt in the Księginki locality [1]. Lack of bulk rock Ca enrichment, typical for other Fe – peridotites [2] suggests low fraction of carbonated-eclogite-derived melts [3, 4] to be a metasomatic agent in Krzeniów locality.

The Fe-enriched peridotites among mantle xenoliths have not been found to the south of IFZ (Lądek Zdrój [3], Kozákov [5]). Moreover, xenoliths from the southern and northern domains differ in respect to texture, modal composition and style of metasomatic processes. Hence, we suggest that IFZ constitutes also a boundary between two litospheric mantle domains.

Analysis of heavy metals in floodplains of the Morava and Jizera rivers

TOMAS MATYS GRYGAR[2], TEREZA NOVAKOVA[1,2]*, VERONIKA LUKESOVA[2,3] AND MARTIN MIHALJEVIC[1]

[1]Charles University, Faculty of Science, Albertov 6, 128 43, Prague (Mihal@natur.cuni.cz) (*correspondence: Tereza.Novakova@natur.cuni.cz)
[2]Institute of Inorganic Chemistry AS CR (grygar@iic.cas.cz)
[3]Department of Soil Science and Soil Protection, Faculty of Agrobiology, Food and Natural Resources, Czech University of Life Sciences in Prague (lukesovav@af.czu.cz)

Regional pollution by Cu, Pb and Zn during the 20th century was studied in floodplains of two rivers in Czech Republic, usually considered less contaminated - the Morava and the Jizera; the latter is one of three water sources for Prague. Sediments were obtained by hand-drilled cores (2-4 m long) and in the case of the Morava River from outcrops in erosion banks. To describe realistically the pollution of floodplain sediments, facial analysis and outline of floodplain architecture are essential for two main reasons: to distinguish anthropogenic impact from natural background and evaluate possible post-depositional migration of pollutants. Geochemical analysis by laboratory ED XRF spectrometer offers handy tools for both these subtasks, which we have learnt in the Morava River floodplain and now apply to Jizera River floodplain. Additional subtask is sediment dating, which can be achieved by careful examination of depth dependences of activities of ^{137}Cs and unsupported ^{210}Pb; the use of ^{14}C of plant debris is, unfortunately, limited. For reliable reconstruction of the past pollution, fine sediments (silty clay with small sand content) should be used, which slow down the vertical migration of both pollutants and ^{137}Cs. Cu, Pb and Zn start to migrate substantially in floodplain sediments of both studied rivers at depths larger than 1.5 m, where they follow lithofacial boundaries and redox accumulations of Fe and Mn oxides. Extensive correlations of densely and continuously sampled cores must be performed to avoid lithofacial biases and migration - and only that can allow sound interpretations. Approximate dating of sediments from the Morava River area can be based on the onset of Pb and Zn contamination at about 1900, Pb fastest enhancement at moderate Zn in the 1950's, stagnating Pb 1960's – 1980's), and stagnating Zn and declining Pb since 1990's.

Acquisition of Fe by aerobic microorganisms: Effects of Fe oxide nanoparticle size

P.A. MAURICE[1], C. DEHNER[2], J. DUBOIS[2] AND L.E. BARTON[1]

[1]Dept. of Civil Engineering & Geological Sciences, and
[2]Dept. of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN, 46556, USA (pmaurice@nd.edu, cdehner@nd.edu, jdubois@nd.edu, lbarton@nd.edu)

Most organisms require Fe as a fundamental nutrient; yet, Fe-bearing minerals tend to be highly insoluble in circum-neutral aerobic environments. Many aerobic microorganisms overcome Fe limitation by releasing low molecular weight organic ligands known as siderophores into the environment. Siderophore-Fe(III) 1:1 complex stability constants range from 10^{23}-10^{52}.

Using an obligate aerobic bacterium *Pseudomonas mendocina* ymp wild type (WT) and a siderphore (-) mutant of the species (MT; i.e. a mutant that can not produce siderophore), along with a reporter strain that signals Fe deficiency, our group investigated Fe acquisition from hematite (nano)particles of different average particle sizes. Fe associated with < 10 nm hematite was considerably more bioavailable than Fe associated with larger particles. Hematite nanoparticles < 10 nm have more transient or labile Fe, dissolve at about an order of magnitude faster rate in siderophore at circumneutral pH, and support enhanced growth (relative to growth on 72 nm hematite) by *P. mendocina* WT under Fe-limited conditions. The greater bioavailability is also related in part to mechanism (s) that depend on cell/nanomineral proximity, but not on siderophores. MT bacteria readily acquire Fe from particles < 10 nm but must be in direct physical proximity to the nanomineral. Addition of the reducing ligand ascorbate is particularly effective at supplying nano-hematite Fe to the bacteria under siderophore-free conditions. Even a small amount of cell-surface associated reducing activity, as further suggested by results of ferrozine assay, therefore would be likely to enhance cell growth considerably.

P-T-t evolution of metapelitic rocks from the Bushveld contact aureole: Using garnet isopleths thermobarometry and Lu-Hf garnet dating

P.K. MAVIMBELA*, M.J. RIGBY, P.G. ERIKSSON AND P. GRÄSER

University of Pretoria, Pretoria 0002, South Africa (*correspondence philani.mavimbela@up.ac.za, matin.rigby@up.ac.za, pat.eriksson@up.ac.za, peter.graser@up.ac.za)

We employ garnet isopleth thermobarometry and Lu-Hf garnet isotopic system in order to investigate the P-T-t evolution of two garnet bearing metapelitic samples (DY954 and DY918) from the Bushveld contact aureole. Two types of garnets porphyroblast were identified in sample DY954, garnet included in biotite which records peak metamorphic condition of 551 $\pm 15^0$C at 3.1±0.2kb and a non reactive garnet which records 527±8^0C at 3±0.35kb. The slightly higher temperature of the former may be interpreted to have resulted from garnet reaction overstepping. The DY918 amalgamated garnet porphyroblast does records different P-T conditions (~601^0C at 1.3kb) as compared to the DY954 sample and the fusion of the garnets which will require significant re-crystallization [1] can be attributed to these higher temperatures. The weighted average Lu-Hf garnets isochron ages obtain for the two samples (DY954 and DY918) are 2061.5±5.1Ma and, 2061.4±3.5Ma respectively. The nearly identical garnet isochron ages marks the first robust age of the BIC contact aureole which can be indirectly interpreted as constraints to the emplacement age of the RLS.

Heavy metal fractionation in high temperature fumaroles

JOHN A. MAVROGENES* AND RICHARD W. HENLEY

Research School of Earth Sciences, Australian National University, ACT Australia 0200 (*correspondence: john.mavrogenes@anu.edu.au)

Some volcanoes discharge high temperature gases from which unique metal suites are formed as sublimates. Examples include Vulcano, Italy, where sublimates contain a wide range of rare bismuth-lead sulfosalt minerals. Paradoxically, arsenic minerals do not occur in fumarole discharges but are common in crater lakes. In paleo-fumarole environments such as Chinkuashih, Taiwan, enargite and related sulfosalts occur as almost mono-mineralic assemblages over a depth range of more than 1000 meters. Modelling of vapor-phase stabilities shows that decompressing volcanic gases deposit pyrite below 700°C followed by rapid precipitation of enargite as depressurization proceeds. In consequence, surface discharges are strongly depleted in arsenic, iron, copper and a range of heavy metals.

Based on high resolution microanalysis of As-rich sulfosalt assemblages in paleo-fumaroles, we suggest that fractionation occurs between arsenic-rich sulfosalt melt and vapor within the upper few hundred meters of the surface, leading to heavy metal (Sb, Bi, Te, etc) enrichment of the vapor phase and consequent formation of lead-bismuth sulfosalt minerals and tellurides in surface discharges, such as the metallic snow of the Venus Highlands region. Similar sub-surface fractionation processes result in molybdenum-rhenium enrichment in volcanic systems such as Kudryavy (Kurile Arc, Russia), and gold and silver in others (e.g.Kudryavy and Colima, Mexico). Similar sulfosalt –sulfide melt segregation occurs in the magmatic environment resulting in metal fractionation during the formation of the so-called 'high sulfidation' and porphyry copper-gold deposits.

Effect of aqueous organic ligands on Mg-isotope fractionation during magnesite precipitation

V. MAVROMATIS*, Q. GAUTIER, J. SCHOTT AND E.H. OELKERS

Geoscience and Environment Toulouse (GET), CNRS, UMR 5563, OMP, 14 Avenue Edouard Belin, 31400 Toulouse, France (*correspondence: mavromat@get.obs-mip.fr)

Organic ligands are present in most Earth's surface environments and play a significant role on mineral formation and transformation. This study aims to illuminate the effect of the presence of these organic ligands on isotopic fractionation during mineral dissolution and growth.

Magnesite precipitation experiments were conducted in mixed flow reactors at 120 and 150 ºC following the methods described by Saldi *et al*. [1], in the reactive fluids containing various concentrations of aqueous oxalate and citrate. Supersaturation of the reactive fluid in the reactor was facilitated by the retrograde solubility of magnesite. Magnesite precipitation favored incorporation of isotopically lighter Mg into solid phase, as shown by enrichment of ^{26}Mg in the outlet solutions. Experiments conducted at 120 ºC show larger isotopic fractionation factors $\Delta^{26}Mg_{solid\text{-}solution}$ compared to those performed at 150 ºC indicating a temperature effect on isotopic fractionation. Furthermore, experiments performed in the presence of oxalate and citrate, exhibit lower $\Delta^{26}Mg_{solid\text{-}solution}$ values at similar precipitation rates compared to corresponding experiments performed in the absence of aqueous organic ligands. These observations suggest the preferential complexation of the heavier Mg isotopes by the organic ligands in aqueous solution.

Overall the observations obtained in this study demonstrate that $\Delta^{26}Mg_{solid\text{-}solution}$ during magnesite precipitation depends not only on precipitation rates, but also on the concentration of aqueous organic ligands. This result suggests that the presence of organic ligands may also effect the isotopic fractionation of a large number of other elements, and may be responsible, at least in part for the degree of isotopic fractionation observed in natural systems.

$^{146,147}Sm$-$^{142,143}Nd$ studies of komatiites from western Dharwar Craton, India: Implications for depleted mantle evolution in Early Archean

J.M. MAYA, RAJNEESH BHUTANI* AND S. BALAKRISHNAN

Department of Earth Sciences Pondicherry University, Puducherry 605014 (*correspondence: rbhutani@gmail.com)

Early Earth Differentiation

Variation of $^{142}Nd/^{144}Nd$ ratio in terrestrial samples compared to chondrites has now been demonstrated by several studies indicating an early global chemical differentiation of Bulk Silicate Earth (BSE). (see [1] for a recent review).

These studies, however, raised several outstanding questions related to nature of Early Enriched Reservoir (EER) and Early Depleted Mantle (EDM) and their subsequent evolution.

Results

We have carried out measurements of $^{142}Nd/^{144}Nd$ ratios, along with conventional ^{147}Sm-^{143}Nd studies, on well preserved komatiites with spinifex texture characterized by MgO > 20% that occur at Banasandra, in the western limb of Chitradurga greenstone belt of Dharwar craton in India.

$^{142}Nd/^{144}Nd$ ratios of these komatiites are same as La Jolla and AMES standards within 10 ppm (2 σ) uncertainity. The ^{147}Sm-^{143}Nd whole rock isochron age as yielded by 9 samples is 3136 ± 200 Ma (MSWD =74) with initial $^{143}Nd/^{144}Nd$ =0.50872 ± 0.00033 corresponding to $\varepsilon_{Nd\ (t=3.15)}$=+ 3.5.

Discussion

We calculated time-integrated $^{147}Sm/^{144}Nd$ ratio of source of 3.15 Ga old komatiites of Dharwar craton with the constraints that it got differentiated at 4.2 Ga (No radiogenic $^{142}Nd/^{144}Nd$ anomaly) and that by 3.15 Ga ago it evolved to $\varepsilon_{Nd\ (t=3.15)}$=+ 3.5. The time-integrated $^{147}Sm/^{144}Nd$ ratio of the source, thus obtained, is significantly higher than what has been predicted by Blichert-toft and Puchtel [2] for the source of this age. These results can be explained if source of these komatiites is originated from a second differentiation of the EDM at 4.2 Ga. Further, these results also indicate that Archean depleted mantle has not been homogenous in time and space.

Variability of nitrogen stable isotope in suspended organic matter in waters of the western continental shelf of India and the Mandovi estuary

M.V. MAYA[1]*, S.G. KARAPURKAR[1], M.A. SOARES[1], R. AGNIHOTRI[2], R. ROY[1], H. NAIK[1] AND S.W. A. NAQVI[1]

[1]National Institute of Oceanography (Council for Scientific and Industrial Research), Dona Paula, Goa - 403004, India (*correspondence: mmayae11@gmail.com)

[2]National Physical Laboratory, New Delhi, India (rajagni9@gmail.com)

First direct evidence for the addition of substantial amount of isotopically light nitrogen by *Trichodesmium* in the western continental shelf of India (WCSI), a region of global significance on account of being the largest natural seasonally-occurring coastal oxygen-deficient zone in the world with large efflux of N_2O to the atmosphere. The results for the WCSI and the Mandovi estuary are summarized in Fig. 1, which reveal significant shifts in $\delta^{15}N$ of suspended particulate organic matter (SPOM) before and after the onset of the south-west (SW) monsoon.

Discussion of results

The development of *Trichodesmium* blooms significantly lowers the $\delta^{15}N$ of SPOM during the pre-monsoon season, whereas water-column denitrification makes SPOM enriched in $\delta^{15}N$ during late SW monsoon. Another important result of this study states that the $\delta^{15}N$ of SPOM is generally lower than the mean value (7.38‰) for surficial sediments. The $\delta^{15}N$ of SPOM in the Mandovi estuary also shows significant variation during and after the cessation of SW monsoon. Depletion of $\delta^{15}N$ in SPOM during the SW monsoon could be preferential utilization of $^{14}NO_3^-$ by phytoplankton, as has been observed in other NO_3^- replete areas, whereas post-monsoon season are characterized by relatively high $\delta^{15}N$ of SPOM.

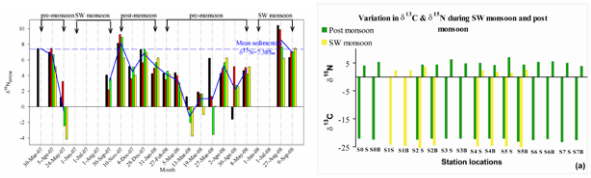

Figure 1: A) Intra-annual variations in $\delta^{15}N$ of SPOM along the WCSI. B) SW monsoon and post-monsoon changes in the Mandovi estuary.

Isotopic analysis of microarrays to link microbial identity and function

X. MAYALI[1]*, P.K. WEBER[1], E.L. BRODIE[2], S. MABERY[1], P.D. HOEPRICH[1] AND J. PETT-RIDGE[1]

[2]Lawrence Berkeley National Laboratory, Berkeley CA 94720 USA

Most microorganisms remain uncultivated, and typically their ecological roles are inferred from diversity and genomic studies. To directly measure functional roles of uncultivated microbes, we developed Chip-SIP, a high-sensitivity, high-throughput stable isotope probing (SIP [1]) method performed on a phylogenetic microarray. For this approach, we incubate microbial communities with isotopically labeled substrates, hybridize community rRNA to a microarray, and measure isotope incorporation—and therefore substrate use—by secondary ion mass spectrometer imaging (NanoSIMS).

Chip-SIP analysis of an estuarine community quantified amino acid, nucleic acid or fatty acid incorporation by 81 taxa. The resulting resource use profile (Figure 1) demonstrates that some generalist bacteria can incorporate multiple organic substrates while others specialize in 1 or 2 out of 3. We also found that bacterial functional capacity can be decoupled from phylogeny. This approach provides a means to test genomics-generated hypotheses about biogeochemical function in natural environments.

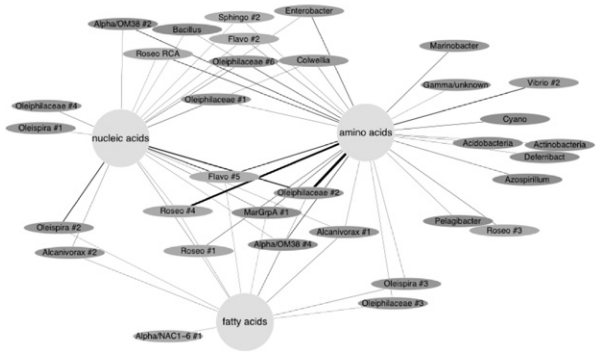

Figure 1: summary network diagram of Chip-SIP analysis of San Francisco Bay, linking substrates (circles) to microbial taxa (ovals). The thickness of the lines is proportional to the amount of substrate incorporated.

Absolute isotopic composition of molybdenum reference materials using double spike MC-ICP-MS

A.J. MAYER[1]*, B. PROEMSE[2] AND M.E. WIESER[1]

[1]Department of Physics and Astronomy, 2500 University Drive NW, University of Calgary, Calgary, AB, T2N 1N4, Canada (*correspondence: ajmayer@ucalgary.ca)
[2]Department of Geoscience, 2500 University Drive NW, University of Calgary, Calgary, AB T2N 1N4, Canada

Molybdenum isotope abundance measurements have enabled unique insights into the study of oxic conditions in the oceans [1], high-temperature hydrothermal ore deposits [2], and the heterogeneity of molybdenum in the early solar system [3]. Useful interpretations are only possible when isotopic compositions are reported relative to commonly available reference materials. Chemical processing of samples can alter isotopic composition, so it is important to test methods on matrices of known molybdenum isotopic composition and concentration.

At present, researchers are using a variety of commercially available and in-house standards. Recently, Wen *et al*. measured the relative isotopic composition of five reference solutions and proposed using NIST SRM 3134 as the delta zero reference for molybdenum [4]. However, the absolute isotopic compositions of these standards were not reported and none of the chosen materials were in a natural matrix.

In this study, we have determined the absolute isotopic composition of molybdenum in a variety of reference materials including NIST SRM 3134, BCR-1, BCR-2 (basalt), USGS SCo-1 (shale), SRM 1547 (peach leaves), Johnson-Matthey pure Mo metal rod, and SCP Science Mo PlasmaCal. Measurements were made using a Thermo Scientific Neptune MC-ICP-MS. Instrumental fractionation was corrected by measuring a mixture of the sample with a fully calibrated double spike. The fractionation correction assumed an exponential fractionation law and used computational root finding methods to solve for the fractionation due to chemical processing and instrumental mass bias.

Chemical and isotopic composition of Cenozoic hornblende-bearing basalts from the Rhön area (Germany)

B. MAYER[1]*, S. JUNG[1] AND A. STRACKE[2]

[1]Mineralogisch-Petrographisches Institut, Universität Hamburg, Grindelallee 48, 20146 Hamburg, Germany (*correspondence: Bernhard.Mayer@uni-hamburg.de)
[2]Westfälische Wilhelms Universität, Institut für Mineralogie, Corrensstraße 24, 48149 Münster, Germany

Primitive, alkaline mafic volcanic rocks provide important information about the chemical composition of the Earth's mantle. The source of intra-continental volcanic rocks are either the subcontinental lithospheric mantle, the asthenospheric upper mantle or upwelling mantle material (mantle plumes). In contrast to the asthenosphere, the lithospheric part of the mantle has been isolated from the convecting part and may have had a complex geological history of ancient depletion and enrichment events.

Unusual hornblende-bearing basanites from the Rhön area (Central European Volcanic Province; CEVP) are mostly primitive to differentiated volcanic rocks (Mg#: 65-45, Ni: 190-60 ppm, Cr: 400-100 ppm) with higher TiO_2, lower MgO contents and slightly lower Ce/Pb ratios (15-20) at a given SiO_2 content relative to other alkaline rocks from the CEVP. Rare Earth element patterns show LREE enrichment but only moderate depletion in HREE relative to primitive mantle. Rare earth element patterns can be reproduced by about 4 to 8 % partial melting of a spinel peridotite containing 10 % of modal amphibole. In multi-element diagrams, the basanites are enriched in Nb, but depleted in Rb and K relative to the neighboring elements, compatible with partial melting with residual amphibole.

Incompatible trace element abundances and ratios and Nd and Sr isotopes overlap those of other volcanic rocks from the CEVP. Initial $^{87}Sr/^{86}Sr$ ratios range from 0.7034 to 0.7040 at almost constant initial $^{143}Nd/^{144}Nd$ of ca. 0.51279-0.51285 (εNd of +3.3 to +4.6). The Sr and Nd isotope data suggest that contamination of the lavas with the ambient lower crustal rocks is relatively minor (< 5%). The variable Sr at constant Nd isotope compositions could also result from melting heterogeneous sources with variable Rb/Sr ratios as a result of mantle metasomatism. Based on their high TiO_2 but low MgO, elevated $^{87}Sr/^{86}Sr$ ratios and low Ce/Pb ratios relative to other basanites from the CEVP, the hornblende-bearing basanites appear to contain a signifcant proportion of the lithospheric upper mantle.

Modeling the relationship between sorption and residence times

M.A. MAYES*, S. JAGADAMMA, W.M. POST, J. FRERICHS AND G. WANG

P.O. Box 2008, Oak Ridge, TN 37831
(*correspondence: mayesma@ornl.gov)

We seek to improve representations of stabilization and degradation of organic carbon in soils in terrestrial C cycling models. Major processes considered in the model include sorption of dissolved compounds onto mineral and particulate soil fractions, incorporation into microbial biomass, enzyme-facilitated degradation, and mineralization of dissolved and native carbon. Soils from temperate, tropical, and arctic climates will be used. The sorptive capacity of three orders of magnitudes of dissolved compounds common to soil solutions (sugars, starch, lipids, etc.) will be measured using ^{14}C labelling. Subsequently, the soils containing adsorbed compounds will be subjected to short-term incubation experiments to determine rates of mineralization from each soil fraction. Chloroform fumigation will be used to measure ^{14}C allocated to microbial biomass. Enzyme assays will be used to determine the potential for enzyme activities in response to various treatments. This presentation will consist of initial experimental findings and presentation of the model framework. The initial findings will be evaluated in terms of project goals produce a testbed for modelling microbially-faciliated sorptive and degradative processes at the soil mineral interface.

The effect of *M. thermoflexus* on the Fe-bearing mineral assemblage associated with low temperature basalt-water reactions

L. MAYHEW[1]*, G. LAU[1], T. MCCOLLOM[2] AND A. TEMPLETON[1]

[1]Dept. Geological Sciences, University of Colorado–Boulder (*correspondence: mayhewl@colorado.edu)

[2]Laboratory for Atmospheric and Space Physics, University of Colorado–Boulder

Water-rock reactions, such as serpentinization of ultramafic rocks in the ocean crust, alter Fe(II)-bearing silicate minerals producing secondary minerals and H_2 gas and are therefore thought to support chemolithotrophic life in extreme environments (e.g. the deep subsurface). However, the alteration of Fe-bearing silicate minerals present in these rocks has not been extensively studied under low temperature, anoxic conditions. We inoculated a low temperature (55°C), anoxic water-Fe^0-basalt system with a methanogenic Archaeon, to determine if 1) microbial growth could be supported by *in situ* production of H_2 gas and 2) the presence of the microorganisms influenced the production of H_2 gas and the Fe-bearing secondary mineral assemblage.

Growth of *M. thermoflexus* is evidenced by time series measurements of H_2 and CH_4 showing the continuous production of H_2 in the abiotic control while in cultures microbial methanogenesis draws down H_2 and produces CH_4. Upon saturation, purging the headspace gases destabilizes Fe-bearing minerals and releases Fe and Si to solution. $[Si_{(aq)}]$, while buffered to relatively constant values, was lower in the abiotic control than cultures. $[H_2]$ appears to affect the speciation of Fe in the solid phase products. Collection of synchrotron-based μXRF maps at multiple energies within the Fe K-edge and μXANES analyses integrated with principal components analyses and XANES fitting enables visualization and quantification of the distribution of the Fe-species. After ~1 year of reaction, Fe-bearing secondary mineral assemblages associated with high $[H_2]$ (abiotic control) are different than those associated with low $[H_2]$ (culture experiments). For example, minnesotaite, an Fe-phyllosilicate, is ubiquitous in the abiotic control but much less abundant in the culture experiments. We will discuss how the geochemical reaction paths and Fe-speciation differ between the abiotic control and the culture experiments. This work suggests that at low temperatures microorganisms may have a profound effect on what has long been thought to be solely an abiotic reaction and may produce diagnostic mineral assemblages that may be preserved in the geological record.

The petrological, geochemical and tectonic setting of metabasites from Mashhad, North East of Iran

S.A. MAZAHERI[1], R. BIERESDORFER[2] AND F. ARMSTRONG[2]

[1]Geology Department, Faculty of Sciences, Ferdowsi University of Mashhad, Mashhad, 91775-1436, Iran
[2]Department of geological and Environmental Studies, Youngstown State University, Ohio 44555, USA (mazaheri@ferdowsi.um.ac.ir)

Metabasites of Mashhad area are part of Virani (Nourabad) Ophiolite in the Binaloud region. The ophiolite extends to Aghdarband area, north east of Fariman. Ultramafic rocks are predominantly peridotite (lherzolite, wherlite and hursburgite). Mafic rocks are mainly metabasalt, metagabbro and metadolerite. Large pillow lavas (>45 Cm in diameter) crops out in Zakaria and Nowdarreh areas.

Metabasites subjected to a low to medium grade metamorphism (greenschist to amphibolites facies), characterized by Ab + Act + Epid + Chlo; Na-Plag + Hbld + Epid and Ca – Na Plag + Hbld assemblages. Plagioclase (Ab to Ande), Amphiboles (Actinolite and Hornblende), Epidote, Chlorite, Quartz, Sphene, Apatite and Iron – Oxides are the most common minerals of metabasites.

Selected samples have analysed by XRD, XRF and ICP methods. Major and trace elements data indicates that metabasites are tholeiitic in nature and characterized by low potassium (0.25 wt%), and high magnesium (maximum 23.23 wt%), high chromium (maximum 2110 ppm), and high nickel (maximum 2970 ppm) contents. The metabasite samples have low Zr/TiO2 (0.0011 – 0.0092) and Nb/Y (0.06 – 0.15) ratios, similar to those of tholeiitic basalts.

The Metabasites of Mashhad area are believed to be remnant of the Paleo – Tethys oceanic plate that were subducted beneath the Turan plate. Later on the Turan plate have obducted over the Iranian Micrcontinent, and formed the northeasten Iran.

Importance of syntrophic acetate oxidation during thermophilic municipal solid wastes anerobic digestion

L. MAZEAS[1]*, J. GROSSIN-DEBATTISTA[1], X. QU[1,2], A. GUENNE[1], P.J. HE[2], H. BUDZINSKI[3], M. LE MUNIER[4] AND T. BOUCHEZ[1]

[4]Suez Environnement, CIRSEE, 38 rue du Président Wilson, 78230 Le Pecq, France

During anaerobic digestion of organic matter, acetate and H_2/CO_2 are expected to be responsible of around 67% and 33% of the methane production respectively [1]. Our results show that temperature has a significant influence on methanogenic pathways as indicated by the different CH_4 isotopic composition ($\delta^{13}CH_4$) evolutions observed under mesophilic and thermophilic conditions. The contribution of the hydrogenotrophic pathway appears to be much more important in thermophilic condition due to the occurrence of the syntrophic acetate oxidation (SAO) reaction.

Using different molecular microbiological tools (Fluorescent *in situ* hybridization and cloning sequencing) microbial communities involved during those MSW incubations have been identified. It appears that strict hydrogenotrophic archaea from the Methanomicrobiales order are highly dominant in thermophilic condition which is in accordance with a SAO reaction implication.

Petrogenesis of Zoozan pluton, NE of Lut, Eastern Iran

S.A. MAZHARI[1]* AND M. SAFARI[2]

[1]Department of Geology, Payame Noor University, 19395-4697 Tehran, I.R. of Iran (*correspodence: ali54894@yahoo.com)

[2]Geological Survey of Iran, North-East Territory, Mashhad, Iran (petrolsaf@yahoo.com)

The Zoozan pluton is one of the Tertiary plutonic bodies in the northeastern of the micro-continental Lut block in Eastern Iran. This pluton is composed of two geochemically unrelated mafic and granitoid units. All rocks are calc-alkaline, with LILE/REE and HFSE/REE compatible with arc magmas. Mafic phase consists of gabbro to quartz diorite and emplaced as small stocks and dykes. These rocks exhibit relatively high contents of incompatible elements, low Na_2O and Mg#>44.0. These features suggest their origin from enriched lithospheric mantle above subducted slab.

Granitoid phase includes granite-granodiorites which show high-K calc-alkaline metaluminous to slightly peraluminous I-type granitoid characteristics. Their Chondrite-normalized REE patterns mark enrichment of LREE (La_N/Lu_N= 7.6-12.5) and small negative anomaly (Eu/Eu^*= 0.63-0.74). They have geochemical composition typical of volcanic arc granitoids and have been originated from metabasaltic to tonalitic sources. Furthermore, fractional crystallization may have played significant role during the formation of Zoozan granitoids.

Variation in carbon stable isotope ratios of organic matter in Bay of Bengal during the last glacial episode

A.MAZUMDAR*, R.K. JOSHI, A. PEKETI AND B.G. NAIK

Geological Oceanography, National Institute of Oceanography, Donapaula, Goa, 403004, India (*correspondence: correspondence: maninda@nio.org)

We report here a high resolution total organic carbon content (TOC) and $\delta^{13}C_{TOC}$ variations from a 30m long core from Bay of Bengal. The core (MD161-8, water depth: 1033 m) was collected on board *Marion Dufresne* as part of our on going gas hydrate exploration program in the Krishna-Godavari basin. TOC content is constrained within 1-2 wt%. Our studies show dependence of TOC content on grain size distribution. During the last glacial episode, the $\delta^{13}C_{TOC}$ varied between 14 and 17‰ VPDB indicating a significant contribution of C4 vegetation. Within 16-18 mbsf we have observed presence of pentamethyl icosane with carbon isotope ratios <-100‰. Presence of PMI has resulted in the isotope excursion. Post LGM rise in pCO_2 resulted in the diminished C4 contribution. Most depleted C isotope ratio is noted at ~7-8 ky BP suggesting enhanced contribution of terrestrial organic matter. For rest of the Holocene contribution from marine productivity dominates.

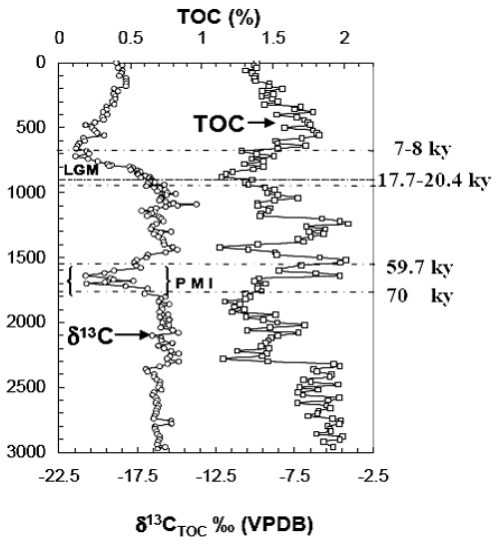

Figure 1: TOC and $\delta^{13}C_{TOC}$ profile of MD161-8

Pristine mantle xenoliths from the active Bismarck Arc

SARLAE R.B. MCALPINE* AND RICHARD J. ARCULUS

Research School of Earth Sciences, Australian National University, ACT Australia 0200
(*correspondence: sarlae.mcalpine@anu.edu.au)

Peridotites samples were recovered during the Marine National Facility Voyage (SS06-2007; WeBiVE) from three volcanic cones northwest of Ritter Volcano, New Britain-West Bismarck Arc system of Papua New Guinea. Wedge-derived peridotites are extremely rare even in well-explored subaerial arcs; the Ritter suite is the first global occurrence of peridotites recovered from an active submarine volcanic arc front edifice.

The peridotites occur as rounded (≤15cm diameter) and angular blocks and fragments. The host basalt is a Cr spinel-olivine-diopsidic augite-bearing, medium-K tholeiite. It is the most MgO-rich basalt (~15wt%) reported in the West-Bismarck-New Britain Arc system; the high-MgO might derive in part from the cumulative and/or xenocrystic nature of some olivine.

The xenoliths are pristine (serpentine-free), predominantly harzburgitic but also include lherzolite, orthopyroxenite, and a single gabbro. Preliminary petrological analysis shows complex textural relationships between the constituent minerals olivine ($Fo_{94.4-86.3}$), orthopyroxene, clinopyroxene, and spinel. The spinel is highly refractory with Cr/(Cr+Al) > 0.9 accompanied by high Mg/(Mg+Fe^{2+}) consistent with quenching from high-temperature. Deformation textures include olivine kink-banding and wavy exsolution lamellae in the pyroxene. Secondary clinopyroxene reflects some metasomatism. Bulk trace element charateristics include relatively unfractionated rare earth element abundances (0.6 to 1*chondritic), elevated Pb/Ce (>1), and negative Nb, Ta, Zr, Hf, and Ti anomalies.

Temperatures range from ~900 to 1100 °C; fO_2 ranges from ΔFMQ -2 to +0.5. These samples show extremely refractory, relatively reduced harzburgites are present in the mantle section beneath a modern subduction system. Ongoing detailed mineralogical and petrological studies will provide important insight into the mantle below the New Britain-West Bismarck Island Arc.

Arsenic in Ground Water

J.M. MCARTHUR

Earth Sciences, UCL, London WC1E 6BT, UK.
(j.mcarthur@ucl.ac.uk)

Arsenic in groundwater presents a hazard to health globally [1]. In the Bengal Basin, one of the regions worst affected by such pollution [2, 3], the distribution of pollution reflects the geological evolution of the basin during the past 125,000 years [3], and the same explanation, with local modifications, must apply to As-polluted deltaic aquifers worldwide. The As-pollution is confined largely to sediments laid down after the last glacial maximum, a fact that explains the vertical inhomogeneity in As-pollution. The lateral inhomogeneity in As-pollution reflects, in part, the distribution of As-polluted palaeo-channel aquifers and As-free palaeo-interfluvial aquifers [4].

Flow of As-polluted palaeo-channel water into As-free palaeo-interfluvial aquifers has been ongoing since sea-level stabilized around 6 ka. The flow has been accelerated by abstraction of water for irrigation since the 1970s. Natural and enhanced flows explain the development of a strong redox gradient at the palaeo-interfluvial margins. Flows enhanced by abstraction for irrigation explain rising concentrations of As in marginal palaeo-interfluvial wells, especially where the flow is counter to the natural hydraulic gradient. In this talk, some of these aspects will be explored.

Reaction rind formation in Mèlange in the Catalina Schist, California

C.A. McCallum[1]*,
S.C. Penniston-Dorland[1] and G.E. Bebout[2]

[1]Department of Geology, University of Maryland, College Park, MD 20742, USA
(*correspondence: mccallum@umd.edu)
[2]Department of Earth and Environmental Sciences, Lehigh University, Bethlehem, PA 18015, USA

Reaction rinds between differing lithologies are commonly thought to have formed due to fluid-assisted metasomatic alteration, however, enrichment in relatively fluid-immobile elements such as Cr and Ni suggests an additional process may be responsible for their formation. Eleven samples along a 17cm transect through one amphibolite grade block and a reaction rind with an ultramafic-rich matrix from the Catalina Schist, CA show distinct changes across the block-rind contact in mineral abundance and whole rock major and trace element and Li isotope composition. Whole rock rind concentrations of SiO_2, K_2O, Rb, Ba, MgO, Cr and Ni are enriched in the rind relative to the core and FeO is depleted. Lithium concentrations are enriched in the rind (10-16ppm) relative to the core (8-11ppm) with δ^7Li ranging from -3 to +1‰. The distribution of Li concentrations and isotope compositions is consistent with diffusion on the scale of almost the entire 17-cm profile. Garnets in the core and rind are similar in FeO content, however whole-rock FeO of the core and rind differs significantly, suggesting garnet growth before the depletion in whole-rock FeO. Rind garnets are pseudomorphed extensively by decussate chlorite, suggesting that infiltration by H_2O-rich fluid occurred after garnet growth. Rind concentrations of Cr, Ni Al_2O_3 and CaO can be most simply explained by mechanical mixing of mafic block (50-70%) with melange matrix (30-50%). Mixing cannot explain the increases in SiO_2, K_2O, Li, Rb and Ba or the depletions in FeO, and we propose that the concentrations of these elements in the rind are due to relatively late-stage fluid infiltration. We propose an early episode of mechanical mixing where mixing of mafic block and melange matrix produced rind-like material which was then accreted onto the outside of basaltic blocks. Garnets likely grew in both block core and rind after mechanical mixing. Fluid infiltration in the rind occurred after peak metamorphism of the block. The source of this fluid was likely metasedimentary rocks within the subduction zone, as has been proposed based on O isotope compositions of this amphibolite-facies mélange unit.

Serpentinization and hydrogen generation

T.M. McCollom[1], F. Klein[2], W. Bach[3],
N. Jöns[3] and A. Templeton[4]

[1]Laboratory for Atmospheric and Space Physics, University of Colorado, Boulder, 80309, USA
(mccollom@lasp.colorado.edu)
[2]Woods Hole Oceanographic Institution, MA, USA
[3]University of Bremen, Germany
[4]University of Colorado, Boulder, CO, USA

Much of the current scientific interest in serpentinites revolves around the production of molecular hydrogen (H_2) during serpentinization, which can serve as a source of metabolic energy for autotrophic microbial communities, or as the reductant for abiotic formation of organic compounds. While it has been known for some time that fluids generated during serpentinization can be highly reducing and enriched in H_2, the processes responsible for producing these conditions remain poorly understood. Serpentinization of ultramafic rocks is commonly portrayed by the simple generalized reaction: olivine + water → serpentine + brucite + magnetite + H_2, where production of H_2 occurs as a result of oxidation of ferrous Fe [FeO] from the mineral comp-onents of the original rock (olivine and pyroxene) to ferric Fe [$FeO_{1.5}$] in the reaction products, especially magnetite. However, petrologic studies and laboratory experiments make it increasingly evident that the process is much more complex than this simple expression would indicate. For instance, rather than going directly into magnetite, Fe from the reactant minerals is partitioned among all solid products including serpentine and brucite, so that the relative distribution and oxidation state of Fe among these minerals determines the amount of H_2 generated. Petrologic, lab-oratory, and theoretical studies indicate that the proportions and oxidation state of Fe in the product minerals is highly variable, and appears to be dependent on a number of factors including temperature, bulk rock composition, extent of reaction, and 'openess' of the system. To complicate matters further, the Fe components of serpentine and brucite may become unstable as the reaction progresses, so that Fe-rich minerals formed during the initial stages of serpentinization may decompose over time in favor of more Fe-poor compositions and magnetite. We will present results from ongoing laboratory experiments and modeling studies that are an attempt to unravel the sequence of reactions controlling Fe distribution and H_2 formation during serpentinization, and their dependence on reaction conditions.

The future of marine calcifiers in a high CO_2 world: Boron isotope systematics of pH up-regulation

M.T. McCulloch[1,2], J.A. Trotter[1], J. Falter[1,2] and P. Montagna[3]

[1]The University of Western Australia Oceans Institute and School of Earth and Environment, Western Australia
[2]ARC Centre of Excellence in Coral Reef Studies, UWA
[3]Laboratoire des Sciences du Climat et de l'Environnement, Av. de la Terrasse, 91198, Gif-sur-Yvette, France

Rising atmospheric CO_2 is not only causing global warming, but also lowering the oceans pH and hence carbonate ion concentration upon which many marine organisms depend to calcify their skeletons. Declining calcification rates combined with an increased frequency of coral bleaching from unusually high seawater temperatures has the potential to cause major disruption to marine ecosystems. Which marine calcifiers can sustain skeletal development as pCO_2 increases is however highly uncertain. Here we present new boron isotopic constraints on the degree of physiological control of the pH of the calcifying medium. Biological up-regulation of pH is linked to abiotic calcification rates using the inorganic kinetics of carbonate precipitation.

Boron isotope systematics of aragonitic corals show a species dependent ability to up-regulate the pH at their site of calcification, with changes in internal pH being approximately one-half of those in ambient seawater [1]. This pH buffering capacity is present in both non-symbiont and symbiont bearing aragonitic corals and serves to raise the saturation state of the calcifying fluid, thereby increasing their potential rate of calcification. The ability of biogenic calcifiers to raise the internal saturation state via pH up-regulation is not however ubiquitous, being absent for example in many key species of calcitic foraminifera. Ocean acidification and global warming are thus likely to cause a major bi-polar shift in the abundance and distribution of marine calcifiers. Those that lack internal pH regulation will continue to undergo rapid declines, while in cold-water corals enhanced rates of aragonite precipitation from pH elevation and rising temperatures has the potential to counter the effects of decreasing seawater pH. However the ability of tropical corals to maintain calcification rates by pH up-regulation will mainly depend on their capacity to adapt to thermal stress caused by rapid increases in ocean temperatures.

Interfaces and exchange coupling

S.A. McEnroe[1], P. Robinson[1], K. Fabian[1], R.J. Harrison[2], N. Miyajima[3] and F. Langenhorst[3]

[1]Geological Survey of Norway, Trondheim 7041 Norway (*correspondence, suzanne.mcenroe@ngu.no)
[2]Cambridge University, Cambridge, UK
[3]BGI, Universitaet Bayreuth Bayreuth Germany

Natural oxides in the ilmenite-hematite system are now known to have contact layers [1] at the interface between the two phases. Contact layers, reduce charge imbalance at interfaces [2] and result in magnetic properties that are different from the bulk host or lamellae. Magnetic coupling across interfaces provide a mechanism for the stability of extremely small lamellae. These samples with lamellae < 1nm thick show exchange bias with shifted hysteresis loops more than 13, 000 Oe. This shift is the largest that has ever been measured in any material, natural or synthetic.

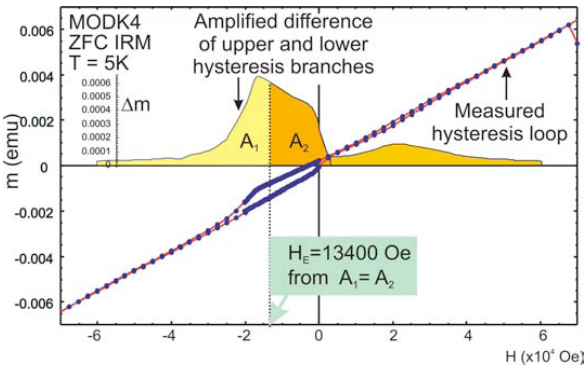

Figure 1: Shifted hystereis loop measured at 5 K. [3]

Combined TEM analyses and images with low-temperature magnetic studies are powerful tools to describe the chemical, structural and electronic nature of the interfaces. To date these are the smallest stable magnets ever known. There is wide interest in under-standing these natural samples and their interfaces, which may well provide blueprints for future technological designs.

Simulations of multicomponent aerosol processes on the regional scale

G. McFiggans*, S.R. Utembe, D. Lowe, S. Archer-Nicholls and D.O. Topping

Centre for Atmospheric Science, SEAES, The University of Manchester, Oxford Road, Manchester, M13 9PL, UK (*corresponence: g.mcfiggans@manchester.ac.uk)

Organic material is a significant and variable component of tropospheric aerosol, accounting for between 10 and 90 % of fine particle mass. Owing to its complexity, large-scale models must represent the organic fraction and its interactions with inorganic aerosol components using highly simplified methods. Bottom-up representations usually underestimate organic particulate mass and more simplified bottom-up treatments may be expected to perform even more poorly. It is difficult to evaluate the reasons for such behaviour, in part because of the lack of traceability of the representation to more complex and realistic mechanistic approaches.

In this work, we present the coupling of the reduced Common Representative Intermediates (CRIv2-R5) scheme [1] describing tropospheric degradation of methane and 22 emitted non-methane hydrocarbons and oxygenated volatile organic compounds (comprising 220 species and 609 reactions), and traceable to the Master Chemical Mechanism (v3.1), to a sectional aerosol microphysics representation within the WRF-Chem model to enable prediction of the regional transformation of multicomponent aerosol in the oxidising atmosphere. The aerosol treatment uses the hyprid Partial Derivative Fitted Taylor Expansion (PD-FiTE) [2] coupled to the MTEM inorganic reprentation in WRF-Chem to provide computationally efficient calculation of the multicomponent gas / liquid equilibria in the particles. The model can be used to investigate the regional evolution of aerosol in the moist atmosphere and the organic contribution to aerosol mass predicted by a mechanism traceable to a more realistic representation of tropospheric VOC oxidation.

We will present results of the first simulations investigating the formation and transformation of tropospheric aerosols in the UK under a range of changing emission profiles and oxidant conditions.

Monogenetic, but not monotonous: Basaltic eruptions in the Auckland Volcanic Field, New Zealand

L.E. McGee[1]*, I.E.M. Smith[1], M.-A. Millet[2], C. Beier[3,4], J.M. Lindsay[1] and H. Handley[3]

[1]School of Environment, Auckland University, Private Bag 92019, Auckland 1142, NZ (*correspondence: l.mcgee@auckland.ac.nz)

[4]Now at Universität Erlangen-Nürnberg, Germany

How melts are extracted from their mantle sources and what happens to them *en route* to the surface are fundamental questions in the workings of basaltic volcanic fields. The well-sampled Auckland Volcanic Field (AVF) – an intraplate volcanic system in northern New Zealand – offers excellent opportunities to build up a more detailed picture of the plumbing systems feeding such fields. Here we present major and trace element data along with new Sr-Nd-Pb and U-series isotopic data, in order to investigate the processes involved in the large chemical heterogeneity seen in the AVF.

Detailed sampling has shown that individual trends for each centre can be explained by either high-pressure clinopyroxene or shallow olivine fractionation. Near-primary magmas show a range in degrees of partial melting from ~5% down to <0.5% in the smallest centres. Trace element ratios and high (^{230}Th/^{232}Th) ratios (1.16-1.33) show melts are primarily formed within the garnet stability zone and involve two mantle sources: a FOZO-like source and a source displaying more radiogenic Pb isotope ratios. Mixing between these 2 end-members is seen at both the single volcano and the field-wide scale.

U-series isotopic data for the two most chemically extreme centres, both of which erupted twice, are used to model subtle changes in magma dynamics. Both volcanoes follow the same trend of eruption of an early, less primitive, smaller-volume magma with a higher ^{230}Th-excess, then a more voluminous, more primitive magma with a lower ^{230}Th-excess. Parameters including melting and upwelling rates, conduit lengths and porosities are modelled and found to be within the range of other intraplate volcanic fields, yet show considerable variation between AVF eruptions. Together with the lack of any spatial or temporal trend in the chemistry of the field, these results suggest that melt batches evolve in isolation, being subject to differing processes and are able to move at variable speeds and through variable porosities in the mantle, resulting in dispersed plumbing systems for such fields and an erratic pattern of eruptions.

Unusual U-REE deposits at Mt Isa, Australia and potential links to mid-crustal anorogenic granites

M. McGloin[1]*, A.G. Tomkins[1] and C.M. MacRae[2]

[1]School of Geosciences, Monash Univ, VIC, 3800, Australia (*correspondence: matthew.mcgloin@monash.edu)
[2]Microbeam Laboratory, Minerals Down Under Flagship, CSIRO, Clayton, VIC, 3168, Australia

The unusual Uranium-Rare Earth Element (U-REE) deposits of Mount Isa, Queensland, associated with immobile element enrichment (Y, Zr, Nb, LREE, locally Ti) show a significant spatial relationship to radiometrically anomalous intrusive phases of the mid-crustal Sybella Granite Batholith. The high K and U radiometric anomalies in recent phases of the Sybella Batholith suggest a possible link with the U-REE deposits. Geochemical results for the most anomalous Sybella microgranite phase, indicates enrichment in several incompatible and high field strength elements, including elevated mean LREE content (189ppm Zr, 26ppm Y, 44ppm La and 90ppm Ce).

In the largest U-REE deposit, Valhalla, LREE enrichment (≥500ppm) is well correlated with the highest U (≥3.2wt% U_3O_8), associated with brannerite and uraniferous zircon [1]. The textural association of fluoroapatite surrounding brannerite [2, 1] suggests involvement of F in controlling U, REE and Zr mobility. The Sybella microgranite phase has geochemical characteristics typical of anorogenic granites [3], which are associated with U-REE mineralisation at other localities worldwide. Previous geochronological work on the Sybella microgranite gives ambiguous emplacement age constraints, allowing the possibility of a syn-Isan intrusion significantly later than the main intrusive Sybella phase (ca. 1670Ma [4]), possibly around 1555-1510Ma [1].

Our geochemical results, combined with a younger microgranite age, would support a genetic association with the ~1530Ma U-REE deposits, and more geochronological work is in progress to further test this possibility. Given that magmatic fractionation promotes enrichment of the incompatible elements seen at Valhalla, and that these elements are generally immobile in typical metamorphic fluids, we suggest that this unusual style of mineralisation most likely has a magmatic-hydrothermal origin.

Impact of biotic and abiotic factors on the mobilization of heavy metals in Al-Ghadir river sediments (Lebanon)

Amale Mcheik[1], Mohamad Fakih[2], Noureddine Bousserrhine[1], Joumana Toufaily[2], Vanessa Alphonse[1], Hiba Noureddine[2] and Evelyne Garnier-Zarli[1]

[1]IBIOS – BIOEMCO, Faculty of sciences and technology, University Paris-Est, 61 avenue de general chales de gaulles, 94010 Creteil Cedex, France
[2]Laboratory MCEMA, Faculty of Sciences (I), Lebanese University, Hadath Beirut, Lebanon

Although there is no doubt about the importance of bacterial activity on solubilisation and distribution of metal in aquatic sediments, hydromorphic soils and ground waters very little is known about the involvement of bacterial dissolution in periodically anaerobic environments like that found in dredged sediments and little is known about the processes and environmental factor controlling this process.

Our study aims at underlining the role of autochthonous bacteria in the biodegradation of organic matters and the mobilization of metals (Zn, Pb, Co, Cr, Cd, Al, Mn and Fe) contained in sediments in Al-Ghadir river. In order to do so, we have follow over time the evolution of carbon metabolism (Organic matter evolved, carbon consumption, organic acids production) and metals release in batch reactor where the sediments were mixed with a culture medium. The experiments were monitored under standard anaerobic conditions.

Under the adopted conditions, the incubated sediments showed a significant release of organic carbon corresponding to bacterial development.

Mineral analysis showed an important solubilisation of iron and manganese (in reduced form) indicating the presence of Fe and Mn-reducing bacteria in sediments. Co and Cr solubilisation were also observed and appeared concomitant to Fe and Mn indicating that Co and Cr are associated to Fe and Mn in sediment. Al and Zn were associated to organic matter while Cd and Cu were associated to organic matter and to Fe and Mn oxides.

At the end of the incubation, the molecular techniques showed (i) the disappearance of some bacterial strains due to the toxicity of the released heavy metals and (ii) the growth of new population of microorganisms tolerant to the same heavy metals.

Silicic acid: An experimental and *ab initio* study of explicit solvation and reaction kinetics

G.J. McIntosh*, P.J. Swedlund and T. Söhnel

Department of Chemistry, University of Auckland, Private Bag 92019, Auckland, New Zealand (*correspondence: g.mcintosh@auckland.ac.nz)

Ab initio quantum chemistry has become a powerful supplement to experimental studies of gas-phase systems in particular. However, while the application to species of geochemical interest such as silicic acid, H_4SiO_4, is achievable, it is dramatically complicated by the presence of water. As both computer speed and the efficiency of quantum chemical algorithms progress, it is becoming increasingly feasible to go beyond simple continuum descriptions of the solvent to the inclusion of explicit solute-solvent interactions.

We have recently benchmarked the effects of explicit solvation in a theoretical study of a counter-intuitive reverse isotope shift observed in the vibrational spectra of aqueous H_4SiO_4 and D_4SiO_4 [1]. Upon deuteration, the antisymmetric ν (Si-O) stretching modes shifts to higher frequencies, in opposition to what is anticipated from reduced mass arguments. DFT/B3LYP/6-31+G (d)-based models are unable to describe this shift without the inclusion of explicit water molecules. Specific hydrogen bonding interactions, present only within an explicit solvation framework, are found to significantly stiffen and blueshift the δ (Si-O-H/D) bending modes. In D_4SiO_4, these bends subsequently couple with the ν (Si-O) modes; resonance effects blueshift the stretching modes by a greater extent than the increased mass-induced red shift, leading to a net reverse-isotope shift. Similarly, the positions of δ (Si-O-H/D) modes in the IR and symmetric ν (Si-O) modes in the Raman, and peak widths and heights are also only reproduced with the inclusion of explicit solvation effects.

On the strength of these results, we have begun exploring the feasibility of deriving a kinetic model of silicate polymerization and hydrolysis almost entirely from first principles. We present preliminary results benchmarking transition state theory approximations and the roles of implicit and explicit solvation in modelling the kinetics of H_4SiO_4 dimerization. Early results suggest that this approach may provide a surprisingly good model of reaction kinetics and thermodynamics in pH- and temperature-dependent systems.

How and where redox-sensitive trace metals can answer the question productivity or ventilation

J.L. McKay[1]*, T. Ivanochko[2] and T.F. Pedersen[3]

[1]COAS, Oregon State University, Corvallis, OR 97330, USA (*correspondence: mckay@coas.oregonstate.edu)

[2]EOS, University of British Columbia, Vancouver, BC, V6T 1Z4, Canada (tivanoch@eos.ubc.ca)

[3]SEOS, University of Victoria, Victoria, BC, V8W 2Y2, Canada (tfp@uvic.ca)

The enrichment of redox-sensitive trace metals such as Re and Mo is commonly used to infer changes in paleo redox conditions of marine sediments. Determining why redox conditions changed is trickier because both organic carbon flux (e.g. export productivity) and changes in bottom water oxygen (e.g. ventilation) can influence sedimentary redox. Which of these factors is the dominant control can be sorted out by analyzing Ag along with the redox-sensitive metals noted above. Unlike these other metals, Ag does not accumulate after sediment deposition. Rather it is scavenged from the water column by organic particles and transported to the sediment as part of the biogenic particle flux. Its accumulation in sediments is therefore related to productivity. Thus, high Ag in combination with high Re and/or Mo suggests that high productivity is controlling sedimentary redox while a combination of low Ag and high Re and/or Mo suggests a lack of ventilation. Some environments, however, don't lend themselves well to the use of redox-sensitive trace metals. Surface sediments from the OMZ on the Pakistan Margin, for example, are characterized by relatively low Re and Mo concentrations in comparison to oceanographically similar regions off Mexico and Peru. Silver concentrations are also anomalously low except near the base of the OMZ indicating post-depositional oxidation and loss of Ag. Together these trace metal data suggest that OMZ sediments on the Pakistan Margin are at best weakly suboxic despite their high organic carbon content and the low bottom water oxygen values.

[4]School of GeoSciences, , University of Edinburgh, Edinburgh EH9 3JW, UK (Godfrey.Fitton@ed.ac.uk)

We compare trace element and isotopic (Sr, Nd, and Pb) geochemical data from the mafic intrusive complex of Slieve Gullion with new data from the thick sills (up to 100 m) at Portrush, Carrickarede and Fair Head in N Antrim and make comparisons to the Antrim Lava Group (ALG) flood basalts.

Slieve Gullion rocks (56.5±1.3 Ma) are characterised by flat ~10x chondritic HREE with slight +ve Eu-anomalies and LREE enrichment ($(La/Pr)_{CN}$ = ~2.5). Portrush sill rocks (54.9±0.6 Ma) show similar flat HREE patterns, +ve Eu anomalies and faint LREE enrichment ($(La/Pr)_{CN}$ >1). By way of contrast Carrickarede and Fair Head (60.2±0.3 Ma) rocks show convex upward REE patterns, with maximum REE enrichment at Nd ($(La/Pr)_{CN}$ < 1, $(Nd/Lu)_{CN}$ ~ 4). Multielement plots of incompatible elements for Slieve Gullion and Portrush rocks display similar flat patterns for HREE and HFSE, with distinctive +ve spikes at Pb, Sr and Rb and –ve Nb anomalies, that strongly resemble subduction modified melts or continental crust. The Fair Head rocks show distinctive, smooth upwardly convex patterns.

The Lower Basalts (~60-62 Ma) of the ALG show similar convex upwards REE patterns as the Fair Head and Carrickarede rocks, whereas many of the younger Upper Basalts (~59-57 Ma) resemble the younger intrusions at Portrush and Slieve Gullion, but with flat or LREE depleted REE patterns.

A key to understanding the evolution of the N.E. Irish sector of the North Atlantic Igneous Province is explaining such differences in temporally related rocks, which cannot be rationalised solely by partial melting of a similar source. We suggest that the LREE enrichment and Pb, Sr, Rb spikes so distinctive of the Slieve Gullion magmas, and also hinted at in Portrush, might derive from a lithospheric mantle component, as the melting regime penetrates into lithospheric mantle as extension developed across the Province.

Complex Al and P zoning in pallasite olivine: Constraints on high-T history

Seann J. McKibbin[1]*, Hugh St.C. O'Neill[1], Guilherme Mallmann[1,2] and Angela Halfpenny[1,3]

[1]Research School of Earth Sciences, Australian National University, Canberra ACT, Australia (*correspondence: seann.mckibbin@anu.edu.au) (hugh.oneill@anu.edu.au)
[2]Institute of Geosciences, University of São Paulo, São Paulo SP 05508-080, Brazil (guil.mallmann@gmail.com)
[3]Earth Science and Resource Engineering, CSIRO, Kensington WA, Australia (angela.halfpenny@csiro.com)

Pallasites are mixtures of olivine and Fe-Ni metal, possibly formed near the core-mantle boundary of a differentiated asteroid [1]. The distribution of trace elements in pallasite olivine appears to reflect diffusion profiles [2] although complex structure has also been reported [3]. It has recently been shown experimentally [4] and in various natural samples [5] that Al and P diffuse very slowly in olivine and these elements can preserve early distributions which are resistant to later thermal modification.

To search for evidence of the early history of pallasite olivine, we have used Laser-Ablation Inductively-Coupled-Plasma Mass-Spectrometry (LA-ICP-MS) to produce trace-element maps of olivine from two pallasites: Brahin (with fragmental olivine) and Brenham (rounded olivine). Heterogeneous distributions are found over scales of ~100 microns for Al and elements likely to associate with it in coupled substitutions. P is also heterogeneously distributed but is negatively correlated with or unrelated to Al. In Brahin, these distributions bear no relationship to the olivine morphology; for Brenham, Al concentrations decrease at grain margins but the interiors have complex distributions.

Heterogeneous distributions of Al and P in pallasite olivine provides some constraints on its residence time in a high-T environment. Taking the diffusion parameters for Si [6] as a proxy for the diffusion behaviour of these elements (since they reside in the same crystallographic site), at 1650 K (~OPX out for a fertile peridotite composition; [7]) the characteristic timescale for diffusion over 100 microns is ~1 Ma. This represents an upper limit on the time between the establishment of trace element systematics in olivine and formation of pallasites by mixing with metal.

Relationships between the composition of planetary crusts and their sedimentary records

SCOTT M. MCLENNAN

Dept. of Geosciences, SUNY at Stony Brook, Stony Brook, NY, 11794-2100, USA (Scott.McLennan@sunysb.edu)

Planetary crusts possess variable sedimentary records in terms of origin, size, lithology, age and composition. At one extreme, Earth has a complex sedimentary record formed in response to weathering, erosion, transport, deposition and recycling. The highly dynamic terrestrial rock cycle precludes preservation of any significant planetary regolith (eolian deposits being the closest analog). At the other extreme, airless bodies like the Moon, and probably Mercury, possess classic impact-derived planetary regoliths as their only sedimentary deposit. Mars provides the intermediate case where a long-lived sedimentary rock record exists but the surface is also covered widely by regolith. Controls on planetary sedimentary records are related to (1) impact and volcanic history, (2) presence and nature of atmospheres (i.e. climate), (3) occurrence, composition and physical state of near-surface volatiles, and (4) presence and nature of crustal tectonics, crustal evolution, and so forth. In turn, the composition of planetary sediments reflects their crustal sources in complex, but generally understandable ways. The terrestrial sedimentary record is lithologically differentiated (shales, sands, carbonates, evaporites) due mainly to large bodies of water. Nevertheless, terrestrial sediments reflect widespread sources and accordingly have long been used to estimate upper crustal composition and to trace crustal evolution. For impact-derived lunar regolith, absence of water and air restricts reworking or transport on any significant scale after initial deposition. Disruption and mixing take place but by impact gardening that operates on local scales and largely in a vertical sense. The result is that lunar regoliths do not sample widespread regions and so are compositionally variable, matching the crust in the vicinity of where they form. Martian sedimentary rocks and regolith formed by a wider array of processes than did lunar regolith, including impact, volcanic, glacial, eolian and subaqueous processes, and are far more complex mineralogically. On the other hand, much less lithological differentiation takes place than is seen on Earth. Sedimentary mixing processes at the surface (e.g. eolian, glacial, impact gardening) were of sufficient scale to minimize variations in regolith composition. Although local geological influences are observed, Martian regolith is of broadly uniform composition, reflecting the average upper crust even for the major elements.

A 4-dimemsional landscape geochemical framework for the remote arid landscapes of Australia's Musgrave Province

S.M. MCLENNAN[1]* AND S.M. HILL[2]

[1]The University of Adelaide, Adelaide, 5005, Australia (*correspondence: stephanie.mclennan@adelaide.edu.au)
[2]The University of Adelaide, Adelaide, 5005, Australia (steven.hill@adelaide.edu.au)

This study integrates geochemical and biogeochemical datasets generated from the remote arid landscape of the Musgrave Province in Central Australia. It demonstrates the inter-relationships between the chemistry of the region and its landscape evolution. Many previous geochemical studies of the arid landscapes of Australia have tended to focus on a single system or sampling medium. Where datasets for several media are combined and compared they have tended to be considered within the context of a featureless ‘space’ rather than their landscape setting. In this study bedrock geochemical, regolith geochemical, groundwater hydrogeochemical and plant biogeochemical systems are sampled, chemically characterised and compared based on their landscape setting. This study utilises the importance of the evolution of regolith materials that have evolved within the landscape's history as the context.

An initial focus has centred on the Mt Caroline ultra-mafic intrusion, which is considered prospective for Ni-Cu sulphide deposits. Variably think sedimentary cover (10s to 100s m), Aboriginal land access restrictions, and a lack of tracks and roads through the region have limited the development of previous landscape geochemical models. Access to some exploration tenements, however, has allowed the development of a geochemical sampling program incorporating regolith materials, biota (especially Triodia basedowii), and groundwater. Given the extent and variation in thickness of sedimentary cover in the area, however, plotting and comparing these datasets in two dimensions is an over-simplification of the dispersion processes at play in this system. This project optimises the presentation of these datasets to show differences between the results and similarities between anomalies to assist in further developing future exploration programs. The study proposes an effective means of presenting data that incorporates the geochemistry across the landscape in two dimensions but also the role of landforms and varying lithologies in surface expression of concealed mineral deposits.

The origin of carbonate globules in silicate melts: Solids or liquids?

S.C. McMahon*, D.K. Bailey, M.J. Walter and L. Caricchi

Department of Earth Sciences, University of Bristol, BS8 1RJ (*correspondence: Sorcha.McMahon@bristol.ac.uk)

Carbonate globules found in mantle xenoliths, as inclusions in mantle minerals and in juvenile silicate melt lapilli are possible examples of primitive carbonatitic melts from the mantle [1]. Here we present findings from carbonate globules from Finca La Nava, a matrix-supported carbonatite tuff in the Calatrava Volcanic Province in central Spain; an alkaline mafic-ultramafic province comprising over 250 monogenetic cones and vents [1]. Carbonate globules are prolific within silicate melt lapilli. Silicate melts of at least two different compositions, melilitite and kamafugite, have been discovered within this one outcrop.

The origin of the carbonate globules within melt lapilli is debatable. Globule textures including curved menisci against silicate melt, budding, and coalescing of the globules, are compelling evidence for liquid immiscibility. However, recent experimental results suggest that similarly-shaped globules formed as solid calcite crystals in equilibrium with silicate melt [2]. Many, but not all, globule interiors in the Calatrava lapilli are apparently nearly phase-pure calcium carbonate with minor Mg, but Si, Al, and Na are virtually absent. Yet experiments show that carbonatitic melts equilibrated with mantle silicates or silicate melts can dissolve significant amounts of these elements, suggesting that the globules may have originated as solid calcite, as in the experiments. So did these carbonate globules originate as solids or liquids?

The 'pure' globules are in fact both compositionally and texturally heterogeneous on a micron scale. Initial findings made on the basis of sub-micron elemental mapping using a FEG-SEM demonstrate that considerable quantities of additional components of Si and Al, amongst other major elements, appear to have been exsolved and segregated to the globule rims during crystallisation. Such a mechanism may explain the observed 'pure' calcium carbonate composition of many globule interiors, and supports an immiscible liquid model for carbonatite tuff genesis in Calatrava.

Timing and duration of Heinrich events in the North Atlantic

Jerry F. McManus

Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY 10964, USA (*correspondence: jmcmanus@ldeo.columbia.edu)

The repeated iceberg discharges into the North Atlantic during the Pleistocene, known as Heinrich events, are widely believed to have influenced the global climate. Their millennial pacing, abrupt occurrence, and widespread impact make them important targets for understanding the rates of climate change. Efforts to date the sedimentary layers associated with these events have achieved some success, particularly for the few events within the range of ^{14}C methods. Similarly, the duration of the youngest events has been estimated by foraminifera ^{14}C and sedimentary ^{230}Thxs. Beyond these most recent events, the Heinrich layers of ice-rafted sediments have typically been dated by correlation to other sedimentary archives with independent chronologies, such as ice cores and speleothems. In this study, two different approaches to ^{230}Thxs profiling have been utilized to explore directly the absolute timing and duration of each of the Heinrich events that occurred during the last large climate cycle of the Pleistocene. Both approaches incorporate new sedimentary data generated by ICP-MS at locations where initial results were produced by alpha counting. Heinrich event H11 is shown to occur within the penultimate deglaciation identified in foraminifera $\delta^{18}O$. Using Thxs profiling in a core from the Caribbean sea with an approximately constant accumulation rate, an age estimate of 133 ky is derived for the timing of H11, following Broecker and van Donk [1]. In core V28-82 from the subpolar North Atlantic, with a variable accumulation rate, the inventory of sedimentary ^{230}Th is shown to be in balance with the overlying seawater production of ^{230}Th, and Sackett's method [2] to quantifying the passage of time can be applied to estimate both the absolute age and duration of each of the Heinrich events. The results support previous estimates that the sedimentary layers associated with the events were deposited rapidly over the course of centuries, not millennia.

Maximising precision and accuracy in laser quadrupole ICPMS U-Pb geochronology

SEBASTIEN MEFFRE, LEONID DANYUSHEVSKY, MARCEL GUILLONG AND SARAH GILBERT

School of Earth Sciences & Australian Research Council Centre for Excellence in Ore Deposit Studies, University of Tasmania, Australia, (smeffre@utas.edu.au)

Laser mass spectrometry is widely used to determine the age of rocks throughout the earth science. However, analytical problems related to ablation cells, standards, mass spectrometers and calculations have meant that it is difficult to fully characterise precision and accuracy of the technique.

Experiments performed at the University of Tasmania over the last 10 years have shown that the following parameters affect the precision and accuracy of measurements: 1) homogeneity of the signal in the ablation cell, 2) type, number and position of standards analysed within the analytical sequence 3) accuracy dead time corrections 4) amount of instrumental drift, 5) contamination during cleaning and polishing 6) calculation method used 7) tuning parameters and signal intensity 8) harmonic interference between the laser and the mass spectrometer (spectral skew).

The contribution of each of these parameters to the uncertainty of the final measurements is complex and changes with age and uranium concentration of the crystals. For example young and low U zircons (those which have accumulated <0.2 ppm radiogenic Pb) must be carefully cleaned and calculated using the 'ratio of the mean' rather than the 'mean of the ratio' method but are relatively insensitive to the position and homogeneity of the standards, dead time corrections, harmonic interferences and instrumental drift compared to older high U zircons.

Mechanical instabilities induced by sulfate adsorption

M. MEGAWATI[1]*, A. HIORTH[2] AND M.V. MADLAND[3]

[1]University of Stavanger, 4036 Norway (*correspondence: megawati.megawati@uis.no)

[2]International Research Institute Stavanger, 4068 Norway (ah@iris.no)

[3]University of Stavanger, 4036 Norway (merete.v.madland@uis.no)

We present experimental data and analytical calculations which demonstrate the effect of negative surface charge caused by sulfate adsorption in high porosity chalks. Rock mechanical tests on three high-porosity outcrop chalks flooded with Na_2SO_4 at 130 ^{0}C show a significant decrease in the yield strength and in the bulk modulus compared to that of NaCl flooding. At 50 ^{0}C, however, no significant difference in the mechanical strength between cores exposed to Na_2SO_4 and NaCl is observed. Relative to that of the distilled water flooding (i.e. no sulfate present) a decreasing strength of 20-40% in the yield and 10-70% in the bulk modulus are correlated well with the increasing sulfate concentration in the pore water at higher temperature (130 °C). In addition standard creep tests at constant stress level of 10.7 and 18.9 MPa show similarly high creep rate along the creep stages. We measured sulfate adsorption of 0.2 μmol/m^2 and 0.5-1 μmol/m^2 at 50 °C and 130 °C, respectively, while dissolution was found to be low (below 0.4 mM Ca^{2+} produced after 14 PV's flooded). The sulfate adsorption process is interpreted by using surface complexation model together with Gouy-Chapman theory to describe the electrical double layer. The analytical calculations give fairly good agreement with the measured sulfate adsorption and comparable with ζ -potential measurement data respectively. The reduced mechanical strength is related to the sulfate adsorption which leads to a negative (pH dependent) surface charge. We suggest that the interaction between charged surfaces specifically in the weak overlaps of electrical double layer gives rise to the total disjoining pressure, which acts as normal forces in the grains vicinity, and it counteracts the shear forces during the failure mechanism. Increasing magnitude of the disjoining pressure when chalk cores are exposed to different Na_2SO_4 concentration at 130 °C correlate well with the reduced strength from the mechanical test results. The correlation remarkably reproduces the same trend as observed in the yield strength and bulk modulus as a function of Na_2SO_4 concentrations.

The effect of sulfate adsorption on the cation exchange capacity of high porosity chalks

M. MEGAWATI[1], A. HIORTH[2]* AND M.V. MADLAND[3]

[1]University of Stavanger, 4036 Norway (megawati.megawati@uis.no)
[2]International Research Institute Stavanger, 4068 Norway (*correspondence: ah@iris.no)
[3]University of Stavanger, 4036 Norway (merete.v.madland@uis.no)

Understanding the process of sulfate adsorption onto the chalk surfaces is important as it has been associated with wettability change [1, 3] and it was also shown to impact the mechanical stability of high porosity chalks [2]. In this paper we determine the cation exchange capacity (CEC) from core floods with and without sulfate present in the pore fluids. We model the sulphate adsorption in terms of interaction with positive Ca sites at the calcite mineral surface [1]; resulting in a net negative surface charge. The cation exchange is believed to take place in the diffusive counter ion layer. Our experimental results remarkably show that CEC increases with almost a factor of 2 upon adsorption of sulfate and the retardation of Na+/K+ front as well increases significantly (see Table 1). The enhanced CEC due to sulfate adsorption could thus contribute to an improved understanding of the enhanced compaction as observed during rock mechanical tests.

Chalk	T	Sulfate ads.	With adsorbed SO4		Without adsorbed SO4	
			CEC	Retard. of Na^+/K^+	CEC (Exp.)	Retard. of Na^+
	^{0}C	μmol/m^2	mEq/L	PV	mEq/L	PV
Liege	50	0.36	0.10	2.18	0.06	1.35
	90	0.80	0.11	2.05	0.05	1.28

The structural determinants of silicon fractionation properties of silicate minerals: A first-principles density functional study

M. MÉHEUT[1]* AND E.A. SCHAUBLE[2]

[1]GET, Université Paul Sabatier, Toulouse, France (*correspondence: meheut@lmtg.obs-mip.fr)
[2]ESS Dept., UCLA, Los Angeles, USA

Ab initio methods based on density functional theory have proven to be successful in reproducing the physical and chemical properties of complex systems. Within this framework, we have recently developed a methodology to predict equilibrium fractionation factors as a function of temperature (1). We use PBE functionals, combined with the use of pseudopotentials and planewave basis sets. Our previous work focused on the effect of the polymerization of the silicate network on Si-isotope fractionation (2), which had previously been predicted to be a determining factor. Our work does not confirm this assumption. To investigate the origin of this fractionation, we studied minerals with identical polymerization structures such as talc, pyrophyllite, muscovite, phlogopite or clinochlore. In the case of muscovite and phlogopite, the calculated quartz-mineral fractionations are in qualitative agreement with natural estimates. In this family of silicates, a strong correlation can be shown between the mineral-quartz fractionation of silicon and cationic content. Together with the simple shape of the fractionation laws, this permits to propose the following approximate law, valid for any temperature T (in K):
$\ln\alpha(\text{phyllo.,qtz,Si,T}) = a(T)*[Mg(o)] + b(T)*([Al(o)]+2*[Al(t)])$, where [Mg(o)], [Al(o)] and [Al(t)] represent the content of octahedric magnesium, aluminium and tetrahedric aluminium relative to 4 tetrahedral units, and $a(T) = -12.834x^2 + 14.39x^3$; $b(T) = -5.040x^2 + 4.20x^3$, with $x = 10^2/T$

This relationship can apparently be extrapolated to fractionation properties of tectosilicates (quartz and albite) and inosilicates (enstatite) but fails to reproduce the properties of forsterite. To better understand the limits of this apparently general correlation, we plan to present calculations for several chain silicates (diopside, wollastonite, jadeite), and potentially nesosilicates (fayalite, zircon, garnet). We will also focus on the interpretation of this relationship in terms of cationic force field effects.

Petrogenesis and geochemistry of the Dajing Cu-Sn-Pb-Zn-Ag Ore Deposit in Chifeng, Inner Mongolia

WEI MEI[1], XINBIAO LÜ[1,2]*, ZHILONG AI[1], RANKUN TANG[1] AND ZHI LIU[1]

[1]Faculty of Earth Resources, China University of Geosciences, Wuhan 430074, China (meiwei09@qq.com) (*correspondence: lvxb_01@163.com)

[2]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

The Dajing deposit is the largest tin deposit at the north of North China, which is a fissure-filling hydrothermal ore deposit located at the south of Daxinggan Mountain with Sn, Cu, Pb, Zn, Ag mineralisation. The deposit is controlled by multistage of fracture systems, mainly including NE striking sinistral compresso-shear fractures, a suite of SN striking compresso-shear fractures, and NW striking tenso-shear fractures (with ore veins mainly filling in this group of fractures). The widely outcropped magmatic rocks in the ore district are sub-volcanic rocks. They intruded into the Upper Permian Linxi Group that was formed in the inshore lake basins environment. The sub-volcanic dykes are divided into four main types: aphanophyre, acidic to intermediate rocks (dacite porphyry, rhyolite porphyry and granite porphyry), intermediate to basic rocks (andesitic porphyrite, diabasic porphyrite and basaltic prophyrite) and lamprohpyre, which scattered in the ore district. However, the subvolcanic rocks are dominated by acidic rocks in the central part, and intermdiate to basic rocks in the eastern part. K-Ar bulk isotopic age of the dykes ranges from 155.3 to 177.2 Ma. Wall rock alterations are weak silicification, carbonatization, chloritization and sericitization. They occur on both sides of ore veins.

The acidic rocks in the central are a suit of high-K calc-alkaline dacite with high content of Cu and Sn, while the basic rocks in the eastern are a suit of shoshonitic basalt to basaltic-andesite rocks with high content of Pb and Zn. All the rocks are characterized by enriched LILE and LREE, but acidic rocks have lower REE content with intermediate negative Eu anomaly (δEu=0.56-0.58). All the rocks originated from the same mantle source. They underwent high degree of differentiation and evolution when entered into the secondary magma chamber.

This work is founded by 305 Project of State Science and Technology Support Program (Grant No. 2007BAB25B04).

Ab initio molecular dynamics simulation of copper(I) complexation in chloride/sulfide fluids

YUAN MEI[1,2,3], DAVID M SHERMAN[2], JOËL BRUGGER[1] AND WEIHUA LIU[3]

[1]School of Earth and Environmental Sciences, The University of Adelaide, Adelaide, SA 5000, Australia

[2]Department of Earth Sciences, University of Bristol, Bristol, BS8 1RJ, UK

[3]CSIRO Earth Science and Resource Engineering, Clayton, VIC 3168, Australia

Chloride and hydrosulfide are the primary ligands believed to control the transport of copper in hydrothermal fluids. Recent studies of Cu complexation in hydrothermal Cl^-, HS^- solutions have been done using X-ray Absorption Spectroscopy (XAS). However, coordination numbers have a large uncertainty and are strongly correlated with Debye-Waller factors; moreover, it is very difficult to distinguish between chloride and sulfur ligands. *Ab initio* molecular dynamics simulations based on density functional theory enable us to interpret EXAFS results and, potentially, predict stability constants of metal complexes.

In this study, we investigated the species of copper(I) complexes via *ab initio* Car-Parrinello Molecular Dynamics simulations for copper(I) solutions with different hydrosulfide/chloride ratios at 500bar and 600K. Calculations were done using Vanderbilt ultrasoft pseudopotentials and the PBE exchange-correlation functional.

In the absence of Cl-ligands, copper forms a $Cu(HS)_2^-$ complex with a Cu-S bond length of 2.17 Å (vs. an expt. value of 2.15 Å); moreover, the S-Cu-S bond angle is ~162°, in excellent agreement with experiment (150-160°). In the presence of excess chloride, however, we find that Cu forms previously unknown $Cu(HS)Cl^-$ and (minor) $CuCl_2(HS)^{-2}$ complexes. Such complexes would be difficult to resolve from $CuCl_2^-$ or $Cu(HS)_2^-$ using EXAFS. We also explored the complexation of Cu in a low density (0.29 g/cm^3), high T (1273K) fluid (vapour). Here, we find that Cu forms $Cu(HS)_2^-$ (not the neutral CuHS, as expected). We tentatively suggest that charged complexes may be significant in high temperature, low density fluids.

Ultimately, we hope to predict stability constants of metal complexes. To this end, we are testing metadynamics and thermodynamic integration with respect to metal-ligand distances or coordination numbers. Using these techniques, we estimate the free energy difference between $CuCl_2^- + HS^-$ and $CuCl(HS)^- + Cl^-$ to be ~40 KJ/mol.

NanoSIMS: New results of relevance to biomineralization and biology

ANDERS MEIBOM

Muséum d'Histoire Naturelle, Paris, France

The NanoSIMS is a relatively new type of ion microprobe that can deliver a primary beam of Cs^+ or O^- to a sample surface, focused to a minimum spot size of ~50 nanometers and ~150 nanometers, respectively. (On non-conducting materials, bombardment with Cs+ causes strong charging effects. Such positive charge build-ups are compensated by electrons, which can be delivered to the sample surface by an electron gun.) Secondary ions sputtered from the sample surface and charged opposite to the primary beam are transferred with high transmission to a high mass-resolution, multi-collection mass-spectrometer that allows simultaneous collection of five or seven (depending on the model) different isotopes in electron multipliers and/or Faraday cups. This means that five (or seven) different images can be simultaneously recorded from the same sputtered volume. This capability can be used to create images or maps of elemental and isotopic variation within a sample. Such images can be generated from the lightest elements, such as H (D/H ratios), C ($^{13}C/^{12}C$ ratios), N ($^{15}N/^{14}N$ ratios), O ($^{17}O/^{16}O$ and $^{18}O/^{16}O$ ratios) and S (e.g. $^{34}S/^{32}S$ ratios) to the heaviest elements in the periodic table, including uranium.

Ion images of the sample surface are created by a precisely controlled raster of the primary beam across the sample surface. The NanoSIMS is therefore a powerful analytical instrument in conjunction with biological labeling experiments, where high spatial resolution is required and high analytical precision is not a requirement. Importantly, it is possible to do high quality NanoSIMS imaging even on very thin sections prepared for TEM analysis.

This presentation will include examples of the combination between dynamic isotopic labeling experiments, SEM, TEM, STXM, and NanoSIMS imaging to study skeletal formation dynamics and single-cell-level ammonium assimilation in reef-building corals.

Quantification of environmental proxy precision

ANDERS MEIBOM AND CHRISTOPHE KOPP

Muséum d'Histoire Naturelle, Paris, France

The extent and causes of recent environmental variations represent a vitally important problem for scientists, lawmakers and society in general. Essential to the ongoing scientific debate is the development of proxies that can reconstruct environmental change on both short (10-1000 years) and long (i.e. geologic) timescales. However, for every such proxy, a fundamental question exists that is rarely addressed: To what *precision* can the proxy reconstruct environmental variation? Only by answering this question quantitatively is it possible to decide if a given proxy is precise enough to be applicable and useful.

Here, we illustrate and discuss the vital effects that plague the major proxies for e.g. ocean sea-surface temperature. This will be based on recently acquired micro-analytical data, in particular with the NanoSIMS ion microprobe. Subsequently, the precision of linear environmental proxies is quantified with a general and easily applicable method. The precision of a selection of existing proxies is evaluated against the requirements of e.g. anthropogenic global warming.

Automated characterization of Eyjafjallajökull ash cloud particles

M.F. MEIER[1]*, K. WEBER[2], A. VOGEL[2], C. FISCHER[2] AND B. GROBÉTY[1,3]

[1]Univ. of Fribourg, Dept. of Geosciences, 1700 Fribourg, Switzerland (*correspondence: mario.meier@unifr.ch)
[2]Univ. of Applied Science, 40474 Düsseldorf, Germany
[3]Univ. of Fribourg, FRIMAT, 1700 Fribourg, Switzerland

The Eyjafjallajökull (EFJ) ash cloud crisis caused an airspace closure over Europe in April 2010 and had an important impact on economy. During this crisis the Dusseldorf University of Applied Sciences performed several measurment flights over north-western Germany with a light aircraft equipped among other with an optical particle counter (OPC) [1]. The primary goal of the airborne campaign (two flights F1 and F2, 18th May, different routes) was to compare the model calculation of the Volcanic Ash Advisory Center (VAAC) with *in situ* observation. The aim of this work is to present results of computer controlled scanning electron microscopy (CCSEM) coupled with engergy dispersive X-ray spectroscopy (EDX) applied on particles sampled on PTFE filters obtained from the OPC outlet. CCSEM/EDX generates morpho-chemical data of over 1000 particles in a few hours.

Many of the particles sampled during F1 were silicate dominated particles with compositions similar to the ones obtained from ash particles sampled on Iceland during and after the eruption of EFJ. Augitic clinopyroxenes could be identified morphologically. X-ray diffraction analyses of the eruption products confirm the presence of augite phenocryst. This points to the conclusion that the aerosol sampled during F1 was indeed volcanic ash from EFJ. Volcanic particles up to 6.5 µm were present, much larger than the conventional dispersion model would predict. The maximum mass concentration recorded inside the ash cloud by OPC was 330 µg/m^3. On the filter, sampled during F2, clays, carbonates, sulfates and quartz were present. Volcanic ash particles, however, were almost absent.

Chemical fingerprints of *in situ* collected samples are one way to ascertain the volcanic nature of an aerosol cloud. CCSEM can deliver such fingerprints. We were able to confirm the presence of the volcanic cloud over some parts of north-western Germany the 18th May 2010, but also to show that not all higher aerosol concentrations in the free troposphere could be attributed to the presence of volcanic ash. The obtained results from the measurement flights agree with the model of VAAC at its scale.

A record of Paleoproterozoic sulfur cycling from ~2 Ga Zaonega Formation, NW Russia

D. MEISTER[1]*, V.A. MELEZHIK[2,3], A. LEPLAND[2] AND H. STRAUSS[1]

[1]Institut für Geologie und Paläontologie, WWU Münster, 48149 Münster, Germany (*correspondence: dmeis_01@uni-muenster.de)
[2]Geological Survey of Norway (NGU), Trondheim, Norway
[3]University of Bergen, Centre of Geobiology, Bergen, Norway

Major environmental upheavals of global nature characterize the early Paleoproterozoic including the deposition of unprecedented amounts of organic matter during the Shunga Event ~2 billion years ago. Within the depositional environment, this organic matter fueled respiratory processes, among them the microbial reduction of an oceanic sulfate pool that developed in the aftermath of the Great Oxidation Event (GOE ~2.4 Ga). Ample evidence for microbially driven turnover of sulfate is provided by sedimentary pyrite in the organic-rich deposits of the Zaonega Formation, Onega Paleobasin, NW Russia.

Three drillcores were obtained from the Zaonega Formation in the course of the Fennoscandian Arctic Russia – Drilling Early Earth Project (FAR-DEEP) under the auspices of the International Continental Drilling Program (ICDP). Organic carbon rich samples from the Zaonega Formation contain abundant sedimentary Fe-sulfides exhibiting different morphologies suggestive of multiple stages of sulfide generations. In terms of diagenetic timing, these range from early diagenetic sedimentary pyrite to late generation pyrite and pyrrhotite occurring in cross cutting veins together with migrated bitumen.

Different forms of sulfur (AVS: acid volatile sulfide; CRS: chromium reducible sulfur) extracted from bulk rock samples throughout the succession yielded highly variable $\delta^{34}S$ values ranging between -8.1 and +25.6‰. Stratigraphic variations are discernible. The observed range in $\delta^{34}S$ values is consistent with a microbial origin via sulfate reduction and confirms previously published sulfur isotope data [1]. Guided by petrographic observations using transmitted and reflected light microscopy, a detailed sampling of different pyrite generations for subsequent sulfur isotopic work has been performed.

[4]Center for Geomicrobiology, Århus University, 8000 Århus, Denmark

Microbial degradation of organic matter deposited on the seafloor and buried over geological time within marine sediments leads to the onset of a redox zonation. This zonation may strongly shift over geological timescales due to variations of organic matter composition and burial rate. However, such dynamics in subsurface redox zonation is generally not obvious from measured porewater profiles.

Redox zonations may leave characteristic imprints in the geological record and therefore document the diagenetic history of a particular biogeochemical setting. We report the finding of diagenetic barite and dolomite layers that document past positions of the sulphate/methane transition zone (SMTZ) at ODP Site 1229 drilled on the Peruvian continental shelf. The layers co-occur with a focussed enrichment in isotopically light archeol, a lipid biomarker indicative of anaerobic methane oxidation.

Using a time-transient reactive transport model for sulphate and methane allowed to reproduce a SMTZ migrating upward and downward over a depth range of 30 m (below seafloor) over a time period of 100 ka. These variations were caused by variation in the organic matter content, the initial age of organic matter, and burial rate. Organic matter was assumed to decay according the reactive continuum model [1] whereby the different parameters were constrained by bulk TOC and ^{35}S radiotracer rate data.

The diagenetic imprints and modelling results are evidence of a sub-surface redox zonation more dynamic than we would expect from measured porewater profiles. Therefore, the diagenetic record in combination with non-steady state geochemical modelling must be taken into account for an assessment of diffusive fluxes between marine sediments and the water column and their contribution to global biogeochemical cycling.

Development of methodologies based on Field-Flow Fractionation for the characterization of engineered nanoparticles in complex samples

B. MEISTERJAHN, S. LEGROS, F. VON DER KAMMER* AND T. HOFMANN

Univ. of Vienna, Dept. of Env. Geosciences, Vienna, Austria (*correspondence: frank.kammer@univie.ac.at)

Engineered nanoparticles (ENPs) are more and more introduced into consumer products, leading to environmental and health concern. This development has been so rapid that methods to detect, quantify and characterize ENPs in environmental and biological media are still widely lacking. Field Flow Fractionation (FFF) is one of the most promising techniques currently developed for these tasks.

The strategy adopted for the analysis of ENPs in complex matrices depend strongly on the type of the ENPs and the nature of the matrix. Therefore, different methodologies have to be specifically developed for the e.g. analysis of nanoparticles of silver (AgNP) in an environmental matrix and nanoparticles of silica (SiO_2NP) in a biological matrix. These new developments have been performed on reference samples and are presented here.

Standard AgNP (i.e. 15-20 nm NM300 from OECD repository) were spiked to a standard soil (i.e. IME RefeSol from the German Federal Environment Agency) while Standard SiO_2NP (here 40 and 100 nm) were spiked to tomato soup (preparation from JRC in the course of FP7 Nanolyse project). The sample preparation can be done by density separation (AgNP) and by acid digestion (SiO_2NP). Flow-FFF coupled to UV-DAD spectrometry, online static and dynamic light scattering and ICP-MS were used to characterize compositions and properties of nanoparticles as a function of size.

Conventional ICP-MS coupled to FFF seems to be suitable for complex samples containing AgNP, because Ag has a low background in the environment.

These optimized methods helped in the investigation of complex mixtures of ENPs and matrix which finally led to the conclusion that ENPs do not always intensively interact with natural nanoparticles coming from the matrices and can occur as stable single particles in the environment. This results mitigate the current assumption that hetero-aggregation will be the most probable mechanism occurring in the environment. This is important in order to predict the impact of ENPs on the environment and human health.

Melts migrating through the mantle wedge: evidences from Patagonian and Western Pacific mantle xenoliths

M. MELCHIORRE[1], B. FACCINI[1], M. COLTORTI[1], M. GREGOIRE[2], C. BONADIMAN[1] AND M. BENOIT[2]

[1]Department Earth Sciences, University of Ferrara, Italy (massimiliano.melchiorre@unife.it)
[2]Observatoire Midi Pyrénéese, Université de Toulouse, France (gregoire@dtp.obs-mip.fr)

A suite of anhydrous spinel-bearing mantle xenoliths from Estancia Sol de Mayo (ESM, Patagonia) has been studied and compared with a large number of mantle xenoliths from other Patagonian localities. ESM xenoliths are devoid of modal metasomatic features as well as of amphibole. ESM cpx and opx plot on the high mg# side of three different trends, depicted by peridotites and pyroxenites of the other Patagonia localities. On the whole the three trends point towards refertilization/metasomatic events caused by saturated and undersaturated melts which largely affected the Patagonian sublithospheric mantle. These melts are similar to those responsible for the formation of various plateaux located behind the Austral Volcanic Zone. Cpx and opx of mantle xenoliths found in calc-alkaline lavas from the western part of the Pacific plate are also included in the comparison. They appear to be substantially depleted in Al_2O_3 and depict the fourth distinct trend. Investigation is currently undertaken to evaluate if this difference can be 'simply' related to different partial melting degree or to compositionally distinct metasomatic agents.

Diverse mantle sources for Ninetyeast Ridge volcanoes

P. MELENEY[1]*, F.A. FREY[1], M. PRINGLE[1], E. O'BRIEN[1], S. HUANG[2], I. NOBRE SILVA[3] AND D. WEIS[3]

[1]EAPS, MIT, Cambridge, MA 02139, USA (*pmeleney@mit.edu)
[2]EPS, Harvard University, Cambridge, MA 02138, USA
[3]EOS, UBC, Vancouver, B.C., Canada V6T 1Z4

The Ninetyeast Ridge (NER) is a 5, 000 km long N-S oriented submarine volcanic ridge in the eastern Indian Ocean. The N to S linear decrease in age, 77 to 43 Ma, is consistent with the NER forming as a hotspot track as the Indian Plate migrated northward over the Kerguelen hotspot. In 2007 the R/V Revelle recovered over 2, 000 kg of dominantly tholeiitic basalt from 22 dredge sites along 3, 200 km of the NER. The basalts have been variably altered in the submarine environment and 7 whole rock-glass pairs show that Rb and U are enriched and Ba is depleted in the altered whole rocks. Based on abundance ratios of REE and HFSE, and their correlations with Nd and Hf isotopic ratios, we identify several mantle sources that contributed to formation of the NER (see Fig. 1). We infer that two are related to the hotspot: one enriched in incompatible trace elements similar to the source of flood basalt in the Kerguelen Archipelago and the other is depleted in incompatible elements, but some trace element ratios (like Y/Nb) differ from the source of recently erupted SEIR MORB [1] (see Fig. 2). A third source is incompatible element-depleted similar to the source of SEIR MORB; this source is consistent with the inferred proximity of the hotspot to a spreading ridge during NER construction. However, Sr and Pb isotopic ratios of acid-leached whole rocks are not consistent with this inference [2, 3].

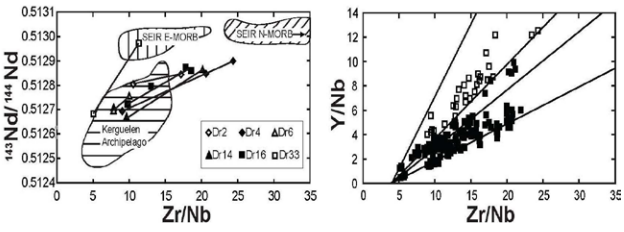

Figure 1: Dredges show trends between KA and SEIR E-MORB and N-MORB
Figure 2: Y/Nb anomalies in NER basalts.

Abundant marine sulphate in the Palaeoproterozoic: Models come and go, but the rock record endures

V.A. MELEZHIK[1,2]*, A.E. FALLICK[3], D.V. RYCHANCHIK[4] AND FAR-DEEP DRILLING TEAM

[1]NGU, Postboks 6315, N-7491 Trondheim, Norway (*correspondence: victor.melezhik@ngu.no)
[2]University of Bergen, Postboks 7803, N-5020 Bergen, Norway
[3]SUERC, East Kilbride, Glasgow G75 0QF Scotland
[4]Geological Institute, 185610 Ptrozavodsk, Russia

An important consequence of progressive oxygenation of the Earth's biosphere through the Proterozoic was an increased rate of sulphide oxidation during continental weathering, with concomitant increase in marine sulphate concentration. Hence, accurate assessment of the marine sulphate reservoir is crucial for correct interpretation and reconstruction of the oxygenation history of Earth's early emvironments. The currently accepted view is that the Proterozoic biosphere shows protracted oxidation, but marine sulphate remains low until c. 800 Ma [1]. This view and the estimated size of the marine sulphate reservoir through the Proterozoic, was essentially based on (*i*) a model that involves S isotope variability, and (*ii*) the absence of massive Ca-sulphates in the geological record until the late Mesoproterozoic. A contrasting, and less popular view, based on geological evidence, suggests otherwise [2]. Recently, the controversy has been resolved by discovery of massive anhydrites [3]. At a depth of 2115 m in a c. 3500-m-deep drillhole in the Onega Basin in eastern Fennoscandian Shield ^{13}C-rich dolostones of Lomagundi-Jatuli age (335 m) were intersected followed by massive anhydrite and anhydrite-magnesite rocks (c. 100 m), nodular shale interbedded with massive anhydrite (190 m) and a c. 194-m-thick halite formation (70-75% halite, 12-20% anhydrite, 10-15% magnesite) containing large blocks (up to 1 m) of bedded, coarse-grained anhydrite and magnesite. The c. 500-m-thick sulphate-halite interval survived orogenic deformation and associated greenschist metamorphism. Thick dissolution-collapse breccias occurring basin-wide at more shallow depths suggest that the preserved section represents only a small fraction from that what was originally precipitated. Hence, the geological record in the Onega basin endured and revision of current models is essential.

U-Pb dating of columbite-tantalite from Variscan rare-elements granites and pegmatites

J. MELLETON[1], E. GLOAGUEN[1], D. FREI[2] AND A. LIMA[3]

[1]BRGM, Mineral Resources Division, Orléans, France (j.melleton@bgrm.fr, e.gloaguen@brgm.fr)
[2]Stellenbosch University, Central Analytical Facility & Department of Earth Sciences, Stellenbosch, South Africa (dirkfrei@sun.ac.za)
[3]Porto University, Center of Geology, Porto, Portugal (allima@fc.up.pt)

Rare-elements (Li, Cs, Ta, Be, Sn…) magmatism is well expressed in the European Variscan belt with mainly pegmatites and granites. These bodies are known in most of the different realms of the belt, but they are particularly abundants in localized parts of the Iberian massif, the French Massif Central and the Bohemian Massif.

U-Pb dating of columbite-tantalite from selected Variscan rare-elements granites and pegmatites of these three massifs has been performed using laser ablation system connected to a single collector magnetic SectorField - Inductively Coupled Plasma - Mass Spectrometer (LA-SF-ICP-MS). The main aims of this study are to investigate the timing of this magmatism in the Variscan belt and the chronological relationship with the surrounding granitoid suites. Our results highlighted the existence of several emplacement episods :

- in the Moldanubian domain of the Bohemian Massif, rare-elements pegmatites emplaced at around 340-330 Ma.
- in the North of French Massif Central, the Montebras and Beauvoir granites and the Chèdeville pegmatite lead to emplacement age at 315-310 Ma.
- in the North of Iberian massif, three different events have been recognized, with the emplacement of the Argemela granite at 326 ± 3 Ma, a first group of pegmatites emplaced at 310 ± 5 Ma, a second at 301 ± 3 Ma.

In this context, rare-elements magmatism do not look to be related to lower crust processes (i.e. granulitic metamorphism) and rare metal magmatism event appears diachroneous and polyphased.

Microbial iron(II) oxidation in littoral freshwater lake sediments; Competition between phototrophic versus nitrate-reducing iron(II)-oxidizers

E.D. MELTON*, C. SCHMIDT AND A. KAPPLER

Geomicrobiology, University of Tuebingen (*correspondence: emily-denise.melton@uni-tuebingen.de)

The temporal and spatial distribution of microbial iron redox transformations are determined by local geochemical conditions and the resident microbial diversity. In the anoxic part of the top layer of littoral freshwater lake sediments, nitrate-reducing and photoferrotrophic microorganisms compete for the same electron-donor, i.e. reduced iron. Though a conceptual framework for biogeochemical iron cycling has been proposed [1], it is not yet empirically understood how these microbes co-exist in the sediment, what their spatial distribution is relative to one another and what role they play in the overall iron cycle. In this study, freshwater littoral lake sediment from Lake Constance was incubated in microcosm experiments with various additives to stimulate microbial photoferrotrophic and nitrate-reducing iron (II) oxidation in order to distinguish between the two processes and assess their individual contributions to the sedimentary iron cycle. One set was incubated under constant light, whilst a parallel set was incubated in the dark at 23°C. Additionally, a high-resolution MPN depth profile was performed for iron (II)-oxidizing organisms utilizing light or nitrate to reveal their spatial distribution in the natural sediment. These experiments combine microbial and geochemical techniques to provide key information needed not only to determine the contribution of microbial activity to the overall iron oxidation budget and their spatial distribution, but also to define the role of geo (photo)chemical iron conversion rates and its general importance in littoral freshwater lake sediments.

Subsurface environments harbor diverse and active microbial populations that influenced the Earth's chemistry throughout geological times by mediating elemental fluxes from the lithosphere to the oceans and atmosphere. However, the exploration of their metabolic diversity, energy sources, and biogeochemical transformations at the appropriate scale remains highly challenging, especially within hard rocks. We present here dedicated cutting-edge approaches combining molecular labelling (as fluorescence *in situ* hybridization and immunodetection) with an array of high-resolution techniques (coupled confocal laser scanning microscopy and Raman spectroscopy, transmission and scanning electron microscopies, synchrotron-based X-ray microimaging). Altogether they allow localizing specifically individual prokaryotic cells, investigating their phylogenetic affiliation at the micrometric scale while characterizing concomitantly the nature and the stucture of their microhabitats and past interactions (i.e. mineral dissolution and metabolic byproducts such as biomineralizations). Our ability to reveal chemical, mineralogical, genetic and metabolic diversity in subsurface environments will be illustrated by integrated field and laboratory investigations. Special attention will be dedicated to hydrogen-driven chemolithoautotrophic ecosystems associated with ultramafic rocks from the oceanic lithosphere, in the double fundamental perspective: to explore analogs for early biological systems on the primitive Earth or other planetary bodies, and for industrial purposes being a major target for CO_2 geological storage where microbial activity allow enhancing carbonation processes and reducing the energetic balance.

Late Paleozoic tectonic evolution in eastern Heillongjiang Province, NE China: Constraints from detrital zircons and volcanisms

E. MENG, W.L. XU*, F.P. PEI AND F. WANG

College of Earth Sciences, Jilin University, Changchun 130061, China (mengen08@mails.jlu.edu.cn) (*correspondence: xuwl@jlu.edu.cn, mengen08@mails.jlu.edu.cn)

Geochronology of detrital and magmatic zircons and geochemistry of the volcanic rocks from the late Paleozoic strata in eastern Heilongjiang province of NE China, provide constraints on the Late Paleozoic tectonic evolution of the eastern segment of the Central Asian Orogenic Belt between the Siberian and the North China cratons [1].

LA-ICP-MS U-Pb dating results for detrital zircons from the Early Devonian sandstones show that the detrital zircons from the rocks in the Songnen-Zhangguangcai Range Massif (SZM) have age populations of 2503, 1833, 903~802, and 551~403 Ma, different from those from the coeval rocks in the Jiamusi Massif (JM) with ages of 569, 542, 509, and 484 Ma [2]. This finding indicates that (1) they deposited after 403 and 484 Ma, respectively; (2) ancient crustal remnants existed in the SZM in the Late Paleozoic; (3) the amalgamation of the SZM and JM could happen before 403 Ma.

Zircon U-Pb dating results for the magmatic zircons from the Late Paleozoic volcanic rocks in the region indicate that three volcanical events exist in the Late Paleozoic, i.e. the Middle Devonian (386 Ma), Early Permian (291 Ma), and Middle Permian (268 Ma). Their geochemical data and Sr-Nd-Hf isotopes reveal that: (1) the Middle Devonian volcanic rocks in eastern margin of the JM consist of basalt and rhyolite, a bimodal volcanism, suggesting an extensional environment, which is consistent with the existence of coeval A-type rhyolites in the SZM; (2) the Early Permian volcanic rcoks in the eastern margin of the JM are composed mainly of a calc-alkaline volcanic rocks such as basalt, basalt-andesite, and minor dacite, indicating an active continental margin setting, whereas the coeval bimodal volcanical rocks in the SZ suggests an extensional environment similar to a back-arc basin setting [3];. and (3) the Middle Permian syn-collisional rhyolites in the southeastern margin of the JM imply the amalgamation of the JM and the Khanka Massif.

[3]School of Earth Sciences, Jilin University, Changchun 130061, China (xuwl@jlu.edu.cn)

Worldwide granulites usually do not exhibit decoupled Hf-Nd systems expected for crustal melting at the presence of garnet. Here we present whole-rock Nd–Hf isotopic data for a rare suite of lower crustal eclogitic xenoliths and their host early Cretaceous high-Mg adakitic porphyries from the Xuhuai area from the eastern North China craton. The xenoliths and their host intrusions are considered to represent residues and melt formed by melting of eclogitic lower crust that foundered into the convecting mantle based on their complementary major and trace element compositions and similar zircon age patterns. Nine of the eleven analyzed xenoliths plot significantly above the terrestrial Hf-Nd array with ε_{Hf} up to +60, while the porphyries fall essentially along the array. Hf-Nd isotopic modelling shows that the eclogitic xenoliths can be interpreted by 30-50% extraction of melt, which after reaction with 10-30% depleted mantle can produce the observed porphyry. The retarded time-integrated Hf isotope ingrowth of the porphyries is due to its very low Lu/Hf ratio and a relatively short time span after its formation. Our results also indicate that garnet is the major factor controlling Lu/Hf ratio of the residue with accessory minerals rutile and titanite also playing a role. Granulite with <10% garnet will not evolve to show significant decoupled Hf-Nd isotopic signatures even after 500 Ma of melt extraction. The generally terrestrial Hf-Nd compositions of worldwide granulites may be because they have never experienced partial melting at presence of abundant garnet. Instead, the lower crustal granulite may transform into eclogite during crustal thickening. Such an eclogitic lower crust is short-lived, and will be recycled into the mantle. Decoupled Hf-Nd isotopic signatures are expected to be more pronounced in eclogite foundering-related basaltic magma than eclogite-derived TTG melt, as observed in some of Cenozoic basalts from the eastern North China craton.

Thermometry of quartz from the metaconglomerate of Jack Hills, Western Australia

M. MENNEKEN[1]*, A.A. NEMCHIN[2] AND T. GEISLER[3]

[1]Institut für Mineralogie, Westf. Wilhelms Univ. Münster Correnstr. 24, 48149 Münster , Germany (*correspondence: m.menneken@uni-muenster.de)
[2]Department of Applied Geology, Curtin Univ. of Technlogy, Kent Str. Bentley, 6102 WA, Australia
[3]Steinmann Institut, Rheinische-Friedrich-Wilhems Univ. Bonn, Poppelsdorfer Schloss, 53115 Bonn, Germany

The original sample site W74 in the Jack Hills meta-sedimetary belt, Western Australia [1], is well known for containing detrital zircon grains as old as 4.4 Ga [2]. Various geochemical investigations on these detrital zircons and their inclusions have been utilized in trying to establish conditions that existed on the early Earth [3 and ref. therein]. We extended the focus of this research to quartz, the main component of the conglomerate containing old zircons. In a comparative study we determined Ti temperatures of quartz [4] in both the quartzite pebbles and the matrix of the conglomerate, as well as of quartz from inclusions in zircons. The quartz grains of the conglomerate pebble record an average temperature of 437 ± 22°C (2σ, n=21), which is significantly lower than the temperature of 509 ± 80°C (n=15) obtained from the matrix quartz. The temperatures obtained from quartz inclusions in separated zircon grains, on the other hand, are all around 700°C, and are in agreement with Ti-in-zircon temperatures obtained from the host zircons, proving previous assumption that the quartz inclusions were incorporated during zircon growth. We interpret the matrix quartz temperature as recording the late metamorphism of the Jack Hills sedimentary belt at upper greenschist lower amphibolite conditions [5]. The pebble quartz, however, might inherit the temperature of an earlier metamorphic event in the source region. This, in combination with the restriction of the mineral paragenesis to nearly purely quartz, suggests that grains, deposited in the Jack Hill sedimentary belt, are derived from a meta-sedimentary host rock. Zircons, found in the conglomerate, would thus have experienced at least one metamorphic event before being re-deposited in the Jack Hill sedimentary belt.

SoilTrEC: An international consortium to assess soil processes and functions using a global network of Critical Zone Observatories

M. MENON AND SOILTREC RESEARCH TEAM

Kroto Research Institute, University of Sheffield, Broad Lane, Sheffield, S3 7HQ, United Kingdom (m.menon@sheffield.ac.uk)

Soil Transformation in **E**uropean **C**atchments (SoilTrEC) is an international consortium that aims to develop a comprehensive understanding of soil processes and functions. The project will combine experiments and modelling to describe soil formation and functions using a global network of Critical Zone Observatories (CZOs) that focus multidisciplinary expertise onto the study of soil processes. The specific objectives of the project are the following: (1) describe from 1st principles how soil structure impacts processes and function at soil profile scale, (2) establish 4 EU Critical Zone Observatories to study soil processes at field scale (3) develop a Critical Zone Integrated Model of soil processes and function (4) create a GIS-based modelling framework to delineate soil threats and assess mitigation at EU scale (5) quantify impacts of changing land use, climate and biodiversity on soil function and economic value (6) form with international partners a global network of CZOs for soils research, and (7) deliver a programme of public outreach and research transfer on soil sustainability [1].

Four experimental CZOs are chosen for this study [1]; the Damma Glacier CZO (Switzerland) allows the study of incipient soil formation in the glacial forefield as the glacier retreats, to study earliest stages of soil formation. Lysina CZO (Czech Republic) and Fuchsenbigl CZO (Austria) are included to study soil processes under well managed forest and arable landscapes, respectively. The Koiliaris CZO (Greece) represents highly degraded soils after millennia of intensive agricultural land use, including grazing, and is under additional threat from desertification due to modern climate change. These CZOs provide field data and new measurements which will be used for the modelling of water flow, reactive transport, biogeochemical processes and nutrient cycles. Finally, an intergrated regional scale model will be developed for soil ecosystem services and threats in Europe, which will be further validated with other CZOs in Europe, USA and China. Soil profile sampling from the CZOs was completed in 2010 and preliminary data will be presented.

Quantitative reconstruction of millennial-scale temperature variations in Central Europe

G. MENOT* AND E. BARD

CEREGE, Univ. Aix-Marseille, CNRS, IRD & College de France, Technopole de l'Arbois BP 80, 13545 Aix-en-Provence Cedex 04, France
(*correspondence: menot@cerege.fr, bard@cerege.fr)

The amplitude of the environmental changes associated with the Last Deglaciation provides a useful test bench for the climatic and oceanic responses and their attendant feedbacks to major reorganizations of the atmospheric circulation and the surface hydrology. We present the first quantitative reconstruction of millennial-scale temperature variations in Central Europe during the last 40, 000 years based on newly developed temperature proxies measured in a sediment core from the Black Sea (MD04-2790). Despite the shift from lacustrine to marine conditions (and therefore associated salinity changes) that affected the basin, the tetraether-based paleothermometer (TEX_{86}) properly records the increase in surface water temperatures during the Last Deglaciation. To our knowledge, no quantitative temperature reconstruction has been published for the Black Sea area so far, a comparison of the amplitude of temperature changes reconstructed for the Last Glacial Maximum and the actual in the Mediterranean basin shows that the Black Sea values are consistent with that of the western basin and colder than the eastern basin [1]. Interestingly and in contrary to what is seen in nearby archives (pollen assemblages [2], [3] and speleothems [4]) Heinrich events deeply imprint our glacial temperature record, whereas the signature of Dansgaard-Oeschger interstadials are comparatively attenuated. The high-resolution record also provides snapshots of the basin responses to specific abrupt climatic events such as the Younger Dryas and the Bølling-Allerød.

Application of thermal analysis and NMR to study soil organic matter biodiversity and biodegradability in afforested lands

AGUSTÍN MERINO*, CÉSAR PÉREZ-CRUZADO, JOSEFA SALGADO AND NIEVES BARROS.

Escuela Politécnica Superior, University of Santiago de Compostela, Lugo, Spain

Calorimetry and thermal analysis can be applied to studies of the stabilization of soil organic matter (SOM) under different environment situations and types of management. In this study, differential scanning calorimetry (DSC) and isothermal calorimetry were applied, along with ^{13}C CPMAS NMR, to assess the changes in SOM quality in afforested lands under pine and eucalypt in a humid temperate region.

Samples with the highest carbon percentages contained highly diverse mixture of aliphatic fractions, carbohydrates, cellulose, aromatic C and carboxyl groups. The heat of combustion was also highest in these samples. The loss of SOM and the C decay affected the aliphatic fraction and carbonyl groups, which could not be identified in the NMR spectrum or in the DSC curves of those samples. Carbohydrates and aromatic C persisted in the samples with the lowest C percentages. C gain after afforestation predominantly affected the aliphatic and aromatic fractions in the pine stands and the aliphatic and carbohydrate fractions in the eucalypt stands. The method was sensitive to detect differences in the OM nature attributable to the tree species.

[3]CRPG (CNRS UPR2300), BP 20, 54501 Vandoeuvre-lès-Nancy, France (reisberg@crpg.cnrs-nancy.fr)
[4]Université de Genève, 13 rue des Maraîchers, 1205 Genève, Switzerland (Massimo.Chiaradia@unige.ch)

The Central Atlantic Magmatic Province (CAMP) is one of the largest CFB provinces on Earth, extending over a surface in excess of 10^7 km^2 in circum-Atlantic regions. Here we document the geochemical characteristics of CAMP lavas flows, sills and dikes from NE U.S.A. and Nova Scotia (Canada).

All the samples are low-Ti basalts and compared to N-MORBs they display LILE and LREE enriched patterns with negative Nb anomalies. Based on major and trace element characteristics (REE patterns, TiO_2 vs La/Yb diagrams), three groups can be defined: (1) the Talcott-Orange-Mt Zion Church flow units, all the Nova Scotia samples (North Mountain basalts and Shelbourne dike) and the lower part of the Palisades sill (TiO_2 ≈ 0.5-1.3 wt%, La/Yb ≈ 4-6), (2) the Holyoke-Preakness-Sander-Hickory flow units (TiO_2 ≈ 0.7-1.1 Wt%, La/Yb ≈ 2.5-3.5) and (3) the Hampden-Hook flow units (TiO_2 ~ 1.3-1.5 wt%, La/Yb ~ 2).

All the samples plot in the field of CAMP low-Ti basalts in Pb-Pb and Sr-Nd isotope plots ($^{206}Pb/^{204}Pb$ = 18.16-18.69, $^{207}Pb/^{204}Pb$ = 15.57-15.67, εNd from -4.1 to 2.3). Most of the samples display initial $^{187}Os/^{188}Os$ ratios in the range of typical upper mantle magmas. Nevertheless, some samples have quite radiogenic initial ratios (up to 0.479) suggestive of crustal contamination.

The Talcott-Mt Zion Church-Orange-North Mountain-Shelbourne group shows continental-like Sr-Nd-Pb isotopic ratios, which coupled with their mostly non-radiogenic Os compositions, may argue for a dominant source contribution from subduction-metasomatised sub-continental lithospheric mantle (SCLM). The Hook-Hampden and the Holyoke-Sander-Preakness-Hickory units as well as the Rapidan sill are slightly distinct from the other samples since they yield $^{206}Pb/^{204}Pb$ >18.5 and are closer to the NHRL. These characteristics may suggest a contribution from an asthenospheric component.

Evaluating the impact of marine organic aerosols on climate

NICHOLAS MESKHIDZE, JUN XU AND BRETT GANTT

Department of Marine, Earth, and Atmsospheric Sciences, North Carolina State University, Raleigh, NC, USA (nmeskhisze@ncsu.edu, jxu5@ncsu.edu, bdgantt@gmail.com)

A large fraction of the uncertainty in predicting future climate may be related to the number concentration of marine aerosol that are prescribed or diagnosed in global climate models. Therefore, correct assessments of aerosol number concentration, size distribution and chemical composition over pristine marine regions may have profound effect on model predicted extent of human-induced climate change.

The effects of marine organic aerosols on microphysical properties of shallow clouds and the Earth's radiative budget are explored by the NCAR Community Atmosphere Model (CAM5.0), coupled with the PNNL Modal Aerosol Model. Sea spray enrichment by organics is estimated using wind speed dependent size-resolved parameterization, while marine-source secondary organic aerosol is inferred from the ocean emissions of biogenic trace gases. The ability of sea spray to act as cloud condensation nuclei (CCN) are not fully understood; therefore CAM5 simulations cover the range of possible scenarios in aerosol mixing sate and hyroscopicity parameter based on our recent lab experiments. The size, number, and CCN distributions of aerosols generated by a bubble-bursting process were determined using a differential mobility analyzer (DMA)-condensation particle counter (CPC)-CCN counter (CCNc) system. Predicted concentration of organic aerosol and CCN in remote marine atmosphere was compared to *in situ* data. Simulations show that over the oceans marine organics can yield up to 10% increase in surface CCN (0.2%) (see Fig. 1). Changes associated with liquid water path and droplet number can increase short-wave forcing by -0.2Wm^{-2}. The disproportional effects of marine aerosols between pre-industrial and current climate and land vs. ocean have also been observed.

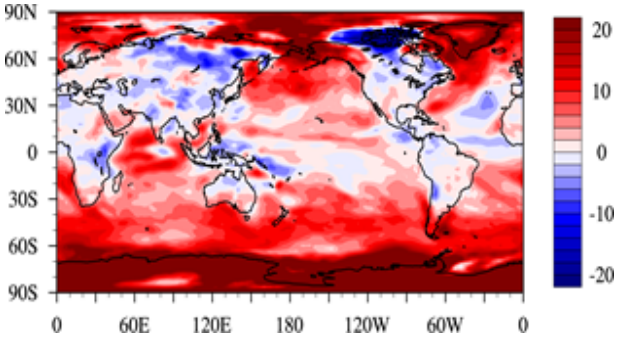

Figure 1: Annual average percentage change in surface CCN (0.2%) concentration due to marine emissions.

Evolution of the δD value in water-rich basaltic melt inclusions during volcanic processes

N. METRICH[1]*, E. DELOULE[2] AND A. DI MURO[1]

[1]Institut de Physique du Globe, Sorbonne Paris Cité, UMR CNRS 7154, Univ. Paris Diderot, Paris, France (*correspondence: metrich@ipgp.fr, dimuro@ipgp.fr)
[2]CRPG-CNRS, Vandoeuvre Les Nancy, France (deloule@crpg.cnrs-nancy.fr)

Melt inclusions (MI*s*) hosted in Mg-rich olivines are powerful tools to record magma evolution and degassing during their decompression and ascent toward the surface. However their ability to loose H_2O during magma ascent and degassing through proton diffusion is widely debated [e.g. 1].

H_2O contents and δD values were measured in two series of melt inclusions representative of Ca-rich basalts to arc basalts, rich in H_2O, in using the Cameca IMS 1270 ion microprobe (CRPG-CNRS, Nancy, France) and Raman spectroscopy (Saclay, France, [2]), respectively. In lapilli samples from Vulcano island (Aeolian arc), MIs are hosted in olivine Fo_{89-90}, they contain on average 4.4 wt% of H_2O (±0.2 wt%; 18 measurements) and the post-entrapment olivine crystallizaton is negligible. In Aoba samples (Vanuatu arc), MIs are entrapped in olivine Fo_{86-90}, with 2 to 5 % of post-entrapment crystallization; their H_2O is more variable (1.7-2.3 wt%). In both cases their low CO_2 concentrations indicate shallow olivine crystallization.

As a whole the δD values (42 measurements) vary from -96‰ to +38‰ (with two values even higher). Isotopic analyses have been duplicated in single inclusions of Vulcano samples to verify the data reproducibility.

Hydrogen diffusion out of Mi*s* is required to explain negative trends between the H_2O concentrations and δD, in particular in one series of Aoba samples showing δD values ≥0‰. Leaving apart these latter values, most of the measured δD are comprise between -19‰ and -40‰. They plot in the field of Mariana arc Mi*s* (from -55‰ to -12‰; [3]). The question that arises is to what extent our δD values are representative of the last stage of melt equilibration with their surroundings at time of their entrapment and olivine crystallization or bring constraints on the magma source. The different processes able to reproduce the trends registered by Aoba and Vulcano MI*s* will be discussed.

Am(III) retention by cement corrosion products under highly saline conditions

V. METZ, C. BUBE, E. BOHNERT, M. SCHLIEKER AND B. KIENZLER

Institute for Nuclear Waste Disposal (INE), Karlsruhe Institute of Technology, Herrmann-von-Helmholtz-Platz, 76344 Eggenstein-Leopoldshafen (volker.metz@kit.edu, bube@kit.edu, elke.bohnert@kit.edu, schlieker@kit.edu, bernhard.kienzler@kit.edu)

Cementition is a common method to fix and solidify low and intermediate radioactive waste (LLW/ILW). Alteration of radionuclide bearing cement products in diluted aqueous solutions has been studied quite extensively. Yet, in chloride-rich solutions, which are relevant for final LLW/ILW disposal in rock salt, there is still a lack of thermodynamic data and understanding with respect to both cement corrosion and radionuclide behaviour. In the present work, cement interaction with $MgCl_2$-rich brines have been studied experimentally on laboratory-scale and with full-scale waste simulates. In addition, Am (III) retention by cement corrosion products was quantified from the laboratory experiments.

Due to dissolution of portlandite, ettringite and other solid cement phases, the initially $MgCl_2$-rich solutions alter to alkaline $CaCl_2$-rich solutions. Besides reprecipitation of gypsum, formation of hydrotalcite phases, Mg-Ca-Al hydroxochloride and brucite is observed. Compositions of the altered solution and solid phases depend strongly on the cement / brine ratio. Measured solution compositions agree well with results of thermodynamic calculations for the studied cement / brine systems. After equilibration of the systems, they are doped with small quantities of acidic ^{241}Am (III) and ^{243}Am (III) solutions (10^{-9}, 10^{-8} and 10^{-7} mol Am (kg H_2O)$^{-1}$). Am concentrations and solution composition have been monitored for 1000 days in the non-agitated batch experiments. Within six months a sorption equilibrium is achieved, demonstrating strong retention of Am (III) by the corroded cement products. Data of equlibrated systems are characterized by linear sorption isotherms, which allow determining apparent sorption coefficients, R_s. In $MgCl_2$-$CaCl_2$ and weakly alkaline $CaCl_2$ systems ($7.3 < -\log(m_{H+}) < 9.0$), R_s is measured in the range of 3000 to 6000 ml g^{-1}, whereas in highly alkaline $CaCl_2$ systems ($-\log(m_{H+}) \sim 11.5$) R_s = 10000 ml g^{-1} is observed. The retention of radionuclides on corroded cement products has often been claimed not only for dilute solutions, but also for saline brines. This work enables to quantify the retention of Am and thus corroborates previous estimations with experimental data.

Coupled high-resolution $\delta^{13}C_{carb}$ and $^{87}Sr/^{86}Sr$ chemostratigraphy on the North American craton: Identifying the source of the Late Ordovician Guttenberg Isotopic Carbon Excursion

J.G. METZGER AND D.A. FIKE

Dept. of Earth and Plentary Sciences, Washington Univ., St. Louis, MO 63130, USA. (gmetzger@levee.wustl.edu, dfike@levee.wustl.edu)

The Guttenberg isotopic carbon excursion (GICE) is a ~2‰ positive excursion in $\delta^{13}C_{carb}$ found in Late Ordovician (Early Katian) strata on three different continents and represents a major perturbation of the global biogeochemical carbon cycle. We applied $\delta^{13}C_{carb}$ chemostratigraphy to two Missouri (MO) sections containing the GICE in the Decorah Formation. Our data show the Kings Lake Member of southern MO and the Guttenberg Member of northern MO are coeval rather than successive, thereby revising the erosional and depositional history of Late Ordovician sediments in MO.

The cause of the GICE remains uncertain. Although enhanced burial of organic carbon is often invoked, definitive evidence for this has yet to arise. We couple $\delta^{13}C_{carb}$ and $^{87}Sr/^{86}Sr$ chemostratigraphy with biogeochemical cycling models of C and Sr to constrain possible causes for the GICE. Parallel variation in $\delta^{13}C_{carb}$ and $^{87}Sr/^{86}Sr$ suggest a change in oceanic weathering inputs as the most likely explanation for the GICE. Modelling results indicate that a single mechanism, a drop in the total weathering flux (F_w) and/or proportion of silicates being weathered, can explain the apparent inverse relationship between $\delta^{13}C_{carb}$ and $^{87}Sr/^{86}Sr$ in our two sections from MO. The drop in F_w could have resulted from flooding of the North American craton, which thereby lowered the amount of exposed land. Significant stratigraphic evidence of sea level rise is found across the North America craton and is coincident with the onset of the excursions in both isotopic systems. However, a widespread drowning surface at the end-GICE across the Upper Mississippi Valley suggests a decoupling between $\delta^{13}C_{carb}$ and sea level or the presence of more than one mechanism. Despite the challenges of non-uniqueness in reconciling chemostratigraphy and model results, we are able to show that coupling multi isotopic systems and elemental cycling models can constrain the range of possible source mechanisms, while precluding others. Furthermore, our results suggest that small excursions in $^{87}Sr/^{86}Sr$ may exist over relatively short periods of time (<1 Myr) in Paleozoic deposits.

Characteristics and origin of the Lala iron oxide Cu-Co-(U, REE) deposit: Sichuan, Southern China

F.M. MEYER[1]*, C. SCHARDT[1], S. SINDERN[1], M. GEHLEN[1], P.E. HALBACH[2], J. LAHR[2] AND J. LI[3]

[1]Institute of Mineralogy and Economic Geology, RWTH Aachen University, Wüllnerstr. 2, 52062 Aachen, Germany (*correspondence: m.meyer@rwth-aachen.de)

[2]Institute of Geological Sciences, Free University Berlin, Malteserstr. 74-100, 12249 Berlin, Germany

[3]Qingdao Institute of Marine Geology, 62 Fuzhou Nan Road, Qingdao, 266071, People's Republic of China

Cu-Co-REE-U mineralization at the Lala mine is multistage, controlled by the geologic-tectonic evolution of the region. The deposit has been interpreted as volcanic-hosted massive sulfide [1], metavolcanic-sedimentary with hydrothermal remobilization [2], or IOCG-type mineralization [3, 4]. The ore deposit is hosted by a Middle Proterozoic volcano-sedimentary succession, metamorphosed at upper-greenschist to amphibolite-facies conditions, early during the Sibao Orogeny (~1 Ga). Mineralization occurred during the Neoproterozoic at ca. 830 Ma [5].

The host rocks are metamorphosed and hydrothermally altered intermediate to mafic volcanics and mica schist. The main alteration styles include albitization and sericitization. Textural evidence allows recognition of 3 modes of sulphide mineralization with a distinct sequence of formation, indicating a complex and multiphase genetic evolution. There are strong indications that the mineralization is essentially epigenetic-hydrothermal in origin and the formation of hydrothermal breccias may be attributed to fluid release from an underlying magma. While there is no strict statistical correlation between La and Cu, Cu-rich samples are always enriched in REE elements. Other characteristic features include the abundance of iron-oxides and Cu-sulfides, a low-Ti magnetite chemistry, REE-mineralogy, and the presence of uraninite.

These new data lend evidence to the conclusion that, in contrast to previously proposed ore genesis models, the mineralization at Lala possesses many features that warrant its inclusion within the global IOCG deposit class.

[3]Istanbul University (yasegulecal@gmail.com)
[4]Washington University in St. Louis (amend@wustl.edu)

Mounting evidence indicates that microbial diversity varies substantially between hydrothermal systems of differing provenances. For example, among terrestrial hydrothermal systems, it has been shown that diversity and distribution of microorganisms may be related to geographical location or physical separation [1, 2]. There is, however, minimal evidence concerning differences in the diversity and distribution of genes associated with biogeochemical functions. Of particular interest is the nature of biogeochemical cycles such as nitrogen or carbon cycling in hydrothermal systems. Recent work has revealed snapshots of genetic potential for nitrogen cycling processes in hydrothermal systems such as nitrogen fixation and nitrification, and potential correlation with geography and other physicochemical parameters [for example, 3-6]. As of yet, no comparison of these processes between terrestrial and shallow-sea hydrothermal systems has been made.

We surveyed over 100 locations, representing terrestrial hydrothermal systems in Yellowstone National Park [USA] and Turkey, and shallow-sea hydrothermal systems in Sicily [Italy] and Papua New Guinea. In each area, we have characterized the geochemical environment, energetic potential, and functional genes diagnostic for stages of the nitrogen cycle. Our results show that the distribution of nifH [nitrogen fixation], amoA [nitrification], and narG/nirKS/nosZ [denitrification] genes differs between samples in sediments and biofilms. In addition, the genetic potential for nitrogen cycling is dependent on metabolic zonation within the hydrothermal system; for example, chemosynthetic vs. photosynthetic zones. The diversity of nitrogen cycling genes also varies with the provenace of the sample location, showing evidence for adaptation.

Multi-proxy ($\delta^{18}O$, χ_m , Nd and Pb isotopes) study for paleoclimate and paleoweathering in the Maldives area

L. MEYNADIER[1], C.J. ALLEGRE[1], A.T. GOURLAN[1] AND F.M. BASSINOT[2]

[1]IPGP (Sorbonne Paris Cité, Université Paris Diderot, UMR7154 CNRS), 1 rue Jussieu, 75238 Paris Cedex 05, France
[2]LSCE (CNRS/CEA/UVSQ), Domaine du CNRS, 91190 Gif-sur-Yvette, France (allegre@ipgp.fr, meynadier@ipgp.fr, gourlan@ujf-grenoble.fr, franck.bassinot@lsce.ipsl.fr)

On the MD900963 sediment archive cored on the edge of the Maldives Plateau (Equatorial Indian Ocean), we measured $\delta^{18}O$, $CaCO_3$, Magnetic susceptibility (χ_m), Neodymium and Lead isotopic compositions of both the ancient seawater and the detrital fraction. Our analyses cover the last 250 Ka.

The observed variations show fluctuations, which mimics the glacial-interglacial variations shown by $\partial^{18}O$. The two dominant frequencies are 100 Ka and 23 Ka.

The coherent results of Nd (ε_{Nd}) and Pb isotopes on the detrital fraction and carbonated corrected χ_m on one hand and Nd and Pb isotopes of the ancient seawater on the other hand show without doubt that these variations reflect the regional weathering and regional sedimentation. These data will also be in perspective with ODP Site 758 [1] and additional lead isotopes data from this eastern site.

All together, these results confirm that rain, physical & chemical erosion were larger during warm periods than during cold periods. These variations reflect the fluctuations of the summer monsoon rain intensity. Therefore the study gives strong limitations for the processes driving the relationship between climate, rain and weathering in the equatorial Indian Ocean region over the Glacial/Interglacial alternate.

Origin of Earth's volatile elements: Constraints from Rb isotopes

K. MEZGER[1], O. NEBEL[2] AND W. VAN WESTRENEN[3]

[1]Universität Bern, Switzerland (klaus.mezger@geo.unibe.ch)
[2]The Australian National University, Canberra, Australia
[3]Free University Amsterdam, Amsterdam, The Netherlands

Compared to the composition of C1-meteorites the Earth is strongly depleted in volatile elements. This depletions may be due to incomplete condensation or volatile loss caused by impact heating during the early stages of the planet formation. The elemental depletion correlates roughly with the half-condensation temperatures of the elements. This general depletion trend for the volatile element abundances in bulk silicate Earth (BSE) is modified due to core formation which further fractioned elements based on their siderophile and/or chalcophile behavior. The combined cosmochemical and geochemical effects result in the irregular trends observed in the abundances of the volatile elements in BSE. In order to separate the different depletion processes that affected the final composition of BSE we compare the abundances of Rb and Pb and their isotope compositions in terrestrial samples and meteorites In order to evaluate the variability of Rb isotopes in different solar system materials the Rb-isotope compositions of 17 primitive meteorites and terrestrial samples was analysed by MC-ICP-MS with Zr as an internal standard. This technique results in a reproducibility of ± 0.2 ‰ for $^{87}Rb/^{85}Rb$. The observed variation of the Rb-isotopes in all materials studied is less than 2 ‰. The variation does not correlate with the Rb elemental abundances. The unfractionated Rb-isotopes of the Earth imply that the volatile element depletion is not due to evaporation or incomplete condensation alone but requires at least a two step process. A more realistic model is that the Earth consists primarily of a large component of essentially volatile free material that was later mixed with a component that was not depleted in volatile elements. In this model the Rb-isotope composition of the mixture is dominated by the isotope composition of the undepleted component. Mass balancing with a 90% depleted Proto-Earth and gain of 10% C1 material can account for the Rb isotope distribution and abundance in the present day BSE. If Pb behaved approximately like Rb, as is suggested by its similar half condensation temperature, BSE requires an additional Pb depletion event to account for its observed U/Pb and Pb-isotope systematics. Comparison of Rb abundances and isotopes with Pb abundances and isotopes implies that the Pb-depletion in the BSE was not solely due to core formation but most of the Pb was already missing from the Earth prior to final core mantle equilibration.

Simulating experiments on gas generation of coal under different fluid pressure

MI JINGKUI, ZHANG SHUICHANG AND HE KUN

Key Laboratory for Petroleum Geochemistry, China National Petroleum Corporation.

It is still a controversy whether fluid pressure has a retardation for the hydrocarbon generation of source rock or not [1-2]. 4 groups experiments of gas generation of coal were conducted under different fluid pressure (25Mpa, 50Mpa, 75Mpa and 100Mpa) and temperature (300°C-650°C) in gold tube closed system. The maximum amount of total hydrocarbon gas are 102.32ml/g. coal, 95.63ml/g. coal, 122.26ml/g. coal and 124.56 ml/g. coal under 25Mpa, 50Mpa, 75Mpa and 100Mpa, respectively. So, fluid pressure action on gas generation of coal is not acceleration or retardation simply, but retardation in a relatively low scope of fluid pressure, and acceleration for gas generation of coal with fluid pressure increasing. The amount variation of methane generated by coal with fluid pressure increasing is consistent with that of total gases, but the volume variations of other gas components (such as H_2, H_2S, CO_2) have great difference, this indicate the influences of fluid pressure on these gases formation are different.

There is no explicit correlation between the value of $\delta^{13}C_1$ and the fluid pressure below 430°C, the value of $\delta^{13}C_1$ becomes from light to heavy first, then to light with the fluid pressure increasing in main period of gas generation (above 470°C) in all 4 groups experiments. The more of gas generating from coal is, the lower of H/C value of coal residue is. The R_O value of pyrolysis residue under 50MPa is lower than that under others fluid pressure in 470°C-575°C, in a point of other range temperature, there is no measurable difference of residue R_O in 4 group experiments

Transport of solutes through hydraulically and chemically heterogeneous sediments of the Bengal Basin

H.A. MICHAEL

University of Delaware, Newark, DE 19716, USA (hmichael@udel.edu)

The sedimentary history of the Bengal Basin has determined the structure and pattern of an aquifer system more than 250, 000 km^2 in area and up to 16 km deep. Rivers carrying huge sediment loads from the Himalayas have deposited and eroded floodplain sediments through avulsion cycles; this combined with transgressions and regressions of sea level have produced complex stratigraphic sequences that make up a highly heterogeneous hydrogeologic system.

The sedimentary architecture plays a major role in determining groundwater flowpaths and subsurface transport of solutes. The depositional history also contributes to sediment chemistry, which can affect sorptive properties and other biogeochemical reactions. The effects of hydraulic and chemical heterogeneity in the Bengal Basin are considered generally and in two specific contexts: sustainability of arsenic-safe groundwater resources and groundwater salinization in the coastal zone.

Widespread contamination of shallow groundwater with As concentrations above world health standards occurs throughout much of the lower Bengal Basin, in Bangladesh and West Bengal, India. High concentrations are limited to the upper 100m in many areas; thus deep groundwater has been targeted as a mitigation option. The sustainability of deep resources depends on hydraulics and chemistry: both flowpaths and sorption may reduce vulnerability. Simulation of these protection mechanisms on a regional scale assuming basin-wide effective properties suggests a sustainable resource if properly managed. However, small-scale simulations that incorporate explicit heterogeneity in physical and chemical properties suggest that As migration may be highly variable, with short breakthrough times in some areas.

In the coastal zone, groundwater resources are threatened by salinization, which may become worse as sea level rises in the future. Currently, fresh groundwater exists at depth (>~200m) beneath a brackish zone. Mechanisms and timescales of salinization, both lateral and vertical, were investigated with variable-density numerical models. Subsurface salinity distributions, particularly in transient states, are highly dependent on heterogeneity in hydrogeologic properties as well as the history of sea level and storm surge inundations.

Geologic and hydrologic control of porewater chemistry and submarine groundwater discharge into Indian River Bay, Delaware

H.A. MICHAEL[1]*, C. FERNANDEZ[1], C.J. RUSSONIELLO[1], A.S. ANDRES[2], K.D. KROEGER[3], D.E. KRANTZ[4], J.F. BANASZAK[4], A. MUSETTO[1], K. MYERS[1], L.F. KONIKOW[5] AND J.F. BRATTON[6]

[2]Delaware Geological Survey, Newark, DE 19716, USA
[3]U.S. Geological Survey, Woods Hole, MA 02543, USA
[4]University of Toledo, Toledo, OH 43606, USA
[5]U.S. Geological Survey, Reston, VA 12201, USA
[6]NOAA Great Lakes Environmental Research Laboratory, Ann Arbor, MI 48108, USA

Fluxes of nutrients transported by groundwater contribute to eutrophication in Indian River Bay, Delaware. Fresh and saline groundwater discharge rates and porewater salinity depend on system hydrology, mechanisms of groundwater-baywater exchange, and geologic heterogeneity. The interactions between these factors produce complex flowpaths and mixing that may affect nutrient bioavailability by causing biogeochemical transformations prior to discharge.

The hydrology, stratigraphy, subsurface salinity and N-species distributions, and submarine groundwater discharge (SGD) rates and patterns were characterized at Holts Landing State Park. A buried paleochannel and near-bottom confining beds, expected to control both flow and mixing in the subsurface, were located with offshore chirp seismic profiling and coring. Electrical resistivity surveys and vertical porewater salinity profiles to depths of up to 17m indicate that a zone of freshened groundwater extends hundreds of meters offshore. Onshore and offshore multi-level wells were sampled to obtain a 3D distribution of N species in the subsurface. SGD measurements from Lee-type seepage meters were collected to better understand discharge salinity, rates, and spatial and temporal SGD patterns. Measurements indicate that SGD is primarily saline, and that the lowest salinity groundwater discharges near the shoreline in the area away from the paleochannel feature and along the submerged paleochannel/interfluve boundary. Hydraulic head and permeability measurements in onshore and offshore wells provide information on site hydrology and temporal change. Data were incorporated into a groundwater flow model of the Indian River Bay watershed, which provides a larger-scale estimate of groundwater flowpaths and SGD fluxes and patterns along the entire bay shoreline.

Chemical composition of low-temperature biomass ash

M. MICHALIK[1]*, R. GASEK[2], W. WILCZYŃSKA-MICHALIK[2]

[1]Institute of Geological Sciences, Jagiellonian University, ul. Oleandry 2a, 30-063 Kraków, Poland (*correspondence: marek.michalik@uj.edu.pl)
[2]Institute of Geography, Pedagogical University, ul. Podchorążych 2, 30-085 Kraków, Poland (wmichali@up.krakow.pl)

The aim of the study of chemical composition of biomass ash is to evaluate its possible influence on composition of ash obtained during co-combustion of biomass and coal. Modification of composition of fly ash by biomass co-combustion with coal often reduce possibility of its utilization. Environmental impact of biomass combustion is poorly studied. There is a common opinion that biomass ash does not contain toxic metals like in the case of coal ash. The study is based on eight samples of biomass used in power plants in southern Poland.

Biomass was ashed at 475ºC and the yield of ash was from 0.5wt% (sawdust) to 10.8 wt% (olive kernel). Ash is usually rich in Ca (highest content ca. 16wt% in sawdust ash; content above 10wt% in three other samples; and the lowest ca. 1.9wt% in bran biomass ash), K (six samples with content above 10wt%, the lowest value for beechwood biomass), and P (two samples with content above 5wt% and the lowest content ca 0.5wt%).

Content of trace elements in studied samples of ash in often higher comparing with typical coal ash, e.g. Mn from 321 to >10 000 ppm; Ag from 0.02 to 5.3 ppm; Cd from 0.13 to 71.3 ppm; Cr from 3.8 to 988 ppm; Cu from 18 to 588 ppm; Mo from 2 to 14.7 ppm; Zn 106 to 1923 ppm and Hg from <5 to 35 ppb.

Ash is usually enriched in metals comparing with biomass samples. Highest enrichment (measured as ratio of content of element in ash/content of element in biomass) is observed for sawdust ash (e.g. Mo – 150; Cu - 193; Zn – 196; Ag – 143; Ni – 91; Co – 287; Mn – 156, Fe - 270; Cd – 230; Bi – 250; Cr – 177; Ba – 198; B – 464).

Obtained results indicate that both the composition of low temperature biomass ash and degree of enrichment in selected elements during ashing varies within broad range. Systematic study is necessary to predict the influence of biomass co-combustion on properties of ash and possible environmental impact.

Evidence for habitable environments deep in the Martian crust

J.R. MICHALSKI[1,2] P.B. NILES[3] AND J. CUADROS[1]

[1]Natural History Museum, South Kensington, London, UK
[2]Planetary Science Institute, Tucson, AZ, USA (*correspondence: michalski@psi.edu)
[3]NASA Johnson Space Center, Houston, TX, USA

Observations

Using infrared reflectance spectroscopy and high-resolution imaging, we have detected the presence of Fe/Ca-carbonates and Fe/Mg-rich phyllosilicates on Mars within rocks exhumed from deep in the subsurface by meteor impact [1]. The carbonates occur within layers or bands that are interbedded with or injected into layered and foliated chlorite, chlorite-smectite-, pumpellyite-, and possibly serpentine-bearing bedrock (Figure 1). This category of deposit is fundamentally different from previous detections of clay minerals [2-3] and carbonates [4-5] on Mars because in this case: a) carbonates and putative hydrothermal phyllosilicates occur together, b) the materials reflect a subsurface environment, rather than surface materials, and c) the minerals occur within rocks that have metamorphic and hydrothermal textures.

Implications

The carbonate- and clay-bearing rocks observed within Leighton Crater were excavated from ~6 km depth. These rocks may represent some of the most ancient sedimentary rocks on Mars (also in the Solar System) that were subsequently buried and metamorphosed. Alternatively, they may be evidence for deep-seated hydrothermal activity in a habitable subsurface environment.

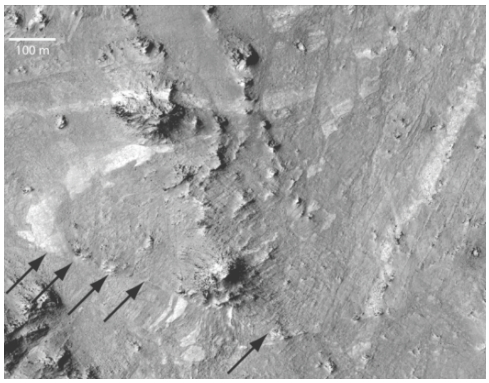

Figure 1: A HiRISE image of the central peak of Leighton Crater, Mars, where carbonates are detected within light-toned rocks that occur within exhumed, phyllosilicate-rich bedrock. Arrows point to a fault that offsets carbonates.

Geochemical and geophysical coupling study of the karstic aquifer between Saïs Basin and the Causses of the Middle Atlas (Morocco). Fez-Meknès area

HÉLÈNE MICHE[1], ADRIANO MAYER[1], GINETTE SARACCO[1], MOHAMED ROUAI[2], ABDELILAH DEKAYIR[2], KONSTANTINOS CHALIKAKIS[3] AND CHRISTOPHE EMBLANCH[3]

[1]CNRS-UMR6635, CEREGE, UPCAM, Europole de l'Arbois, BP 80, F-13545 Aix en Provence, France (*correspondence: saracco@cerege.fr)
[2]Université M. Ismail, Département de Géologie, Quartier Zitoune, Meknès, Marocco
[3]EMMAH (UAPV, INRA) CNRS-UMR_A 1114, 33 rue pasteur, 84000, Avignon, France

The population growth in the region of Fez-Meknès (1.6 Million), accentuated by the increasing number of wells for agriculture, and by the increasing aridity in recent years, poses the problem of controlling water of sufficient quality and quantity over time.

This fractured karstic Basin mainly composed of Liassic dolomitic limestones overlying Triassic basalts, shales and evaporites, is the main drinking water supply in the region. The karstic reservoir presents a decline in its chemical quality and ponctually some turbidity problems.

To better understand this system and the interactions between different aquifers and aquitards, we conducted coupling study on:

i) geochemistry (major and minor elements, $\delta^{18}O$, δD and ^{222}Rn) of the main springs of Liassic and Triassic origin that could be connected each other and with the major spring of Bittit;

ii) electromagnetic multi-scale tomography for separating draining faults from not draining faults (geological structure).

The geochemistry of water during the three surveys in 2009 and 2010 shows a major Liassic origin for Bittit, Ribaa, Aguemguam, Amansayarmine, Bou Youssef and El Hajeb springs, and a major Triassic origin for El Mir, Sbaa 2, Maarouf1 and Maarouf2 springs. Radon 222 (T=3.85days) has highlighted the existence of areas of rapid exchange between waters of Liassic aquifers characterized by low Radon activity (3500 Bq/m^3) and waters of Triassic aquitards characterized by a high Radon activity (> 12000 Bq/m^3). The transit time from the Triassic aquifer is less than two weeks. Analyses of $\delta^{18}O$ versus δD show only a slight excess of Deuterium, this characterizes a local recharge of the groundwater.

Geophysical measurements of resistivity and conductivity show anomalies in the direction of Bittit and perpendicularly to the Causses, confirming the presence of a preferential drainage where Liassic waters of high quality mix with those in contact with the Triassic aquitard.

Acknowledgment: These studies are funded by the CNRS, Program of the Fédération de Recherche ECCOREV, and the Conseil Régional PACA, BREMEX Program.

Natural ferrihydrite: Impact of structure and composition on redox cycling

F.M. MICHEL[1,2], A.C. CISMASU[1], J.S. LEZAMA[2], M. MASSEY[1], S. FENDORF[3], G.E. BROWN, JR.[1,2] AND J.R. BARGAR[2]

[1]Geological & Environmental Sciences, Stanford University, Stanford, CA 94305, USA
[2]SLAC National Accelerator Laboratory, Menlo Park, CA 94025, USA
[3]Department of Environmental Earth System Science, Stanford University, Stanford, CA 94305, USA

Synthetic ferrihydrite (Fh) is typically used in laboratory studies and in the field, to a lesser extent, as a model compound for natural Fh in terms of understanding its sorption capacity, reactivity, stability, and dissolution and transformation behavior. All are properties that make naturally occuring Fh one of the most important natural Fe (III) oxyhydroxides in geochemical systems undergoing biogeochemical cycling of iron and redox-active contaminant metals such as U.Although much is known about synthetic Fh, recent research by our group calls into questions its relevance to natural systems. Many past studies have suggested that natural Fh often contains a suite of impurities (e.g. Zn^{2+}, Cr^{3+}, Al^{3+}, silicate, phosphate, organic carbon complexes) that can range widely depending on the conditions of Fh formation. It is less clear, however, how impurities impact the bulk and surface structure of Fh and its reactivity and stability. Our recent work [1] on natural Fh formed in an acid mine drainage system demonstrated that impurities, mainly Al, Si, and natural organic matter, increased structural disorder and decreased average particle size. Such details are important as they are likely to have significant impact on the biogeochemical reactivity of Fh.

While our picture of synthetic Fh structure continues to improve, little is known about the individual and cumulative effects of structural disorder (e.g. lattice strain and cationic vacancies), size, and composition on electron transfer processes occurring in Fh under reducing conditions. Processes related to the Fe (II)-induced reductive transformation are important, for example, because of the potential for environmental contaminants such as uranium to be directly incorporated in Fh transformation products. Our current work aims to better understand the links between the structure/composition and biogeochemical reactivity for both natural Fh and synthetic analogues to natural samples.

Oxygen and hydrogen stable isotope composition of precipitation in Friuli-Venezia Giulia (Northeastern Italy)

M. MICHELINI*, F. CUCCHI, O. FLORA, B. STENNI, F. TREU AND L. ZINI

Department of Geosciences, University of Trieste, Italy (*correspondence: marzia.michelini@phd.units.it)

Introduction

Oxygen and hydrogen stable isotopes, being natural tracers of the hydrological cycle, have been extensively used as tools to characterize regional aquifers. In particular, the knowledge of the mean annual-weighted isotopic composition of precipitation is a very important tool to determine the origin of the waters that feed aquifers and rivers, their recharge area and its mean altitude, thanks to the definition of the vertical isotope gradient. The knowledge of the relationship between isotopic composition of local precipitation and local environmental conditions is also essential for hydrological studies. In order to provide an overview of the isotopic composition of the precipitation in Friuli-Venezia Giulia region a monitoring of the regional rain gauge network has been carried out at the University of Trieste from 2004 to 2010.

Results and Discussion

Here we present $\delta^{18}O$ data obtained from monthly precipitation collected by rain gauges; where possible the $\delta^{18}O$ data were compared with temperature data weighted for precipitation (fig. 1) showing generally a good correlation. Vertical $\delta^{18}O$ gradients for homogenuos areas and an average gradient for the region as a whole were also calculated.
Finally the local meteoric water line was calculated using $\delta^{18}O$ and δD long-term weighted values for all the sampling sites.

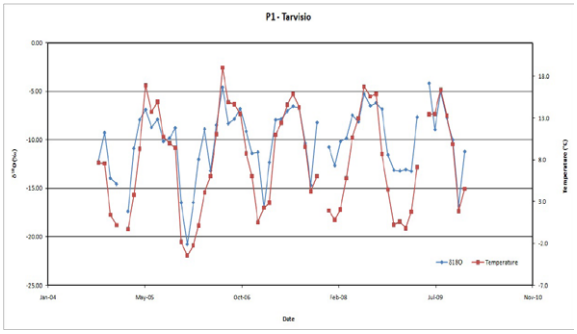

Figure 1: Monthly trends of $\delta^{18}O$ and temperature for the Tarvisio sampling site.

Metastable accessory phases in high heat-producing felsic igneous rocks

A.W. MIDDLETON*, S.D. GOLDING AND I.T. UYSAL

University of Queensland, St. Lucia, QLD 4066, Australia (*correspondence: alexander.middleton@uqconnect.edu.au)

High heat-producing felsic igneous rocks are characterised by enriched values of U, Th and K relative to upper continental crust, and are of specific interest when seeking to exploit geothermal energy through enhanced geothermal systems. The elevated values reflect the evolved nature of the felsic rock; common examples include granites and rhyolites. The current study focuses on famous HHP systems of Soultz-sous-Forêts, France, Cornwall, UK, and the novel HHP rhyolite of central Queensland, Australia.

Samples from Soultz and central Queensland show evidence that metasomatised titanite can form rutile + calcite + quartz with accessory hydrothermal zircon and Ca (REE, Y)CO_3 (OH, F)$_?$ or cheralite, respectively. The accessory phases reflect how Zr, Th, Y and REE can substitute into titanite's structure in an evolved system. EPMA of the anhedral hydroxyl-, fluoro-carbonate phase found elevated values of both Ca and Ce with variable LREE, Y and Th. The occurrence of Ca (REE, Y)CO_3 (OH, F)$_?$ in place of cheralite may result from elevated [CO_2] and [F-] as opposed to [PO_4^{3-}] and [CO_2]; as indicated by cogenetic chloritisation of F-bearing biotite and intercleavage-grown ankerite. Mobilisation of incompatible elements as fluoro-carbonate ligand complexes was minimised by the presence of Ca^{2+}, resulting in precipitation within or proximal to the titanite void. By contrast, SEM analyses of the F^--dominated Cornish metasomatic system shows monazite solid-solution phases along cleavage planes of chloritised biotite, implicating the uncommon mobilisation of Th^{4+}. Further EMPA will better define these phases and constrain their palaeometasomatic conditions.

Analysed primary accessory phases such as titanite were relatively enriched in incompatible elements that formed polymineralic assemblages following metasomatism. The volatile content of metasomatising fluids played a significant role in the production of these metastable phases. Titanite specifically, destabilised in the presence of CO_2 or F- [1, 2]. Volatiles not only helped destabilise the primary phases but also mobilised constituent elements; as seen when halide ligands drastically increase the mobility of incompatible elements such as REE and HFSE [3]. By analysing metastable accessory phases, this study will further constrain under which conditions HHP systems undergo metasomatism as well as better understand the extent of metasomatic incompatible element immobility.

An experimental study of the stability of hydrosulfide species of Fe(II) at hydrothermal conditions

ART. MIGDISOV[1]*, D. ZEZIN[2] AND A.E. WILLIAMS-JONES[1]

[1]Earth & Planet. Sci., McGill Univ., Montreal, H3A 2A7 Canada (*correspondence: artas65@gmail.com)
[2]Institute of Geochemistry and Petrology, ETH Zurich, CH-8902 Zurich, Switzerland

Iron is one of the most abundant elements in the Earth's crust, and is actively involved in the processes of hydrothermal alteration and ore mineralisation. Iron-bearing sulphides dominate most hydrothermal sulphide ore bodies and form in a wide variety of geological environments at conditions ranging from those of magmatic intrusions to those of sediments undergoing diagenesis. However, our knowledge of the speciation of this metal in sulphide-bearing fluids is surprisingly limited. Despite the participation of iron in processes involving reduced sulphur-bearing fluids, the behaviour of the hydrosulphide species of this metal is effectively unknown at elevated temperature. Partly because of this, the hydrothermal transport and deposition of iron is commonly modelled exclusively using chloride species. The goal of our study was therefore to determine stability constants for hydrosulfide complexes of Fe (II) experimentally at temperatures up to 350-400 °C, and to evaluate the contribution of these complexes to the mobilisation of iron in nature.

Our experiments were performed in light-weight titanium autoclaves and involved measurement of the solubility of pyrite (FeS_2) in acidic solutions (pH<3) saturated with respect to H_2S at partial pressures of this gas varying from 15 to 120 bars. The acidity of the solutions was controlled using $HClO_4$ for experiments at T≤250 °C, and HCl at higher temperature. After equilibrium was attained, the autoclaves were quenched, pyrite was removed, and samples of the quenched solutions were analysed for Fe and Cl. Precipitates that formed during quenching were dissolved by washing the autoclaves with HCl; the washing solutions were also analysed for Fe. All analyses were performed using NAA.

The data obtained in our study suggest that, at temperatures up to 300 °C, the dominant hydrosulphide species of iron are $FeHS^+$ and $Fe(HS)_2°$. They also suggest that the concentration of these species is sufficient for them to play an important role in the transport and deposition of Fe (II) in H_2S-rich hydrothermal systems.

Isotope-geochemical features of enriched mantle source of rift tholeiites from Bouvet Triple Junction (South Atlantic)

NATALIA A. MIGDISOVA[1]*, NADEZHDA M. SUSHCHEVSKAYA[1] AND BORIS V. BELYATSKY[2]

[1]Vernasky Institute of Geochemistry RAS, Moscow, Russian Federation (*correspondence: nat-mig@yandex.ru)
[2]VNIIOkeanologia, Antarctic Geology, St.Petersburg, Russian Federation (bbelytsky@hotmail.ru)

Bouvet triple junction (BTJ) is formed by three spreading ridges: Mid-Atlantic (MAR), American-Antarctic (AAR), South-West Indian (SWIR) and is marked by especially complicated construction and evolution. The isotopic analysis of glasses from the Spiess Ridge and Bouvet segment of SWIR revealed the relatively high $^{206}Pb/^{204}Pb$ (18.4 to 19.2) and low $^{143}Nd/^{144}Nd$ values (0.512603-0.513103) indicating the source enrichment compared to the depleted oceanic mantle [1]. Differences in $^{207}Pb/^{204}Pb$ vs $^{206}Pb/^{204}Pb$ contents in tholeiites from BTJ region and adjacent structures imply diverse magmatic sources. We assume that type of enrichment of BTJ mantle source is like HIMU and is close to those of lamprophyres from Antarctic Ferrar province formed during the Karroo - Ferrar plume influence about 180 m. y. ago [2]. Pyroxenite component in parental source was established by olivine composition [3] and generally constituted about 30-40 % of parental melts [3, 4].

One of the plausible explanations of so considerable amount of the ancient substance is the formation of the west end of SWIR over some crustal blocks which were separated during/ after Gondwana breakup. These microplates could comprise parts of a pre-existing retro-arc fold thrust belt [5].

Cu isotope geochemistry in the unusual Las Cruces supergene copper deposit

N.G. MIGUELEZ[1]*, R. MATHUR[2], F. TORNOS[1], F. VELASCO[3] AND J.C. VIDEIRA[4]

[1]IGME, Rios Rosas, 23. 28003, Madrid, Spain & UNIA, 21819 La Rábida, Huelva, Spain (f.tornos@igme.es) (*correspondence: n.miguelez@igme.es)

[3]Universidad del País Vasco, Apdo. 644, 48080 Bilbao, Spain (francisco.velasco@ehu.es)

[4]Cobre Las Cruces, S.A., 41860, Gerena,, Sevilla, Spain (juancarlos.videira@cobrelascruces.com)

The Las Cruces deposit (17 Mt @ 6.7% Cu) is the last on-going mine of the Iberian Pyrite Belt (IPB). The ore deposit consists of an unusual supergene copper enrichment zone of a common late Devonian VMS. This is located below the Guadalquivir river Basin, which hosts an aquifer on its base that is still interacting with the deposit nowadays. Late Alpine faults crosscut the deposit and act as fluid pathways related to the latest enrichment process; thus, three Cu-sulphides generations are identified: granular non-cemented Cu-sulphides formed during the weathering process, chalcocite related to late calcite-quartz veins, and euhedral chalcocite crystals grown over calcite veins. Textures and isotope geochemistry suggest a critical influence of microbial activity during the enrichment processes.

The primary sulphides show enrichment on δ^{65}Cu (1.96±0.70‰) in comparison to other primary sulphides worldwide [1]. The secondary Cu-sulphides are largely depleted on δ^{65}Cu and they show consecutively steeply enrichment on δ^{65}Cu in the three Cu-sulphides mineralization generations: δ^{65}Cu=-6.39±0.10‰ in granular non-cemented Cu-sulphides, δ^{65}Cu= -5.36±0.19‰, in chalcocite related to late calcite-quartz veins and δ^{65}Cu= -3.77±0.17‰ in euhedral chalcocite crystals. These would show the three steps of the evolution of a mineralizing fluid, which is also enhanced by biogenic activity [2]. Finally, the gossan samples show a very large variation in δ^{65}Cu, including both positive and negative values (δ^{65}Cu= -7.79‰ & 3.84‰).

The δ65Cu composition of the Las Cruces ore deposit present unusual values in comparison with studies developed on other VMS and gossan related.

The nanoscale structure of complex perovskite-type oxides with superb dielectric properties

BORIANA MIHAILOVA

Mineralogisch-Petrogrpahisches Institut, Universität Hamburg, Grindelallee 48, 20146 Hamburg, Germany, email: boriana.mihailova@uni-hamburg.de

The perovksite (ABO_3) structure type is an outstanding example of how chemical variations can tune the nanoscale atomic arrangements and thus influence the properties of complex oxide materials. Thanks to V. M. Goldschmidt who formulated the relation between the chemical composition and the structural stability, the perovksite-type crystals are nowadays key functional materials used in a number of technological applications. Pb-based relaxors are advanced ferroelectrics with remarkable dielectric, electromechanical and electrooptic responses. The exceptional properties of relaxors are due to their structural inhomogeneities. At ambient conditions, the average structure is pseudocubic but rich in ferroic nanoregions too small to be directly studied by conventional diffraction analysis. However, combining *in situ* temperature and pressure diffraction and Raman scattering allows us to resolve the structural complexity of relaxors. Due to the different length and time scales of sensitivity, diffraction probes the long-range order, i.e. the structure averaged over time and space, while Raman spectroscopy can detect local structural deviations from the average structure via the anomalous Raman activity of the phonon modes that, when the symmetry of the average structure is considered, should not generate Raman peaks. Hence, the combined analysis of the long-range order induced at low temperatures or high pressures and of the phonon anomalies enhanced on temperature decrease or pressure increase can reveal the energetically preferred structural nanoclusters existing at ambient conditions. The structural analysis of series of model compounds, namely stoichiometric and A-site doped (Ba^{2+}, Bi^{3+}, La^{3+}, Sr^{2+}) $PbSc_{0.5}Ta_{0.5}O_3$ and $PbSc_{0.5}Na_{0.5}O_3$ as well as solid solutions with three cationic types on the B-site showed that at ambient conditions, on the mesoscopic scale, polar order coexists with antiferrodistortive order, which may be the key reason for the relaxor behaviour. Chemically-induced local elastic fields influence the nanoscale atomic clustering more strongly than chemically-induced local electric fields do.

Dissolution kinetics of Pd and Pt from automobile catalysts by naturally occurring complexing agents

MARTIN MIHALJEVIČ[1], ONDŘEJ ŠEBEK[2], LADISLAV STRNAD[2], VOJTĚCH ETTLER[1], JOSEF JEŽEK[3], ROBIN ŠTEDRÝ[1] AND PETR DRAHOTA[1]

[1]Institute of Geochemistry, Mineralogy and Mineral Resources, Charles University in Prague, Albertov 6, CZ-128 43 Prague 2, Czech Republic

[2]Laboratories of the Geological Institutes, Charles University in Prague, Albertov 6, CZ-128 43 Prague 2, Czech Republic

[3]Institute of Applications of Mathematics and Information Technologies, Charles University in Prague, Faculty of Science, Albertov 6, CZ-128 43 Praha 2, Czech Republic

Powder samples prepared from gasoline (Pt, Pd, Rh, new GN/old GO) and diesel (Pt, new DN/old DO) catalysts and recycled catalyst NIST 2556 were tested by kinetic leaching experiments following 1, 12, 24, 48, 168, 360, 720 and 1440-hour interaction with solutions of 20 mM citric acid (CA), 20 mM $Na_2P_4O_7$ (NaPyr), 1 g L^{-1} NaCl (NaCl) and a fulvic acid solution (FA- DOC 50 mg L^{-1}). The mobilization of Pt metals into solution was fastest through the effect of CA and NaPyr. In the other interactions (NaCl, FA), the release of PGE is probably followed by immobilization processes and the interactions cannot be considered to correspond to simple release of Pt metals into solution. Because of their low concentrations, the individual complexing agents did not have any effect on the speciation of Pd and Pt in the extracts; both metals are present in solution as complexes ($Me(OH)_2$, $Me(OH)^+$). Immobilization can take place through the adsorption of the positively charged hydroxyl complexes or flocculation of fulvic acid complexing the Pt metals on the surface of the extracted catalysts. The calculated normalized bulk released NRi values are similar to the reaction rate, highest in solutions of CA and NaPyr.

$^{87}Sr/^{86}Sr$ isotope ratios in single benthic foraminifera by LA-MC-ICPMS

TAMÁS MIKES[1,2]*, AXEL GERDES[2], NATÁLIA HUDÁČKOVÁ[3] AND ANDREAS MULCH[1,2]

[1]Biodiversity and Climate Research Centre (BiK-F), Frankfurt am Main, Germany

[2]Institute of Geosciences, Goethe University, Frankfurt am Main, Germany
(*correspondence: mikes@em.uni-frankfurt.de)

[3]Department of Geology and Palaeontology, Comenius University, Bratislava, Slovakia.

$^{87}Sr/^{86}Sr$ analysis of foraminifera is usually performed from solution samples using either TIMS or MC-ICPMS techniques. With increasing precision offered by recent advances of laser ablation instrumentation, the LA-MC-ICPMS approach rivals solution work in terms of precision, and outperforms conventional solution techniques in terms of sample throughput and time needed per analysis.

Within an ongoing paleoclimatic study, we have determined $^{87}Sr/^{86}Sr$ isotope ratios from single tests of the benthic foraminifera *Quinqueloculina* sp. from a Neogene hyperhaline paralic sequence in Central Anatolia, Turkey. The analytical setup used consists of a RESOlution M-50 excimer LA instrument (λ=193 nm) including a factory-built Laurin two-volume sample cell, coupled to a Thermo Neptune MC-ICPMS. During 60 seconds of data acquisition a 200-300 μm long line was ablated (8 Hz, 3.5 J/cm^2) with pit diameter varying between 53 to 140 μm. After correction for interferences from Rb, Kr, Ca-dimers and doubly-charged REE, all Sr isotope data were corrected for mass fractionation ($^{86}Sr/^{88}Sr$ = 0.1194) and normalized to NIST SRM987 using $^{87}Sr/^{86}Sr$ of 0.71025. Repeated measurements on a recent coral from the Red Sea (~3000 ppm Sr) yielded $^{87}Sr/^{86}Sr$ ratios of 0.709235 ± 0.000023 (2σ s. d.).

For the *Quinqueloculina* sp. tests, pit diameter were adjusted to 80 or 120 µm and the ablation path was located at the topmost part of the curved, quasi-globular test surface. $^{87}Sr/^{86}Sr$ ratios cover a range from 0.707174 ± 0.000032 to 0.707255 ± 0.000027, with calculated net reproducibilities being in the range of as low as ±0.00004 (2σ s. d.).

Overall, the LA-based analysis of $^{87}Sr/^{86}Sr$ in foraminifera is likely most suitable in cases where low sample amounts (e.g. high-resolution stratigraphic work on drillcores) and/or high sample numbers are dealt with; i.e. for material otherwise not providing the necessary Sr concentration in the final solution, or requiring time-consuming Sr separation and solution work.

The abiogenic generation of low $\delta^{13}C$ reservoirs in the deep Earth

S. MIKHAIL[1,2]*, A. SHAHAR[3], S.A. HUNT[1], A.B. VERCHOVSKY[2], I.A. FRANCHI[2], S, BASU[1] AND A.P. JONES[1]

[1]Department of Earth Sciences, UCL, Gower Street, London, WC1E 6BT, UK (*correspondence: s.mikhil@ucl.ac.uk)
[2]PSSRI, The Open University, Walton Hall, Milton Keynes, UK
[3]Geophysical Laboratory, Carnegie Institution of Washington, Broad Branch road, Washington, DC 20015, USA

The stable isotopes of carbon from mantle diamonds (expressed as $\delta^{13}C$) provide a direct proxy used to understand the Earth's deep carbon cycle (carbon speciation, reservoir identification and exchanges between such reservoirs). Carbon speciation is highly dependent upon the local fO_2 and variations of this parameter in an open system can result in isotopic fractionation of carbon where two species are stable and one is mobilised and removed [1]. The largest measured fractionation factor in nature for ^{13}C under mantle conditions is between graphite and Fe-carbide (circa +12 ‰) [2] and at a higher temperature between diamond and Fe-carbide (circa +7 ‰) [3]. This system may have a large impact on the BSE deep carbon cycle and if not considered, and well quantified, may cause significant errors in the interpretation of low $\delta^{13}C$ values determined from terrestrial and extra-terrestrial mantle samples. This system requires fO_2 conditions to be lower than the IW buffer and also requires the presence of Fe^0. Frost *et al*. [4] provided experimental evidence for the stability and predicted existence of Fe^0 with magnesium silicate perovskite and ferropericlase in the lower mantle. More recently Rohrbach *et al*. [5] demonstrated that from depths < 250 km, the upper mantle can also host stable Fe^0 with subcalcic pyroxene and majoritic garnet buffering the fO_2 to IW -2. Therefore it is plausible that two solid phases of carbon could be stable; diamond and Fe-carbide. We present new data for a measured fractionation factor between natural and synthetic diamond and Fe-carbide samples and place constraints upon the P-T effects of ^{13}C fractionation from 2-25 GPa and 14-2000 K in the system Fe-C. This data probes conventional ideas surrounding the modelling of ^{13}C fractionation during mantle-core differentiation, geodynamic cycling of carbon as inferred using empirical data from mantle xenoliths and xenocrysts and the nature and source (abiogenic vs. biogenic) of low $\delta^{13}C$ values determined from terrestrial and extra-terrestrial mantle samples.

Kirschsteinite exsolution lamellae in olivine from young angrites: Implications for their thermal history

T. MIKOUCHI[1]*, M. MIYAMOTO[1] AND G.A. MCKAY[2]

[1]Dept. Earth & Planet. Sci., Univ. of Tokyo, Tokyo 113-0033, Japan (*correspondence: mikouchi@eps.s.u-tokyo.ac.jp)
[2]NASA-JSC, Houston, TX 77058, USA (deceased)

Angrites are among the oldest known basaltic rocks in the solar system characterized by unique mineralogy and chemistry. They can be mainly divided into two subgroups by difference in texture and crystallization ages (~4564 Ma 'quenched' angrites and ~4558 Ma 'plutonic' angrites) [e.g. 1]. Among them, young plutonic angrites are important to understand prolonged igneous activity in the angrite parent body (APB), and understanding of their geological settings can offer good information about the crustal evolution of APB. Kirschsteinite exsolution lamellae present in olivine from LEW86010 (LEW) plutonic angrite could be used to estimate its cooling rate and burial depth by calculating Ca diffusion profiles [2]. Similar exsolution was found in recently discovered plutonic angrite NWA4590 (NWA) [3], and we performed the same calculation. The obtained cooling rate of NWA olivine is 0.15 ºC/year, corresponding to the burial depth of 240 m. This cooling rate is ~1 order of magnitude slower than that of LEW (1.7 ºC/year: 75 m depth [2]). The lamella growth in NWA was from 975 to 700 ºC, and the LEW lamellae grew in a similar temperature range (1000-700 ºC) [2, 4]. Amelin *et al*. [5] obtained a cooling rate of 540±290 ºC/Ma for NWA by using the Pb-Pb age difference of pyroxene and silico-apatite. This cooling rate is too slow and will homogenize pyroxene zoning observed in NWA, and thus the age difference is unrelated to cooling as also suggested by [5]. A geological setting for the 75~240 m depth might be in a lava lake or hypabyssal intrusion. Although LEW and NWA share similar mineralogy and crystallization ages [1, 2, 5], their cosmic-ray exposure ages are different [6], suggesting sampling from different regions of APB. If this is the case, a rock unit with the lithology similar to LEW and NWA may show wide and deep spatial distribution in the crust of APB.

Evaluation of matrix effects during laser ablation MC ICP-MS analysis of boron isotopes in tourmaline

JITKA MÍKOVÁ[1,2]*, JAN KOŠLER[2] AND MICHAEL WIEDENBECK[3]

[1]Czech Geological Survey, Klárov 3, Prague 1, CZ-118 21, Czech Republic (*correspondence: jitka.mikova@geology.cz)
[2]Centre for Geobiology and Department of Earth Science, University of Bergen, Allegaten 41, Bergen, N-5007, Norway
[3]Helmholtz Centre Potsdam, GFZm German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany

This study evaluates the effects of laser ablation ICP-MS instrument parameters and sample matrix composition on data accuracy and precision. Laser ablation MC ICP-MS was used to determine boron isotopic compositions of several natural tourmaline group minerals with variable chemical composition. Some of the studied samples have been previously used as reference materials for *in situ* isotopic analysis (98144 elbaite [1, 2], 108796 dravite [1, 2], 112566 schorl [1, 2] and B4 [3]). The choice of laser and ICP-MS instrument parameters has a significant effect on the measured $^{11}B/^{10}B$ ratios, namely as a result of different signal intensities and $^{40}Ar^{4+}$ spectral interferes on the ^{10}B mass peak. This interference can be suppressed by optimizing mass resolution of the instrument. Laser induced isotopic fractionation of B was negligible for single laser spot and laser raster sampling strategies, allowing for a choice of an optimal sampling mode depending on the size, shape and homogeneity of the sample. It can be demonstrated that the tourmaline matrix affects significantly the obtained $\delta^{11}B$ values and impacts on data accuracy, especially if a non matrix-matched reference material is used for calibration. In case of matrix-matched calibration, the accuracy of LA MC ICP-MS boron isotopic data is comparable to the previously published values obtained by TIMS technique. The measurement precisions associated with the average $\delta^{11}B$ values achieved by LA MC ICP-MS are between 0.2 and 0.5‰ (1 s).

Re-Os age of molybdenite from the Tatra Mountains, Poland

S.Z. MIKULSKI[1], A. GAWĘDA[2] AND H.J. STEIN[3,4]

[1]Dept. of Mineral Deposits Geology, Polish Geological Institute - National Research Institute, Warsaw, Poland (stanislaw.mikulski @pgi.gov.pl)
[2]Faculty of Earth Sciences, University of Silesia, 41-200 Sosnowiec, Poland (gaweda@us.edu.pl
[3]AIRIE Program, Colorado State University, USA (hstein@cnr.colostate.edu)
[4]Norges Geologiske Undersøkelse, 7491 Trondheim, Norway

The Tatra Mountains are a tectonically uplifted piece of Variscan crust emplaced during the Alpine orogeny and forming part of the Central Western Carpathians. Mesozoic sedimentary formations overlie a pre-Alpine core composed of a polygenetic granitoid intrusion and its metamorphic envelope, extensively migmatized [1]. The contact zone of metamorphic rocks and hybrid granite [2] is well exposed in the western part, called Western Tatra Mts.Textural, geochemical, and isotopic studies point to a mixed I- and S-type character for the Tatra granitoid intrusion, formed by multiple magma batches in the age interval 370–345 Ma [2, 3, 5]. The polygenetic granitoid intrusion, defined as a tongue-shaped, tabular body [4], is concordant with regional metamorphic foliation.

Molybdenite was collected from the northern debris slope (*ca*. 1580 m a. s. l.) below the Wołowiec peak. Molybdenite is observed as single isolated blades (<3 mm) or small aggregates of crystals (<5 mm in diameter) in pegmatite, within a coarse-grained leucocratic porphyritic granite. Molybdenite is associated with K-feldspar, albite, quartz and coarse-grained muscovite. In this area the local brecciation of the granite and its envelope by boron-rich fluid is observed.

The analyzed molybdenite sample has a Re concentration of 16.58 ± 0.01 ppm, and an ^{187}Os concentration of 61.04 ± 5 ppb, providing a ^{187}Re-^{187}Os model age of 350 ± 1 Ma indicating a period of molybdenite crystallization in Carboniferous Lower Missisippian (Tournaisian) and is in accordance (within brackets) with WR Rb-Sr isotopic age of pegmatites and U-Pb dating of magmatic zircons [6]. We suggest molybdenite crystallized from fluids locally derived from the hosting coarse-grained leucocratic granite. This is the first report on the presence of molybdenite in the Tatra Mts. and its age can be interpreted as the timing of fluid exsolution from the cooling granite.

Linking structural isomerism of organic ligands to the precipitation and structure of ferrihydrite

C. MIKUTTA

Institute of Biogeochemistry and Pollutant Dynamics , ETH Zurich, Switzerland (christian.mikutta@env.ethz.ch)

The extent of interference of organic ligands with the polymerization of Fe(III) has not been systematically studied as a function of structural ligand properties. Here I tested how the number and relative phenol group positions in hydroxybenzoic acids affect both ferrihydrite formation and its local (<5 Å) Fe coordination. To this end, acid Fe(III) nitrate solutions were neutralized up to pH 6.0 in the presence of increasing concentrations of 4-hydroxybenzoic acid (4HB), and the two constitutional isomers 2,4-dihydroxybenzoic acid (2,4DHB) and 3,4-dihydroxybenzoic acid (3,4DHB). The precipitates formed were dialyzed, lyophilized, and subsequently studied by means of X-ray absorption spectroscopy and synchrotron X-ray diffraction.

The solids contained up to 32 wt% organic C. Only precipitates formed in 3,4DHB solutions comprised significant Fe(II) ($Fe(II)/Fe_{tot}$ ≤6 mol%), implying the abiotic mineralization of the catechol-group bearing ligand during Fe (III) hydrolysis under oxic conditions. Ferrihydrite formation was significantly impaired by the ligands (4HB ~ 2,4DHB << 3,4DHB). Coordination numbers of edge- and corner-sharing Fe in the precipitates decreased with increasing initial ligand concentration by up to 100%. Linear combination fitting (LCF) of Fe K-edge X-ray absorption near edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) spectra, however, revealed that these decreases were due to increasing proportions of organic Fe(III) complexes. All ligands reduced the coherently scattering domain (CSD) size of ferrihydrite as indicated by synchrotron X-ray diffraction analysis (4HB < 2,4DHB << 3,4DHB). With decreasing particle size of ferrihydrite its $Fe(O,OH)_6$ octahedra became progressively distorted as evidenced by an increasing loss of centrosymmetry of the Fe sites. Pre-edge peak analysis of the Fe K-edge XANES spectra in conjunction with LCF results implied that ferrihydrite contains 11 ± 2% tetrahedral Fe(III).

The results suggest that especially hydroquinone moieties of NOM effectively suppress Fe(III) polymerization and ferrihydrite formation. Organic chelates seem to control ferrihydrite formation mainly by kinetically modulating the availability of Fe(III) for nucleation and/or polymerization reactions. As a consequence, NOM may trigger the formation of smaller ferrihydrite nanoparticles possessing increased structural strain.

Helium rain and core erosion in gas giant planets

BURKHARD MILITZER*

University of California, Berkeley, CA 94720, USA (*correspondence: militzer@berkeley.edu)

Starting with a brief overview over the search for extrasolar planets, this talk will discuss the state of matter at high temperature and pressure conditions that prevail in the interiors of giant planets. We describe how data from the Galileo mission to Jupiter has been combined with *ab initio* simulations to demonstrate that there exists helium rain on this planet [1]. Furthermore we use such simulations to predict two new phases of water ice (figure) at megabar pressures and characterize the associated structural and electronic transitions [2]. Since water ice is assumed to be one of the primary components of the cores of gas giants, we analyzed its stability when it is exposed to metallic hydrogen. We show that the cores of Jupiter and Saturn have been eroded [3]. We conclude with discussing the erosion of heavier materials.

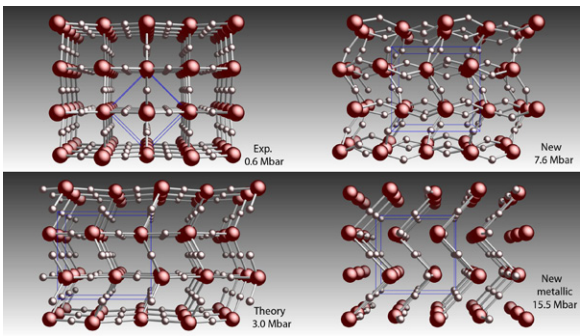

Figure 1: High pressure phases of water ice. The large and small spheres denote the oxygen hydrogen atoms, respectively.

The top left panel shows ice X, the highest pressure phase seen in experiments. On the lower left, the Pbcm phase is shown that was predicted theoretically in 1996. Recently we used *ab initio* simulations to predict the existence of the two new phases shown on the right [2]. The lower one is metallic.

Isotope distribution of dissolved carbonate species in Serbian thermal waters

N. MILJEVIC[1]*, D. GOLOBOCANIN[2], J. COLIC[1] AND M. MARTINOVIC[3]

[1]Jaroslav Cerni Institute for Development of Water Resources, Jaroslava Cernog 80, 11226 Belgrade, Serbia (*correspondence: emiljevi@vinca.rs)
[2]Vinca Institute for Nuclear Sciences, POB 522, 11001 Belgrade, Serbia
[3]University of Belgrade, Faculty of Mining and Geology, Belgrade, Serbia (martinovic@rgf.bg.ac.rs)

In this paper we will discuss the results relative to the major ion composition of the thermal waters, along with the $\delta^{13}C$ composition of the dissolved inorganic carbon, and to evaluate the interaction processes occurring between gas and thermal reservoirs in different geodynamic environments as well as the origin of dissolved CO_2. The $\delta^{13}C$ of CO_2 leaving thermal springs ranges from -8.2 to 5.6 ‰ (vs. PDB, n=9), while the $\delta^{13}C$ of dissolved inorganic carbon (DIC) in water ranges from -18.4 to +1.8 ‰ (n=53) [1] (Fig. 1).

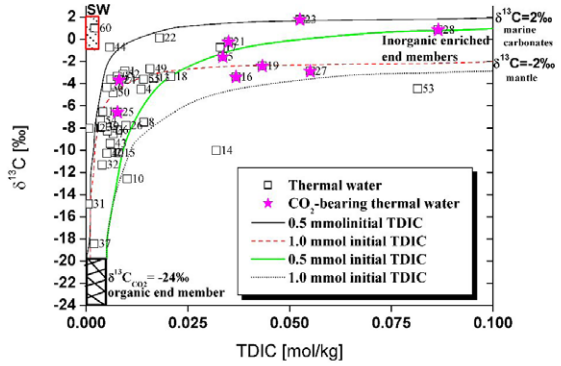

Figure 1: TDIC (Total Dissolved Inorganic Carbon) contents vs. $\delta^{13}C_{DIC}$ togather with $\delta^{13}C_{CO2gas}$ (theoretical) for thermal waters [2].

Water isotope compositions indicate that most waters are meteoric in origin or resulting from mixing between meteoric water and heavy isotope end members.

Effect of ocean acidification on processes in the ocean

FRANK J. MILLERO

Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL USA 33149

The burning of fossil fuels has increased the pCO_2 in the atmosphere from 280 ppmv to 385 ppmv over the last 200 years. This increase is larger than has occurred over the past 800 ky. Equilibration of this CO_2 with surface waters will decrease the pH (called Ocean Acidification) from current values of 8.1 to values as low as 7.4 over the next 200 years. The decrease in the pH of ocean waters can affect chemical and biological processes that occur in the oceans. Many recent studies have shown that ocean acidification can affect the production and dissolution of $CaCO_3$ (s) microorganisms in surface waters. Ocean acidification can also affect ionic equilibria such as acid-base and the formation of metal complexes. Many oxidation-reduction reactions of metals are also affected by changes in the pH.

In this paper, I will examine how ocean acidification of seawater can affect the state of metal ions. The decrease in pH can cause a decrease in the concentration of inorganic (OH^-, CO_3^{2+} ions) and organic ligands that complex many metals in natural waters. This will change the speciation of many metals in seawater. Uncomplexed Cu^{2+} is toxic to bacteria and phytoplankton while uncomplexed Fe^{2+} is more available for the growth of phytoplankton Since organic ligands in natural waters can form strong complexes with metals, more studies are needed on the effect of metal organic complexes.

Redox- and diffusion-controlled fractionation of Fe stable isotopes in silicate minerals of igneous rocks

MARC-ALBAN MILLET, JOEL BAKER, MONICA HANDLER, CONSTANCE PAYNE AND JESSICA DALLAS

School of Geography, Environment and Earth Sciences, Victoria University of Wellington, New Zealand

Amongst the non-traditional stable isotopic systems available for study in high temperature geochemistry, Fe isotopes have received particular attention. However, the controls of Fe stable isotope fractionation in high temperature magmatic systems are not fully understood, mainly due to poorly constrained isotopic fractionation factors between silicate minerals and melts.

We present new Fe stable isotope data obtained using a high precision double-spike technique ($\delta^{56}Fe \pm 0.02‰$, 2 sd) for minerals from terrestrial (basalt-rhyolite, gabbro-granite, boninite) and extraterrestrial igneous rocks (angrites, eucrites, mesosiderites). Results show that significant mineral isotopic fractionations exist in terrestrial samples that appear to be controlled by Fe redox state ($\delta^{56}Fe_{IRMM-14}$ = -1.0 to +0.85‰). Fe^{2+}-rich minerals like olivine display enrichments in light Fe ($\delta^{56}Fe_{IRMM-14}$ = -0.35 to -0.25‰) compared to host melt ($\delta^{56}Fe_{IRMM-14}$ = +0.05 to +0.22‰). Conversely, Fe^{3+}-rich minerals like plagioclase have heavy Fe ($\delta^{56}Fe_{IRMM-14}$ = +0.25 to +0.42‰), and alkali feldspar exhibits markedly heavy Fe ($\delta^{56}Fe_{IRMM-14}$ = +0.85‰). Clinopyroxene typically has a Fe stable isotopic composition the same or only slightly lower than host melt. In contrast to the terrestrial samples, olivine, pyroxene and plagioclase from basaltic meteorites formed on planetesimals that differentiated in the early Solar System under reducing magmatic conditions do not show measurable Fe stable isotope fractionations. This demonstrates isotopic fractionation between Fe^{2+} and Fe^{3+} in high temperature magmatic systems, which is then captured in terrestrial igneous rocks when minerals incorporate various proportions of these two Fe pools according to their mineral chemistry.

Analyses of single olivine crystals from a basaltic andesite erupted in a subduction zone setting display an extreme isotopic range ($\delta^{56}Fe_{IRMM-14}$ = -0.96 to +0.19‰). Evidence for chemical zonation in the olivine related to Fe-Mg interdiffusion between olivine and melt suggests that significant stable Fe isotopic fractionation in the olivines may be due to diffusion-driven processes. This dataset will be complemented by Mg stable isotopes of the same grains in order to assess the relative importance of redox- and diffusion-controlled processes on Fe stable isotopic fractionation in high temperature magmatic systems.

Carbon isotope fractionation associated with $CaCO_3$ precipitation induced by ureolysis

S.C. MILLO*, M. DUPRAZ, F. ADER, C. GUYOT, R. THALER AND B. MENEZ

IPGP-Sorbone Paris Cité, Univ. Paris Diderot, UMR7154 CNRS, Paris, France (*correspondence: millo@ipgp.fr)

It is increasingly recognized that carbonate precipitation by microorganisms presents some similarities with the carbonate biomineralization of skeleton-forming organisms. For example, in both processes crystallization often starts with the formation of amorphous carbonate, and the polymorphism and habit of carbonate crystals are influenced by interactions with the cell membrane or with extracellular organic products. However, if the occurrence of vital isotopic effects has been extensively documented for skeleton-forming organisms, so far the potential vital effects associated with microbial carbonate precipitation have remained unexplored. Paleoenvironmental reconstructions based on microbial carbonates therefore rely on the assumption that the carbon isotope fractionation expressed during microbial carbonate precipitation is equal to that expressed during inorganic precipitation at isotopic equilibrium.

We performed an experimental study of the carbon isotope fractionation expressed during $CaCO_3$ precipitation associated with ureolysis induced by *Sporosarcina pasteurii* used as a model organism for carbonate precipitation by heterotrophic bacteria. The crystallization sequence initiates with the formation of amorphous calcium phosphate followed by vaterite and then calcite, which dominates the $CaCO_3$ products at the end of precipitation. The carbon isotope composition of $CaCO_3$ evolves following a typical Rayleigh distillation pattern, which can be modeled assuming precipitation with no isotopic re–equilibration between $CaCO_3$ crystals and dissolved inorganic carbon (DIC). According to this model, the first stage of precipitation, possibly of vaterite, is characterized by an increasing ^{13}C–depletion of $CaCO_3$ relative to DIC of up to 2‰. The second stage, probably of calcite, proceeds very close to calcite precipitation isotope equilibrium. These results suggest that vital isotopic effects are probably not limited to skeleton-forming organisms but may also occur during microbial biomineralization, where they might be related to the initial precipitation of metastable mineral phases.

U-Pb geochronology and Lu-Hf isotope data from meta-carbonatites in the southern Canadian Cordillera

LEO J. MILLONIG[1]*, AXEL GERDES[2] AND LEE A. GROAT[1]

[1]Department of Earth and Ocean Sciences, University of British Columbia, 6339 Stores Road, Vancouver, BC, Canada, V6T 1Z4 (*correspondence: lmilloni@eos.ubc.ca) (lgroat@eos.ubc.ca)

[2]Institut fuer Geowissenschaften, Goethe University Frankfurt, Altenhoeferallee 1, Germany (gerdes@em.uni-frankfurt.de)

Of the 14 carbonatites in British Columbia [1] only 7 have been dated yielding a wide range of dates interpreted as intrusion ages, which cannot be explained within a coherent tectonic setting. The scope of this study is to provide reliable age data for several undated and/or previously unknown carbonatites.

U-Pb and Th-Pb ages of zircons and accessory phases from meta-carbonatites, obtained by LA-SF-ICP-MS techniques, of the southern Canadian Cordillera provide evidence for two episodes of carbonatitic magmatism during the Cambrian at around 500 Ma and the Late Devonian to Early Carboniferous at ~360-340 Ma. Furthermore, episodes of regional metamorphism are recorded by Pb-loss of the zircons and/or new zircon growth at ~170 Ma, 70-65 Ma and ~50 Ma. Lu-Hf isotope data from these zircons show a complex pattern of homogenous to strongly varying values between and within samples, indicating isotopic differences in the magmatic sources or different degrees of isotopic disturbance during metamorphism. In addition, U-Pb age dating of the accessory phases allanite, apatite, baddeleyite, monazite, pyrochlore, titanite and zirconolite will be conducted in order to determine the intrusion ages and the timing of high-grade metamorphism as well as its effect on the different minerals.

In this study 10 carbonatite, 2 mafic and 4 syenite samples are currently being processed and the results will provide new constraints on the geodynamic evolution of the Canadian Cordillera with regard to carbonatitic-alkaline magmatism. This in turn will help to elucidate why some of the investigated carbonatite-alkaline complexes are of economic interest with regard to the Rare Earth Elements (REE) and Ta and Nb.

Long period oscillations in the Neoproterozoic carbon cycle

BENJAMIN MILLS[1]*, ANDREW J. WATSON[1], COLIN GOLDBLATT[2], RICHARD BOYLE[1] AND TIMOTHY M. LENTON[1]

[1]School of Environmental Sciences, University of East Anglia, Norwich, NR4 7TJ, U.K (*correspondence: b.mills@uea.ac.uk)

[2]Astronomy department and Virtual Planetary Laboratory, University of Washington, Box351580, Seattle, WA 98195, USA

The proposed Neoproterozoic snowball Earth events imply a super-greenhouse period following deglaciation, in which the high CO_2 concentration required to initiate glacial retreat coupled with the decrease in planetary albedo causes greatly elevated surface temperature [1]. In this situation, increased reaction kinetics would drive greater silicate weathering fluxes, which draw down CO_2 until a steady state is achieved [2].

However, the speed at which the system returns to steady state is highly dependent on the global erosion rate. When temperature and runoff are very high, the supply of cations to the weathering zone becomes a limiting factor for silicate weathering [3]. Using estimates for post-snowball CO_2 concentration [1, 4] and the Phanerozoic average erosion rate [5] yields a stabilisation time of $>10^7$ years in the COPSE biogeochemical model [6], comparable with the timing of Neoproterozoic glaciations.

Extended periods of high temperature and nuteirnt abundance following a snowball glaciation may help to explain the biological advances made over the Neoproterozoic, as well as the geochemical features such as long positive excursions in $\delta^{13}C$ and massive deposition of phosphorus. Conversely, evidence that CO_2 concentration quickly returned to low levels might help constrain our views on snowball Earth.

Experimental evidence for coarsening of crystals and bubbles during thermal cycling of mafic and silicic magmas

R.D. MILLS* AND A.F. GLAZNER

Dept. of Geological Sciences, Univ. of North Carolina, Chapel Hill, NC 27599, USA
(*correspondence: rdmills@email.unc.edu)

Porphyritic textures in igneous rocks are commonly interpreted as evidence for low nucleation rates and/or high growth rates, but experiments in both magma analog systems and ice cream show that temperature oscillations can promote crystal cannibalism and coarsening, and thus porphyritic texture. Here we show that thermal cycling significantly increases crystal and bubble size during experiments on a basalt at 1-atm in a gas-mixing furnace and on a water-saturated rhyolite at 100 MPa in a cold-seal furnace.

The basalt experiments clearly show that temperature cycling dramatically increases crystal sizes. Experiments were performed on an alkali basalt at 1160°C, Ni-NiO buffer, for durations of 20 to 120 hours. After thermal cycling with amplitudes of 5 to 20°C and periods of 20 to 40 minutes, the larger plagioclase crystals were ~20 times more massive, and the larger olivine crystals ~5 times more massive, than in comparable static experiments. Cycle amplitude and period interact in complex ways with crystal structure to produce coarsening, but all cycled experiments show increased coarsening compared to the experiments at constant temperature.

Initial results from experiments in a water-saturated rhyolitic system at 100 MPa and 810°C indicate that cycling of 10°C at a period of 40 minutes greatly increases the size of plagioclase (mass ratio ~12) and hornblende (~4). These results indicate that temperature cycling may offer a way to attack the kinetic problems inherent in experimental work in high-silica systems.

In both sets of experiments, thermal cycling caused marked coarsening of bubbles. Although the processes by which bubbles coarsen are probably different from those that govern crystal coarsening, the results are very similar. Thermal cycling greatly increases the size of bubbles and decreases their number, suggesting that thermal cycling could play an important role in degassing of magmas and ultimately in determining the explosivity of eruptions.

Jiaodong gold district, Northeast China: Discrepancies with orogenic gold mineralisation

S.E. MILLS* AND A.G. TOMKINS

School of Geosciences, Monash Uni, Melbourne, Australia
(*correspondence: stephanie.mills@monash.edu)

The world-class gold deposits of the Jiaodong Peninsula represent the most important gold-producing area in the world's leading gold-producing country. They are considered by some researchers to be orogenic gold deposits; however this study shows this classification ignores fundamental differences in mineralisation character.

Typical orogenic gold mineralisation is associated with compressional or transpressional tectonics in a collisional/accretionary setting and is commonly hosted in metamorphosed terranes. In Jiaodong, it is well accepted that mineralisation occured in extensional tectonics that included lithospheric thinning and large-scale granitic emplacement [1]; fieldwork from this study also shows evidence for mineralisation during normal faulting. Likewise, at the time of mineralisation Jiaodong was far inboard of the active subduction front (Paleo-Pacific Plate subducting benath the East Asian margin), and although metamorphosed Precambrian basement is present, mineralisation is almost exculsively hosted in Mesozoic granitic intrusions. Also, the Precambrian basement reached upper-amphibolite to granulite facies metamorphism at ~2.5Ga, resulting in devolitalization and making it unlikely that mineralisation is related to basement metamorphism [2].

Results from this study also illustrate that deposit scale characteristics are contrary to orogenic deposits, including high base-metal enrichment (600, 150, 35 times background for Cu, Pb, and Zn respectively) in the form of polymetallic mineralisation (chalcopyrite and galena) proximal to controlling faults in high-grade Au zones. Gold-associated enrichments include Ag, Bi, As ± Sb, Mo, W with low Au:Ag (0.005 to 1.66, average 0.4). Sulfur isotope analyses on pyrite show $\delta^{34}S$ values ranging from +6‰ to +13‰ with an average of +9‰.

These regional to deposit scale characteristics show that although Jiaodong deposits have some similarities to orogenic systems, major discrepancies exist. It is likely that dynamic processes in the lithosphere and asthenosphere (i.e. mantle lithosphere destruction, asthenospheric upwelling) were instead the regional drivers behind mineralisation.

The fate of organic pollutants in soil – Emerging views on the relevance of non-extractable residues

ANJA MILTNER[1]*, KAROLINA NOWAK[1], CRISTOBAL GIRARDI[1], ANDREAS SCHÄFFER[2] AND MATTHIAS KÄSTNER[1]

[1]UFZ - Centre for Environmental Research, Department of Environmental Biotechnology, Leipzig, Germany (*correspondence: anja.miltner@ufz.de)

[2]RWTH Aachen, Department of Environmental Biology and Chemodynamics, Aachen, Germany

C from soil pollutants partitions into parent compound, metabolites, non-extractable residues (NER), CO_2 and microbial biomass. This distribution must be known to assess the fate of a compound in soil, but simulation tests in soils are rarely performed because they are expensive and complex. Data from aqueous systems are much more abundant, and using them for fate assessment in soils would increase the database enormously. The main obstacle for this is that NER formation cannot be simulated in aqueous systems. In the past, NER were considered to mainly consist of adsorbed and sequestered parent compound or metabolites and thus hazardous. However, they may partly derive from bacterial biomass, resulting in harmless biogenic residues. We compared the biodegradation of isotope labeled 2, 4-D, ibuprofen and ciprofloxacin in aqueous systems and soil and quantified the contribution of microbial residues to NER in soil. Both 2, 4-D and ibuprofen were mineralized fast in aqueous systems. In soil, mineralization was lower, and significant amounts of NER were formed. The amount of label found in biomolecules indicated that virtually all of the NER derived from microbial biomass. We found no mineralization of ciprofloxacin in aqueous systems, but a low mineralization in soil. NER formation from ciprofloxacin was fast and independent of microbial activity. Ciprofloxacin reduced microbial activity more in aqueous systems than in soil, because sorption and spatial inaccessibility reduced the toxicity in soil. In conclusion, for readily degradable compounds, mineralization is lower in soil than in water, and a significant part of the carbon is channeled to microbial biomass, which later is stabilized in soil organic matter, resulting in biogenic residues. Toxic compounds are mineralized more easily in soil than in water, because NER formation, spatial heterogeneity, and microbial biodiversity in soil reduce the toxicity of the compounds. NER formation without corresponding mineralization indicates formation of potentially hazardous NER derived from the parent compounds or (toxic) metabolites. In contrast, NER formed along with significant mineralization are biogenic and thus non-hazardous.

Boron isotopes by laser ablation MC-ICPMS

J. ANDY MILTON*, FRANCES DEMUTH, GAVIN L. FOSTER AND MARTIN R. PALMER

School of Ocean and Earth Science, National Oceanography Centre, Southampton, Southampton, UK (*correspondence: jam2@soton.ac.uk)

The invention of multicollector inductively coupled plasma mass spectrometers (MC-ICPMS) has revolutionised the way in which a number of isotope systems are measured. Not least the light dual-isotope systems such as boron where the large, but stable, mass fractionation of the plasma ion source allows accurate correction using bracketing standards of known isotope composition [1]. An additional advantage of these instruments is the ability use a laser ablation introduction system that allows relatively precise isotopic analysis, without prior chemical purification, on the scale of 10-100's of microns (e.g. [2]). The few studies that report boron isotopes by LA-MCICPMS [3, 4] are very encouraging, especially given the obvious advantages offered by rapid sample throughput and high spatial precision by LA and the difficulties associated with boron isotope analysis by solution MC-ICPMS (e.g. poor washout, low sensitivity, and the difficulties associated with silicate dissolution).

Here we present our recent efforts investigating the accuracy and precision of boron isotope analysis by LA-MCICPMS of a variety of samples and reference materials (glass, tourmaline, carbonates). Our initial results suggest accurate and precise data, rivalling the most precise solution analyses [1], can be generated *in situ* on samples amounting to <0.5 ng of boron.

[3]Max Planck Institute of Biochemistry, 82152 Martinsried, Germany

Anaerobic oxidation of methane (AOM) coupled to sulfate reduction, performed by consortia of methanotrophic archaea (ANME) and sulfate-reducing *Deltaproteobacteria*, plays a crucial role in biogeochemical carbon and sulfur cycling in marine sediments. We developed a method that allowed us to visualize single cells in AOM consortia, identify these cells based on the presence of key enzymes and determine their elemental and isotopic composition.

First, thin sections of AOM aggregates were prepared and examined by fluorescence microscopy. The discrimination between ANME and *Deltaproteobacteria* was achieved by using fluorescent antibodies targeting specific enzymes of each of the two organisms. Next, the sample preparation and immunolabeling protocol was successfully adapted for nanometer-scale secondary ion mass spectrometry (nanoSIMS). We selectively targeted the ANME with primary antibodies against methyl-CoM reductase – the key enzyme of AOM – and NanoGold-coupled secondary antibodies. The obtained nanoSIMS images revealed an unusually high phosphorus and iron content of the ANME-associated bacteria. The transmission electron microscopy coupled to energy-dispersive X-ray spectroscopy (TEM/EDX) showed that these bacterial cells contained peculiar amorphous iron- and phosphorus-rich particles in their cytoplasm.

Based on these results we speculate that AOM might also play a – yet unrecognized – role in iron and/or phosphorus cycling in marine sediments. This demonstrates that imunodetection of key enzymes in combination with nanoSIMS can be used to assess the involvement of functional groups of organisms in biogeochemical processes.

Reaction of silicate with released CO_2 by inorganic precipitations of marine carbonate in sandstone: Evidence from $^{87}Sr/^{86}Sr$, $\delta^{18}O$ and $\delta^{13}C$ isotopes in calcareous sandstone

MASAYO MINAMI[1], TSUYOSHI TANAKA[2]*, MAKOTO TAKEUCHI[3] AND SAEKO MITO[4]

$^{87}Sr/^{86}Sr$, $\delta^{18}O$ and $\delta^{13}C$ isotopes of carbonate in calcareous sandstone show intermediate values between marine carbonate and silicate phase of the sandstone.

Triassic Hiraiso Formation of the South Kitakami Terrane in Japan contains calcareous sandstone. The carbonate distributed homogeneously in lithic fragments and partly replaced plagioclase of the sandstone. It is considered that the early Triassic period was a dried climate and the Hiraiso Formation was deposited at near shore marine. The carbonate phase and silicate phase were separately examined. $^{87}Sr/^{86}Sr$ and $\delta^{18}O$ isotopes of the carbonate phase are lower than the values of limestone at that Triassic period. The values show the intermediate between silicate minerals and marine carbonate, while $\delta^{13}C$ shows the value of marine carbonate. The $^{87}Sr/^{86}Sr$ and $\delta^{18}O$ isotopes indicate that these are the mixed ones of marine Sr and oxygen with those in silicate phase. Very few carbon is contained in the silicate phase and the $\delta^{13}C$ value shows always that of marine. It shows *simultaneous* formations of the 1st: Carbonate precipitation from seawater in the sandstone with 2nd: Precipitation of carbonate by the quick reaction of silicates and the nascent carbon dioxide released at that time.

an integral component of the Earth's hydrological cycle, the South Asian summer monsoon is critical for the well-being of over one-fifth of the world's population. Observations show that South Asia underwent a widespread drying during the second half of the twentieth century, but it is still largely unclear whether this prolonged shift was due to natural variations or human activities. Here we use a series of perturbation experiments with a state-of-the-art climate model, which realistically simulates the observed historical trend when driven with all known climate forcings, to investigate the South Asian monsoon response to natural and anthropogenic factors, with particular focus on aerosols and greenhouse gases. We find that the observed precipitation decrease is very likely to be of anthropogenic origin, and can be attributed almost entirely to aerosols. The drying is a robust outcome of a slowdown of the tropical meridional overturning circulation, which is fundamentally driven by the need to counteract the aerosol-induced energy imbalance between the northern and southern hemispheres. In contrast, greenhouse gases give rise primarily to a weakening of the equatorial zonal overturning circulation. These results provide compelling evidence of the prominent role of aerosols in shaping regional climate change over South Asia.

Volatiles (H_2O, CO_2, S, Cl, F) in primary magmas of Kliuchevskoy volcano (Kamchatka)

N. MIRONOV[1]* AND M. PORTNYAGIN[1,2]

[1]V.I. Vernadsky Institute of Geochemistry and Analytical Chemistry (GEOKHI RAS), Kosygin str. 19, 119991 Moscow, Russian (*correspondence: nmironov@geokhi.ru)
[2]Leibniz Institute of Marine Sciences (IFM-GEOMAR), Wischhofstr. 1-3, 24148 Kiel, Germany

We carried out a melt and fluid inclusion study to estimate the amount of volatiles (H_2O, CO_2, S, Cl, F) in primary magmas of Kliuchevskoy volcano in Kamchatka. Volatiles in melt inclusions were analyzed by EMP (S, Cl), SIMS (H_2O, F) and FTIR (CO_2, H_2O). Fluid inclusions were studied criometrically. More than 400 melt and fluid inclusions in olivine (Fo_{92-67}) were studied. We found that diffusive H_2O loss from inclusions, redistribution of CO_2 between melt and fluid and sulfide immiscibility inside inclusions preclude straightforward interpretation of volatile concentration in glasses of primitive MIs (Ol-host Fo>85) as representative for primary melts. Careful selection of the least modified after entrapment melt inclusions allowed us to define the most plausible range of volatile concentrations in primitive Klyuchevskoy magmas (minimum-maximum, average, wt. %): H_2O=2.8-3.6, 3.2; S=0.13-0.23, 0.16; Cl=0.02-0.13, 0.08; F=0.022-0.051, 0.032. A minimum CO_2 content in primitive melts is estimated from density of CO_2 fluid inclusions in primitive olivines to be 3500 ppm. Inclusions in more evolved olivines (Fo<80), which were trapped shortly before eruption, reflect variable extent of magma degassing and were nearly undisturbed by the later processes of melt modification after entrapment.

The concentration of volatiles in Kliuchevskoy melts are similar to those estimated in other, much less productive Kamchatkan volcanoes [3]. Given the large productivity of this volcano (on average 60 Mt /year), the flux of volatiles from Kliuchevskoy volcano is however very high during the Holocene (e.g. H_2O flux amounts at 3.27 Mt/year). The high volatile flux may indicate a large part of subducting plate delivered fluids focused to the source of Kliuchevskoy and/or perhaps additional contribution of volatiles from serpentinites in the subducted plate.

Chronology of early solar system inferred from precise Al-Mg isotope systematics of Vigarano CAIs

R.K. MISHRA AND M. CHAUSSIDON

Centre de Recherches Petrographiques et Géochimiques, CRPG - CNRS, UPR 2300, 15 rue Notre Dame des Pauvres, BP 20, 54501Vandoeuvre les Nancy, France (ritesh@crpg.cnrs-nancy.fr, chocho@crpg.cnrs-nancy.fr)

Calcium, Aluminium-rich Inclusions (CAIs) are the oldest solar system solids that have been absolutely dated to have an age of ~4.57 Ga [1-2]. High precision *in situ* Al-Mg isotope systematics studies of CAIs, and other early formed solar system objects, using secondary ion mass spectrometer (SIMS) provides an opportunity to obtain very precisely time of last melting event (from $^{26}Al/^{27}Al$ ratio) and Mg isotope composition at this time (from $\delta^{26}Mg_0$) [3-6]. This allows better understanding of high temperature events in the solar accretion disk by constraining their durations with greater precision (~10^5 years), the components involved (gas or solids) and the history of these components. Eight CAIs of different types from one of the least altered meteorite Vigarano ($CV_{reduced}$ 3.1-3.4) were analysed for Al-Mg isotopic composition in order to answer several first order questions: (i) did condensation/melting of CAI precursors happen only during a unique single event in the accretion disk, (ii) how many high temperature events did CAI undergo, (iii) whether some of these events were related with chondrule formation? In addition, it provides arguments for quantifying the level of homogeneity of Al, and Mg isotopes in the inner solar system [3, 7]. Results obtained so far suggest melting of CAIs at different periods of time from precursors extracted earlier, in a short time interval, from the solar gas. No indication of ^{26}Al heterogeneity has been found.

Formation of the nitrogen B-aggregates in type Ib diamond

Y. MITA[1]*, Y. NISIDA[1] AND M. OKADA[2]

[1]Graduate School of Engineering Science, Osaka University, Toyonaka, Osaka 560-8531, Japan (*correspondence: mita@mp.es.osaka-u.ac.jp)

[2]Research Reactor Institute, Kyoto University, Sennan, Osaka 590-0451, Japan

Most of natural diamonds contain nitrogen atoms more or less and they form many types of aggregates by annealing. When the diamonds contain nitrogen atoms in single substitutional form, in substitutional nitrogen pairs (named A-centers) or in B-aggregate form, they called type Ib, type IaA or type IaB, respectively. As many natural diamonds are their mixed types and contain impurity atoms in reality, all types of diamonds must be obtained artificially for investigation. However to form the nitrogen B-aggregates consist of four substitutional nitrogen atoms surrounding a vacancy from isolated nitrogen atoms of type Ib diamond the samples must be annealed for an extraordinary long time under high temperature and high pressure conditions. Therefore it was thought till recently that to form the B-aggregates artificially is preposterously difficult and a diamond which contains the B-aggregates is natural. Collins [1] observed formation of the A-centers in the electron irradiated and annealed type Ib diamond and thought that the aggregation of nitrogen is enhanced by vacancies introduced due to the electron irradiation. However this treatment was not enough powerful for generating big nitrogen aggregates like the B-aggregate.

We studied the neutron irradiation effects on the nitrogen aggregation in type Ib diamonds. The nitrogen concenteration of samples were ranged from 50 to 340 ppm and the neutron irradiation was carried out with doses of 1.1×10^{16} n/cm^2 to 2.8×10^{18} n/cm^2. The samples were annealed at various temperatures between 1000 to 1700 centigrade degrees for several annealing times under a pressure of 6 GPa. It was observed that the aggregation due to the high temperature and high pressure annealing is highly accelarated by vacancies introduced through the neutron irradiation and a large amount of B-aggregate was generated from single nitrogen. The best record of generation time of B-aggregates at present is shorter than 30 minutes.

River red gum biogeochemical expression of buried Broken Hill type mineralisation

C. MITCHELL[1]* AND S.M. HILL[2]

[1]The University of Adelaide, Adelaide, 5005, Australia (*correspondence: charlotte.mitchell@adelaide.edu.au)
[2]The University of Adelaide, Adelaide, 5005, Australia (steven.hill@adelaide.edu.au)

River red gums (*Eucalyptus camaldulensis*) are a tree native to Australia but now widely grown in warm and semi-arid parts of the world. In Australia, they are one of the most widely distributed tree species, especially in riparian zones of arid regions. Their distribution closely corresponds to areas where sediments and and alluvial aquifers are well developed. As such, they tend to colonise settings where the underlying bedrock geochemistry is poorly defined. These long-lived and deep-rooted trees therefore have potential to provide important biogeochemical expressions of the geochemistry of buried bedrock. This study provides an overview of multi-element (ICP-MS and XRF) analysis of leaf samples from about 500 river red gum trees from the Broken Hill region in semi-arid central Australia. Particular attention is given to the biogeochemical expression of sites of known Broken Hill type (Ag-Pb-Zn) mineralisation. It shows that biogeochemistry can provide an effective recognition of buried mineralisation, even when the overlying sediments do not contain a geochemical expression that distinctly highlights mineralisation. It also provides an indication of some of the highly elevated metal and trace element contents that can be hosted in native vegetation near the natural occurrences of ore bodies.

Samples from trees overlying mineralisation near the Pinnacles Mine and along the Broken Hill Line of Lode show highly elevated contents of Ag (max. 1.36 ppm), Pb (max. 411 ppm) and Zn (max. 338 ppm), where regional 'background' values are typically low or approaching analytical detection limits (e.g. Ag 0.01 ppm; Pb 1 ppm; and, Zn 17 ppm). Some samples from near mineralisation also contain elevated Cd, Au, In and Tl contents, however, values are variable, and these elements are best considered within the context of the major ore forming elements (e.g. In/Zn). The spatial extent of the elevated biogeochemical response depends on the size and grade of mineralisation but also the characteristics of the physical and chemical dispersion that vary in different parts of riparian zones.

Selenium adsorption and associated selenium isotope fractionation

K. MITCHELL[1]*, R.-M. COUTURE[1], T.M. JOHNSON[2], P.R.D. MASON[3] AND P. VAN CAPPELLEN[1]

[1]Georgia Institute of Technology, Atlanta, USA (*correspondence: kristen.mitchell@eas.gatech.edu)
[2]University of Illinois at Urbana-Champaign, Urbana, IL, USA
[3]Utrecht University, Utrecht, The Netherlands

Riverine input is a source of selenium to the coastal oceans: between 5 and 12% of Se input consists of particulate selenium. Depending on the site, particulate organic Se is estimated to account for 40 to 100% of the particulate Se pool, suggesting that up to 60% of particulate selenium is in another form, possibly as selenium oxyanions adsorbed onto either organic matter or iron (Fe) oxides

Among the Fe oxides, goethite has been put forth as the dominant authigenic Fe(III) phase in freshwater and marine sediments. Hematite is found in association with goethite, though generally it is not as widespread. Ferryhydrite, while short lived, is a precursor to the latter phases. Thus, these ubiquitous phases are important carrier of adsorbed Se species to oceans.

Nevertheless, sorption behavior of selenate and selenite as well as the isotope fractionations associated with these reactions has not been systematically investigated. Here, we measured total Se concentrations as a function of time during the equilibration of selenate and selenite with suspensions of 2-line ferryhydrite, hematite, goethite (Table 1).

	2-line ferryhydrite	Hematite	Goethite
Selenite	50	0.5	275
Selenate	~0	~0	1

Table 1: Calculated partition coefficient (Kd; L g^{-1}) for Se sorption onto selected Fe(III) oxyhydroxide minerals.

We show that selenate does sorb onto goethite (Table 1), contrary to expectation, albeit to a much lower extent than selenite. We conclude by discussing the isotope shifts associated with these sorption reactions and the potential use of Se isotopes to fingerprint the sorption mechanism of Se removal by Fe oxides in the aquatic environment.

Adsorption/sorption of heavy metal ions on clay minerals

Clay minerals are expected as one of the most effective adsorbent/sorbent for heavy metal ions in soil. Miyazaki *et al*. [1] reported that solid-liquid interfacial reaction of Zn^{2+} ions on alumina can be divided into three processes: adsorption due to formation of inner-spehre complex, desorption of Zn^{2+} accompanied with dissolution of Al^{3+} and then co-precipitation of Zn^{2+} with Al $(OH)_3$. Shlegel and Manceau [2] reported that after adsorption of Zn^{2+} onto montmorillonite, which was exchanged with Al^{3+} or Keggin Al_{13}, the Zn^{2+} located in vacant octahedra of gibbsite-like layers. These reactions for Zn^{2+} may correspond to transfer from adsorption to sorption. In order to access and control the mobility of heavy metals in soil systems, it is essential to understand the relationship between their sorption and adsorption onto clay minerals. One of the crucial problems is the role of Al^{3+} in the process of adsorption/sorption. In this study, Zn^{2+} was adsorbed onto Al $(OH)_3$ and change in the chemical state of Al^{3+} in Al $(OH)_3$ after the adorption was analyzed using ^{27}Al MAS NMR.

Results and discussion

Al $(OH)_3$ was prepared by hydrolisis of Al^{3+} in $KAl(SO_4)_2{\cdot}12H_2O$ solution. In the ^{27}Al MAS NMR spectra for Al $(OH)_3$, a peak was observed around 5 ppm. In case of Al $(OH)_3$ after adsorption of Zn^{2+}, the NMR peaks were observed around 15 and 60 ppm depending on the experimental condition such as pH, concentration etc. These peaks may be AlO_6 octahedral species adsorbing Zn^{2+} and AlO_4 tetrahedral species, respectively. Interestingly, the peak at 60 ppm was also found in the co-precipitates of Zn^{2+} with Al $(OH)_3$. From these results, it can be assumed that adsorption of Zn^{2+} onto Al $(OH)_3$ induces Al^{3+} dissolution and the Al^{3+} precipitates on the solid forming Keggin-like structure which correspond to the sorption.

The composition of Earth's oldest iron formations: The Nuvvuagittuq Supracrustal Belt (Québec, Canada)

A.M. MLOSZEWSKA*, E. PECOITS[1], N.L CATES[2], S.J. MOJZSIS[2], J. O'NEIL[3] AND K.O. KONHAUSER[1]

[1]Earth and Atmopsheric Sciences, University of Alberta, Edmonton, Alberta, T6E 1Y1 (*correspondence: mloszews@ualberta.ca)
[2]Geological Sciences, University of Colorado at Boulder, 90309-0399, USA
[3]Terrestrial Magnetism, Carnegie Institution of Washington, Washington DC, 20015-1305, USA

The composition of iron formations in the >3.8 Ga year old [1, 2] Nuvvuagittuq Supracrustal Belt in northern Québec provide a proxy for seawater composition of the Eoarchean, and perhaps Hadean oceans, as well as constraints on the types of nutrients available to Earth's earliest life forms. Having precipitated directly out of seawater, it is thought that the primary iron minerals that comprised the initial BIF sediments (e.g. ferric oxyhydroxides) retained the chemical signature of this seawater in the process. Integrated petrologic and geochemical relationships mapped between mineral phases in thin section and whole-rock chemistry provides a framework for interpreting bulk and micro-scale variations in these chemical sedimentary precipitates. Results show that there are two distinct chemical sedimentary units in the Nuvvuagittuq belt: i) a BIF unit, consisting of alternating micro-bands of magnetite, Fe-Mg-Ca-silicates and quartz, and ii) a more silicate-rich (Fe-poor) banded silicate-formation (BSF) unit of alternating micro-bands of quartz and Fe-Ca-silicates. Precursor BIF and BSF deposits were layered amorphous silica and ferric oxyhydroxides, fine-grained carbonate oozes and/or Ca-Mg-Fe rich silicate gels deposited in a marine setting. Low Al_2O_3, TiO_2 and HFSE concentrations show that they are relatively detritus-free, with distinctively seawater-like REE+Y profiles and consistently positive Eu anomalies. These features suggest that the rocks preserved their seawater-like compositions despite metamorphic overprinting. The most significant trace elements in the sediments are Ni and Zn. Experimentally-derived partitioning coefficients show that Earth's earliest oceans had relatively high dissolved Ni concentrations (up to ~300 ppm) while those for Zn were relative low (up to ~20 ppm) compared to modern seawater. Compositional resemblances between the Nuvvuagittuq sediments and those documented in the ca. 3.8 Ga Isua supracrustals (west Greenland) provide a plausible case that global ocean processes had reached steady-state by the Eoarchean.

Petrogenesis and tectonic significance of Shuangjianshan highly evolved I-type granite, Beishan orogen, NW China

YALONG MO[1,3], XINBIAO LÜ[1,2]*, ZHUJIANG[1], DENGJIE[1], XIAOFENG CAO[1] AND YUCAI DAI[4]

[1]Faculty of Earth Resources, China University of Geosciences, Wuhan 430074, China (*correspondence: lvxb_01@163.com, myl7004@126.com)

[2]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

[3]Yunnan provincial tourism school, Kunming 650221, China

[4]No. 6 Geological Party, Xinjiang Bureau of Geology and Mineral Exploration, Hami 839000, China

We have studied the petrology, major and trace element geochemistry, isotope geochemistry of the Shuangjianshan intrusion and discussed its petrogenesis and tectonic significance. The Shuangjianshan intrusion is located in south of Hongshishan ophiolitic mélange in Beishan orogeny belt, Gansu, north of Tarim. It is a monzogranite. The content of SiO_2 is 73.04-74.39 %, A/CNK ranges from 0.996 to 1.065, total alkalis ranges from 8.29 to 8.44 % with Na_2O over 3%, calculated corundum is less than 1 % and DI ranges from 91.29 to 93.26. Thus, it is a highly evolved I-type granite with total REE (146.79-157.5 ppm), $(La/Yb)_N$ (8.08-8.80) and δEu (0.64-0.73). It is enriched in Rb, Ba, Th, U and depleted in Ta, Nb, Sr, Ti. Its geochemistry characters show the affinity of island arc magmatic rock. LA-ICP-MS zircon U-Pb dating gave the intrusive age of 322.3±1.7Ma (weighted $^{206}Pb/^{238}U$ age). Its has high εNd (t) (+1.9 to +2.7), low $(^{87}Sr/^{86}Sr)_i$ (0.70312 ~ 0.70343) and the samples from the intrusion plots in the orogeny evolution trend on the $^{206}Pb/^{204}Pb$ vs. $^{207}Pb/^{204}Pb$ diagram. It falls in the area of syn-collisional granite area on R1-R2 diagram, however in the volcanic arc granite area on the Y vs. Y+Nb and Y vs. Nb diagrams. The characteristics described above indicate that the Shuangjianshan intrusion is a highly evolved I-type granite originating from the mantle wedge. Trace elements exibit the characteristics of subduction zone. The granite also contaminated by crust and underwent highly fractional crystallization. Combining with the 334 Ma adakite, we believe that the intrusion is a later product of the subducted North Tianshan ocean crust, which closed before 322 Ma and then came to the syn-collisional stage.

This work is founded by 305 Project of State Science and Technology Support Program (Grant No. 2007BAB25B04).

Quaternary soil and climate change inferred from TL Dating of Quaternary terraces in Taleghan basin, Iran

A. MOEINI[1] AND E. ALIZADE PAEEN AFRAKATY[2]

[1]Department of Agriculture and Natural Resources, Science & Research Branch, Islamic Azad University (IAU), Iran (abmoeini@yahoo.com)

[2]Faculty of Environment, University of Tehran, Iran.

Introduction and methods

We report the first thermoluminescence ages for the quaternary sediments of the Taleghan Drainage Basin, Tehran, Iran.

Results

Teracces	Terrace Name	Age (y)
Q4	Toria War	4650+ 520
Q3	Wurm	9100 ± 800
Q2	Wurm	15600 ± 2000
Q1	Riss	54900± 8700

Table1. Result of TL dating [1, 2]

The carbonates appeared in the field as nodules in the wurm terrace and laminar or conglomeratic massive cemented accumulation (Petrocalcic horizons) in the Riss terrace and the Toria war (youngest terraces), rejuvenates by flooding, and has not secondary carbonate within the profile.

Discussion

Based upon the above observations, we theorize that, at the ~100 ky ago climate was cold and arid, at the ~15 ky ago climate was tardi glacial, at the ~9 ky ago climate was pluvial and temperate with arid transitions and at the ~4 ky ago climate was flooding [3].

Cu, Zn and Fe isotope systematics of low-T hydrothermal Fe-Si deposits

K. MOELLER[1]*, R. SCHOENBERG[2], I.H. THORSETH[1] AND R.B. PEDERSEN[1]

[1]Centre for Geobiology and Department of Earth Science, University of Bergen, Allegaten 41, 5007 Bergen, Norway (*correspondence: Kirsten.Moller@geo.uib.no)
[2]Institute for Geoscience, University of Tuebingen, Wilhelmstrasse 56, 72076 Tuebingen, Germany

The formation of Si-rich ferric oxyhydroxide deposits is observed distal to the white smoker-type Jan Mayen hydrothermal vent fields at the Mohns Ridge, North Atlantic, in an area of diffuse low-temperature venting. Individual stratified laminated layers within these deposits are largely composed of branching, twisted filaments resembling encrusted stalks of Fe-oxidising bacteria, indicating biologically influenced precipitation of ferric iron.

In this study, we used stable isotope systematics of transition metals from different layers of the Fe-Si deposits in order to trace the evolution of hydrothermal fluids within the oceanic crust, from which these deposits ultimately formed. Isotope measurements show fractionation of the redox-sensitive elements Fe and Cu, whereas Zn with its singular oxidation state behaves more conservatively. Isotopically light Fe (δ^{56}Fe = -2.09 to -0.66 ‰) points to abiogenic partial, subsurface Fe oxidation [1] and/or dissimilatory iron reduction in combination with re-oxidation by Fe-oxidising bacteria. The reactive surface of the ferric oxyhydroxides of the Fe-Si deposits may absorb Cu and Zn from the venting fluid, thereby preferentially incorporating the heavy isotopes of these elements [2]. However, measured Zn isotope data do not show a significant enrichment relative to hydrothermal fluids [3] and Cu is isotopically lighter than primary hydrothermal Cu sulphides [4]. We hypothesize that precipitation and/or adsorption processes below the seafloor lead to the depletion of heavy isotopes in the evolved hydrothermal fluids from which the Fe-Si deposits formed.

Geochemistry of Cheshmeh Sefid manganese deposit, Sabzevar, Khorasan province, Iran

S.J. MOGHADDASI* AND M. GANBARI

Payame Noor University, Department of Geology, 19395-4697, Tehran, Iran (*correspondence: sjmoghad@pnu.ac.ir)

Cheshmeh Sefid manganese deposit is located in 60 km south of Sabzevar, a major city in Khorasan province, northeast of Iran. The study area is situated in central Iran structural zone. Manganese mineralization is occurred in a volcano-sedimentary succession consisted of grey limestone, submarine volcanic, Neogene sediments and flysch-like deposits. Manganese mineralization is mainly hosted by green colored rhyolitic tuffs of Eocene age. Manganese rich stratiform bodies are enclosed in jasper and overlain by grey colored dacite and rhyodacite. They are often syngenetic, based upon the stratigraphic persistence of the manganese horizon and the observed interstratification of manganese ore and hosting volcanics. Manganese deposits occur as lenses and stratiform bodies of different sizes. Upper and lower contacts of the ore bodies are characteristically sharp. Ore mineralography and XRD examinations were indicated that pyrolusite, psilomelane and cryptomelane were major manganese ore minerals in the studied deposit.

Geochemically, iron and manganese were characteristically fractionated, producing low Fe/Mn ratios. Si-Mn-Fe and Al-Si discrimination diagrams were also used to recognize between hydrothermal and hydrogenous manganese deposits. The collected geochemical data from the study area plot in the characteristic field of hydrothermal deposits. The manganese ores were indicated relatively low concentrations of Ni, Co, and Cu compared with those concentrations in hydrogenous manganese deposits. Diagnostic plot to Mn-Fe-10 (Ni+Co+Cu) discrimination diagram was indicated a characteristic depletion in Ni, Co, and Cu, suggesting a hydrothermal origin for the studied manganese deposit. Geochemical composition of manganese deposits of the studied area and their host rocks indicates that manganese oxides of the study area are the result of rapid deposition from Mn-rich fluids. These fluids have a hydrothermal exhalative nature and were probably associated with volcanic activities in Eocene period.

Removal of seawater ^{234}U incorporated in Holocene basaltic sediments from the Reykjanes ridge

K.J. MOHAMED[1,2]*, L.F. ROBINSON[2,3] AND J.F. MCMANUS[2,4]

[1]University of Vigo, Vigo, Spain (*correspondence: kmohamed@uvigo.es)
[2]Woods Hole Oceanographic Instit., Woods Hole, MA, USA
[3]University of Bristol, Bristol, UK
[4]Columbia University, Lamont-Doherty Earth Observatory, Palisades, NY, USA

The ratio ($^{234}U/^{238}U$) of detrital sediments is a potential tool for direct determinations of sediment transport time and provenance. Changes in grain size, shape and mineralogy after deposition can obscure the ($^{234}U/^{238}U$) variation with time, providing erroneous estimates of transport time. Addition of Uranium from external sources can also change this ratio, even to values higher than secular equilibrium.

Icelandic sediments recovered from the eastern flank of the Reykjanes ridge, in the Björn drift, showed ($^{234}U/^{238}U$) values higher than 1. Basalts, the main rock in the area, are known to incorporate Uranium from seawater with a ($^{234}U/^{238}U$) of 1.14, which may explain the anomalously high ($^{234}U/^{238}U$) measured in our samples. To identify the source of this ^{234}U addition, we performed a leaching of Holocene and deglacial sediments from the same site with increasing concentrations of HCl.

Older sediments with initially low ($^{234}U/^{238}U$) showed little variation with increasing acid concentration. On the contrary, younger samples with high ($^{234}U/^{238}U$) show steep decreases at concentrations lower than ~2.5 N HCl, and little changes from 3 to 9 N.

Leachates exhibit higher ($^{234}U/^{238}U$) than residues in all cases. In low ($^{234}U/^{238}U$) samples, leachates decrease initially and reverse the trend at HCL concentrations higher than 2.5 N HCl reaching values close to secular equilibrium. Leachates from samples with high ($^{234}U/^{238}U$) show similar behavior as the residues.

The incorporation of seawater uranium in Holocene samples suggests that these sediments have a higher contribution from Icelandic basalts. This ^{234}U contamination from seawater can be removed by leaching with 2.5 N HCl, which increases the reliability of transport time estimates based on the ($^{234}U/^{238}U$) ratio. Higher HCl concentrations may dissolve the sediment grains, which releases detrital ^{234}U and would explain the reversed trend observed in the leachates above 2.5 N HCl.

Helium in Michigan Basin sediments: A tracer for pore fluid migration and age

R.K. MOHAPATRA[1]*, I.D. CLARK[1], R.E. JACKSON[2], K. RAVEN[2] AND M. JENSEN[3]

[1]Dept. of Earth Sciences, University of Ottawa, Ottawa, ON Canada, K1N 6N5 (*correspondence: ratan.mohapatra@uottawa.ca)
[2]Geofirma Engineering, Ottawa
[3]Nuclear Waste Management Organization, Toronto

As a central component of hydrogeological investigations at a proposed site for low and intermediate level nuclear waste disposal, we have measured He in Ordovician strata from the Deep Geological Repository site in the Michigan Basin near Tiverton, Southern Ontario. Samples were micro-cored (6mm dia., 20mm length) from full 76 mm core samples of shales and argillaceous limestones shortly after recovery from depths between 450 and 850 m, for measurement of He on a MAP 215-50 mass spectrometer (MAPL). Supplemented by stable isotope measurements and major and trace element geochemistry, the labile helium fraction is used to estimate pore fluid age and source location. The xRa profile shows a consistent value near 0.0200 ± 0.0015 in the very low permeability Upper Ordovician shales, with a shift to 0.0360 ±0.0020 in the underlying Middle Ordovician limestones. *In situ* production rates for ^{3}He from ^{6}Li fission and ^{4}He from U and Th decay in the shales provide a calculated xRa that, within the margin of uncertainty, is the same as the measured ratio, suggesting an autochthonous source for He in that section. Pore fluid age, based on the calculated ^{4}He production rate and measured He concentrations in the shales, indicates accumulation over ~ 200 Ma. In the very low permeability limestones the calculated *in situ* xRa of 0.001 to 0.004 suggests an allochthonous He source. The xRa value of 0.036 measured in the limestones was indistinguishable from that measured in the thin basal Cambrian sandstone aquifer groundwater collected during the study. This value may be explained by a mixture of a mantle ^{3}He-enriched end member derived from the rifted base of the Michigan Basin and He from the Canadian Shield.

Isotopic data from the Pomarinho enclave swarm (SW Iberian Chain)

P. MOITA[1], J.F. SANTOS[2] AND P. SILVA[3]

[1]HERCULES, CGE, Univ. Évora (pmoita@uevora.pt)
[2]GeoBiotec, Univ. de Aveiro (jfsantos@ua.pt)
[3]IDL, ISEL, Lisboa (pmsilva@fc.ul.pt)

Mafic microgranular enclaves are a common feature of calc-alkaline granitoids (e.g. tonalites and granodiorites) in active continental margins and collisional orogens. They correspond to dark-coloured globules that, although widespread throughout the host rock, usually constitute only a small proportion of the whole volume of the intrusion. When the enclaves occur strongly concentrated in a restricted area, they form an enclave swarm (e.g. [3]). At Pomarinho, the Granialpa quarry is a privileged exposure of a cluster of dark igneous enclaves that has been targeted for geochemical and geophysical studies (GeoRadar and AMS).

The Pomarinho swarm is located in the SW edge of Évora granitoid (Carvalhosa, 1983), in the Portuguese sector of the Ossa-Morena Zone (Iberian Variscides). The enclaves have tonalitic and granodioritic compositions, whereas the host correspond to a very homogeneous light-coloured granodiorite. Preliminary geochemical information, based on major and trace elements [2], suggests that the enclaves and the host rock are probably derived from co-genetic magmas.

Rb-Sr isotope data now obtained in four enclaves and three host-rock samples yield an isochron corresponding to 335±14Ma (MSWD=0.96), which fits into the spectrum of ages of the Variscan granitoids in the region. Additionally, the homogeneity of both $^{87}Sr/^{86}Sr_{335}$ (0.704758 to 0.705133) and εNd_{335} (-0.10 to 1.13) values corroborates the hypothesis of derivation of the enclaves and the host granodiorite from a common primitive melt through magmatic differentiation. Low $^{87}Sr/^{86}Sr_{335}$ and high εNd_{335} values suggest that ultimately the parental melt is related to a mantle source, with no or only small contribution of metasedimentary crustal materials.

Compiled U-Pb zircon ages of the oldest components of the Acasta Gneiss Complex (AGC) on the western margin of the Archean Slave Province [1] span 4.05-3.90 Ga [2-5]; even older (4.2 Ga) ages [2, 3] have also been noted. AGC outcrops cover a large (>50 km) area across several domal basement antiforms, but only a small subset of these is documented. We report ion microprobe conventional 2-D spot and 3-D depth-profile geochronology coupled with whole-rock (WR) and zircon REE and Ti thermometry, in petrographic thin sections and from mineral separates, of a diverse suite of AGC lithologies including orthogneisses and gabbroic hornblende schist enclaves. Samples were collected from photo-mapped outcrops (1:25) to guide sampling. Discrete cm-scale gneissic domains show distinctive $[Th/U]_{zirc}$ vs. $[Ti]_{zirc}$ temperatures correlative with zircon U-Pb ages and rock compositions. We used lattice-strain theory to model zircon/WR REE of zircon domains (cores/rims) in different generations of gneisses and relate these to ages of original igneous emplacement and subsequent polyphase metamorphic histories. We confirm that the earliest geological history of the AGC is at 4.2 Ga, followed by magmatic incursions at mid-crustal depths (4.05-4.02 Ga) and thermal modifications at 3.96-3.85 Ga concurrent with some lunar basin formation ages. Eoarchean AGC ages (3.74-3.72) are also preserved, contemporaneous with documented emplacement times for the 3.85-3.71 Ga Itsaq Gneiss Complex in West Greenland [6] and 3.78-3.75 Ga Nuvvuagittuq belt in northern Québec [7].

REE geochemistry of iron-apatite deposits in Central Iran

M.A.A. MOKHTARI[1], M.H. EMAMI[1], N. ABEDIAN[1], M. KHEZRI[1] AND J. BABUREK[2]

[1]Geological survey of Iran, Exploration, Regional exploration group (Mokhtari1031@gmail.com)
[2]Czech geological Survey (Jiri.baburek@geology.cz)

REEs in different ore types display characteristic patterns, related to different modes of formation of the ore. The apatites of iron- apatite ores of Bafq region (Central Iran) show a strong LREE/HREE ratio and a pronounced negative Eu anomaly. This pattern is a distinct characteristic of igneous apatites. Mentioned REE pattern is similar to that of apatites from Kiruna iron ore and the other Kiruna- type iron ores in elsewhere of the world.

In the all Iron-Apatite deposits of Central Iran, the REE patterns of apatites, phosphate- bearing iron ores and iron ores with no or very little phosphate, are similar and have a different REE contents. This similarity indicates a common source for these rocks and deposits. On the other hand, the REE patterns of granitic intrusions which are located adjacent to the iron-apatite ores have a similar REE patterns to that of iron- apatite ores. This similarity, in turn, also indicates a genetic relation for these rocks.

In general, it can be consider a basic alkaline magma rich in iron and some incompatible elements such as P, REE, Th-U, Cl and F, have been parent magma for Iron-Apatite ores and granitic intrusions. This parent magma had been differentiated into immiscible silicate- oxide- phosphate units in route of ascend to the earth's surface.

Modelling of nanoparticles: Aggregation of oxides and hydroxides

M. MOLINARI[1]* D.C. SAYLE[2] AND S.C. PARKER[1]

[1]Dept. of Chemistry, University of Bath, Bath, BA2 7AY, UK (*correspondence: m.molinari@bath.ac.uk)
[2]Dept. of Engineering and Applied Science, Cranfield University, Shrivenham, SN6 8LA, UK

We use molecular dynamics simulations to study the aggregation of CeO_2 (ceria) and $Mg(OH)_2$ (brucite) nanoparticles (NPs). Calculations are running in vacuum and in water in order to include the effect the solvent during aggregation. We employ the DL_POLY code [1] and a potential model fitted in the METADISE [2] and the GULP [3] codes against *ab initio* data derived using the VASP code [4]. We use ceria, an extended solid oxide, and brucite, a layered material, as models. Forcing oriented aggregation during the crystal growth of such important materials for catalysis and sorption processes can facilitate the production of tailor-made structures with enhanced properties.

The free energy change due to aggregation NPs can be evaluated considering different interparticle orientations. Results for 1ns run for ceria NPs in vacuum are shown in Figure 1. The calculations predict no free energy barrier to aggregation when the NPs approach along crystallographic orientations as previously reported by Spagnoli *et al*. [5]. Finally, a comparison between aggregation in dry and wet conditions is considered.

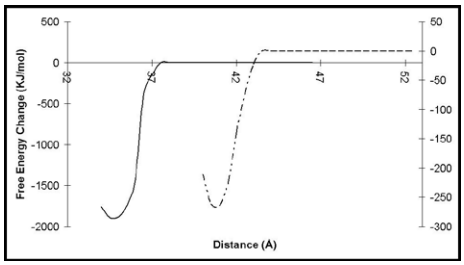

Figure 1: Free energy change of aggregation as a function of distance for a 5nm diameter octahedral CeO_2 NPs with a fixed orientations: dashed line, approaching edges; solid line, approaching faces.

Direct pore-scale numerical simulation of precipitation and dissolution

S. MOLINS*, D.B. SILIN, D. TREBOTICH AND C.I .STEEFEL

Lawrence Berkeley National Laboratory 1 Cyclotron Road, Berkeley, CA 94720 USA (*correspondence: SMolins@lbl.gov, MS 90R1116) (DSilin@lbl.gov, DPTrebotich@lbl.gov, CISteefel@lbl.gov)

Mineral precipitation and dissolution driven by field applications such as carbon sequestration or remediation strategies can modify the geometry and structure of porous media in relatively short time scales. In this context, feedback processes between geochemical reactions and flow that take place at the pore scale affect continuum scale parameters such as permeability or reaction rates. Beyond the insights gained by innovative experimental and imaging techniques such as x-ray computed micro-tomography, modeling provides a unique tool to mechanistically understand and quantify these feedback processes at the pore scale and inform continuum scale models. In this work, we develop strategies to perform efficient direct numerical simulation of flow and reactive transport on idealized and complex pore scale geometries building on existing platforms. We apply these approaches to a range of pore geometries from single pores to 1-cm-long columns to calculate average reactions rates and porosity-permeability evolution and illustrate model capabilities and limitations.

Simulations show that dissolution and precipitation reactions affect the pore space nonuniformly. As a result, a simple porosity-permeability correlation may be insufficient to describe the complexity of the reaction-induced pore space evolution. The relative magnitude of the reaction rate constants affects the evolution of the permeability-porosity relationship. In dissolution simulations, fast reactions result in localized effects and further evolution of permeability is relatively unaffected by subsequent porosity increase. In contrast, slow reactions cause a less localized dissolution, with the result that the permeability increase is consistent with the porosity increment. Simulations show that in columns with the same average parameters, including column porosity, reactive surface area, and flow rate, different pore structures with different flow patterns can result in different average reactions rates.

Sequential coupling between transport and geochemical reactions allowed us to use an efficient and flexible computational fluid dynamics platform that implements higher-order algorithms, while implicit coupling shows promising results for efficient simulation of pore geometry evolution. We discuss further model development for interpretation of experimental results.

Genetic relation between Skarn ore deposits and magmatic activity in the Ahar region, Western Albuorz, northwest of Iran: Evidence for metasomatism and copper mineralization

HABIB MOLLAEI AND RAHIM DABIRI

Department of Geology, Mashhad Branch. Islamic Azad University, Mashhad -Iran. Office Phone No.: 0098 5118446361 (mollai@mshdiau.ac.ir)

Numerous skarn deposits formed in the contact between the Upper Cretaceous impure carbonate rocks and Oligocene–Miocene Magmatic rocks in the Ahar region. The aim of this study is to understand how magmatic activity led to the copper skarn mineralization in this region. The history of skarn formation starts with the emplacement and upwelling pluton body, followed by the assimilation of limestone by the magma. The skarnification process occurred mainly in two stages: the first stage is starting with prograde metasomatism and anhydrous minerals, this stage followed by four stages of retrograde skarn deposit. In addition to Fe, Si and Mg, substantial amounts of Cu, along with volatile components such as H_2S and CO_2 were added to the skarn system. Consequently considerable amounts of hydrous calc-silicates, sulfides, oxides and carbonates replaced the anhydrous calc-silicates and the chemistry of the host granodiorites, Mineralogical and chemical characteristic indicate that an island arc or Subduction-related origin of Fe-Cu skarn deposit.

Thermodynamic models of aqueous systems to high temperature and concentration

N. MOLLER* AND J.H. WEARE

Chemistry and Biochemistry, UCSD, San Diego, CA, 92093 (*correspondence: nweare@ucsd.edu)

We have developed thermodynamic models, using the Pitzer specific interaction equations, that describe interactions as well as solid-liquid-gas equilibria to high temperature and concentration within the H^+, Na^+, K^+, Ca^{2+}, Mg^{2+}, Al^{3+}, Al $(OH)^{2+}$, Al $(OH)_2^+$, Al $(OH)_3^0$, Al $(OH)_4^-$ Cl^-, OH^-, HSO_4^-, SO_4^{2-}, HCO_3^-, CO_3^{2-}, Si $(OH)_4$, SiO $(OH)_3^-$, SiO_2 (aq), CO_2 (aq/g), H_2S (aq/g), CH_3 (aq/g), H_2O system. In this presentation, the construction of two models that produce predictions with accuracy near the uncertainty of the experiments is discussed. One, correctly calculates solute/solvent activities and solid-liquid equilibria in the H-Na-K-OH-Cl-HSO_4-SO_4-H_2O system from dilute to high solution concentration and from low to high pH within the 0° to 250°C temperature range. The other correctly predicts solvent/solute activities and monomeric aluminum hydrolysis speciation as well as solid-liquid equilibria in the H^+, Na^+, Al^{3+}, Cl^-, Si $(OH)_4$, SiO $(OH)_3^-$, OH^-, Al $(OH)^{2+}$, Al $(OH)_2^+$, Al $(OH)_3^0$, Al $(OH)_4^-$ system as a function of pH to high salt concentrations ($I \leq 5$ m NaCl), for temperatures up to 300°C and for saturation pressures. The latter model accurately predicts the fluid compositions for the low Al ($\leq 10^{-5}$ m) and Si $(OH)_4$ ($\leq 10^{-4}$ m) concentrations commonly encountered in the intermediate pH ranges typical of most natural fluids. For high and low pH regions where the formation of polymeric Al hydrolysis species is low, the model will apply to higher total aluminum concentrations. The successful prediction of the solubility of aluminiosilicate solid phases falling within this system is also described.

REE in groundwater as indicators of catchment lithology in semi-arid regions

P. MÖLLER[1], C. SIEBERT[2] AND S. GEYER[2]

[1]Helmholtz Zentrum Potsdam, Deutsches GeoForschungsZentrum, D-14473 Potsdam

[2]Helmholtz Center for Environmental Research-UFZ, Halle/Saale 06120, Germany

REE in groundwater (GW) in regions with little soil coverage characterize the lithology of its recharge area because interaction of precipitation with soil coverage is short to absent. Under such conditions the dissolution of minerals in the catchment area becomes an important tool in particular in regions with dominant transboundary GW flow in politically unstable regions.

REE patterns in GW recharged over limestones resemble those of the limestones. GW recharged over olivine bearing basalts yield REE patterns that are controlled by dissolution of the least stable minerals such as olivine and by scavenging during weathering by ferric hydroxides and calcite. Bowl-shaped REE patterns are typical. REE in GW from sandstones are controlled by leachable minerals of their cements. In the presences of gypsum and phosphates the intermediate REE are enriched in GW.

REE in GW from aquifers of the same lithology of fthe recharge area are controlled by strong sorption of REE onto mineral surfaces. In case of limestones overlaying basalts the GW from basalts shows nearly the same pattern as in GW from the limestone above because the high REE abundance in GW is adsorbed by minerals of the basalt and thus with time GW passes the basalt without significant changes. In case of basalts overlaying limestones the REE abundance in the final GW is lower than expected from interaction with limestones. Due to high Ca and Mg concentration from weathering of plagioclase and olivine in basalts dissolution of calcite from limestones is limited and thus the REE patterns achieved from the basalt is not significantly altered during the passage of limestone.

Mineral textures and fluid inclusion characteristics of ore samples from the Guanajuato district, Mexico

D. MONCADA* AND R.J. BODNAR

Dept. of Geosciences, Virginia Tech, Blacksburg, VA 24061 USA (*correspondence: moncada@vt.edu, rjb@vt.edu)

Successful exploration for mineral deposits requires tools that the explorationist can use to distinguish between targets with high potential for mineralization and those with lower economic potential. In this study, we describe a technique based on petrographic and fluid inclusion characteristics that may be applied in exploration for precious metal deposits to identify areas of high-grade mineralization.

The Guanajuato mining district in Mexico is one of the largest silver producing districts in the world with continuous mining activity for nearly 500 years. Ore shoots in the district are localized along three major northwest trending vein systems, the La Luz, the Veta Madre and the Vetas de la Sierra. Mineralization in the district shows much variability between and within individual deposits, from precious metal-rich to more base-metal-rich zones, and from gold-rich to silver-rich zones. Ore textures also vary and include void space that formed during multiple fissuring events, banded quartz veins, massive quartz veins and stockworks. More than 1, 200 samples representing all the different mineralization styles were collected from all three vein systems in the Guanajuato mining district, and the mineral textures and fluid inclusion characteristics of each sample have been defined. In addition, each sample was assayed for Au, Ag, Cu, Pb, Zn, As and Sb.

Samples from the Guanajuato district show a wide range in silica textures. Some of these textures, including colloform texture, plumose texture and jigsaw texture, are indicative of rapid precipitation, such as occurs when fluids boil. Other mineral phases, including illite, rhombic adularia and bladed calcite are also indicative of rapid growth in a hydrothermal system and are characteristic of boiling systems. Because boiling is an effective mechanism for precipitating gold and silver from hydrothermal fluids, the presence of mineral textures indicative of boiling is a desirable feature in exploration. In many samples, textural evidence for boiling is supported by coexisting liquid-rich and vapor-rich fluid inclusions, or Fluid Inclusion Assemblages consisting of only vapor-rich inclusions, suggesting 'flashing' of the hydrothermal fluids. Textural and fluid inclusion evidence for boiling has been observed in the deepest levels of the Guanajuato mining district, suggesting that additional precious metal resources may occur beneath these levels.

Sulfide mineralogy of West Greenland kimberlitic mantle xenoliths

SISIR K. MONDAL[1]*, STEFAN BERNSTEIN[2] AND MINIK T. ROSING[2]

[1]Department of Geological Sciences, Jadavpur University, Kolkata-700032, India (*correspondence: sisir.mondal@gmail.com)

[2]Natural History Museum of Denmark, University of Copenhagen, 1350 Copenhagen, Denmark (sb@avannaa.com, Minik@snm.ku.dk)

Sulfide minerals control the platinum group element (PGE) budget of mantle rocks along with PGE behaviour during melting and thus trace the Earth's differentiation processes. We have conducted mineralogical study of the sulfide assemblages of mantle xenoliths sampled from two West Greenland kimberlites dykes of presumed Neoproterozoic age. One dyke from the Sarfartoq area, is situated in 2.8 Ga continental crust, and part of the ca. 1.8 Ga Nagsoqtoqidian mobile belt. The second kimberlite dyke comes from the Aasivik terrain which represent early Archaean, 3.5 to 3.7 Ga crust. The Sarfartoq- and Aasivik-dykes can therefore be classified as Proton and Archon, respectively. The xenoliths from the Sarfartoq kimberlite dyke are relatively fresh but commonly contain pockets of fine-grained magnetite, mica and hydrothermally altered silicates interpreted to represent melts invaded from the kimberlitic host. The Sarfartoq-dyke xenoliths are garnet-lherzolite (olivine Fo 86.8-91.1), garnet-dunite (olivine Fo 90.1-91.2), spinel-dunite (olivine Fo 91.4-93.0) and dunite (olivine Fo 89.2-92.5). Sulfide minerals are present as rounded blobs mostly within olivine and rarely within garnet and clinopyroxene. Minor amount of interstitial sulfide is also present. Both types commonly occur in a single sample. Blobs are dominated by pentlandite with minor chalcopyrite and pyrrhotite and veined by late generated magnetite. The xenoliths from the Aasivik kimberlite dyke are nearly all extensively altered and appear to be mostly dunite (olivine Fo 87.8-92.5). Only relicts of olivine grains are present, and these contain blobs of sulfides as inclusions. Our study suggests that the sulfide was initially monosulfide solid solution, re-equilibrated at low temperature.

The Pan-African reconstruction of NW Angola: Petro-structural and temporal constraints

P. MONIÉ[1], D. BOSCH[1], O. BRUGUIER[1], A. VAUCHEZ[1], P. NSUNGANI[1,2] AND Y. ROLLAND[3]

[1]Géosciences Montpellier, UMR-CNRS-5243, Univ. Montpellier 2, Place E. Bataillon, 34095 Montpellier, Cedex 05, France (bosch@gm.univ-montp2.fr)
[2]Agostinho Neto University, Avenida 4 de Fevereiro 7, Luanda, Angola
[3]Géosciences Azur, UMR 6526 CNRS, Université de Nice Sophia Antipolis, Parc Valrose, 06108 Nice cedex 2 – France

At the end of Neoproterozoic times, assembly of the Gondwana supercontinent resulted in the closure of several oceanic domains and accretion of large cratons. Various tectono-metamorphic belts developed et the margins of these cratons during the Panafrican orogeny. During this work, we developed a study combining petro-structural and geochronological investigations on the West Congolian belt (NW Angola) resulting from the collision between the Congo and Sao Francisco cratons. Two main tectono-metamorphic units have been recognized in the studied area, namely eastern and western internal units, and show a westward increase of deformation and metamorphic grade. The WIU consists of high-grade gneisses and migmatites with intercalation of amphibolites, quartzites and pegmatites. This sub-unit experienced metamorphic conditions that increase upward and westward. Maximum P-T conditions for high-grade gneisses have been estimated at 10-12 Kbar and 600-650°C. One garnet amphibolite intercalated with gneisses has been dated and yields ages of 539±7Ma and 498±5Ma for U-Pb and Ar-Ar methods, respectively. A pegmatitic dyke concordant to the regional foliation provides a concordant U-Pb age of 544±13Ma taken as our best estimate for pegmatite emplacement. Two paragneisses have been also dated with ages ranging from 589±12Ma to 678±48Ma suggesting a detrital origine and indicating that detritus was derived from Neoproterozoic source material. At least monazites from one of this gneiss show a complex U-Pb age distribution (three batches between 560-490Ma) and Ar-Ar biotite age of 487±5Ma. All this age underlines the predominance of the Pan-African deformation and metamorphism in the construction of this belt.

Characterization of hyperalkaline fluids produced by serpentinization of mantle peridotites in Oman and in Liguria (Northern Italy)

C. MONNIN*, V. CHAVAGNAC, G. CEULENEER, C. BOULART AND G. HOAREAU

Geosciences Environement Toulouse, 14 Avenue Edouard Belin, 31400 Toulouse, France (*correspondence: monnin@get.obs-mip.fr)

High pH waters and gases produced by serpentinization of mantle peridotites as well as precipitates forming at the springs have been sampled between 2008 and 2011 in the Semail nappe of the Oman Mountains and the Voltri group of the Ligurian Alps (Northern Italy).

Factors influencing the composition of the hyperalkaline waters are: 1) alteration of the ultramafic basement, 2) formation of precipitates at the water discharge, 3) interaction of the waters with the atmosphere, 4) mixing with surface (runoff) waters, 5) concentration by evaporation.

In Oman the springs are located along major geological discontinuities (Moho, basal contact between the ophiolite and the underlying Cretaceous sedimentary formations).
The increase in the Na, K and Ca contents of the Oman waters with chlorinity cannot be explained by evaporation, pointing to the reactivity of these elements (formation of clays and Ca-carbonates).

In Liguria, the alkaline springs are located above the river beds and their waters do not mix with the river waters. In Oman this mixing leads to a continuous range of pH from the normal runoff (6 to 8) and the extreme values (12.1). In this case, the pH change can be very rapid (dropping by two pH units in half a meter at the site 'Grande Ligurie'). Conversely the pH drop of the alkaline waters collected in the irrigation channels (falaj) is very slow, being due to the sole uptake of atmospheric CO_2.

Minerals forming at the springs are mainly calcite, aragonite and brucite.

Larger values of the H_2 content of the gas phase bubbling at the springs are found in Oman while CH_4 is more important in Liguria.

The reaction of the infiltrating surface waters with the ultramafic formation almost entirely removes the Dissolved Inorganic Carbon indicating that the alteration of ophiolites is indeed an efficient sink for carbon.

Our observations ask the question of the hydrologic pathways of the water in ophiolites: percolation through the ultramafic formation or circulation along major geological discontinuities?

Towards modelling biogenic magnetite, Fe_3O_4

AMY MONNINGTON[1], DAVID J COOKE[1] AND COLIN L FREEMAN[2]

[1]Department of Chemical and Biological Sciences, University of Huddersfield, UK (Amy.Monnington@hud.ac.uk)
[2]Department of Engineering Materials, University of Sheffield, UK (c.l.freeman@sheffield.ac.uk)

There is an increasing number of new, exciting and dynamic uses for magnetic nanoparticles (MNPs), including many in the field of medicine (site-specific chemotherapy), technology (spintronics) and industry (ferrofluids). Magnetotactic bacteria produce chains of nanosized magnetite, Fe_3O_4, particles that operate as internal magnets. This biosynthesis of magnetite is the earliest known example of biomineralisation, having first occured some two billion years ago. Despite this, much of the detailed atomistic mechanism by which the process occurs is unknown. Therefore, we have begun to develop an atomistic model for the system, in an attempt to understand the processes involved, particularly the role of the 1-5% Co that is present in the biomineral.

In this work we report initial results for modelling the different surfaces of magnetite, using differing methods. Comparison of the related surface energies produced for these methods, using energy minimisation (METADISE [1]) and molecular dynamics (DL_POLY [2]), identified the {100} surface as the most stable. For all methods, elasticity constants were compared to the data produced from previous studies [3]. Subsequent to this, attachments of simple organic molecules to the magnetite were analysed and modelling of interactions between these molecules and the {100} surface were performed.

Future work will validate the potentials for the interactions between the simple organic molecules and the magnetite surface, enabling us to fit the required organic/ inorganic cross parameters to a system where the stable surfaces are well defined, allowing us to better access the validity of each of the components of the model. This is in the aim of progressing to more complex protein attachments.

Neodymium isotopic composition of gorgonian corals as reliable tool to reconstruct water mass circulation

P. MONTAGNA[1,2,3]*, M. LOPEZ CORREA[4], S. GOLDSTEIN[2], M.T. MCCULLOCH[5], A. FREIWALD[6], M. TAVIANI[3], J.A. TROTTER[5] AND J. RADDATZ[7]

It has recently been shown that intermediate and deep ocean circulation can be reliably reconstructed using the neodymium (Nd) isotopic composition of the aragonitic skeleton of scleractinian deep-water corals [1,2,3,4]. Motivated by these findings, we have investigated the Nd systematics of the high-magnesium calcite skeleton of deep-water gorgonian octocorals. These corals have centennial-scale lifespans and are distributed worldwide, representing potential archives of past oceanic circulation at sub-decadal resolution. Live-collected corals, belonging to the families *Isididae* (genus *Keratoisis*) and *Coralliidae* (genus *Corallium)*, were retrieved from the Atlantic, Pacific, and Southern Oceans as well as from the Mediterranean Sea at water depths between ~500 to ~1300m. Seawater samples from two profiles in the Mediterranean Sea were collected at the same locations and depths as the coral samples in order to compare seawater Nd isotopic compositions with the coral skeletons. The isotopic ratio ($^{143}Nd/^{144}Nd$) was obtained using a VG Sector 54-30 thermal ionization mass spectrometer by dynamic multicollection. The neodymium concentration was analysed along different tracks parallel to the growth bands using a 193nm laser ablation microsampling system connected to a Varian 820 inductively coupled plasma mass spectrometer.

The gorgonian calcite skeletons and the surrounding seawater share equivalent Nd isotopic compositions, which clearly show that these calcite corals are reliable archives of water mass circulation.

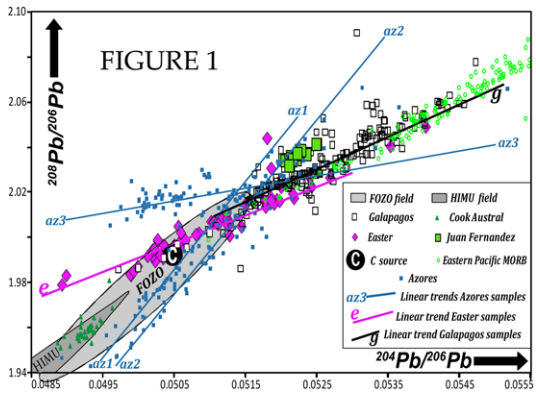
OIB's from South Eastern Pacific: Notes from key geochemical features

P. MONTECINOS MUÑOZ* AND K. PINTO LOGUERCIO

Emilio Vaisse 332c, Santiago, Chile
(*correspondence: pmonteci@gmail.com)

We summarize some geochemical features of basalts from Easter, Juan Fernandez and Galapagos. Data were obtained from GEOROC on March 2011. Elemental concentration were normalized to primitive mantle displaying strong enrichment for Juan Fernandez ($[U]_N$~98, $[Pb]_N$~49, $[Th]_N$~40, $[Nb]_N$~70, $[Ta]_N$~78) similar to EM2 source [1]. Easter and Galapagos exhibit a moderately enrichment for Nb and Ta ($[Nb]_N$~35,$[Ta]_N$~50), and small enrichment for U, Pb, Th ($[U]_N$~22,$[Pb]_N$~9,$[Th]_N$~17). These enrichment factors are less than those for samples from EM and HIMU sources, and the $[U/Pb]_N$ and $[Th/Pb]_N$ ratios of Easter and Galapagos are different from EM and HIMU sources, suggesting that the sources of the two islands contain Pb whose origins were not explained by subduction-related process invoked for EM2 [1] and HIMU [2].

That statement is supported by Pb isotopes plotted on a ^{206}Pb-normalized space (Fig. 1). In this plot a linear trend composed by ~90% of Easter (**Line e**) is noticeable. Principal component analysis calculation shows that Line e is an eigenvector explaining a 94% of variability of Easter. Some Easter samples are outside FOZO field [3] suggesting influence from DM source and possibly other extreme component located at left beyond FOZO. Azores samples composing Az3 line (Fig.1) seems to confirm such extreme component. Az1-Az2 lines go beyond Fozo field suggesting another possible component different to HIMU and FOZO.



We thank to Professor Shun'ichi Nakai (University of Tokyo) by his suggestions.

Style and chronology of growth by oblique accretion and oroclinal bending: The Panama Isthmus

C. MONTES*[1,2], A. CARDONA[1,2], G.A. BAYONA[2], R. MCFADDEN[1], S.E. MORON[1], C.A. SILVA[1], S.RESTEPO-MORENO[1] AND D.A. RAMIREZ[1]

[1]Smithsonian Tropical Research Institute, Box 0843-03092, Balboa, Ancon Republic of Panama, (montesc@si.edu)
[2]Corporación Geológica Ares, Calle 44a # 53-96, Bogotá, Colombia

The Panama Isthums displays, in approximatley 500 km (or ~15 Ma), the transition from: 1) ongoing subduction and magmatism in a normal intra-oceanic arc setting; 2) a deformed, exhumed and extinct magmatic arc, still in an intraoceanic setting, and 3) an extinct arc accreted to a continental margin. This west to east geographic progression from active arc to accreted is also a proxy for the chronology of this arc-continent collisions. The oblique accretion of the Panama arc to northwestern South America is documented with geologic mapping and multidisciplinary analytical studies. A new geologic map with >2000 field stations, 40 petrographic analyses, 24 paleomagnetic sites, and over 30 new geochronological and thermochronological analyses, supports the middle Miocene accretion of the Panama arc to northwestern South America and a late Eocene initiation of tectonic interaction. The extinct arc segment in central Panama arc is composed of a folded-faulted, ~ 3 km-thick basaltic sequence, intruded by granitoid bodies and onlapped by mostly undeformed shallow marine and continental strata. Existing geochronological data, and new whole-rock Ar/Ar (2), and U/Pb zircon ages (6), reveal intense late Paleocene to middle Eocene magmatism, a temporary cessation of magmatic activity between 38 and 28 Ma, and renewed magmatism after 28 Ma in a position approximately 75 km south of the former magmatic axis in central Panama. The geographic patterns of these magmatic pulses is interpreted as a collison that left-laterally offset, and oroclinally bent the axis of the arc, and terminated magmatic activity in the 28 to 38 Ma interval. Magmatic activity restarted after 28 Ma but lasted only until ~15 Ma east of the Canal Basin and west of the Uramita suture, defining an arc segment approximately 400 km in length that shows no sign of magmatic activity younger than 15 Ma, probably the result of this part of the arc getting detached and overthrusted the Caribbean Plate to the north. The sigmoidal part of the Panama arc is therefore the result of an extinct arc that has been obliquely accreting to the northwestern margin of South America for the last 15 Ma.

Nucleation and growth of acicular goethite from ferric hydroxide gel under moderate temperature (30 and 70°C)

G. MONTES-HERNANDEZ[1]*, P. BECK[2], F. RENARD[1], E. QUIRICO[2], B. LANSON[1], R. CHIRIAC[3] AND N. FINDLING[2]

[1]CNRS-UJF, Institute of Earth Sciences (ISTerre), OSUG/INSU, BP 53, 38041 Grenoble Cedex 9, France (*german.montes-hernandez@obs.ujf-grenoble.fr)

[2]CNRS-UJF, IPAG, OSUG/INSU, BP 53, 38041 Grenoble Cedex 9, France

[3]Laboratoire des Multimatériaux et Interfaces UMR CNRS 5615, 43 bd du 11 novembre 1918, 69622 Villeurbanne Cedex, France

The present study describes a simple and novel synthesis route for sub-micrometric acicular goethite (α-FeOOH) using high OH/Fe molar ratio (=5) and moderate temperature (30 and 70°C). Two different alkaline sources (NaOH and Ca $(OH)_2$) and two iron (III) sources ($FeCl_3.6H_2O$ and Fe $(NO_3)_3.9H_2O$) were investigated. FESEM, XRD, FTIR, N_2 sorption isotherms, colour evolution and pH monitoring have been used to determine the formation mechanism, the particle size, specific surface area, and morphology of goethite. Three pH regions were determined during goethite formation and each region was qualitatively associated to (I) the formation of ferric hydroxide gel, leading to acid conditions (pH<2.5); (II) spontaneous nucleation of goethite, leading to alkaline conditions (pH>11) and fine sedimentable particles; (III) growth of goethite in alkaline conditions (11<pH<13.5). The kinetic behaviour depends clearly on the reaction temperature; globally the nucleation-growth of goethite at 70 °C was about three times faster than at 30 °C. For example, well-crystallized goethite particles (high acicular goethite < 1μm in length with moderate specific surface area, S_{BET}=31.2m^2/g) were produced after 7h of reaction at 70 °C while about 24h of reaction are required to produce well-crystallized goethite particles (low acicular goethite < 0.5μm in length with high specific surface area, S_{BET}=133.8m^2/g) at 30 °C using in both cases iron chloride. In summary, the temperature and iron (III) source have a significant effect on the particle size, specific surface area and morphology of goethite. Herein, single-phase goethite particles were formed. When Ca $(OH)_2$ particles are used as alkaline source, a complex mineral composite with high specific surface area (87.3 m^2/g) was synthesized; this powdered material was mainly composed of unreacted Ca $(OH)_2$ coated by nanosized particles (possibly amorphous iron hydroxide), calcium iron oxide chloride hydrate and calcite. The best conditions to prepare uniform goethite particles, possibly with high potential as adsorbents or pigments, have been established.

Uncertainty assessment in quantification of silicate weathering rates in global rivers

SEULGI MOON[1]*, C. PAGE CHAMBERLAIN[2] AND GEORGE E. HILLEY[1]

[1]Department of Geological and Environmental Sciences, Stanford University, Stanford, CA 94305, USA (*correspondence: sgmoon@stanford.edu, hilley@stanford.edu)

[2]Department of Environmental Earth System Science, Stanford University, Stanford, CA 94305, USA Department of Geology, University of California, Davis, CA 95616 (chamb@stanford.edu)

Chemical weathering is important for understanding landscape evolution, nutrient supply to ecosystems, and global geochemical cycles. Total silicate weathering fluxes to oceans have been quantified using compilations of catchment-wide measurements of concentration and water discharge [1-3]. Sources of chemical elements were differentiated using geochemical mass balance models (forward and inverse models) to partition the fluxes of each of the measured elements into carbonate, silicate, evaporite, and rain-water pools.

In this research, we analyze time-series of elemental concentrations and discharge from 52 global rivers provided by the GEMS/Water compilation, which together constitute a database of ~9000 data points. With these comprehensive datasets, we estimate uncertainties within silicate weathering rates in global rivers that consider the effects of infrequent sampling, covariation between river discharge and concentration, and uniqueness of attribution of weathering fluxes to the different pools. This is accomplished using a Bayesian Metrolpolis-Hastings algorithm to estimate the overall uncertainties within, and covaration between weathering fluxes that are attributed to the different pools based on the GEMS/Water database. Knowing the overall uncertainties in global estimates will provide information about required sampling frequencies, number of sites, and chemical elements that will help to design future catchment-scale studies.

The origin of Darreh-Zanjir lead-zinc Deposit, 'Central Iran'

F. MOORE, E. SAJEDIAN, B. TAGHIPOUR

Department of Earth Science, College of Science, Shiraz University, Shiraz, Iran

The Darreh-Zanjir Zn-Pb deposit is located 25 km south-west of Yazd province within Cenozoic magmatic belt of central Iran. It occurs in the Lower Cretaceous dolomitized limestones of Taft Formation and is underlained by Albian shales of Biabanak Formation. A major fault known as Darreh-Zanjir thrust fault is associated with minor faults and trending east, north-east seems to control the mineralization. This fault is also responsible for pushing Lower Cretaceous carbonate strata over the older Albian shales. Cretaceous dolomite formed by metasomatism of Lower Cretaceous orbitolinous limestone, hosts the Pb-Zn mineralization.

The carbonated-hosted epigenetic mineralization consists of primary galena and sphalerite and secondary carbonates such as cerussite and smithsonite. The principal type of mineralization is irregular, open space filling, forming vein and stockworks. Two stages of mineralization are indicated. The first being the dolomitization of limestone followed by invasion of metal-bearing hydrothermal solutions. Mineralization is confined to fault planes, fractures and their margins. Several factors including geologic setting, lithology, and hydrothermal solutions have played a role in the mineralization. Minor faults and fractures have also provided suitable conditions for secondary dolomitization and mineralization. Field observations, mineralogy and geochemical investigations show that Darreh-Zanjir Pb-Zn deposit is a Mississippi Valley Type deposit.

Natural attenuation of metal contaminants in a large mine-impacted river: A long-term case study of temporal and spatial trends

J.N. MOORE AND H.W. LANGNER*

University of Montana, Missoula, MT 59812-1296, USA (*correspondence: heiko.langner@umontana.edu)

We conducted a 20-yr study to determine environmental trends in a mine-impacted watershed in Northwestern Montana, USA. About 100 million tons of waste from copper and precious metals mining were disposed of in the headwaters of the Clark Fork River (CFR) between 1880 and 1982. Large amounts of contaminated material were transported downstream and deposited on the floodplain, where it acts as a secondary source of contamination to the river. Our study focuses on spatial and temporal trends of As, Cu, Cd, Pb and Zn in fine-grained bed sediments along a 200-km river section below a set of tailings ponds that were constructed to cut off the source of contaminants upstream. Remediation in this section has been minimal, providing an excellent area to study natural attenuation of contamination. We collected monthly sediment samples from three locations for most months between 1991 and 2010. In addition, four sets of about 40 sediment samples were collected longitudinally in 1991, 1998, 2001 and 2009. The longitudinal concentration profiles showed decreasing contaminant concentrations, with temporal trends being less obvious than for monthly samples at the three sites. Initial concentrations for As, Cd, Cu, Pb and Zn at the most upstream monthly sampling site were 140, 8.3, 1400, 220, 1500 mg/kg, respectively, in 1991. Monthly samples for all elements and sites trended down over time following a first-order exponential decay model. However, half-lives of sediment concentrations differed considerably between elements, suggesting element-specific processes affecting their transport and retention in the system. Half-lives for Cd were 10 ± 0.5 yr for the three locations in the watershed. Half-lives for Cu, Pb and Zn were 22 ± 5 yr, and for As 35 ± 10 yr. Our monthly sampling also revealed high variability without obvious relationships to seasonal or annual variations of the hydrograph, showing that sediment sampling in long intervals (e.g. annually) is insufficient to accurately estimate trends. Our exponential 'decay' model predicts when acceptable contaminant levels will occur without human intervention. Thus, these results may assist with the selection of cleanup strategies, for example where natural mixing and transport processes may be preferable over engineering approaches to remediation.

The lower regolith boundary revisited in unmatched detail with a new global lithological map

NILS MOOSDORF, JENS HARTMANN AND RONNY LAUERWALD

Institute for Biogeochemistry and Marine Chemistry, KlimaCampus, University of Hamburg, Bundesstrasse 55, 20146 Hamburg, Germany (nils@moosdorf.de)

Bedrock is the lower boundary of the regolith column. It represents one control on regolith formation. For this bedrock types and properties are more relevant than its age, which most geological maps focus on. A new high-resolution global lithological map (GLiM) could provide a valuable tool for global analyses of the regolith zone.

GLiM consists now of more than one million polygons that were assembled from more than 65 geological maps; some natively in digital format, some digitized by hand. Most of the maps are at a scale of 1: 2, 500, 000 or finer. The lithology information was gathered from metadata of the maps or from additional literature, totalling more than 220 different sources. The classification was expanded from the system introduced by Dürr *et al*. [1, 2]. The map distinguishes six classes of sediments, six classes of igneous rocks, as well as metamorphic rocks. Additional information levels add further detail (e.g. sediment grain size).

A presented comparison between maps of the uppermost regolith layer (soil) and GLiM shows expected significant spatial correlations between the lithological classes and soil types. This highlights the impact of lithology on regolith generation, which is one possible explaination of the impact of lithology on chemical erosion[3]. Due to its high resolution, the new global lithological map can be applied to numerous global problems that require high levels of detail.

Organic nitrogen cycling during organic matter decomposition

M. MOOSHAMMER[1]*, W. WANEK[1], A.H. FRANK[1], F. HOFHANSL[1], K.M. KEIBLINGER[2], S. ZECHMEISTER-BOLTENSTERN[2] AND A. RICHTER[1]

[1]Dept. of Chemical Ecology and Ecosystem Research, University of Vienna, 1090 Vienna, Austria (*correspondence: maria.mooshammer@univie.ac.at)

[2]Federal Research and Training Centre for Forests, Natural Hazards and Landscape, BFW, 1131 Vienna, Austria

Proteins represent the dominant input of organic N into soil ecosystems. The breakdown of proteins to amino acids is anticipated to be the critical process determining the underlying mechanisms in litter and soil N dynamics. This includes initiating the N mineralization sequence by providing substrates for ammonification and microbial uptake. However, the release and fate of organic N-containing compounds during decomposition of organic matter is largely unknown.

We developed a new ^{15}N pool dilution assay to quantify gross rates of protein depolymerization (i.e. amino acid production) and amino acid immobilization [1]. The assay is based on the concurrent labeling of the pool of 18 proteinogenic amino acids, which are present in a free form in soil and litter, and the measurement of ^{15}N:^{14}N ratios in the individual amino acids by GC-MS over time.

The results from a litter decomposition experiment showed that gross protein depolymerization exceeded gross N mineralization by >8 fold indicating that only a small fraction of amino acids released by extracellular enzymes was actually mineralized to ammonium. These results point to an important direct role of dissolved organic N (i.e. amino acids) for microbial N nutrition and a negligible contribution of MIT ('mineralization-immobilization turnover'; extracellular deamination of amino acids) to N mineralization in decomposing litter. Furthermore, controls such as litter quality and microbial community structure and the effect of stress (i.e. temperature) on organic and inorganic N cycling processes will be discussed in more detail.

[3]NanoBioEarth Group, Applied Research Center of Geological Survey of Iran (zohre.boromand@gmail.com)

Arsenic is a toxic element that the maximum allowable concentration for it in drinking water is about 0.5 mg/lit. Arsenic Inorganic compounds include As_2O_3, FeAsS, AsS and As_2S_3. Although arsenic has a multi allotrope element with yellow, gray and black colors, but only the gray ones that are solid metalloid, crystalline and fragile, are persistent in the nature. Approximately 100, 000 tones arsenic are produced per year in the world because of excavating metals such as copper, lead, cobalt and gold. It causes cancer because of impairing synthesis of DNA and RNA.

One of the most essential problems in Zarshouran gold mine, in northwest of Iran, is existence of too much arsenic in wastewater of mining. Different methods are presented to remove arsenic from the wastewaters such as: Arsenic can be removed by composite of graphene oxide and ion exchange method, but these methods are so high expense that has limited using them. We prepared magnetic nanoparticles with different methods in laboratory. These nanoparticles were less than 50 nanometers in diameter that we used it for removing arsenic as a very light expense method from Zarshouran wastewaters. A natural bond creates between arsenic and magnetic nanoparticles. After separating of arsenic, nanoparticles can be separate from the solution with a simple magnet. We succeed to remove arsenic with over 99 percent in volume by this method.

Mobility of nitrogen and heavy metals in biosolid amended soil

D. MORAETIS*, S. VOUTSADAKI, M. KOTRONAKIS, G. KONTOLAIMAKIS[1], F.E. STAMATI, N.P. NIKOLAIDIS AND N. KALOGERAKIS

Technical University of Crete, Chania 73100 Greece (*correspondence: moraetis@mred.tuc.gr)

The potential leaching and availability of nitrogen and heavy metals in biosolid-amended soil were investigated using batch and column studies. The mobility of heavy metals were assessed with SPLP and TCLP tests while the availability of nitrogen with a KCl extraction test. In addition semi-continuous column studies were conducted to assess the leachability of nitrogen and heavy metals from biosolid-amended soil under simulated-unsaturated soil conditions. One type of biosolids, a compost derived from municipal solid waste recycling of the organic fraction together with a clayey soil typical of Crete were used in this study. Two application rates of 100 and 200 t/ha were tested. The results were compared with soil lysimeter measurements of a parallel experiment in an olive grove.

Results

The total input of N was 1160 and 2320kg/ha for the two amendments. KCl extraction showed that 15 and 96 kg/ha of N ($N\text{-}NO_3$+$N\text{-}NH_4$) was bio-available which correspond to 1.3% and 4.2% of the total N input for the 100 and 200t/ha application rates respectively. Columns packed with soil amended with 200t/ha compost and receiving synthetic rain released 34 kg/ha of N ($N\text{-}NO_3$+$N\text{-}NH_4$). Using lysimeter measurements the average release of N in olive grove compost amended soil was estimated to be 16kg/ha N. The results from all measurements were consistent.

Heavy metal mobility from compost-amended soil was assessed with the SPLP and TCLP batch tests, semi-continuous column studies and field measurements with lysimeters. All results were consistent and orders of magnitude lower than EPA standards [1]. Zn was shown to be the most mobile metal in all measurements. Results suggest that one-time application of biosolids at agronomic rates will not impact the groundwater.

Long-distance transport of North Gondwana Cambro-Ordovician sandstones: Evidence from detrital zircon Hf isotopic composition

NAVOT MORAG[1]*, DOV AVIGAD[1], AXEL GERDES[2], ELENA BELOUSOVA[3] AND YEHUDIT HARLAVAN[4]

[1]Institute of Earth Sciences, The Hebrew University of Jerusalem, Jerusalem 91904, Israel (*correspondence: navot.morag@mail.huji.ac.il)
[2]Institut für Geowissenschaften, Johann Wolfgang Goethe Universität, D-60438 Frankfurt am Main, Germany
[3]GEMOC, Department of Earth and Planetary Sciences, Macquarie University, NSW 2109, Australia
[4]The Geological Survey of Israel, Jerusalem 95501, Israel

A voluminous Early Paleozoic sequence of quartz-rich sandstones was deposited in northern Gondwana following its assembly during the Neoproterozoic-Cambrian Pan-African Orogeny. Field evidence for the sense of transport indicate that sediments were carried from Gondwana hinterland towards the supercontinent margins in the North (present coordinates). Derivation from Pan-African terranes is evident from the ubiquity of detrital zircons with Neoproterozoic U-Pb ages, but the exact provenance of these siliciclastic deposits remains unclear. Herein we present new Hf isotopic data from U-Pb dated detrital zircons of the Cambro-Ordovician sandstone that top the juvenile Neoproterozoic basement of the Arabian-Nubian Shield in Israel and Jordan. Remarkably, the detrital zircon Hf isotopic signal stands in marked contrast with Nd and Hf isotopic signature of the underlying basement. A preponderance (61%) of the Neoproterozoic-aged detrital zircons from the Cambro-Ordovician sandstones in Israel and Jordan yielded negative $\varepsilon_{Hf(t)}$ values incompatible with a juvenile source. Therefore, rather than from the adjacent Arabian-Nubian Shield, most of the detrital zircons were derived from distant terrane(s), comprising pre-Neoproterozoic crust reworked during Pan-African orogeny. Because our sampling sites are situated at the northern tip of the Arabian-Nubian Shield, sand must have been transported several thousand kilometers before deposition. This finding also implies that the Arabian-Nubian Shield and other Pan-African orogens of NE Africa were completely warned down by the onset of Cambro-Ordovician deposition and that vast areas in the northern part of Gondwana were then low-lying such as to allow transfer of sand across the continent.

Macroscopic anhydrite interacted with Pb-doped solutions

JUAN MORALES[1], J.M. ASTILLEROS[1,2], AMALIA JIMÉNEZ[3] AND L. FERNÁNDEZ-DÍAZ[1,2]

[1]Dpto. Cristalografía y Mineralogía. Universidad Complutense de Madrid. 28040 Madrid. Spain
[2]Instituto de Geociencias (UCM-CSIC). 28040 Madrid, Spain
[3]Facultad de Geología de la Universidad de Oviedo, 33005, Oviedo, Spain

Pb is a toxic metal that affects the vital functions of living organisms. A previous study showed that Pb sorption by gypsum is an effective uptake mechanism [1]. Here the ability of anhydrite to uptake Pb from aqueous solutions is evaluated and its effectiveness as Pb-remover compared with that of gypsum. Experiments were performed by placing 2g of crushed pure anhydrite in 100 mL of Pb-bearing aqueous solutions (ranged from 10 to 1000 mg/L) and, after specific reaction periods (1 minute to 5 weeks), analyzing the aqueous solution and examining the solids formed on the surface of the anhydrite crystals. DRX data revealed that anglesite formed on anhydrite after short interaction periods (Figure 1). ICP-OES analyses showed that when the initial Pb concentration, [Pb]ini, was ≥ 50 ppm, it decreased very rapidly to reach a constant value (≈ 5 ppm) after about six hours. The evolution of the solution composition is consistent with a coupling between anhydrite dissolution and anglesite precipitation. Our results indicate that anhydrite and gypsum surfaces have similar ability to remove Pb from aqueous solutions.

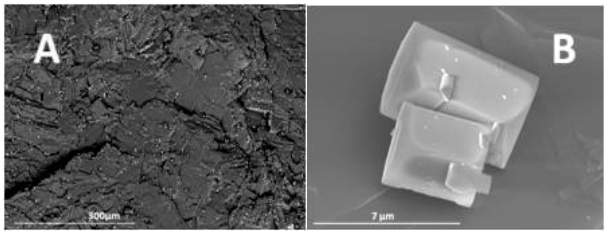

Figure 1: SEM images of anhydrite surface after interaction with a Pb-bearing aqueous solution ($[Pb]_{ini}$ =100ppm). (A) BSE image showing the distribution of anglesite crystals (bright spots) formed on anhydrite surface after 5 minutes interaction. (B) After a 24 hours interaction period of anglesite reach sizes in the range 3 to 10 microns.

Partitionning of Pt-Re-Os between solid and liquid metal in the Fe-Ni-Si system

G. MORARD[1,2], J. SIEBERT[1,2], D. ANTONANGELI[1,2] AND J. BADRO[1]

[1]Institut de Physique du Globe de Paris, France
[2]Institut de Minéralogie et de Physique des Milieux Condensés, Paris, France

The Earth evolved into a layered body early in its history with silicates and oxides forming the mantle while molten metal was gravitationally segregated to form the core. Cooling of the Earth causes the liquid core to crystallize. In the meantime, small amount of liquid outer core material could be remixed by dynamical entrainment in the deep mantle. This mechanism was proposed as responsible for the Os isotopic anomalies observed in some mantle-plume derived lavas (OIBs). In that model, a radiogenic Os signature would be produced in the outer core as a result of inner core crystallization, and would then be remixed with the mantle and imprint the isotopic composition of some OIBs.

Here we investigate the solid-liquid fractionation of Os, Re and Pt in the metal at high pressure. As these partition coefficients depend on metal composition, we choose to study the most realistic candidate for core composition, the Fe-Ni-Si system, for which no data exist so far.

He-Pb lead evidence for marble cake under the Pacific-Antarctic ridge

M. MOREIRA[1]*, C. HAMELIN[1] AND L. DOSSO[2]

[1]Institut de Physique du Globe de Paris, Sorbonne Paris Cité, CNRS (UMR 7154), 1 rue Jussieu, 75238, Paris Cedex, France (*correspondence: moreira@ipgp.fr)
[2]CNRS, UMR6538, Domaines Océaniques, IFREMER, B.P.70, 29280 Plouzané, France

Lead isotopes and Helium isotopes were analyzed in glass samples from 10 seamounts located off-axis of the Pacific-Antarctic Ridge between 50.5°S and 41.5°S. Samples were dredged during the Pacantarctic 2 cruise of the R/V L'Atalante in Dec. 2004-Jan. 2005. Helium isotopic ratios vary between the local mean MORB value ($^4He/^3He$=95, 300; R/Ra=7.58) and more radiogenic values ($^4He/^3He$=182, 460; R/Ra=3.96) associated with high He abundances (~10μccSTP/g). The $^{206}Pb/^{204}Pb$ ratio goes up to 20.2. $^4He/^3He$ ratio and $^{206}Pb/^{204}Pb$ ratios are correlated in samples from the pacific ridges [1] and off-axis seamounts (figure). Clearly, this correlation between helium and lead isotopes reflects the marble-cake structure of the mantle where the fertile component carries the radiogenic signatures. Because of a thicker off-axis lithosphere, this fertile component is more likely to be sampled off-axis as it melts preferentially to the peridotitic mantle.

A geochemical approach to the Sado saltmarshes (Portugal)

S. MOREIRA[1]*, M.C. FREITAS[1], C. ANDRADE[1] AND M.F. ARAÚJO[2]

[1]Universidade de Lisboa, Faculdade Ciências, Departamento de Geologia & Centro de Geologia, 1749-016 Lisboa, Portugal (*correspondence: scmoreira@fc.ul.pt)
[2]Instituto Tecnológico e Nuclear, EN 10, 2686-953 Sacavém, Portugal

The Sado estuary develops ca. 20 km south of Lisbon and studies of its subtidal and intertidal sediments, (namely of marginal marshes - Malha da Costa, Faralhão, Carrasqueira, Alcácer) showed that upper estuarine (Alcácer) sediments yield a Zn/Al-normalized ratio up to 14x (channel) and 7x (marsh) higher than in all remaining areas [1, 2]. Zn is sourced in the Iberian Pyrite Belt terranes - exploited for ore since the Calcolithic - which are intersected by the Sado's watershed; weathering and lixiviation of waste-piles input inorganic carriers of Zn into the drainage system, the metal progressing downstream until reaching the high-salinity upper estuarine domain.

This motivated the sedimentological and geochemical study of a 2.7 m-long core taken from the Alcácer saltmarsh, to investigate the variatons in Zn and other heavy metals along time. The core consists of a monotonous accumulation of muddy sediment (coarse fraction <8%), with compatible values of Si (26-28%) and Al (~9%), high in organic matter (~7-10%) and $CaCO_3$-free, thus low (<0.5%) in Ca.

The vertical profiles of terrigenous elements are fairly invariant. K (1.7-1, 9%) and Ti (0.5-0.6%) usually associate with Al-silicates, and may be replaced by Rb (145-157 mg/kg) and Zr (129-161mg/kg), respectively, in those minerals; these elements and Al present identical vertical variation profiles. The elemental content in Zn decreases upcore (3200 to 443mg/kg) and the Al-normalized values range between 50×10^{-4} and 365×10^{-4}. The lowermost 6 cm of the core yielded Zn/Al $>100\times10^{-4}$. The contents of Cr, Ni, Cu and Pb are 95-153, 41-59, 91-228 and 44-73mg/kg, respectively. The vertical variation of the Al-normalized values of these metals show a slight increase of Cr and Pb upward and a clear decrease in Ni and Cu in the top meter.

The closure of several mines and rehabilitation of tailing areas should have decreased the supply of Zn to River Sado tributaries, and consequently in the lower reaches of the river. At this point it is not possible to indicate the factor responsible for the increment of Cr and Pb to the surface.

The plumbing system of the Ischia island: A physico-chemical window on the fluid-saturated and CO_2-sustained Neapolitan volcanism (Southern Italy)

R. MORETTI[1,2], I. ARIENZO[2], G. ORSI[2], L. CIVETTA[2,3] AND M. D'ANTONIO[4]

[1]Dipartimento di Ingegneria Civile, Seconda Università di Napoli, Aversa (CE), Italy
[2]INGV-Osservatorio Vesuviano, Via Diocleziano 328, Napoli, Italy
[3]Dipartimento di Scienze Fisiche, Università di Napoli "Federico II", Napoli, Italy
[4]Dipartimento di Scienze della Terra, Università di Napoli "Federico II", Napoli, Italy

Ischia, a small island located 18 miles NW offshore Naples (Southern Italy), is a densely populated active caldera (last eruption 1302 A.D.). Melt inclusions in phenocrysts of poorly differentiated eruptive products constrain structure and nature of the Ischia deep magmatic feeding system. Volcanic products bear clear evidence for CO_2-dominated gas fluxing, under very oxidized conditions, and CO_2 enrichment in magma portions stagnating at major crustal discontinuities. Volatile concentrations require gas-melt equilibria between 3 and 18 km depth. At Ischia there is much less magma than that needed to directly supply the amount of released magmatic fluid. Comparison with data from the other nearby Neapolitan volcanoes (Procida, Campi Flegrei –CF-, and Somma-Vesuvius –SV-) highlights the pivotal role of deep fluids in originating the volcanism. Despite the compositional and eruptive style differences observed within the small extension of the Neapolitan Volcanic District, and the variable occurrence of mixing, crustal assimilation and fractional crystallization, the different kinds of volcanism are mostly linked by supercritical CO_2 fluids produced by the devolatilization of subducted terrigenous-carbonatic metasediments. Geochemical and isotopic differences among Ischia, CF and SV from one side, and Procida from the other one, reflect the tectonically controlled slab-derived fluids release and upraise trough the mantle wedge, that, in turns, control magma generation.

Climatic conditions during the Holocene based on Levantine continental shelf sediment cores

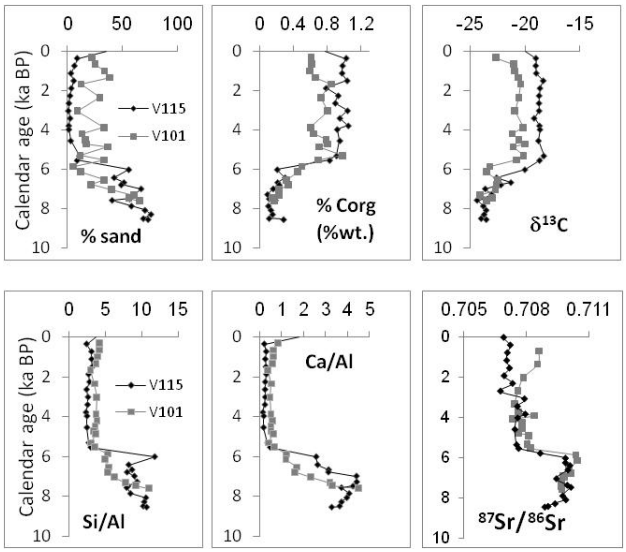
T. MOR-FEDERMAN[1], R. BOOKMAN[1]*, A. ALMOGI-LABIN[2] AND B. HERUT[1,3]

[1]Dept. of Marine Geosciences, Charney School of Marine Sciences, University of Haifa, Mt. Carmel, Haifa 31905, Israel (*correspondence: rbookman@sci.haifa.ac.il)

[2]Geological Survey of Israel, 30 Malkhe Israel, Jerusalem 95501, Israel

[3]Israel Oceanographic & Limnolological Research, Tel Shikmona, Haifa 31080, Israel

Sediments deposited on the southeastern continental shelf of the Levantine Basin are sensitive recorders of climatic and oceanographic variability affected by the north Atlantic and indirectly by monsoonal systems. In order to reconstruct the influence of these climatic systems on Holocene sediments two cores were taken off shore the southern (V115) and central (V101) Israeli coast at water depths of ~35 m. The cores, dated to 7, 630 and 8, 440 ^{14}C years BP, show two distinct sedimentation regimes. High rates, of 190-140 cm/ka, in the lower Holocene, and significantly lower rates of 50-60 cm/ka during the last 5, 500 years. The cores were analyzed for grain size, TOC, $\delta^{13}C$, major and trace elements, and Sr isotopes. Selected results are shown in the figures below. The full data set indicates clearly that two distinct climatic periods governed the eastern Mediterranean and its surroundings during the Holocene.



Timescales of eruption triggering and magma transport from element diffusion in minerals

DAN MORGAN*

School of Earth & Environment, University of Leeds, LS2 9JT UK (*correspondence: d.j.morgan@leeds.ac.uk)

Mixing of magmas of contrasting temperatures and compositions can act as a trigger of a subsequent volcanic eruption. Heating of a magmatic system by basaltic injection can remobilise magma that is close to its solidus, and mixing can further change the character of the magma, lowering viscosity and promoting eruption.

Upon mixing, if the magma system remains saturated in mineral phases inherited from one or both parental melts, strongly-zoned mineral grains will form, as a product of changes in mineral-melt equilibria and melt composition. Subsequent residence at magmatic temperatures will allow such abrupt chemical zoning profiles to relax by diffusion. If magma temperatures are known, we can place constraints on diffusion time and thereby investigate the amount of time that passes between a magma injection – ultimately our eruption trigger – and the ensuing eruption.

Study of large silicic systems implies crystal residence times at magmatic temperatures of the order of tens of years (e.g. Whakamaru Ignimbrite, NZ, [1]) to thousands of years (e.g. Fish Canyon Tuff, USA, [2]), which is still relatively rapid given the large volumes concerned. Looking at smaller systems, the Nea Kameni Dacite of Santorini suggests a remobilisation time of the order of a month between basaltic injection and dacite eruption [3], whilst study of the recent Eyjafjallajokull eruption of 2010 resolves multiple mixing events occurring in the months prior to, and during, the eruption. In contrast, work on Piton de la Fournaise volcano is less clear-cut, and perhaps sounds a cautionary note for determining magmatic timescales from diffusion profiles.

Developments of new software tools and methodologies, and the utilisation of new mineral-element systems promise an expansion of these techniques. However, the petrological context has to be a major concern in these studies as it entirely determines the significance of the results.

[3]HACD, NASA Johnson Space Center, Houston, TX 77058 (scott.m.smith@nasa.gov)

We demonstrate that variations in the Ca isotope ratios in urine rapidly and quantitatively reflect changes in bone mineral balance. This variation occurs because bone formation depletes soft tissue of light Ca isotopes, while bone resorption releases that isotopically light Ca back into soft tissue.

In a study of 12 individuals confined to bed rest, a condition known to induce bone resorption, we show that Ca isotope ratios shift in a direction consistent with net bone loss after just 7 days, long before detectible changes in bone density occur. Consistent with this interpretation, the Ca isotope variations track changes observed in N-teleopeptide, a bone resorption biomarker, while bone-specific alkaline phosphatase, a bone formation biomarker, is unchanged. Ca isotopes can in principle be used to quantify net changes in bone mass. Ca isotopes indicate an average loss of 0.62 ± 0.16 % in bone mass over the course of this 30-day study. The Ca isotope technique should accelerate the pace of discovery of new treatments for bone disease and provide novel insights into the dynamics of bone metabolism.

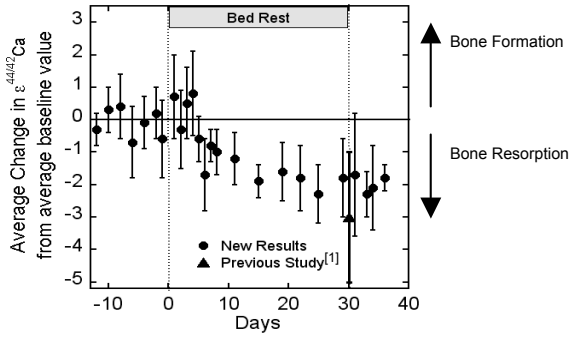

Figure 1: Change in Ca isotope ratios of urine as a result of bed rest.

Improving the accuracy of the $^{40}Ar/^{39}Ar$ geochronometer

L.E. MORGAN[1]*, D.F. MARK[2], K.F. KUIPER[1], O. POSTMA[1], I.M. VILLA[3] AND J.R. WIJBRANS[1]

[1]Faculty of Earth & Life Science, Vrije Universiteit, De Boelelaan 1085, 1081HV, Amsterdam, The Netherlands (*correspondence: leah.morgan@falw.vu.nl)

[2]NERC Argon Isotope Facility, Scottish Univ. Environmental Research Centre, East Kilbride, G75 0QF, UK

[3]Universität Bern, Institut für Geologie, Baltzerstrasse 3, CH-3012 Bern, Switzerland

The accuracy of the $^{40}Ar/^{39}Ar$ system relies on a number of parameters, most notably decay constants for the branched decay of ^{40}K to ^{40}Ar and ^{40}Ca, and the $^{40}Ar/^{40}K$ ratios (or ages) of mineral standards used as neutron flux monitors.

Although these parameters can be assessed to an extent through intercalibration efforts (e.g. [1]), a serious effort to better constrain these parameters based on metrologically traceable measurements, modern technologies, and rigorous uncertainty analyses is overdue [2, 3, 4].

Here we present steps towards a 'first principles' calibration of the $^{40}Ar/^{39}Ar$ system by measurement of ^{40}Ar and ^{40}K concentrations. These measurements will be used both to determine the $^{40}Ar/^{40}K$ ratios of mineral standards (thus allowing for calculations of their K-Ar ages) and also the ^{40}Ar branch of the ^{40}K decay constant via ingrowth experiments in material enriched in ^{40}K.

^{40}Ar concentration measurements are based on sensitivity corrections via a calibrated pipette system working under the principles of the ideal gas law. This system relies on components with calibrations traceable to international standards and will be both renewable, with a lifetime of ca. 1 month for gas in the reservoir, and portable, to permit interlaboratory calibrations.

^{40}K concentration measurements are based on TIMS measurements and NIST standard reference materials for elemental (SRM999b) and isotopic (SRM985) potassium.

This series of measurements aims to directly calibrate the $^{40}Ar/^{39}Ar$ system using measurements traceable to international standards, similar to recent steps taken by the U-Pb community [6].

The research leading to these results has received funding from the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 215458.

Two pyroxene-garnet rock of the Gridino area of Belomorian mobile belt (Northern Karelia), Karelia, Russia: Record of the prograde and retrograde metamorphic events

A.A. MORGUNOVA[1]* AND A.L. PERCHUK[1,2]

[1]Institute of Experimental Mineralogy, Academica Osipyana Street 4, Moscow distr. 142432, Chernogolovka, Russia (*correspondence: almor@iem.ac.ru)

[2]Lomonosov Moscow State University, Geological Faculty, GSP-1, Leninskie Gory, Moscow, Russia (alp@geol.msu.ru)

Archean felsic gneisses in the high pressure Gridino complex host lenses boudins and dikes of eclogitized mafic (gabbro, gabbro-norite) and ultramafic (garnet-pyroxene rock, orthopyroxenite) rocks. The paper is aimed to reconstruct metamorphic evolution of the two pyroxene-garnet rock forms a boudin of size 4*5 m in the amphibole-biotite gneisses on the Visokii Island of the White Sea.

The early episode of the rock evolution is characterized by inclusions of calcite and diabantite (rare Fe-Si chlorite). The diabantite is well-known as product of metasomatic alteration of peridotites. Inclusions of this mineral were found in all rock-forming minerals (garnet, clino- and orthopyroxene). They often associate with REE and U, Th-rich minerals, which tend to crystallize at the walls of the vacuoles. The inclusions are very unusual in term of the surrounding cracks. The inclusions hosted by pyroxenes are surrounded by the both concentric and radial cracks, whereas inclusions in garnets are surrounded by the only radial cracks. Theses features indicate that the inclusions have been recrystallized after their trapping. Thermobarometric study of the rock indicates that unhydrous mineral assemble garnet+clinopyroxene+orthopyroxene that replaced diabantite-bearing metasomatic rock was formed under T-P conditions (690ºC/1.7 GPa) of eclogite facies similar to those determinated for the Archean mafic eclogites within the complex. Rim zones of the rock-forming minerals indicate isothermal decompression down to $P \sim 1.2$ GPa, followed by the episode of cooling to $T \sim 650$ºC and decompression to $P \sim 0.9$ GPa recorded by development of the retrograde amphibole-garnet-orthopyroxene association [1].

Dispersal of tritium and ^{3}He along the outer rim of the Weddell gyre

R. MORIARTY*, Z. ZHOU AND C.J. BALLENTINE

SEAES, University of Manchester, M13 9PL, UK (*correspondence: roisin.moriarty@manchester.ac.uk)

Weddell gyre plays an important role in the southern closure of the Meridional Overturning Circulation (MOC) and in the ventilation of the deep ocean through the formation of Antarctic Bottom Water (AABW). Estimates of AABW production in the region are not very well constrained and range between 3 and 11Sv ($1Sv=10^6$ m^3 s^{-1})[1]. Recent observations [2, 3] suggest that the Weddell gyre may not be the primary region of AABW formation as previously thought. Exchange between the Weddell gyre and the world oceans occurs at the outer rim of the gyre. Determination of the transport of water masses across this boundary is needed to quantify the production and export of AABW in and from the gyre and to determine its contribution to global ocean circulation.

Seawater samples (~500) for tritium and helium-3 analysis were collected along the outer rim of the gyre as part of ANtarctic Deep Rates of EXport (ANDREX) project between (Dec. 2008 and April 2010). These samples covered 48 stations and ranged from suface to a depth of 6000m. Helium-3 values in conjunction with another steady state tracer, PO_4*, will allow the calculation of dilution times using optimum multiparameter techniques. Tritium in conjunction with CFCs and SF_6 will allow the quantification of ventilation ages and the trasist times since a water parcel was last in contact with the atmosphere. They will also give a second estimation of dilution times. Preliminary results for tritium indicate values ~0.15 TU in surface waters, a tritium dead layer at intermediate depths and an increase in tritium concentration at depths ≥4000m. These data provide the basis for modelling mechanisms that control the dispersal and calculation of the AABW production rates.

[3]Surface & Aqueous Geochemistry Group, Department of Geological & Environmental Sciences, Stanford University, Stanford, CA 94305-2115, USA (gordon.brown@stanford.edu)

Nanominerals have been the subject of extensive research for the last decade, especially because of their exceptional surface properties. These properties indeed confer to these nanoparticles an important role in pollutant dynamics via sorption and precipitation reactions, colloidal transport, and redox surface reactions (e.g. [1]).

In this communication we will present recent advances in the identification of such processes in impacted natural systems as contaminated soils and mining environments as well as in laboratory systems relevant of water treatment processes. Microscopic and spectroscopic investigations of these systems emphasize the role of nano – iron oxides [2, 3], oxyhydroxides [1], hydroxides [4, 5] and hydroxysulfates [6, 7] from abiotic or microbial origin. Particular attention will be paid to better understanding the respective roles of physico-chemical factors and microbial metabolisms in controlling the kinetics of nano-mineral nucleation and evolution, and the ability of these solids to scavenge inorganic pollutants, especially arsenic. Finally, recent evidence for surface redox reactions involving reactive oxygen species [8] will be discussed as a promising process for remediation of contaminated surface waters.

Removal of fluoride on Mg–Al mixed oxides prepared at different temperatures

S. MORIYAMA*, K. SASAKI AND T. HIRAJIMA

Department of Earth Resource Engineering, Kyushu University, Motooka 744 Fukuoka, Japan (*correspondence: s-moriyama09@mine.kyushu-u.ac.jp)

Hydrotalcite is in layered double hydroxides (LDHs) structures, the general chemical formula is represented $[M_1 (II)_{1-x}M_2 (III)_x (OH_2)]A_{n-x/n}\cdot mH_2O$, where M_1 (II) = divalent cation (Mg^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, Mn^{2+}, Cd^{2+}), M_2 (III) = trivalent cation (Al^{3+}, Fe^{3+}, Cr^{3+}), An^- = interlayer anion with valence n, x is M_2 (III/M_1 (II) + M_2 (III). In the present study Mg–Al mixed oxides, which were obtained by thermal decomposition of precipitated hydrotalcite-like compounds, were used as sorbents to remove fluoride in aqueous systems. Calcination temperatures were 873 K, 1073 K, and 1273 K.

The XRD peaks for co-precipitation products were assigned to hydrotalcite, but this pattern completely disappeared and assigned to MgO after calcination at each temperature, spinel phase was also observed at 1273 K. Higher calcination temperature provided higher crystallinities and larger crystal size of mixed oxide which was confirmed by TEM images. Fluoride sorption on mixed oxides can be mainly explained by ionic exchange of OH^- to F^-. Mg and Al ions were released during the sorption of fluoride; the behaviors of released Mg and Al during the sorption of fluoride have been affected by the elemental distributions of the surface on mixed oxides. The molar ratio of Al/Mg in hydrotalcite-like compounds before calcinations was determined to 0.33 after acid decomposition; however XPS results indicate that the molarl ratio of Al/Mg on the surface of mixed oxide increased by the calcination temperatures. After sorption of fluoride, hydrotalcite have been reconstructed again with mixed oxide calcined at 873 K and 1073 K, however, less crystalline hydrotalcite, Mg $(OH)_2$, and spinel were observed on mixed oxides calcined at 1273 K. The lowest sorption efficiency of mixed oxide calcined at 1273 K probably due to the small amount of MgO by the phase transition to spinel because the spinel was stable in water and doesn't react with fluoride. On the other hand, removal of fluoride was more easily achieved in mixed oxides calcined at 1073 K than another mixed oxides; this may be caused by good correlation with lattice parameter of MgO. Mg–Al mixed oxides is one of promising products to remove anion including fluoride, but the sorption efficiency are affected by properties of the surface molar ratio and structures, therefore calcination temperatures must to be considered.

H_2O-CO_2 solubility in mafic melts

Y. MORIZET[1], G. IACONO-MARZIANO[2]* AND F. GAILLARD[2]

[1]Université de Nantes, UMR 6112, France
[2]ISTO, UMR 6113 CNRS-Université d'Orléans, France
(*correspondence: giada.iacono@cnrs-orleans.fr)

Water and carbon dioxide are the two most abundant volatile species in volcanic gases. Accurate laws describing their solubilities in silicate melts are therefore crucial to understand volcanic degassing and interpret melt inclusion entrapment depths. We present here new experimental data on H_2O-CO_2 solubility in mafic melts with variable chemical compositions (alkali basalt, lamproite and kamafugite) that extend the existing database. We show that potassium and calcium-rich melts can dissolve ~ 1 wt% CO_2 at 3500 bar and 1200°C, whereas conventional models predicts solubilities of 0.2-0.5 wt%, under similar P-T conditions. These new data, together with those already existing in the literature, stress the fundamental control of melt chemical composition on CO_2 solubility. We present a H_2O-CO_2 solubility model for mafic melts, which employs simplified concepts of gas-melt thermodynamics and accounts for the combined effects of melt chemical composition and structure. The model is calibrated on a selected database consisting of 270 experiments with 43 different mafic compositions. The statistic analyses of the experimental data indicate that the structure and the chemical composition of the melt play a fundamental role in CO_2 solubility in mafic melts, whereas H_2O solubility is negligibly affected by melt composition and structure. CO_2 solubility mainly depends on the amount of non-bridging oxygen per oxygen (NBO/O) in the melt, but the nature of the cation bounded to NBO is also critical. Alkalis (Na+K) bounded to NBO result in a strong enhancement of CO_2 solubility, whereas Ca has a more moderate effect. Mg and Fe bounded to NBO have the weakest effect on CO_2 solubility. Other structural parameters, such as the agpaitic index (Al_2O_3/ [CaO + K_2O + Na_2O]), are shown significant, though not as critical as NBO/O. Finally, we modelled the effect of water on CO_2 solubility and suggest that molecular H_2O enhances its solubility, whereas hydroxyls appear to have the opposite effect. In contrast with CO_2, H_2O solubility in mafic melts shows a weak correlation with NBO/O, and is statistically independent on melt composition.

Migration of europium and uranium in opalinus clay influenced by pH and temperature

C. MÖSER*, R. KAUTENBURGER AND H.P. BECK

Institute of Inorganic and Analytical Chemistry and Radiochemistry, Saarland University, Saarbrücken, Germany
(*correspondence: c.moeser@mx.uni-saarland.de)

Introduction

The development of a disposal in deep geological formations for high-level radioactive waste is a very important task for the future. The migration of radionuclides through soil is one of the critical paths from leaked stored container to the environment [1]. As metals of interest, europium as homologue of americium and uranium as principal component of nuclear fuel elements were used.

Spotlight of our investigations is the sorption of europium and uranium onto Opalinus clay. To get a first understanding for the different sorption processes we used batch experiments. During this experiments we varied the conditions like pH and temperature.

Results

The sorption of the metal ions is strongly pH-dependent. At pH<7 the Eu sorption decreases strongly. The uranium sorption decreases strongly between pH 6 and 9. An explanation afford the formation of the neutral $Ca_2UO_2(CO_3)_3$ species, which doesn´t sorbed onto the clay [2, 3]. The necessary carbonate and calcium was dissolved out of the Opalinus clay. For the investigations synthetic porewater was used. It has an ionic strength of 0.4 M and the concentration of cations is more than $7 g \cdot L^{-1}$. These porewater cations influence the sorption of europium in a pH range <7 significantly. Due to the presence of competing cations the sorption of Eu is inhibited. The uranium sorption is nearly independent from the competing cations. The influence of pH and temperature is significant higher. With an increasing temperature from 298 to 333 K the sorption of the metals increases, too. Investigations at different temperatures allow it to calculate the entropies and enthalpies for the reactions with uranium and europium derived from Van´t Hoff plots.

Monitoring emissions from the Athabasca Oil Sands using stable isotopes from black spruce (*Picea mariana*)

HEATHER MOSHER* AND ALEXANDER P. WOLFE

University of Alberta, Edmonton T6G 2E3, AB, Canada
(*correspondence: hmosher@ualberta.ca)

Atmospheric deposition in boreal forest ecosystems

The Athabasca Oil Sands industrial complex in northeastern Alberta, Canada, emits tons of CO_2, NO_x and SO_x daily, as well as various trace metals and aromatic hydrocarbons. The effects of these emissions on the surrounding, nutrient-limited, boreal forest ecosystem is not yet fully understood, especially with regards to deposition of bio-available reactive nitrogen (Nr). The possibility exists that industrial nitrogen subsidies may increase forest production, although this has not yet been assessed.

Nitrogen and carbon stable isotope data from year-old black spruce needles (*Picea mariana*) collected around the Athabasca Oil Sands suggest a possible fertilization effect promoting tree growth. Observed depleted nitrogen values correspond well with depleted carbon values regionally. However, the most proximal sites show clear signals that increased deposition may result in tree physiological stress, most likely related to the deposition of trace metals, and thus locally annulling any positive effects of Nr deposition on tree growth. Paired C and N sotopes from wood cellulose generally support needle measurements, together providing a detailed overview of the interactions between atmospheric deposition, nutrient cycling and tree ecophysiological stress.

Initial results from a new time resolved microfocus XEOL facility at the Diamond Light Source

J.F.W. MOSSELMANS[1], R.P TAYLOR[1,2], A.A. FINCH[2] AND P.D. QUINN[1]

[1]Diamond Light Source, Didcot, OX11 0DE, UK
(*correspondence fred.mosselmans@diamond.ac.uk)
[2]Dept. of Earth Sciences, St Andrews, KY16 9AL, UK
(aaf1@st-andrews.ac.uk)

Time Resolved spectrometer

We have constructed a Time-Resolved X-ray Excited Optical Luminescence (TR-XEOL) detection system at the Micofocus Spectroscopy beamline I18 at the Diamond Light Source. TR-XEOL allows the study of short lived states in isolation from long-lived cascade generated signals and thus potentially identify and study transient luminescent centres.

The system uses a Horiba-Jobin Triax Spectrometer and Hamamatsu R3809U-50 microchannel-plate photo multiplier tube. Triggering on the RF clock, we are able to record data in time bins of 6.2 ps in the 230 ns gap between the hybrid bunch photons and those from the main group of electron bunches orbiting the ring. We can detect light over the range 180-850 nm using a bespoke optical fibre, with X-ray excitation energies between 2 and 20 keV.

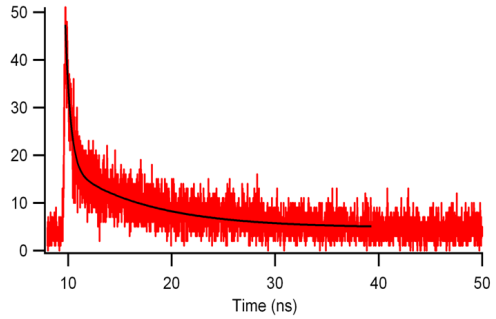

Figure 1: TR_XEOL spectrum from Labradorite Feldspar at 400 nm fitted with 2 exponentials of 1.6 and 29.7 ns.

Initial results

We have examined several different feldspars looking at the short-lived emissions in the UV region. We have observed two exponential decay lifetimes at 400 nm one with a lifetime of 1.6 ns and a second of 29.7 ns from a single crystal labradorite plagioclase feldspar (RT50c, Smithsonian Institute), an untreated single crystal collected from Clear lake Utah USA. In contrast, R1-11a, a microcline cryptoperthite from the Prins Christians Sund granite suite South Greenland [1], showed variable lifetimes at 400 nm, a short lifetime whose mean value was 0.20±0.13 ns and a longer life component of 13.5 ns. The potential of TR-optically detected XAS will be discussed.

Serpentine and brucite intergrowths: effects on $\delta^{11}B$

F.E. MOTHERSOLE[1]*, K.A. EVANS[1] AND J. CLIFF[2]

[1]Curtin University of Technology, Bentley, WA 6845, Australia (*correspondence: f.mothersole@postgrad.curtin.edu.au)
[2]Centre for Microscopy, Characterisation and Analysis, University of Western Australia, Australia

A quantitative understanding of fluid:rock interaction is important for understanding the transfer of elements and fluid circulation within the crust. Serpentinites can provide a sensitive record of fluid-rock interaction, particularly via analysis of isotopes of fluid mobile elements, such as boron.

Previous studies of boron in serpentinised rocks have provided a wide range of values. ^{11}B partitions into seawater, so heavy $\delta^{11}B$ values indicate a sewater influence, while lighter $\delta^{11}B$ reflects mantle influences. Strong fractionation between the two isotopes at temperatures of serpentinisation enables elucidation of the evolving fluid:rock system with progressive serpentinisation.

However, boron isotopic fractionation is influenced by temperature and pH because ^{11}B is preferentially incorporated into trigonal environments, such as those found in the $B(OH)_3$ aqueous species, while ^{10}B is preferentially hosted by the $B(OH)_4^-$ tetragonal species, which dominates in solution at high pH [1]. Additionally serpentine minerals, particularly early grown serpentine, can be intimately intergrown with brucite. Brucite cations are held in a trigonal site, so the presence of brucite is expected to increase $\delta^{11}B$. If this is not recognised, $\delta^{11}B$ values heavier than the true serpentine $\delta^{11}B$ values will be inferred, and erroneous interpretations may be made.

In this study, brucite, serpentine and brucite-serpentine intergrowths of partially serpentinised peridotites from ODP Leg 209 and New Caledonia were identified using micro-raman spectroscopy. Secondary Ion Mass Spectrometry (SIMS) was used to assess the extent to which the presence of brucite affects $\delta^{11}B$. The results enable a quantitative assessment of the magnitude of the effect of brucite on $\delta^{11}B$ and the implications of this for interpretation of fluid:rock interaction during serpentinisation.

Direct molecular simulation of aqueous electrolyte solubility

F. MOUCKA[1,2] AND W.R. SMITH[1]*

[1]Un. of Ontario Institute of Technology, Oshawa, ON Canada L1H 7K4 (*correspondence: william.smith@uoit.ca)
[2]J. E. Purkinje University, 40096 Usti n. Labem, Czech Republic

Introduction

We describe a new and computationally efficient methodology using Osmotic Ensemble Monte Carlo (OEMC) simulation to calculate the solubility of aqueous electrolytes [1]. We apply it to directly determine solubility without the need for calculating chemical potentials. The method avoids calculations for the solid phase, directly incorporating readily available data from thermochemical tables based on well-defined reference states [2].

Methodology

The method performs simulations of the aqueous solution at a fixed number of water molecules, pressure, temperature and specified overall electrolyte chemical potential. Insertion/deletion of ions to/from the system is implemented using fractional ion states, and transitions between the states incorporates Wang-Landau sampling.

Results and Discussion

We have applied the approach to calculate the solubilities of a range of alkali halides, using several water and ionic force-field models from the literature. We consider both individual alkali halides and their mixtures, dissolved in both H_2O and HCl-H_2O solutions. The solubility predictions are generally good. The solubility is very sensitive to the force field employed.

An unusual Hf-Pb signature below the East Pacific Rise – Mathematician Hotspot system

BÉRENGÈRE MOUGEL, ARNAUD AGRANIER, CHRISTOPHE HÉMOND AND PASCAL GENTE

UMR 6538 Domaines Océaniques, IUEM, Université de Brestagne Occidentale, 26980 Plouzané, France

The Northern part of the East Pacific Rise (EPR), between the Riviera and Orozco Fracture zones shows an atypical morphology. It is 300m shallower than the rest of the ridge and is unusually wide. On its western side, a strong alignment of seamounts intersects perpendicularly the ridge in its most inflated part, suggesting a hotspot-ridge interaction.

This study reports new Hf and Pb isotopes and trace element concentrations for 57 MORB samples, collected by submersible 'Nautile' during cruise PARISUB (2010). It covers a 15 km transect along the ridge axis from 15°37'N to 15°47°N with an average sampling of space ~300m.

REE patterns shows typical intermediate E-MORB compositions with relatively flat LREE profiles and significant depletions in HREE.

$^{206}Pb/^{204}Pb$ range from 17.5 to 18.2; $^{208}Pb/^{204}Pb$=36.8-37.6; $^{207}Pb/^{204}Pb$= 15.46-15.51; ε_{Hf}= 8.7-11.5. All the Pb ratios over ^{204}Pb are correlated with each other, as well as with $^{176}Hf/^{177}Hf$. These clean correlations most likely reflect binary mixings occurring in the mantle source between the local DMM and enriched material (EM). $^{206}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ ratios are also unusually low even for MORB. They are actually the lowest values ever reported for the EPR, which is unexpected for a plume-ridge interaction. Moreover, alignments in $^{207}Pb/^{204}Pb$ vs $^{206}Pb/^{204}Pb$ or $^{208}Pb/^{204}Pb$ diagrams are distinct from any geochemical trend known for this ridge ($^{207}Pb/^{204}Pb$, too high for given $^{206}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$).

The positive correlation between Hf and Pb isotopes is even more remarkable, that geochemical enrichments typically lead to radiogenic Pb and un-radiogenic Hf signatures and, therefore, that DMM-EM mixtures usually appear as negative correlations in the Hf-Pb isotope spaces.

The least radiogenic Hf and Pb correspond to the samples the closest to the Seamounts-ridge intersection (15°43'N) suggesting that these unusual compositions reflect the Mathematician EM material.

Interperetaion of microtexture and microstructure in the dynamic metamorphic rocks in Mouteh Mine area, Iran

SEYED ZAHED MOUSAVI[1]* AND KHATEREH PANAHI[2]

[1]Basic Science Department, Islamic Azad University(I.A.U), Meshkinshahr Branch,Meshkinshahr, Iran (*correspondence: z.mousavi@meshkin-iau.ac.ir) (khaterehpanahi@gmail.com)

Introduction

The studied area is located in the central part of Sanadaj-Sirjan belt, 60 km south part of Delijan city, the Muteh mine area. The formations at this area are Devonian silicic volcanic and volcano clastic rocks that have been metmorphed at green schist –amphiboloit facies.This rocks have altered by some Basic intrusive.

Methods and Results

Above 60 thin section have taken from drilling core samples. The aim of this studding is a interpretation of micro texture & microstructure by microscope. The result of studding show some micro texture like CS, C/ fabric, Mineral Fish, Bookshelf Structure, Boudinage, Strain Shadow, σ, δ, Φ pyroclast. In addition we can find three metamorphism setting (D_1, D_2, D_3) at this area. Every one this micro texture & microstructure have made in various metamorphism and deformation setting.

Sulfur and strontium isotope study of hydrothermal mineralization from the SE Afar Rift

N. MOUSSA[1,2,3]*, O. ROUXEL[1,2], P. NONNOTTE[2], Y. FOUQUET[1], E. PONZEVERA[1] AND J. ETOUBLEAU[1]

[1]IFREMER, Centre de Brest, BP 70- 29280 Plouzané, France
[2]UMR 6538 Domaines Océaniques, UBO-IUEM, Place Copernic, 29280, Plouzané, France
[3]IST, Centre d'Etude et de Recherche de Djibouti, BP 486, Djibouti
(*correspondence: nima.moussa.egueh@ifremer.fr)

Epithermal mineralization was recently described in the SE Afar Rift (Republic of Djibouti). To infer fluid sources in hydrothermal veins, sulfur and strontium isotopic analyses were performed on thirty mineralized samples of chalcedony, and/or quartz, ± carbonate containing gold and sulfides. Gypsum occurs as individual mounds and shallow stockwork zones. Isotopic composition of sulfides and sulfates were determined using Multicollector-Inductively Coupled Plasma Mass Spectrometer (MC ICPMS) and Thermal Ionisation Mass Spectrometer (TIMS) methods [1]. Sulfur isotopic composition of sulfides (mainly pyrite) vary from –0.2 to +6.8‰. These values are classically reported for volcanic rocks and hydrothermal sources. Strontium isotopic ratios ($^{87}Sr/^{86}Sr$) of mineralized veins range from 0.70391 to 0.70799. The lowest values of $^{87}Sr/^{86}Sr$ ratios indicate volcanic source of fluid while the highest isotopic composition indicate significant seawater contribution (defined at 0.70903, [2]). Coupled sulfur and strontium isotope compositions of eight sulfate samples hosted in (i) gypsum mound; (ii) evaporites (iii) stockwork veins in sediment or in volcanic rocks were also investigated to characterize the sources of Sr and S. The $\delta^{34}S$ values of the sulfate range from –1 to +14.3‰ while the $^{87}Sr/^{86}Sr$ compositions fall in the range 0.70389-0.70639. The highest values of $^{87}Sr/^{86}Sr$ ratios (0.70639) in gypsum correspond to the lighter values of $\delta^{34}S$ (+14.3‰.). These relatively light $\delta^{34}S$ values can be explained by the disproportionation of magmatic SO_2. This implies that both acidic fluid of magmatic origin and saline fluids contribute to the hydrothermal system in the Afar Rift.

Isotopic fractionation of zinc in planetary basalts

F. MOYNIER[1], R. PANIELLO[1] AND J.M.D. DAY[2]

[1]Dept. Earth Planet. Sci, Washington Univ. St Louis, MO 63130 (moynier@wustl.edu, PanielloR@ent.wustl.edu)
[2]Geosci. Res. Div., Scripps Institution of Oceanography, La Jolla, CA 92093-0244 (jmdday@ucsd.edu)

Zinc is a moderately volatile chalcophile trace element and so preserves evidence for volatility-driven processes during planetary accretion. For this reason, Zn can be used to understand the origin and evolution of planetary bodies, including Earth-Moon system formation. Terrestrial igneous rocks exhibit a limited range in zinc isotopic composition ($\delta^{66}Zn$ = +0.3±0.1‰, 2SE), whereas large variations have been found in lunar soils ($\delta^{66}Zn$ up to +6.4‰ [1]) and tektites (up to +2.04‰ [2]) associated with volatilization processes.

Here we report new Zn isotopic data for low- and high-Ti mare basalts to directly address the origin of the Earth and Moon. We also present new Zn isotopic data for martian meteorites, which have identical Zn isotopic compositions, within uncertainties ($\delta^{66}Zn$ = +0.25±0.03‰, 2SE, n=10), to terrestrial lavas. Absolute Zn concentrations in mare basalts (0.6-12ppm) are generally significantly lower than for terrestrial lavas (typically >75ppm), silicate Earth estimates (~55ppm), CI chondrites (>300ppm), or lunar pyroclastic beads (>90ppm) [1]. With the exception of two outliers, low-Ti and the high-Ti lunar basalts have similar mean $\delta^{66}Zn$ values of +1.31±0.13‰ (n=11) and +1.39±0.31‰ (n=8), respectively, and similar ranges (+0.8 to +1.6‰ and +0.5 to +1.9‰, respectively). By comparison, lunar regolith materials have higher $\delta^{66}Zn$ values due to micrometeorite impacts and/or cosmic ray sputtering, and lunar pyroclastic beads are enriched in light isotopes (-3.7±0.3‰ [1,3]).

Zinc isotopic homogeneity in terrestrial and martian igneous rocks and lack of obvious isotopic fractionation of Zn in low- and high-Ti mare basalts (versus O or Fe [4]) suggest that igneous processes do not fractionated Zn isotopes significantly. Values of $\delta^{66}Zn$ were probably not inherited from the proto-Earth (for Earth) or Theia (for the Moon) because chondrite meteorites have lower $\delta^{66}Zn$ (<0.8‰) than mare basalts [5]. Instead, enrichments in heavy Zn isotopes for mare basalts are likely a consequence of degassing either following giant impact, or during basaltic eruption. Alternatively, Zn isotopic fractionation during giant impact, followed by stochastic late accretion [6,7] led to the Zn isotopic compositions seen in terrestrial, martian and lunar igneous rocks.

Sediment response to persistently low oxygen levels in bottom waters: The Lower St. Lawrence Estuary

A. MUCCI,[1]* S. LEFORT[1] AND B. SUNDBY[1,2]

[1]Dept. of Earth and Planetary Sciences, McGill University, Montreal, Quebec Canada H3A 2A7 (*correspondence: alfonso.mucci@mcgill.ca)

[2]Institut des sciences de la mer de Rimouski, Rimouski, Quebec, Canada

Reports of hypoxia (O_2 concentrations < 62.5 μmol L^{-1}) in the bottom waters of the coastal ocean, and the extent of the areas that are affected by hypoxia, have increased at an alarming rate. Most studies of hypoxic environments focused on the impacts on pelagic and benthic populations, but the impact of hypoxia on sediment chemistry is poorly documented. We compared the chemical composition of sediment and porewater in cores recovered between 1982 and 2007 at two sites in the Lower St. Lawrence Estuary (LSLE), where the bottom water has been persistently hypoxic for more than 25 years. The concentrations and the vertical distributions of total Fe and As in the cores have not changed since the 1980s, but the speciation of solid phase Fe and As have changed significantly. The proportions of reactive Fe and As components have increased while the degree of pyritization of Fe and As has decreased by 50% and 75%, respectively. In addition, the concentrations of porewater Fe and As have increased since 1982. We propose that in marine, iron-rich environments, such as the LSLE, the hypoxia interferes with pyritization, which normally would immobilize elements such as As by incorporating them into stable authigenic pyrite phases.

Fate of As upon microbial Fe(III) reduction of As-bearing biogenic Fe minerals

E.M. MUEHE*, L. SCHEER AND A. KAPPLER

Geomicrobiology, University of Tuebingen (*correspondence: eva-marie.muehe@uni-tuebingen.de)

In arsenic-contaminated groundwater and soil, aqueous arsenic enters the human food chain directly via drinking water or indirectly via plants and animals, potentially leading to devastating health effects on people. Hence, research has focused on the geochemical and biogeochemical processes leading to the mobilization (release) and immobilization (removal) of arsenic from aquifers and soil. Former studies by Hohmann *et al*. [1] demonstrated that Fe(II)-oxidizing bacteria can efficiently immobilize arsenic by forming biogenic Fe(III) hydroxides. In the presence of arsenic these microorganisms form co-precipitates of Fe(III) (hydr)oxides and arsenic and additionally arsenic is sorbed to the mineral surfaces.

However, the co-existence of Fe(II)-oxidizing with Fe(III)-reducing bacteria in the environment could result in Fe cycling by the reduction of biogenic Fe(III) (hydr)oxides. This could lead either to a dissolution of the Fe(III) minerals causing a release of the bound arsenic or alternatively to the formation of secondary Fe(II/III) mineral phases [2] and an immobilization of arsenic.

In this study, we followed the reduction of biogenic arsenic-bearing Fe(III) minerals by the Fe(III)-reducer *Shewanella oneidensis* MR-1. We then compared the As (im-)mobilization during the reduction of these biogenic Fe(III) hydroxides to the As (im-)mobilization from chemically-synthesized Fe(III) minerals including the poorly-crystalline mineral ferrihydrite and the highly crystalline mineral goethite.

The resulting iron minerals were identified and characterized by X-ray diffraction, Mössbauer spectroscopy and electron microscopy. First results show that arsenic is only partially remobilized during microbial reduction of biogenic Fe-As-co-precipitates and that the remaining arsenic is bound either to the non-reduced goethite or to the newly formed Fe (II) carbonate and phosphate mineral phases.

Measuring the elastic properties under simulated Earth's mantle conditions

H.J. MUELLER[1]*, J. LAUTERJUNG[1], F.R. SCHILLING[2], C. LATHE[1] AND M. WEHBER[2]

[1]GFZ German Research Centre for Geosciences, Telegraphenbergm D-14473, Potsdam, Germany (*correspondence: hjmuel@gfz-potsdam.de)
[2]KIT Karlsruher Institute of Technology – Universität Karlsruhe, Engler-Bunte-Ring 14, D-76131, Karlsruhe, Germany (frank.schilling@kit.edu)

The Earth's mantle is only accessible by indirect methods, above all seismological studies. The interpretation of seismic data from the Earth's deep interior requires measurements of the physical properties of Earth materials under experimental simulated mantle conditions. In principle there are 2 common ways of simulating these *in situ* conditions by high pressure techniques - diamond anvil cells (DAC), large volume presses (LVP). The latters are more limited in pressure, but provide sample volumes 3 to 7 orders of magnitude bigger. They also offer small and even adjustable temperature gradients over the whole sample. Ultrasonic interferometry allows the highly precise travel time measurement at a sample enclosed in a LVP under *in situ* conditions. The data transfer function technique (DTF) even makes transient measurements possible. From geophysical point of view the up to 6 orders of magnitude lower frequency range as used for optical techniques in DAC and the option of using complex samples, i.e. polycrystalline, polyphase mineral assemblages, make the results much more representative for comparison with field data. Simultaneous structural and deformation measurements require the installation at a 3rd generation synchrotron light source. We present recent techniques and results of elastic properties measurements performed at different large volume presses.

Using Ambient Pressure X-ray Photoelectron Spectroscopy to investigate the reduction of c(2x2)-O/Ni(100) by hydrogen

KATHRIN MÜLLER[1], ANDERY SHAVORSKIY[2], HENDRIK BLUHM[2] AND DAVID STARR[1]*

[1]Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, NY 11973, USA (*correspondence: dstarr@bnl.gov)
[2]Chemical Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA

X-ray Photoelectron Spectroscopy (XPS) is a powerful tool for the chemical analysis of surfaces. Typically XPS measurments are performed under ultra-high vacuum conditions, which are far removed from many environmental or technologically relevant conditions. The development of synchrotron based Ambient Pressure XPS (AP-XPS) that incorporates a differentially pumped electrostatic lens system into the electron energy analyzer has made possible XPS measurments at pressure up to about 5 Torr. In this presentation, after a brief introduction to the AP-XPS technique, results using AP-XPS to investigate the reduction of a chemisorbed oxygen layer on Ni (100) by hydrogen will be discussed.

Among transition metal oxides, NiO has been the focus of extensive fundamental studies due to its applications in catalysis and potential magnetic devices. The reduction of NiO has been studied at elevated pressure conditions using a broad range of techniques including X-ray Diffraction [1], and Near Edge X-ray Absorbtion Spectroscopy [2] among others. Relatively unexplored is the reduction of chemisorbed oxygen on the surfaces of Ni single crystals at elevated pressures.

We have investigated the reduction of the c (2x2)-O chemisorbed layer on Ni (100) using AP-XPS at temperatures from 100 °C to 150 °C and pressures up to 0.5 Torr. The presence of small NiO clusters, located at step edges as shown by scanning tunneling microscopy, have a significant impact on the reduction kinetics of the c (2x2)-O layer. These clusters are preferntially reduced compared to the c (2x2)-O layer and increase the reduction rate of the c (2x2)-O layer, quite likely from spill-over of dissociated hydrogen from the NiO islands.

Monazite dating of base-metal mineralization, Earaheedy Basin, Western Australia

J.R. MUHLING[1]*, I.R. FLETCHER[2] AND B. RASMUSSEN[2]

[1]CMCA, Univ. Western Australia, Crawley, 6009, Australia (*correspondence: janet.muhling@uwa.edu.au)
[2]Dept Applied Geology, Curtin Univ., Bentley, 6102, Australia (I.Fletcher@curtin.edu.au, B.Rasmussen@curtin.edu.au)

The Paleoproterozoic Earaheedy Basin occupies the eastern end of the Capricorn Orogen that separates the Archean Pilbara and Yilgarn Cratons. The maximum depositional age of the Yelma Formation at the base of the Earaheedy Group is less than ~2.0 Ga from detrital zircon dating [1], while the minimum age is very poorly constrained. Sandstones of the Yelma Formation overlie granitic rocks of the Yilgarn Craton in the Earaheedy Basin, and outliers that extend up to 100 km south of the basin overlie Yilgarn Craton rocks or metasedimentary rocks of the Yerrida Group. The Yelma Formation was deposited on a broad shallow shelf over an extensive area of the northern margin of the Yilgarn Craton. Within the basin, carbonates of the Sweetwaters Well Member of the Yelma Formation host minor Pb-Zn sulphide mineralization of Mississippi Valley type [2]. Secondary Pb mineralization, interpreted to have resulted from weathering and remobilization of sulphide mineralization [3, 4], is being mined in ouliers of Yelma Formation at Magellan and Cano.

$^{207}Pb/^{206}Pb$ dating of authigenic monazite in sandstones of the Yelma Formation within the Earaheedy Basin gave an age of 1.81 Ga, which is interpreted to be the age of metamorphic or hydrothermal fluid flow, and may be related to the MVT mineralization. This age provides a firm minimum for deposition of the formation. At Cano, monazite is intergrown with iron oxides, interpreted to have replaced pyrite, in Pb-bearing greywacke. $^{207}Pb/^{206}Pb$ dating gave a similar, though imprecise, age, with many analyses recording high levels of common Pb. A Pb/Pb isochron age derived from outgrowths of xenotime on detrital zircon gave the same age, within error, and Pb isotope compositions support consanguinity with the MVT mineralization.

REE phosphates are very sensitive to the passage of metamorphic and hydrothermal fluids, often recording multiple fluid events. In the Earaheedy Basin, they constrain the depositional age of the Yelma Formation to ~2.0-1.81 Ga, and the timing of base metal mineralization to ~1.81 Ga.

Concentrations of the volatiles H_2O, CO_2, S, Cl, and F and elemental compositions of primary magmas and their sources can be estimated through the study of olivine-hosted melt inclusions in volcanic rocks, thereby providing insights about melting processes in the mantle. These volatiles play a major role in both the formation and evolution of mantle melts, and yet their impact on intraplate volcanism on the continents and in the ocean basins may be grossly underestimated. We have determined the major-oxide, trace-element and volatile (H_2O, CO_2, S, Cl, and F) concentrations of olivine-hosted melt inclusions from the Columbia River Plateau (CRP)-Snake River Plain (SRP) large igneous province, West Antarctic Rift System, and Iceland, all three areas with intraplate volcanism hypothesized to be related to plume activity.

Most of the samples we have analyzed record minimum H_2O concentrations of 1 wt% or higher, exceeding the largest values obtained for subaerial eruptions in Hawaii of 0.8 wt%. The most H_2O-rich lava in the SRP has 3.3 wt%, and in the Columbia River Basalts (CRB) values reach 4.2 wt% H_2O. Concentrations in Icelandic and West Antarctic Rift melt inclusions reach values of 3.0 and 2.2 wt% H_2O, respectively. Water and CO_2 are correlated and follow magmatic degassing curves. Furthermore, the highest volatile concentrations are always found in the more primitive melt inclusions, based on major oxide and trace element abundances, indicating that the volatiles are of mantle origin, not artefacts of differentiation in the crust. The trace element and volatile variability, high concentrations of water, and recent studies of Os isotopes in these tectonic settings provide compelling evidence that the volatiles and chemical heterogeneity of the magma sources may be caused by the recycling of ancient oceanic crust.

I-Pu-Xe in OIBs and the early separation of the plume source from the MORB source mantle

SUJOY MUKHOPADHYAY

Dept. of Earth and Planetary Sciences, Harvard University, Cambridge, MA 02138, USA (sujoy@eps.harvard.edu)

The noble gases provide unique insights into mantle structure and the origin of the different mantle reservoirs. In particular, the noble gases are thought to provide one of the strongest evidence for regions of the deep mantle to have largely escaped melt extraction. However, the interpretation of the noble gas data remains a matter of active debate. For example, OIBs have lower $^{40}Ar/^{36}Ar$ and $^{129}Xe/^{130}Xe$ ratios than MORBs. This observation has been variously interpreted to reflect the sampling of a relatively undegassed mantle reservoir or preferential sampling of recycled plates with seawater derived atmospheric Ar and Xe. These two interpretations have very different implications for mantle differentiation, and the creation and destruction of mantle heterogeneities. Here I will present new He, Ne, Ar, and Xe data from Iceland that will allow the above interpretations to be critically evaluated.

The relative abundances of ^{4}He, ^{21}Ne, and Ar in the Iceland sample are in the same proportion as the mantle production rates for these isotopes. As a result, the sample preserves an elementally unfractionated pattern that allows the abundance pattern of the priomordial noble gases in the plume source to be reconstructed. Strong linear relationships are observed between isotope ratios and elemental ratios (e.g. $^{40}Ar/^{36}Ar$-$^{3}He/^{36}Ar$, $^{129}Xe/^{130}Xe$-$^{3}He/^{130}Xe$) that reflect mixing between mantle-derived noble gases and shallow-level atmospheric contamination. Importantly, while the gas-rich 'popping rock' from the N. Atlantic ridge and the Iceland sample share a common shallow-level atmospheric contaminant, they trend towards very different mantle $^{40}Ar/^{36}Ar$ and $^{129}Xe/^{130}Xe$ ratios. Additionally, the Iceland sample has a large proportion of Pu-derived to U-derived fission xenon. Hence, for the first time, the Iceland data provides unequivocal evidence that the differences in Ar and Xe isotopic compositions between MORBs and OIBs cannot be generated solely through preferential re-circulation of atmospheric noble gases into the OIB source. The differences reflect a lower degree of outgassing of the plume source. Further, because ^{129}Xe is produced from extinct ^{129}I, the result demonstrates that chemical differences between OIBs and MORBs must have been established within the first 100 Myrs of Earth history and subsequent mantle convection has not wiped out the differences established in the early Earth.

Architecture of submicron organo-mineral domains in soil aggregates – Evaluation by NanoSIMS

C.W. MÜLLER, C. HÖSCHEN AND I. KÖGEL-KNABNER

Lehrstuhl für Bodenkunde, Technische Universität München, 85350 Freising-Weihenstephan, Germany (*correspondence: carsten.mueller@wzw.tum.de)

During soil aggregation primary soil particles such as clay and silt, iron and aluminium (hydro)oxides and particulate organic matter are bound together to complex aggregates. The spatial mixture of mineral and organic components results in diverse interfaces controlling soil organic matter stabilization but also sorption processes. Until nowadays it was hard to analyse the spatial distribution of mineral and organic domains within intact soil aggregates together with its turnover.

The nano-scale secondary ion mass spectrometry (NanoSIMS) enables us to analyse biogeochemical processes and properties of inner aggregate spheres at a submicron scale. NanoSIMS allows the simultaneous analysis of up to seven ion species with high sensitivity and lateral resolution. With Cs^{+} as primary ions, negatively charged ions, like e.g. $^{12}C^{-}$, $^{13}C^{-}$, $^{12}C^{14}N^{-}$, $^{12}C^{15}N^{-}$, $^{27}Al^{16}O^{-}$ and $^{28}Si^{-}$, are collected with a lateral resolution down to 50 nm. Using O^{-} as primary ion, positively charged ions like e.g. $^{24}Mg^{+}$, $^{40}Ca^{+}$ and $^{56}Fe^{+}$, are collected with a lateral resolution down to 150 nm.

For the present study we used soil material of topsoils from an agricultural cropland and a forest. Both soils were derived from labelling experiments using litter enriched in ^{15}N (mustard litter on cropland soil, beech litter on forest soil). The air dried soil aggregates were embedded in an epoxy-resin, cut and polished in order to obtain a smooth inner aggregate surface. A cascade from reflectance light microscopy, scanning electron microscopy to NanoSIMS was used to evaluate architecture, elemental composition and ^{15}N location within intact soil aggregates.

A spatial mixing of mineral compounds into plant residues with still visible cell structures was shown within aggregates. We can demonstrate that the incorporated ^{15}N-labelled organic matter is not distributed homogeneously, but resides at specific micron-scale spots within soil aggregates. The packing of mineral and organic domains in soil aggregates showed distinctively alternating spatial patterns. The NanoSIMS technique therefore allows the combined *in situ* evaluation of specific aggregate structures and their possible functions in terms of organic matter sorption and turnover.

Comparative study of the U(VI) complexation onto γ-Al_2O_3 by ATR FT-IR and EXAFS spectroscopy

KATHARINA MÜLLER*, HARALD FOERSTENDORF, ANDRÉ ROSSBERG, KAROLINE STOLZE AND KATHARINA GÜCKEL

Helmholtz-Zentrum Dresden-Rossendorf, Institute of Radiochemistry, Dresden, Germany (*correspondence: k.mueller@hzdr.de)

Aluminates, representing an essential component of clay minerals, play a decisive role in regulating the mobility of contaminants in rock and soil formations, in particular due to their tendency to form coatings on mineral surfaces [1].

In this work, U(VI) sorption on γ-Al_2O_3 is comparatively investigated using *in situ* vibrational and X-ray absorption spectroscopy. The focus was set to micromolar U(VI) concentrations and a variety of environmentally relevant sorption parameters in order to resolve discrepancies reported earlier [2-4].

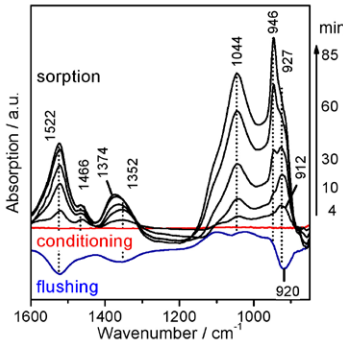

Figure 1: TR ATR FT-IR spectra of U(VI) soprtion on γ-Al_2O_3.

Time-resolved (TR)IR spectroscopic sorption experiments at the alumina-water interface evidence the formation of three different species as a function of surface loading (c. f. Figure 1): a monomeric carbonate complex, an oligomeric surface complex and a surface precipitate. These results are confirmed by IR experiments performed at different flow rates, pH values, ionic strengths, U(VI) concentrations, and in inert gas atmosphere. Results of EXAFS experiments of batch samples are consistent to these findings.

The role of comets as possible contributors of water and prebiotic organics to terrestrial planets

M.J. MUMMA* AND S.B. CHARNLEY

NASA-Goddard Space Flight Center, Solar System Exploration Division, Greenbelt, MD, 20771, USA (*correspondence: michael.j.mumma@nasa.gov)

The question of exogenous delivery of organics and water to Earth and other young planets is of critical importance for understanding the origin of Earth's water, and for assessing the prospects for existence of Earth-like exo-planets. Viewed from a cosmic perspective, Earth is a dry planet yet its oceans are enriched in deuterium by a large factor relative to nebular hydrogen. Can comets have delivered Earth's water? The deuterium content of comets is key to assessing their role as contributors of water to Earth.

Icy bodies today reside in two distinct reservoirs, the Oort Cloud and the Kuiper Disk (divided into the classical disk, the scattered disk, and the detached or extended disk populations). Orbital parameters can indicate the cosmic storage reservoir for a given comet. Knowledge of the diversity of comets within a reservoir assists in assessing their possible contribution to early Earth, but requires quantitative knowledge of their components – dust and ice. Strong gradients in temperature and chemistry in the proto-planetary disk, coupled with dynamical dispersion of an outer disk of icy planetesimals, imply that comets from KD and OC reservoirs should have diverse composition.

The primary volatiles (native to the nucleus) provide the preferred metric for building a taxonomy for comets, and the number of comets so quantified is growing rapidly. Taxonomies based on native species (primary volatiles) are now beginning to emerge [1, 2, 3]. The measurement of cosmic parameters such as the nuclear spin temperatures for H_2O, NH_3, and CH_4, and of enrichment factors for isotopologues (D/H in water and hydrogen cyanide, $^{14}N/^{15}N$ in CN and hydrogen cyanide) provide additional tests of the origin of cometary material. I will provide an overview of these aspects, and implications for the origin of Earth's water and prebiotic organics

Change in lead sorption during transformation of monohydrocalcite to aragonite

T. MUNEMOTO AND T. MURAKAMI

Department of Earth and Planetary Science, the University of Tokyo, Tokyo 113-0033, Japan
(*correspondence: munemoto@eps.s.u-tokyo.ac.jp)

Monohydrocalcite ($CaCO_3 \cdot H_2O$) (MHC) is a metastable calcium carbonate found in the sediments of mordern saline and alkaline lakes. MHC transforms to anhydrous calcium carbonates such as calcite and aragonite [1]. The sorption behavior of aqueous metal ions to calcite, the most stable calcium carbonate, is well known [2], but little to metastable calcium carbonates. We conducted uptake experiments of lead ion on monohydrocalcite to examine change in sorption behavior of lead ion during transformation of monohydrocalcite to aragonite.

Solutions of Na_2CO_3, $NaHCO_3$, $NaNO_3$, NaOH, HNO_3, and 1μM of Pb^{2+} (I = 0.13) were adjusted to pH 8.50, 9.00, and 9.50 by changing the concentrations; the concentration of CO_3^{2-} was kept constant for any solutions. Then, 2g/L of synthesized monohydrocalcite was added to the solutions at 25 °C, and the concentrations of lead and some other cations were measured at the end of each batch experiment. The run duration was up to 15 hours.

Aragonite increased in amount gradually with time while monohydrocalcite decreased with time; the growth rates of aragonite were almost the same between the three different pH conditions. Monohydrocalcite was almost completely replaced by aragonite for 15 hours. The distribution coefficient, $k_d=(Pb)_{sold}/(Pb)_{solution}$ (L/g), generally decreased with time; the difference in pH did not show a significant difference in k_d. The k_d values were almost the same between the three different pH conditions after the 15 hour experiments. And the final uptake of Pb^{2+} was nearly 90% for all the three different-pH experiments. The k_d values during the transformation were higher than those of calcite and aragonite [2]. Our results suggest that the k_d value decreases with increase in aragonite, i.e. during the transformation of monohydrocalcite to aragonite.

Indistinguishable Hf/W in the silicate Earth and the silicate Moon

CARSTEN MÜNKER[1,2], STEPHAN KÖNIG[1,2] AND TONI SCHULZ[1,2,3]

[1]Institut für Geologie und Mineralogie, Universität zu Köln
[2]Steinmann Institut, Universität Bonn
[3]Institut für Geologie, Universität Wien

The W isotope composition and the Hf/W ratio of the silicate Earth and the silicate Moon can help to unravel the relative chronology of the Moon-forming giant impact event and core formation on Earth. It has been established by now that the silicate Earth and the Moon are indistinguishable in terms of their W isotope signature [1]. Yet, it has long been assumed that the Hf/W ratio of the silicate Moon (26.5 [1])is higher than that estimated for the silicate Earth (18.7) [2]. Based on these two values and the similar W isotope composition, a maximum age of the Moon-forming giant impact has been estimated to ca. 60 Ma after solar system formation [1]. Here we evaluate new Hf/W estimates of the silicate Earth and the silicate Moon.

The Hf/W ratio of the silicate Earth has traditionally been estimated assuming near constant W/Th or W/U and chondritic Hf/U or Hf/Th ratios [2, 3]. Our recently published mass balance estimate for W in the silicate Earth challenges this view, as W has been shown to be highly mobile in subduction systems. This leads to substantial W/Th and W/U fractionations in arc lavas/OIBs. An improved mass balance estimate for the silicate Earth, based on Ta/W systematics in major silicate reservoirs has yielded a Hf/W of 25.8 [4].

For the Moon, a re-evaluation of existing W-Th-U-Ta data together with new high precision data yields a Hf/W of 24.9 for the silicate Moon [5], similar within error to previous estimates. Notably, the lunar value is indistinguishable from the revised Hf/W for the silicate Earth.

Together with the identical ^{182}W compositions of the silicate Earth and the silicate Moon [1], the similar Hf/W ratios now strongly imply that the Moon forming giant impact might have triggered an efficient metal-silicate re-equilibration on Earth. It is therefore likely, that radiogenic ingrowth of excess ^{182}W in the Earth's mantle relative to chondrites largely occurred after the giant impact and is to a lesser extent an inherited feature from early formed planetesimals. Morover, the model age for single stage core formation on Earth may in fact be close in time to the age of the Moon forming giant impact.

Dynamical properties of $CaIrO_3$ under high pressure from *ab initio* calculations

A. MUÑOZ AND P. RODRÍGUEZ-HERNÁNDEZ

MALTA Consolider Team, Departamento de Física Fundamental II, and Instituto Universitario de Materiales y Nanotecnologia, Universidad de La Laguna, 38205La Laguna, Tenerife, Spain (amunoz@marengo.dfis.ull.es)

$CaIrO_3$ crystallizes in the orthorhombic Cmcm at normal conditions. This compound is attracting important interest as a low-pressure isostructural analog of the predicted postperovskite high pressure phase of $MgSiO_3$. Here we perform an ab initio density functional calculations of the structural and dynamical properties under hydrostatic pressure for the Cmcm and the Pbnm phase of of $CaIrO_3$.

Our studies have been performed in the framework of DFT with echange correlation taken in generalized gradient approximation (GGA) with the PBEsol prescription. We use the pseudopotential method with ultrasoft PAW pseudopotentials with an energy cutoff of 520 eV. Such a large cutoff was required to achieve highly converged results within the projector augmented wave (PAW) scheme. The PAW method takes into account the full nodal character of all the electron charge density distribution in the core region. We use a dense grid of k-special points for integrations along the Brillouin zone (BZ) in order to assure highly converged results.

Lattice dynamics calculations of phonon modes were performed at the zone centre (Γ point) of the BZ. The calculations provided information about the frequency, symmetry and polarization vector of the vibrational modes in each structure. We use direct force-constant approach (or supercell method). Diagonalization of the dynamical matrix provides both the frequencies of the normal modes and their polarization vectors. It allows us to identify the irreducible representations and the character of phonon modes at the Γ point. We will report the Raman and IR actives modes, the pressure derivarives, the phonon dispersion, the phonon density of states and the projected DOS.

Vertical distribution of iodine in pore water collected from Japan Sea sediments: Origin of iodine-rich fluid associated with methane hydrate

Y. MURAMATSU[1], H. ANZAI[1], H. TOMARU[2], R. MATSUMOTO[2] AND H. MATSUZAKI[3]

[1]Dept. of Chemistry, Gakushuin University, Toshima, Tokyo, 171-8588, Japan: (yasuyuki.muramatsu@gakushuin.ac.jp)
[2]Dept. of Earth and Planetary Sciences, University of Tokyo, Bunkyo, Tokyo, 113-0032, Japan
[3]Dept. of Nuclear Engineering and Management, University of Tokyo, Bunkyo, Tokyo, 113-0032, Japan

In our previous studies, we have analyzed iodine in many geochemical samples systematically and found that nearly 70% of iodine in the Earth's crust is estimated to exist in marine sediments (Muramatsu and Wedepohl 1998). We also studied occurrences of iodine rich brine associated with methane seepage in different areas surrounding Japan (Muramatsu *et al*. 2001, 2007).

In this study we have analyzed halogens and some other elements in pore water samples collected from Japan Sea sediments of methane hydrate areas. Sediment cores were recovered from the Umitaka Spur and the Joetsu Knoll region, eastern margin of the Japan Sea, during the cruises of Umitaka-Maru in 2009 and R/V Marion Dufresne in 2010 (MD179). The depth of the sediments collected were down to about 40m below sea floor. Concentrations of iodine, bromine and some other elements were analyzed by ICP-MS and those of chloride and sulfate were by ion-chromatography.

Analytical results showed that iodine concentration in pore water increased markedly with depth. The slope of the increase was rather constant. The highest concentration found in the Umitaka Spur was 0.4 mM (about 50ppm) which is nearly 1000 times higher than the seawater concentration. No marked increases of iodine were found in the samples collected from control areas without methane seepage.

We also determined $^{129}I/^{127}I$ ratios by AMS in pore water samples at defferent depth. As a result, the $^{129}I/^{127}I$ ratios tended to be lower in the deeper layers. The lowest ratio was about 0.13×10^{-12}, which was older than 50 Ma. This age is before the opening event of Japan Sea. Considering the age of iodine obtained and the depth profile of the iodine concentrations, iodine and possibly methane are originated from deeper layers and transported with aqueous fluids into the surface layers.

This study was supported by MH21 Research Consortium Japan

Sr, Nd, Hf and Pb isotope characterisation of basalts from IODP Site U1346, Shirshov Massif the youngest edifice of the Shatsky Rise, northwest Pacific

DAVID MURPHY[1]*, JÖRG GELDMACHER[2] AND IRINA ROMANOVA[3]

[1]Discipline of Biogeosciences, Queensland University of Technology, Brisbane, Qld. 4001, Australia (*correspondence: david.murphy@qut.edu.au)
[2]USIO- IODP, Texas A&M University, College Station, TX 77845-9547, USA
[3]Discipline of Biogeosciences, Queensland University of Technology, Brisbane, Qld. 4001, Australia

The Shatsky Rise is a large volcanic plateau in the northwest Pacific that formed between 140–150 Ma on the Pacific oceanic crust [1, 2]. Magnetic lineations indicate that the plateau formed along the trace of a triple junction of oceanic spreading ridges [1]. Shirshov Massif is the northern most of the large seamounts within Shatsky Rise. It is a subcircular edifice, ~100 km in diameter. The Shirshov Massif represents a waning phase in the evolution of the Shatsky Rise, intermediate between the main phase of plateau formation at the Tamu Massif to the southeast and the much lower levels of magmatism represented by the younger Papanin Ridge to the northeast. In the parlance of the plume head hypothesis, Shirshov Massif is in the transition between plume head and tail.

During IODP Expedition 324 Hole U1346A, situated on the northern flank of the Shirshov massif, was drilled, penetrating thin sediment cover and into igneous basement. Two volcanic units were recognised, a 1.6m volcanic debris flow and a 50.1m thick succession of pillow lavas (and/or inflation units) that represent a single volcanic event [3].

Here we present Sr, Nd, Hf and Pb isotope data from the basaltic basement samples. We compare the isotope data to previous analyses from the Shatsky Rise [2], to other oceanic plateaus and to estimated mantle end member compositions in order to assess the nature of the mantle material that melted to form the final stage of plateau volcanism at Shatsky Rise.

U-Series disequilibrium in groundwater as a vector for U mineralisation

MELISSA J. MURPHY[1]*, ANTHONY DOSSETO[2], SIMON P. TURNER[1] AND BRUCE F. SCHAEFER[1]

[1]GEMOC, Department of Earth and Planetary Sciences, Macquarie University, Australia (*correspondence: melissa.murphy@mq.edu.au)
[2]GeoQuEST Research Centre, School of Earth and Environmental Sciences, University of Wollongong, Australia

Groundwaters often exhibit ($^{234}U/^{238}U$) activity ratios greater than one as a result of fractionation between ^{234}U and ^{238}U nuclides during rock/water interactions. However, when groundwaters pass through high-grade uranium mineralisation, congruent dissolution of uranium minerals should impart a ($^{234}U/^{238}U$) activity ratio which is at or very close to secular equilibrium.

This research characterises the uranium-series (U-series) disequilibria in groundwater surrounding a high-grade uranium deposit, and investigates the use of disequilibria in groundwater as a proxy for uranium exploration. U-Series isotopes have been analysed by isotope dilution MC-ICP-MS in groundwater samples along the groundwater flow path, within and surrounding the South Australian Four Mile and Pepegoona sediment-hosted uranium mineralised systems.

Samples collected down-gradient of the Four Mile mineralisation have ($^{234}U/^{238}U$) activity ratios ranging from 1.12 proximal to mineralisation, up to 2.08 approximately 10 kms down-gradient from mineralisation. U concentrations range from 0.5 – 200 ppb, with highest concentrations found in samples collected in mineralisation. Groundwaters sampled within the high-grade mineralisation show ($^{234}U/^{238}U$) activity ratios close to unity (1.05), which is consistent with the congruent dissolution of uranium minerals.

The observation of increasing disequilibrium with distance from mineralisation highlights the potential application of U-series isotopes as an indicator of high-grade uranium deposits.

However, the extent and distribution of disequilibrium at the Pepegoona deposit is not entirely consistant with proximity to the mineralisation. Groundwaters samples within mineralisation exhibit much higher ($^{234}U/^{238}U$) activity ratios than at Four Mile, averaging 1.41. Samples collected down-gradient have typically lower U concentrations and ($^{234}U/^{238}U$) activity ratios approaching unity. This signature reflects the highly variable local geology of the Pepegoona deposit.

Global warming and climate change: Impact on India

K.S. MURTY

101/28 Hindustan colony, Amaravati Rd., Nagpur 440033, India (murtysk1931@yahoo. co. in)

Global warming is here to stay and climate change will be intense. The warming could range from 1.8 dgrees to 4 degrees C. , which could lead to water scarcity and droughts as well as higher rainfall and floods. The impact will also affect biodiversity, forests and agriculture. India has seen stupendous growth in the agricultural sector and has become from once-food-importing to food-exportring country, after adopting new technologies and agriculture and its allied industries contribute to nearly 19 per cent of the total Gross Domestic Product (GDP). More than 60 per cent of the work force is dependent on this sector. Nearly two-thirds of the cropped areas in the region is rain-fed. Apart from this, the northern rivers derive much of their waters from the Himalayan glaciers. It has been reported that there has been accelerated rate of melting of these glaciers. Still higher rate of melting could affect fresh water supply sources in the Ganga-Brahnmaputra basin which could directly affect the biodiversity, livelihood of people in that region and lead to dramatc consequences of the country's economy. Hydropower generation could be drastically reduced, leading to an energy crisis. The country has a coastline of 6,000 km around which about 400 million people live. Any rise in the sea level, say by a meter, can lead to welfare loss of $1.859 million in India. As it is, tropical cyclones in the Bay of Bengal cause havoc in the coastal areas and any rise in sea level could mean a loss of 15 per cent of land area by 2020. Biospheres like the Sunderbans can be lost for ever and other mangrove forests may meet the same fate. Forests play a crucial role in the social, economic and cultural spheres of India. Many river systems originate in the forests and anchor rich biodiversity. Some 200,000 villages are located inside or on the fringes of forests and some 200 million people depend on forests for their livelihood. The Indian subcontinent is projected to experience a warming of 2 to 6 degrees by the end of the current century with consequences of reduced or increased rainfall, threat to biodiversity and in general to the rate of growth of its economy. Urgent steps are needed to face these threats and the Government of India is grappling with this problem.

Direct aerosol effect from multimodel simulations in AeroCom

G. MYHRE

Center for International Climate and Environmental Research – Oslo (CICERO), Norway, (gunnar.myhre@cicero.uio.no)

There has been a substantially development of the global aerosol models over the last decade. Despite this development and advanced aerosol observations uncertainties in the direct aerosol effect is substantial. AeroCom is a global aerosol model intercomparison exercise [1, 2] and Phase II simulations have recently been performed. Here we present results from several global aerosol models with simulations of the direct aerosol effect based on aerosol emissions for present and pre-industrial conditions. The solar radiative forcing (RF) of the total direct aerosol effect range between -0.6 and -0.05 Wm^{-2}. All models in the study include anthropogenic changes in sulphate, black carbon (BC) from fossil fuel, organic carbon (OC) from fossil fuel, and biomass burning aerosols (BC and OC). Some of the models also include anthropogenic changes in secondary organic aerosols and nitrate in the model simulations. The spread in the RF is large for the carbonaceous aerosols, with RF for BC from fossil fuel ranging from 0.14 to 0.37 Wm^{-2}. The few models performing RF of secondary organic carbon and nitrate shows even larger relative range in the RF.

We analyze the results with respect to burden, aerosol optical depth, and extinction coefficients to explore the causes for the differences. Further, vertical profile differences which are particularly important for BC is quantified in terms of RF.

X-ray analysis of reactive C-, N-, P-, and S-functional groups in NOM

S.C.B. MYNENI

Department of Geosciences, Princeton University, Princeton, NJ 08544, USA

NOM plays an important role in many biogeochemical processes, and the conentration and chemistry of functional groups of NOM dictate their role in different processes. Traditional laboratory techniques, such as NMR and IR, have been used for decades to examine the functional group composition of isolated NOM. In the last decade, synchrotron based X-ray absorption spectroscopy (XAS) and spectromicroscopy methods allowed the examination of functional groups of NOM in their pristine state in soils and sediments at nanometer resolution. A discussion of XAS of reactive functional groups in NOM and their cycling in terrestrial systems will be presented.

Using XAS, we examined isolated NOM from different environments, and NOM in selected soils without any isolation. The XAS of several simple molecules containing different C-, N-, P-, and S-groups were also examined, and their spectra helped in interpreting the electronic states of different functional groups of NOM. X-ray spectra were also collected in different ways (using electron and fluorescence yield, and transmission) to identify the best detection schemes.

While several functional groups are identified using XAS, the ability to detect different C-moieties with X-rays is not as good as NMR. However, XAS contributes new information on the aromatic-N, amides, and nitrosyls. The detection of P groups using XAS is at par with that of NMR. However, small variations in the XAS of P can be used to detect the bonding environments of phosphate or phosphonate groups. The S-XAS spectra of NOM provide unique information on both the reduced and oxidized functional groups of S.

The electronic transitions, probed using XAS, are highly sensitive to small changes in the local coordination environments of functional groups, and the X-ray spectra change with changes in the protonation state, metal complexation (type of metal, and the number of metals), and symmetry of functional groups. The X-ray spectra are also sensitive to sample thickness and the concentration of the reactive groups, which can influence the relative concentration estimates. Ignoring these variations can result in the incorrect identification of the functional groups.

Geochemical monitoring of reactive percolation experiments using carbon stable isotopes

A. MYRTTINEN[1]*, E. JEANDEL[2], O. UKELIS[2], ALAIN DIMIER[2], V. BECKER[1], R. VAN GELDERN[1] AND J.A.C. BARTH[1]

[1]GeoZentrum Nordbayern, Friedrich-Alexander Universität Erlangen-Nürnberg, 91056 Erlangen, Germany (*correspondence: myrttinen@geol.uni-erlangen.de)

[2]European Institute for Energy Research, D-76131 Karlsruhe, Germany

Reservoir petrophysical property changes (permeability/porosity) are crucial issues, which need to be considered in carbon capture and storage (CCS) and enhanced oil and gas recovery (EOR and EGR). The potential hydrodynamic and geochemical reactions during such initiatives need to be well understood for planning, as well as for monitoring purposes. CO_2-rock-brine interactions are often analysed using geochemical parameters such as ion concentration changes. Stable isotope measurements of carbon ($\delta^{13}C$)are currently used as a method to montor and quantify geochemical changes during CO_2-injection. The applicability of using these isotopes as an additional and new monitoring tool to verify permeabiliy changes in the host rock has been tested in a series of laboratory experiments with a new reactive percolation bench, ICARE 4. Reservoirs, considered suitable for CO_2 injection, often host carbonate phases in contact with brine. Carbonate dissolution, plays a major role in host rock permeability changes during CO_2 injection. In order to test the geochemical effects of such a scenario, supercritical CO_2 was injected into brine in contact with quarzitic limestone. Results indicate good correlations between permeability, $\delta^{13}C$, DIC and calcium concentration data. Once CO_2-breakthrough occurred, permeability increased from a minimum of 0.1 millidarcy (mD) to a maximum of ~ 1.4 mD. This was accompanied by a $\delta^{13}C_{DIC}$ increase from ~ -5 ‰ to 0 ‰; DIC concentration increase from 0 mg L^{-1} to 3000 mg L^{-1} and a calcium concentration increase from below 100 mg L^{-1} to ~ 1400 mg L^{-}. These first data imply that $\delta^{13}C$ is a valid monitoring parameter for observing critical geochemical changes indicating CO_2 rock-brine interaction, which may be used to verify permeability development during CO_2 injection.

P^{5+} and Ti^{4+} solution mechanisms of and partitioning between fluids and melts at crustal and upper mantle pressure and temperature

BJORN O. MYSEN

Geohysical Laboratory, Carnegie Instn. Washington, 5251 Broad Branch Rd., NW, USA (bmysen@ciw.edu)

Solution mechanisms of P- and Ti-bearing, H_2O-saturated silicate melts, silicate-saturated aqueous fluids, and silicate-rich single phase (supercritical) liquids have been characterized *in situ* to 900°C/2.2 GPa with vibrational spectroscopy as structural tool. Partitioning of P- and Ti species between fluid and melt was also determined. Starting materials were aluminum-free $Na_2O•4SiO_2$ (NS4) and with 10 mol % Al_2O_3 (NA10) substituting for SiO_2, with 10 mol % TiO_2 or 5 mol % P_2O_5. The structure of Ti-bearing aqueous fluids in equilibrium with rutile was also characterized.

Aluminosilicate species of Q^o, Q^1, Q^2, and Q^3 type exist in coexisting fluid and melt in both Ti- and P-bearing systems. In melts, the abundance of the most depolymerized silicate species, Q^o, is positively correlated with temperature and pressure, whereas that of the most polymerized species, Q^3, decreases with temperature and pressure. In the silicate solute in aqueous fluids, Q^3 (and Q^1 and Q^2) abundance increases with temperature and pressure. The phosphate species in melts and fluids are of PO_4, P_2O_7, and Q^nP type. In the Ti-bearing silicate systems, isolated TiO_4 tetrahedra in melts and fluids probably share oxygen with neighboring silicate tetrahedra. The Ti in aqueous fluids in TiO_2 (rutile)-H_2O comprises polyhedra with greater oxygen coordination numbers.

The fluid/melt partition coefficients for P_2O_7 and Q^nP species are in the 0.15-0.7 range. The PO_4 fluid/melt partition coefficients are <0.2. These partition coefficients increase with increasing temperature and pressure. There is no clear influence of Al_2O_3. The fluid/melt partition coefficient of Ti in the equivalent Ti-bearing systems increases from ~0.1 to ~0.5 in the 200°-500°C and 0.4-1 GPa temperature and pressure range with greater values in Al-bearing systems. The Ti concentration in aqueous fluids coexisting with rutile in the same pressure and temperature range is ≤10% of that in the silicate systems.

The P-bearing complexes in fluids and melts are associated with Na^+ in the silicate systems, whereas Ti^{4+} in silicate systems may form more complex complexes that involve both Na^+ and Al^{3+}. Formation of such complexes can enhance Ti and P solubility in aqueous fluids can enhance their solubility by at least and order of magnitude compared with silicate-saturated systems.

In situ, high-pressure/-temperature experimental determination of structure-property relations in silicate melt-COHN systems

BJORN O. MYSEN

Geohysical Laboratory, Carnegie Instn. Washington, 5251 Broad Branch Rd., NW, USA (bmysen@ciw.edu)

Voletiles in the COHN system, when dissolved in silicate melts, affect their transport and thermodynamic properties. Quantitative characterization of solution mechanisms, central to characterization of melt properties, has been carried out while melts and coexisting COHN fluids were at the desired pressure and temperature.

In aluminosilicate melt-H_2O, the ΔH of the water speciation equilibrium, $H_2O°(melt) + O(melt) \leftrightharpoons 2OH(melt)$, is ~30 kJ/mol with ΔH positively correlated with Al/(Al+Si) of the melt. This speciation equilibrium coupled with an appropriate silicate speciation equilibrium becomes, Q^n (M) + $H_2O \leftrightharpoons Q^{n-1}$ (H), where (M) and (H) denotes metal cation and protons associated with nonbridging oxygen. The ΔH for the reaction is ~6±2 kJ/mol with a slight positive correlation with Al/(Al+Si).

In melt-COH and melt-NOH systems, f_{O2} is an additional variable affecting solubility and solution mechanisms. From haplobasalt to haploandesite melt-COH, the carbon solubility at upper mantle pressures and temperatures decreases from ~2 wt% to ~1 wt% in equilibrium with CO_2 gas, whereas under reducing conditions, decrease is from about 0.3 to about 0.15 wt% in equilibrium with NH_4+H_2 gas. Oxidized carbon is dissolved dominantly as CO_3 groups, whereas reduced carbon in the COH system is dissolved as a mixture of CH_3 groups and CH_4 molecules. In compositionally analogous NOH-saturated melts, under oxidizing conditions, nitrogen solubity is insensitive to melt composition, whereas in reduced melts, the solubility decreases from ~1 wt% to ~0.3 wt% in equilibrium with NH_3 gas in the composition range from haploandesite to haplobasalt. The solubility increases rapidly with decreasing f_{O2}. Oxidized N is dossolved as N_2 molecules, whereas reduced nitrogen is dissolved as NH_2 groups and NH_3.

By changing f_{O2} from oxidized to reduced, resultant changes of C and N solution mechanisms in melt-COHN systems cause NBO/T changes, which affect transport properties. For example, melt viscosity under oxidizing and conditions is, $\eta=4.4+0.75[0.35-(X_{CO2}/50)]^{-4.1}$, whereas under reducing conditions it is, $\eta=4.4+0.75[0.35+(X_{CH4}/30.3)]^{-4.1}$. This illustrates how redox conditions alone can change melt properties relevant to magmatic processes in the Earth's interior.

Lithium isotope fractionation at the soil–plant interface

O. MYŠKA[1], T. MAGNA[1,2], M. NOVÁK[1], J. ŠIKL[1], V.ZOULKOVÁ[1] AND F. OULEHLE[1]

[1]Czech Geological Survey, Prague, Czech Republic
[2]Universität Münster, Germany

Lithium abundances and isotope compositions were determined for an extensively studied site in the Krušné hory Mts. in order to search for previously unknown stable isotope fractionations of non-nutrient trace elements between soils and vegetation cover (Picea *sp*., Fagus *sp*.). In the soil profile, Li contents decrease from ~60 ppm at 40–80 cm depth to 20 ppm at 0–10 cm depth und to 6 ppm in the uppermost organic layer (Oi+Oe) whereas sup-ppm Li levels were consistently found in roots, stem and needles. Stems have the lowest Li contents of all analyzed tree compartments. The Li contents show tight positive linear correlation with Mg both in soils and trees but less defined correlation with other alkali elements (Na, K). Soil, developed on granitoid bedrock, appears to reflect its magmatic precursor with only limited modification through weathering or fluid circulation. Roots of both Picea *sp*. and Fagus *sp*. show no significant difference relative to δ^7Li of underlying soils despite different rooting depth (shallow for Picea, deep for Fagus). In contrast, stem wood of both species consistently shows significant enrichments in ^{7}Li relative to roots and soils (cf. [1]); in particular, δ^7Li difference of >16‰ has been found for Picea stem and roots. It thus appears that stem may fractionate Li isotopes significantly, irrespective of botanic classification or taxonomy of the corresponding species (gymnospermous, angiospermous) but the extent of this fractionation may depend on qualitative characteristics of the wood, such as proportion of xylem and phloem, structural bonding of celulose etc. In either case, the data require more complex examination of interaction between plants and substrate with respect to different rooting depths, chemistry, bottom water flow, nutrient availability etc.

Overall, the results are best explained by low utilization of Li in biological matter despite modest bioavailability of Li from grown substrate. Whether or not net ^{7}Li enrichments in plants are a general feature remains unconstrained but it could be consistent with positive Li–Mg correlation in plants and high δ^{26}Mg in wheat that has been found to result from preferential uptake of heavy Mg from the nutrient supply into plants [2].

Tracing the source of IRD in the Heinrich Layers of the North Atlantic

B. DAVID A. NAAFS[1,2]*, JENS HEFTER[1], SHUNXIN ZHANG[3] AND RUEDIGER STEIN[1]

[1]Alfred Wegener Institute for Polar and Marine Research, (*correspondence: david.naafs@awi.de) D-27568 Bremerhaven, Germany
[2]Leibniz Center for Earth Surface and Climate Studies, Potsdam University, D-14476 Potsdam, Germany
[3]Nunavut Geosciences Office, NU X0A 0H0 Iqaluit, Canada

Heinrich Events (HEs) are among the most dramatic examples of millennial-scale climate variability. During HEs large amounts of ice-rafted debris (IRD) derived from glacial erosion of continental bedrock accumulated in the sediment of the North Atlantic, forming Heinrich Layers (HLs) [1]. One of the key issues in understanding the still poorly understood mechanisms behind HEs is the development of specific provenance indicators that provide information about the source areas of the IRD [2]. Here we present an organic geochemical study on the type, distribution and relative abundance of biomarker compounds of extractable organic matter from the different HLs of the last glacial at multiple locations in the North Atlantic.

The results demonstrate that an unique assemblage of organic 'petrogenic' compounds such as (benzo)hopanes, mono- and triaromatic steroids, and palaerenieratene and isorenieratene-derivatives characterize the HLs in the North Atlantic. The presence of aromatic counterparts and dominance of mature isomers in the hopanoids and steroids indicates that the biomarker distribution within HLs is incompatible with recent sediments [3]. Rather, these compounds derive from the transportation of ancient organic matter by icebergs because of glacial erosion of bedrock in the Hudson Bay Area. Comparison of the biomarker assemblage of HLs with available geologic and organic-geochemical data allowed narrowing down the assumed source of IRD to a sequence of Upper Ordovician oil shales and limestones outcropping in and close to the Hudson Strait, which have a strikingly similar biomarker signature to that of HLs. Monitoring the presence of these petrogenic compounds in marine sediments thus allows to distinguish organic matter in HLs from adjacent samples and can be used as specific organic-geochemical tracers for the input of continental material from the Hudson Bay Area in northern Canada.

The nature of fluid flow through vertical formations in the aureole of the EJB pluton, White Mountains, California

P.I. NABELEK[1]* AND S.S. MORGAN[2]

[1]Dept. of Geological Sciences, Univ. of Missouri, Columbia, MO 65211, USA (nabelekp@missouri.edu)
[2]Dept. of Geology and Meteorology, Central Michigan University, Mt. Pleasant, MI 48859, USA (morga1ss@cmich.edu)

Petrology and stable isotope compositions of metamorphic rocks in the aureole of the Eureka Valley-Joshua Flat-Beer Creek (EJB) composite pluton, White Mountains, eastern California, were examined to determine nature of fluid flow in the aureole. The White Mountains were an arc terrain in the Jurassic and Cretaceous periods. The metamorphosed sedimentary rocks in the aureole are distinguished by having vertical orientations due to rotation and stretching resulting from forceful emplacement of magma. The sedimentary formations include Cambrian marbles, calc-silicates, schists, and quartzites. Each lithology behaved differently during contact metamorphism. Clean dolomite and calcite marbles did not equilibrate with an external fluid as revealed by unshifted $\delta^{18}O$ and $\delta^{13}C$ values of 20 to 25‰ and –1 to +2‰, respectively. Largest isotopic shifts occurred in calc-silicates where $\delta^{18}O$ decreased to ~15‰. The moderate $\delta^{18}O$ shift suggests that the calc-silicates equilibrated with an aqueous fluid whose oxygen isotope ratio was buffered by surrounding silicate metamorphic rocks. Infiltration of calc-silicates in the inner aureole by an aqueous fluid is also demonstrated by the presence of grossular garnet and vesuvianite.

Variation in mineralogy of schists reflects the variation in the Al/K ratio. Schists with higher ratios have andalusite whereas schists with lower ratios have K-feldspar. On the western side of the pluton, partial melting of inner aureole schists was driven by focused flow of aqueous fluids between the pluton and marbles. *P-T* pseudosections for the schists suggest that partial melting has occurred between 2.5 and 3 kbar and >660°C, and they predict a narrow subsolidus cordierite field. However, cordierite, feldspars, and other silicate minerals were altered by late pervasive fluid flow through the schists below 500°C. This fluid flow was probably driven by slow cooling of the large EJB pluton and/or continued magmatism in the arc terrain.

Overall, the data from the EJB aureole point to highly localized heterogenous flow in vertical calc-silicates and marbles, and pervasive and protracted flow through schists.

Kinetics of condensastion and cosmochemical fractionation of the planet forming materials in the early solar nebula

H. NAGAHARA* AND K. OZAWA

Dept. Earth Planet. Sci., The Univ. Tokyo, Hongo, Tokyo 113-0033, Japan
(*correspondence: hiroko@eps.s.u-tokyo.ac.jp)

Chemical Fractionation

Condensation is the first step of planet formation. The isotopic homogeneity except for oxygen of the planetary and meteoritic materials indicates that the early solar nebula was once totally evaporated and the precursor materials of the planets were subsequently condensed. Homogeneity of heterogeneity of the precursor materials of the planets is controlled by the competition between cooling time scale of the nebula, time scale of condensation, and time scale of transportation of the condensed phases.

Kinetic Condensation Experiments

We have carried out condensation experiments for Mg-silicates and metallic iron, which are the two most important solids for terrestrial planets, and obtained condensation coefficients (probability of condensation against number of collided molecules). The experimental results also showed unexpectedly wetted relationship between silicates and metallic iron, which further indicates heterogeneous condensation of planet forming materials.

Model and Results

We have developed kinetic condensation model and calculated the development of condensed phases as a function of gas cooling time scale, which includes physical separation of the dusts. The model contains two free parameters, the critical size for gas/dust separation and gas cooling time scale. The results show the relationship between the gas cooling time scale and the critical size for dust separation in order to generate chemical (Mg/Si/Fe) condensation. If the dust separation size was 1micron, the cooling time scale of the gas was 1-10^2 years, whereas the separation size was 1mm, the gas cooling time scale was 10^3-10^6 years. Thus, the precursor of the planets could have been fractionated depending on the viscosity of the disc, which predicts planets with diverse compositions in exoplanetary systems.

Molybdenum isotope fractionation in pelagic euxinia: Evidence from the modern Black and Baltic Seas

T.F. NÄGLER[1]*, N. NEUBERT[2], M.E. BÖTTCHER[3], O. DELLWIG[3] AND B. SCHNETGER[4]

[1]Institute für Geologie, Universität Bern, Switzerland (*correspondence: naegler@geo.unibe.ch)
[2]Institut für Mineralogie, Leibniz Universität Hannover, Germany
[3]Marine Geology Section, Leibniz Institute for Baltic Sea Research, Warnemünde, Germany
[4]Institute for Chemistry and Biology of the Marine Environment, University of Oldenburg, Germany

We present a model to explain isotope data of vertical profiles of dissolved molybdenum (Mo) of the Black Sea and the Baltic Sea. The entire water column of the Black Sea, as well as the anoxic waters of the euxinic deeps of the Baltic Sea show δ^{98}Mo values (up to 2.9 ‰) significantly above the homogeneous, open ocean waters (2.3 ‰). Further all water samples are enriched in the heavy isotope compared to published data of sedimentary Mo from the same range of water depths. The observed isotope fractionation between sediments and the anoxic water column of the Black Sea can be reconciled by a model involving published ab initio calculations of Mo isotope fractionation and thermodynamic thiomolybdate distributions parameters in dependence of H_2S_{aq}. The observed pattern can readily be explained as decreasing importance of mono-, di-, or tri- thiomolybdate scavenging with increasing H_2S_{aq}. The model results further imply that Mo isotopic composition of the water column is in equilibrium with that of the sediments. The effective equilibrium fractionation factor at any given depth depends on the relative abundances of the different thiomolybdates, and thus H_2S_{aq} abundance. An extrapolation to a theoretical pure MoS_4^{2-} solution indicates a fractionation constant between MoS_4^{2-} and authigenic solid Mo of 0.5 ± 0.3‰. Results from the Baltic Sea are in principle agreement with themodel, but are slightly offset. The latter is probably related to the occasional large scale inflow events which lead to temporary disequilibrium distribution of thiomolybdate species, due to the slow reaction kinetics of the $MoOS_3^{2-}$ to MoS_4^{2-} transition. δ^{98}Mo values of the upper oxic waters of both basins are higher than predicted by mixing models based on salinity. The results can be explained by non-conservative behaviour of Mo under suboxic to anoxic conditions in the shallow bottom parts of the basin, most pronounced on the NW shelf of the Black Sea.

Isotope study of Neoproterozoic to Lower Palaeozoic successions of the southern Kalahari craton

THANUSHA NAIDOO[1]*, UDO ZIMMERMANN[1], J.T. MIYAZAKI[2] AND J. VERVOORT[3]

[1]Institutt for petroleumsteknologi, Universitetet i Stavanger, Norway (*correspondence: thanusha.naidoo@uis.no)
[2]Institute For Research on Earth Evolution, JAMSTEC Natsushimacho, Yokosuka, Japan (tmiyazaki@jamstec.go.jp)
[3]School of Earth and Environmental Sciences, Washington State University, Pullman, USA (vervoort@wsu.edu)

The southern area of the Kalahari Craton is characterized by isolated Neoproterozoic to Lower Palaeozoic basins containing mostly immature psammites and pelites, and few carbonates. Outcropping conglomerates were falsely interpreted as glacial deposits in the wake of the snowball earth hypothesis, as none of the sedimentary rocks of the basins contain any characteristics of a glacial event or associated cap carbonates. Age constraints for the rocks are weak. Pb-Pb isotopes on carbonates point to an Ediacaran age but might reflect a metamorphic age. Sr and C isotope values do not always reflect primary seawater composition since clastic input and other environmental factors have hampered the results. Microfossil analyses show a low-species assemblage typical for the Early Ediacaran and alternatively the Uppermost Ediacaran, and global biostratigraphic markers are absent. Trace element geochemistry proposes, for some of the rocks, the influence of a mafic source mixed with felsic sediments, but high Ti, Nb and Ta concentration exclude a direct arc source. Detrital zircon analysis revealed the occurrence of Ediacaran zircons, in addition to Mesoproterozoic zircons as major source rock ages. Pb and Nd isotopes are comparable to those from the basement of Patagonia and the Arequipa-West Pampeanas Terrane. Nd model ages vary between 1.3 and 1.8 Ga, which is unexpected for the Kalahari Craton. This similarity to Patagonia suggests that, during the formation of Rodinia, the southern margin of the Kalahari Craton faced Patagonia or even shared the same basement. If so, then Patagonia possibly drifted slightly off the Kalahari craton during the Lower Palaeozoic and finally, into its modern position during the Late Palaeozoic.

Sorption of uranyl and arsenate on SiO_2, Al_2O_3, TiO_2 and FeOOH

SREEJESH NAIR* AND BRODER J MERKEL

Department of Hydrogeology, Technische Universität Bergakademie Freiberg,Gustav-Zeuner Str.12, 09599 Freiberg, Germany (*correspondence: sreejeshmc@gmail.com)

Migration of uranium or arsenic in aquatic environments is often controlled by sorption on minerals present along the water flow path. One of the major controlling factors of sorption is the aqueous speciation of these elements. Hence it is important to know the major species in order to predict the sorption behaviour in the environment. The formation of uranium-phosphate complexes was investigated rather well, but thermodynamic data are still contradictory. On contrary, less information is available about the formation of uranium-arsenate complexes. To investigate the sorption behaviour, batch experiments were conducted for uranium (0.5 μM/l), arsenic (0.5 μM/l) and uranium-arsenic (0.5:0.5 μM/l) together with SiO_2, Al_2O_3, TiO_2 and FeOOH at a pH ranging from 3 to 9. Sorption of U (VI) and As (V) on SiO_2 is almost similar in solutions containing either U (VI) or As (V) separately, or both together. Similar sorption behavior was observed for FeOOH too. In the presence of equimolar U (VI) and As (V) together, a considerable retardation of U (VI) sorption and an enhancement of As (V) sorption on Al_2O_3 was observed for a wide range of pH (Fig. 1). While Al_2O_3 was replaced with TiO_2, an increase in sorption was observed for both uranium and arsenic. This change in sorption retardation/enhancement can be explained by the formation of uranylarsenate complexes or competitive sorption between uranyl and arsenate species.

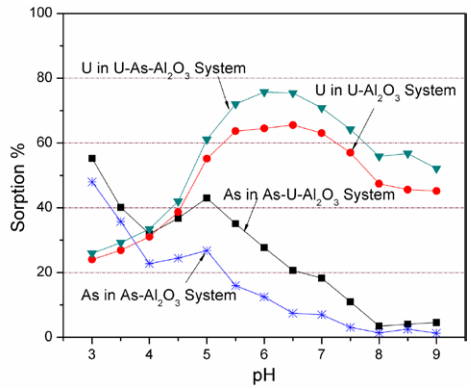

Figure 1: Sorption of U(VI) and As(V) on Al_2O_3 as a function of pH. Either U(VI) or As(V) separately, or both together. (0.5 μM/l U & As, 23ºC, pCO_2 10-3.5 hPa).

Rare Earth Elements in crude oil

R. NAKADA[1]*, Y. TAKAHASHI[1], G. ZHENG[2], S. KATO[3] AND A. WASEDA[4]

[1]Dept. of Earth and Planetary Systems Science, Hiroshima Univ., Hiroshima 739-8626, Japan (*correspondence: ryo-nakada@hiroshima-u.ac.jp)
[2]Institute of Geology and Geophysics, CAS, 382 West Donggang Road, Lanzhou 730000, China
[3]JGI, Inc., Tokyo 112-0012, Japan
[4]Japan Petroleum Exploration Co., Ltd (JAPEX) Research Center

Patterns of the entire range of rare earth element (REE) in crude oils and coexisting water, collected from mud volcanoes in Xinjiang Province of China, are recently reported [1]. Crude oils show light REE enriched patterns with flat or depleted patterns in heavy REE, when normalized to chondrite. Surprisingly, the REE concentrations in crude oils are larger than those in coexisting water by a factor of more than one hundred. Considering the hydrophobicity of oil and the high ionic characteristics of REE, it is strongly suggested that REE forms complexes with ligands present in the crude oils. Based on the ^{13}C NMR spectroscopy, it was found that small amounts of phenol and carboxyl groups are contained in the crude oil samples, which could possibly provide complexing sites for REE.

On the other hand, the REE concentrations in crude oils collected from Sagara and Nagaoka-Higashiyama oil fields, Japan which have much lesser amounts of carboxyl and phenol groups compared with those in Xinjiang. This fact suggests that REE is released from carboxyl and phenol groups during maturation of crude oil. The important key reaction can be the kerogen decarboxylation. By this reaction, carboxyl groups are decomposed into carbon dioxide gas. Since REE cannot form complexes with gas, it can be released from organic phase during maturation from kerogen to crude oil.

Electron transport across a black smoker chimney

R. NAKAMURA[1]*, T. TAKASHIMA[1], S. KATO[1], K. TAKAI[2], M. YAMAMOTO[2] ANDK. HASHIMOTO[1]

[1]Dep. Applied Chemistry, The University of Tokyo, Tokyo, 113-8656, Japan (*correspondence: nakamura@light.t.u-tokyo.ac.jp)
[2]SUGAR Project, Japan Agency for Marine-earth Science and Technology, Yokosuka, 273-0061, Japan

At deep-sea hydrothermal vent systems, sulfide-rich emissions generate a columnar black-smoker chimney structure, which serves as an ideal habitat for physiologically and phylogenetically diverse extremophiles in the present and ancient deep ocean. Here we report the data that suggest a new form of efficient and robust energy transfer from such hot, sulfur-rich hydrothermal fluids to cold, oxygenated seawater via electrical current generation. Black smoker sulfide chimney was found to display a significant electrical conduction potential owing to the densely interconnected structure of micron and submicron crystalline particles of chalcopyrite and pyrite. The current–voltage characteristics, combined with electrocatalysis measurements, clarified that their metal-like conduction generates an electron transport conduit longer than 10 cm across the chimney wall and converts the spatially discrete redox potential to electrical current. These findings suggest that not only the emitted reductive compounds, but also the high-energy electrons delivered from the inner hydrothermal fluid conduit via conductive sulfide networks, supports primary production at the deep-sea hydrothermal vent systems (Figure 1).

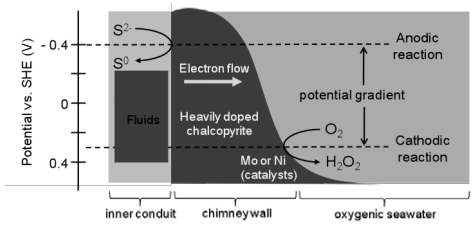

Figure 1: An energy diagram for the anodic and cathodic reactions occurring at the inner and outer surfaces, respectively, of the chimney.

$Cr(OH)_3(s)$ oxidation coupled with heterogeneous Mn(II) oxidation

SEONYI NAMGUNG AND GIEHYEON LEE*

Department of Earth System Sciences, Yonsei University, Seoul, Korea (hysy0514@yonsei.ac.kr)
(*correspondence: ghlee@yonsei.ac.kr)

Soil and groundwater contamination by Cr(VI) of natural origin has been reported over the world. Cr is 21st most abundant element in the earth's crust and commonly exists in the oxidation state of +III as a trace constituent of various aluminosilicate minerals. Under natural conditions, Cr(III) oxidaiton by dissolved oxygen or Mn oxides is thermodynamically feasible. Previous studies showed that Cr(VI) could be effectively oxidized by various Mn oxides under acidic conditions, but the oxidation became ineffective under neutral or higher pH conditions. This inhibition of Cr(III) oxidation was attributed to the precipitation of $Cr(OH)_3(s)$ on the surface of Mn oxides, which blocks the reactive surface sites. Moreover, the oxidation of Cr(III) by dissolved oxygen is known to be kinetically sluggish and favorable only at high pH conditions. The geochemical processes causing the natural contamination of Cr(VI) have not been unveiled yet. This study examined whether $Cr(OH)_3(s)$, which is the most common and stable solid phase of Cr(III) in the environment, could be oxidized indirectly by the product of Mn (II) oxidation. Although dissolved oxygen does not readily oxidize Cr(III), it effectively oxidizes Mn(II) heterogeneously under moderately alkaline pH conditions.

The suspensions were prepared with 1 g/L $Cr(OH)_3(s)$ and/or 50 μM Mn (II) in 50 mM $NaNO_3$ at pH 7 – 9 in the presence or absence of dissolved oxygen. The solution pH was maintained with 10 or 50 mM buffers (MOPS for pH 7 and 8; CHES for pH 9). Under anaerobic conditions, Cr(VI) was not detected at all pHs regardless of the presence of Mn(II). Under aerobic conditions, Cr(VI) was released from $Cr(OH)_3(s)$ oxidation both in the presence and absence of Mn (II) at pH ≥ 8. The amounts of Cr(VI), however, were substantially higher in the presence than absence of Mn(II) and increased with increasing pH. These results indicate that the rate and extent of $Cr(OH)_3(s)$ oxidation would likely be controlled by those of heterogneous Mn(II) oxidation.

Interaction between metamorphism and deformation in eclogite facies shear zones, Lofoten, Norway

P. NASIPURI*, H. STUNITZ, E.J. K. RAVNA, L. MENEGON AND K. KULLERUD

Department of Geology, University of Tromso, Norway
(*correspondence: pritam.nasipuri@uit.no)

Eclogite facies shear zones in lower crustal rocks are argued to have formed by infiltrating fluids during eclogitization [1]. Weakening of the rocks is pronounced during shear zone formation [1]. Our study on eclogites from Lofoten [2], Norway deals with shear zones developed due to near isothermal decompression and subsequent symplectite formation. Mineral abbreviations are after Kretz [3]. Metamorphic Opx and Grt_I corona (M_1) at Ol – Pl interface characterize the undeformed eclogite. Alternate bands of mixture of Pl–amphibole (Amph) and Grt_I (M_1) – Opx – Omp (M_{2A}) characterize the shear zone (D_1). Recrystallized Opx grains and Cpx - Pl symplectite (M_{2B}) mantle Opx (D_{1A}) and Omp porphyroblasts respectively. Grt_{II} (M_3) occurs along the contact of deformed Opx and Pl. Amph (M_4) overgrows the finer grained pyroxene.

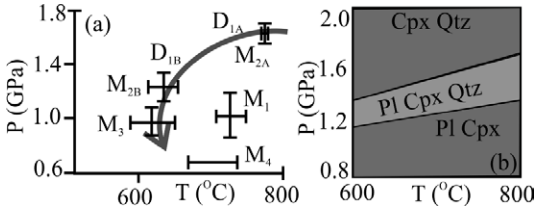

Figure 1: (a) PT estimate [GTB, 4] of different metamorphic stages. $Fe^{total} = Fe^{2+}$ is assumed for Omp. Shear zone PT path is also shown. (b) PT pseudosection [5] of reintegrated composition of Omp shows that exhumation is essential to generate fine-grained reaction products.

We suggest near isothermal decompression for the shear zone development in eclogite. The deformation of Opx and Omp commenced in the Omp stability field. Oriented inclusions of feldspar in Grt_{II} (M_3) indicate that shear zone developed before the Grt_{II} growth. This study reveals that fine-grained anhydrous reaction products can accommodate large amount of strains due to a decrease in grain size and a switch to diffusion creep deformation.

Petrogenesis of Oligo-Miocene granitoid intrusive in west Natanz, central part of Uroma-Dokhtar magmatic belt, NE Isfahan, Iran

ALI KHAN NASR ESFAHANI [1]* AND BEHAFARIN SHOJAEI[2]

[1]Islamic Azad University, Khorasgan Branch, Geology department, Isfahan, Iran.
(*correspondence: nasr@khuisf.ac.ir)
[2]Islamic Azad University, Khorasgan Branch, Petrology department, Isfahan, Iran.

Oigo-Miocene granitoid intrusive is located in west Natanz city, NE Isfahan and is a central part of Uromia-Dokhtar magmatic assemblage in Iran. This plutonic rock is the result of extensive magmatism which occurred during and after the Alpine Orogeny. The Plutonic composition is Granodiorite to Tonalite. The main minerals consist of quartz, plagioclase, alkali-feldspar. It contains a number of dioritic enclaves of different sizes. This granitiod is similar to those of the subalkaline, calc-alkaline series, metaluminous, and displays typical features of magnesian I-type granites. The chondrite normalized REE patterns are characterized by moderate to high LREE enrichment and unfractionated HREE. This granitoid magma involves partial melting of crustal protoliths and mantle-derived basaltic magmas emplaced into the lower crust. The Natanz granitoid stock has mineralogical field and geochemical characteristics typical of volcanic arc granites related to an active continental margin. Probably, Oigo-Miocene granitoid is the result of the subduction of Neo-Tethyan oceanic plate below the Lut microcontinent and this oceanic residual plate during Mesozoic to Cenozoeic time.

The isotopic composition of carbon and oxygen in calcite of veinlets and host rocks within the limits of the Kokhanivka oil field (Carpathian Foredeep, Ukraine)

I. NAUMKO[1]*, V. ZAGNITKO[2] AND YU. BELETS'KA[1]

[1]Institute of Geology and Geochemistry of the Combustible Minerals of NAS of Ukraine, 3a, Naukova St., Lviv, 79060, Ukraine (igggk@mail.lviv.ua)
[2]Taras Shevchenko Kyiv National University of MESYoS of Ukraine, 90, Vasylkivska St., Kyiv, 03022, Ukraine (zagnitko@igmr.relc.com)

Conditions of postsedimentogenous mineralogenesis in sedimentary strata within the limits of the Kokhanivka oil field in Jurassic limestones (Carpathian Foredeep) [1] were specified according to data of isotopic composition of carbon and oxygen research in calcite of veinlets and host rocks.

The isotopic analysis has revealed sufficiently homogenous values both of $\delta^{13}C$, correspondingly, -3.13÷+2.16 and -0.46÷+2.56 ‰ (standard PDB), and $\delta^{18}O$ – 24.25÷25.75 and 25.11÷29.21 ‰ (standard SMOW) that are not correlated with a depth of occurrence and a spatial distribution of a veinlet etc. It is established too that carbon and oxygen from veinlet's calcite is almost always somewhat lighter (enriched by isotope ^{12}C and ^{16}O) compared with carbon and oxygen in calcite of host rocks.

The predominance of CH_4 (56.3–62.8 vol. per cent) and steam among volatile as well as high relative water-saturation (93.9–98.9 vol. per cent) of fluid inclusions and closed cavities in rosks (by data of chemical mass-spectrometry [2]) indicates the important role of carbon-water fluids relicts of which were captured by defects in minerals into processes of postsedimentary transformations of oil-saturated strata.

Migrative processes were reduced to the formation, on the one hand, of oil deposit of the Kokhanivka field, but on the other hand, veinlet-impregnated mineralization at host rocks. Healing of fractures by the mineral substance of deep-seated high-temperature fluid [3, 4] with the formation of the calcite veinlets probably occurred from the single homogenized source similarity to the Lopushna oil field (Ukrainian Carpathians) [5].

[3]Oak Ridge National Laboratory, Oak Ridge TN
[4]Department of Geology and Geophysics, University of Wyoming, Laramie WY

Modeling transport and reactivity of CO_2 at multiple scales is important for evaluating CO_2 sequestration or containment in geological formations. One limitation of modeling complex coupled reaction and flow processes at the pore scale is the challenge of describing the dynamic complex 3D pore structures of real rocks in a reactive environment. Stacked scanning electron microscopy (SEM) images, 3D pore reconstructions and small angle neutron scattering (SANS) provide quantitative information on pore networks at length scales inaccessible by other techniques such as x-ray computed tomography. Data from five CCS carock samples demonstrate the complex nature of the pore network.

Fractal dimensions (determined from SANS data) describing the pore network are similar for four of the five mudstones. These samples are described by a combination of mass and surface fractal dimensions. In contrast, a single mass fractal dimension describes the fifth sample. Differences in pore network geometry appear to be related to lithologic variations. Calculated volume, surface area and pore size distributions from SANS, image analysis and mercury intrusion porosimetry are in agreement.

Two of the caprock samples were reacted with CO_2 and brine at 160C and 150 bars for ~50 days to evaluate pore network changes in a reactive environment. Field-emission SEM images show a marked increase in pores at length scales ranging from 10s of nm to >1 μm. In some cases new precipitates have grown into this porespace. Dissolution features such as pitting and etching is observed on mineral grain faces. Changes in porosity and surface area are quantified with SANS, image analysis and gas adsorption techniques. SANS also provides a measure of changes to the fractal structure of the pore network at nm to 100's of nm length scales.

Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockheed Martin Company, for the U.S. DOE under contract DE-ACOC4-94AL85000.

Field scale organic management of vineyard soils controls copper distribution and bioavailability at the micro-aggregate scale

ALINE NAVEL AND JEAN M.F. MARTINS

LTHE-CNRS-Univ. Grenoble I (UMR 5564), Domaine Universitaire BP 53, 38041 Grenoble Cedex 9, France (jean.martins@hmg.inpg.fr)

In this study we evaluated the effect of organic management of a vineyard soil on the distribution of copper at the micro-aggregate scale. The model vineyard soil used in this study (Macon, Burgundy, France) experienced a field experiment over twenty years that consisted in amendments and vegetations with various materials and plants. We studied specifically the effect of straw (S) and conifer compost (CC) organic amendments and clover (Cl) and fescue (F) vegetation on the fate of copper, used as fungicide, in the surface layer of this loamy soil (non amended, NA, control soil). These five soils were collected in June 2009 and immediately physically fractionated in order to obtain 5 granulometric subfractions, supposed to represent specific habitats for soil microorganisms as well as variable copper-reactive compartments. All soil fractions were quantitatively characterized in terms of contents of solid mass, total nitrogen and organic carbon, major inorganic elements and of copper (total, Ca-exchangeable, free and bioavailable to bacteria or plants). The results showed that each soil fraction presents a specific inorganic and organic composition. Indeed, whatever the treatment, amendment or vegetation, major elements and TOC distribution are highly variable in the soil sub-fractions and between soils. All soil treatments induced TOC increases, especially in Cl and CC soils (x1.8 and x2.8, respectively). Organic carbon accumulated preferentially in the 20-2μm fraction of the 5 soils (ranging from 6.3 to 10.3 mgC g^{-1}) and also in the coarser fraction (>250μm) where freshly added carbon first accumulates. Copper microscale distribution was shown to be different among the five soils. The amended soils accumulated more Cu in the coarser fractions, especially the CC soil, probably in relation with the reactivity increase of added recalcitrant carbon. The vegetated soils, and especially the Cl soil, accumulated much more Cu in the finest and micro-aggregated (20-2μm) subfractions, probably due to the increased rhizospheric development well known to increase soil micro-aggregation. This differential Cu accumulation was also shown to modify copper bioavailability to plants and soil bacteria. Altogether our results show that the field scale organic management clearly modifies the micro-scale Cu distribution and its bioavailability to living soil organisms.

'Table' *vs* 'Bench': Trace elements in fibrous diamonds

O. NAVON[1]*, W.L. GRIFFIN[2] AND Y. WEISS[1]

[1]The Institute of Earth Sciences, the Hebrew University of Jerusalem, Israel
(*correspondence: oded.navon@huji.ac.il)
[2]GEMOC, Macquarie University, NSW, Australia

Fibrous diamonds encapsulate pristine metasomatic high-density fluids (HDFs) of silicic, carbonatitic and saline compositions. In general, the trace element patterns are similar in all HDFs. The REEs are fractionated and most samples show variable negative anomalies of Sr, Ti, Zr, Hf and Y relative to the corresponding REE. Larger diversity exists in the highly incompatible elements (Cs-La), where two patterns are distinguished: one is mostly flat with no significant anomalies and shows a moderate decrease of concentrations with decreasing ionic radius ('Bench'); the other ('Table') has elevated Ba, U, Th and LREE and depleted Nb, Ta, K, Rb and Cs. The two can be best distinguished by the ratios (Nb, Rb)/(La, Pr, U, Th).

The similar signature of incompatible elements in diamonds-forming fluids from various mantle localities, well separated in space and time, the persistence of 'Table' and 'Bench' patterns in HDFs of such diverse major-element compositions and the uniform carbon isotopic composition of fibrous diamonds is fascinating. We seek to explain these features, which require collection from a large source region and/or interaction of the HDFs with a relatively large volume of mantle rocks.

The Nb/(Th, U, La) ratios in HDFs with 'Bench' patterns fall within a narrow range and are similar to MORB/OIB/PM values. This smooth pattern can be approximated by very small degree of melting of a source with PM trace element concentrations. In HDFs with the more fractionated 'Table' patterns the above ratios deviate from the strict MORB/OIB/PM range and decrease by ~2 orders of magnitude with decreasing Nb content. The patterns can be closely produced by low-degree partial melting of a metasomatised continental lithosphere with carbonate, phlogopite and rutile as accessory phases.

Searching for a possible relation between the two patterns, we examined fractional crystallization and percolation. Major elements allow only <20% phlogopite removal from HDFs with 'Bench' patterns, not enough to produce the high depletion in alkalis of the 'Table' patterns. Percolation of a melt with a 'Bench' pattern through SCLM rocks with the above accessory phases does lead to evolution of a 'Table' pattern, with minimal changes to the major elements.

Contrasting sediment and water geochemistry between low and very high arsenic affected areas in Murshidabad, West Bengal, India

A. NEAL[1], K, TELFEYAN[2], J. HAUG[2], R. TAPPERO[3], T. OCHELTREE[4], K. JOHANNESSON[2] AND S. DATTA[1]

[1]Dept of Geology, Kansas State Univ, Manhattan, KS 66506
[2]Dept of Earth and Environmental Sciences, Tulane Univ, New Orleans, LA 70118
[3]NSLS, Brookhaven National Laboratory, Upton, NY 11973
[4]Dept of Biology, Kansas State Univ, Manhattan, KS 66506

Arsenic contamination of shallow groundwater is among the most severe environmental and health threats in SE Asia. Murshidabad, an eastern district in West Bengal, India, where groundwaters are highly As-affected (up to ~4000 µg/l), was chosen as our study area. Objectives were: (1) characterize sediment cores and groundwaters in areas with contrasting As concentrations; (2) describe the extent of spatial variability of dissolved As concentrations in shallow (< 60m) aquifers; (3) identify source (s) of aquifer recharge to understand the bioavailability and mobilization of As from sediments to groundwaters. Surface (0-2m) and core (2-40m) sediments and water from shallow and deep tubewells, irrigation, ponds, and major rivers were collected during two field seasons.

The low-As Pleistocene terrace sediments are orange-brown, whereas the high-As Holocene floodplain sediments are grey. Mineralogical examination reveals the Pleistocene sediments as mainly quartz and feldspars coated with Fe (III) oxides/hydroxides, whereas the Holocene sediments also contain clay minerals, micas, amphiboles, carbonates, and accessories. Sequential extractions show As present chiefly in specifically-sorbed phases and associated with amorphous and poorly-crystalline hydrous oxides of Fe (Al and Mn). Hydrochemistry shows reducing conditions in high-As waters (high Fe, HCO_3^-, PO_4^{3-}, NH_4^+, As (III):As_T; low NO_3^-, NO_2^-, Cl^-, SO_4^{2-}); low-As areas showed converse relationships with these values. The complex spatial variability of dissolved As levels may result from variable flow paths induced by well-pumping and seasonal flooding, buried As-rich lenses, distribution of microbial communities, etc. Stable isotope values for δ^2H and $\delta^{18}O$ in water samples plot on the local meteoric water line between summer monsoon and dry season precipitation, indicating the high As groundwater originates as local precipitation that has not experienced any appreciable evaporation. Furthermore, the stable isotopes demonstrate that the high As groundwaters are not recharged by local pond waters, which have undergone substantial evaporation.

A new Moon

CLIVE R. NEAL

Dept. of Civil Eng. & Geological Sci., University of Notre Dame, Notre Dame, IN 46556, USA (neal.1@nd.edu)

International and commercial interest in exploring the Moon has exploded over the last 5 years. Missions from China, India, Japan, and the USA have explored and are exploring our closest celestial neighbour from lunar orbit. The Google Lunar X-Prize has stimulated commercial teams to compete in landing on the Moon, demonstrating mobility and transmitting data back to Earth. Recent and current lunar missions have revolutionized our view of the Moon through high-resolution photography [1], confirmation of polar volatile deposits [2, 3], as well as diurnal cycling of OH/H_2O [4], and identification of lithologies that are not represented in the return sample collections [5, 6]. New global datasets have been/are being collected (e.g. microwave emissions, gravity, temperature, rock abundance, etc.) that still need to be fully interpreted. Interpretation of 30+ years of laser ranging data indicates the presence of a fuid core [7]. Re-examination of the Apollo seismic data with modern computing techniques suggests that the Moon contains a solid inner and liquid outer core [8]. Continued examination of returned samples have shown that the interior of the Moon may be more volatile rich than previously thought [9-12], although interpretation of Cl isotope data [13] suggests otherwise Finally, quantitative petrography presents a promising method for distinguishing impact melts from pristine basalts [14] and crystal stratigraphy studies allow insights into basalt petrogenesis heretofore unattainable [15, 16]. These new advances demonstrate that old data are still relevant, that lunar samples are 'the gift that keeps on giving, and that new lunar missions always yield exciting results. With lunar missions being launched by NASA in 2011 (GRAIL) and 2013 (LADEE), others being planned (US, Russia, India, Japan), and continued sample and data analysis, lunar research will inevitably produce new and exciting insights into solar system processes.

Hafnium isotope constraints on the origin of layered intrusions and the stabilisation of the Yilgarn cratonic lithosphere

O. NEBEL[1], R.J. ARCULUS[1], J.A. MAVROGENES[1], Y.J. NEBEL-JACOBSEN[2] AND T. IVANIC[3]

[1]Research School of Earth Sciences, ANU, Australia
[2]Centre for Sustainable Energy Systems, School of Engineering, ANU, Australia
[3]Department of Mines and Petroleum, Geological Survey of Western Australia, Australia

Primitive mantle-derived magmas forming the Archaean (~3 Ga) Windimurra layered mafic intrusion (LMI) in the Yilgarn Craton yield radiogenic $^{176}Hf/^{177}Hf$ considerably exceeding that of the age-corrected depleted MORB mantle source. This isotopic character is consistent with derivation from ultra-depleted mantle established as a primitive mantle reservoir in Hadaean/Early Archaean time. Ancient refractory mantle is believed to reside either in deep mantle or buoyantly underpin cratonic sub-continental lithospheric mantle (SCLM). We suggest either an ultra-depleted deep mantle reservoir was tapped by upwelling mantle or the SCLM of the Yilgarn Craton was partly re-melted; both scenarios require the involvement of a hot mantle plume. The refractory Hf isotope signal is complementary to the Hadaean zircon record from the North-Western Yilgarn, suggesting a co-genetic relationship. Unlike the ~2 Ga old Bushveld LMI that partly samples the Kaapvaal SCLM, Windimurra lacks continental isotope signatures or primary hydrous minerals. If LMI share common processes of mantle melting, we conclude: (1) LMI are sourced from deep mantle plumes; (2) the Yilgarn SCLM was not hydrated or metasomatised until ~3 Ga; (3) establishment of the Yilgarn SCLM may be related to melt events complementary to the formation of the Narryer Terrane zircon record.

Characterization of the microbe-biotite interface on field samples from a mine site, Derome, Sweden

K. NEGRICH[1]*, Z. BALOGH-BRUNSTAD[1,2]*, T. HASSENKAM[2] AND S.L.S. STIPP[2]

[1]Hartwick College, Oneonta, NY 13820, USA (*correspondence: negrichk@hartwick.edu, balogh_brunz@hartwick.edu)

[2]NanoGeoScience, Nano-Science Center, Dept. of Chemistry, University of Copenhagen, Denmark

Biological processes, specifically mediated by fungal hyphae and biofilms, play a major role in mineral weathering and facilitating nutrient uptake. This study examines field samples of biotite from an abandoned mine site that was naturally re-vegetated by a mixed conifer and hardwood forest. We hypothesized that hyphal-sized etched channels formed on biotite surfaces by the weathering action of fungal hyphae under protective biofilm cover. Biotite surfaces were examined with atomic force microscopy (AFM) and environmental scanning electron microscopy (ESEM) in their natural state and after removing the biological material from the mineral surfaces [1, 2].

The AFM and ESEM images show extensive hyphal colonization and biofilm cover of the entire biotite surface. Fungal hyphae also grew between layers of the biotite sheets exhibiting an intensive exploration of the available weatherable surfaces. The biofilm that also covers the hyphae shows unique globular features of diameter 10-100 nm on all surfaces (Figure 1).

Force spectroscopy mode of AFM showed that both biofilm and hyphal surfaces are hydrophobic with hyphal surfaces providing higher adhesive forces. However, removal of the biological material resulted in smooth and non-etched surfaces indicating that regardless of the strong surface attachment, etching of the basal surface is not the main mechanism for base-cation nutrient acquisition in these natural biotite samples.

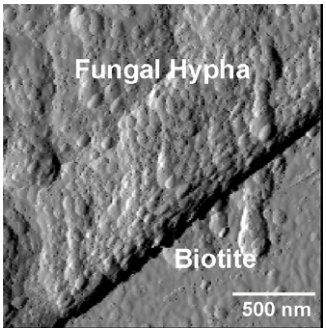

Figure 1: An AFM contact mode deflection image of the globular features of the biofilm layer covering the fungal hypha on a sample of biotite.

Precipitation and surface complexation in systems containing Cu(II), As(V) and goethite

H. NELSON, S. SJÖBERG AND L. LÖVGREN

Department of Chemistry, Umeå University, SE-901 87 Umeå, Sweden (hanna.nelson@chem.umu.se)

The main objective of the present study has been to establish a model for equilibria in the four component system H^+-$HAsO_4^{2-}$-Cu^{2+}-goethite (α-FeOOH). Before the complete four component system can be tackled, equilibria in the different subsystems must be known. Due to the scarce information available in the literature on interactions between Cu (II) and As (V), the possible formation of complexes involving Cu (II) and As (V) in aqueous solution, as well as formation of solid phases were studied. All experiments were performed in 0.1 M NaCl ionic medium. Potentiometric titrations at different Cu to As ratios gave no evidence for the existence of Cu (II)-As (V) complexes in solution below pH of the precipitation boundaries (pH ≈ 4). Mixing of solutions of Cu (II) and As (V) at different proportions and adjusting pH to values ranging from 4 to 9 resulted in precipitation of five different solid phases. The elemental composition of the solids was analysed using XPS and SEM. The average Cu/As ratio was determined by dissolving the solids and analyzing of aqueous solutions. Two of the solids contained significant fractions of Na^+. Stability constants for the five solid phases have been calculated.

The co-adsorption of copper (II) and arsenate onto the surface of goethite were studied by potentimetric titrations and batch uptake experiments. A surface complexation model was developed to describe the experimental results. Models for the binary systems Cu (II) -goethite and As (V)-goethite were acquired separately and the parameters were included together with the stabilities of copper-arsenate solid phases. The adsorption of copper (II) could best be described with four different surface complexes. The surface complexes of As (V) on goethite were best modelled invoking a monodentate coordination of arsenate ions to singly coordinated surface hydroxyls and the arsenate ions are hydrogen-bonded to neighboring triply coordinated surface sites. In the case of co-adsorption of copper (II) and arsenate, the adsorption could not be described by applying the combined model from the two binary systems only. Two ternary copper- arsenate-goethite surface complexes were required.

An isotopic glimpse of the lithospheric mantle beneath the East African Rift System

WENDY R. NELSON[1]*, STEVEN B. SHIREY[1] AND TANYA FURMAN[2]

[1]DTM, Carnegie Institution of Washington, Washington, DC USA (*correspondence: wnelson@dtm.ciw.edu)
[2]Dept. of Gesciences, Pennsylvania State University, University Park, PA 16802, USA

Discerning the influence of various source components (mantle plumes, mantle lithosphere, crust) contributing to >30 Myrs of volcanism in the East African Rift System is difficult because the composition, age, and extent of the lithospheric mantle beneath Ethiopia have remained enigmatic. To better understand the potential role of the lithosphere, we analyzed Re-Os and PGE's of whole rock powders and Sr-Nd-Pb-Hf on clinopyroxene separates of peridotites from NW and S Ethiopia. The peridotites range from lherzolites to harzburgites and websterites. Compared to fertile mantle, all samples have low Os (0.73-2.55 ppb) and Re (0.004-0.075 ppb) concentrations, excepting one websterite (0.56 ppb Os, 0.37 ppb Re). Lherzolites are mildly unradiogenic ($^{187}Os/^{188}Os$ = 0.1236-0.1286) and overlap compositionally with 30 Ma high-Ti flood basalts in NW Ethiopia (0.1247-0.1329 [1, 2]). However, the peridotites have high ε_{Nd} (12.6-18.5), high ε_{Hf} (13.8-27.6), low $^{87}Sr/^{86}Sr$ (0.7019-0.7029) and variable $^{206}Pb/^{204}Pb$ (17.1-17.9 and 18.7-19.3) which, except for Pb, contrasts sharply with flood basalt compositions (ε_{Nd} = 4.7-6.7 [3]; ε_{Hf} = 12.1-13.5 [2]; $^{87}Sr/^{86}Sr$ = 0.7037-0.7043 [2, 3]. This difference demonstrates the lithospheric mantle did not contribute significantly to the production of Ethiopian high-Ti flood basalts. Instead, these flood basalts are derived from the upwelling Afar plume.

Lherzolite model ages calculated for the Re-Os and Sm-Nd isotopic systems vary widely: Re-Os T_{MA} = 0.2-0.6 Ga with one outlier at 1.35 Ga; Sm-Nd T_{DM} = 0.3-0.5 Ga and 1.2-2.6 Ga. Both the model ages and isotopic composition of the peridotites are consistent with mantle xenoliths from Eritrea [4] and Jordan [5]. Not only do the xenolith suites in Afro-Arabia all record the 500-900 Ma Pan-African orogeny, the range in model ages preserve evidence for an earlier, widespread Proterozoic metasomatic event that previously introduced heterogeneities in the lithospheric mantle [5].

Did the AD 1452 Kuwae eruption have global climatic impact?

K. NÉMETH[1]*, S.J. CRONIN[1] AND I.E.M. SMITH[2]

[1]Massey University, Palmerston North, New Zealand (*correspondence: k.nemeth@massey.ac.nz)
[2]The University of Auckland, Auckland, New Zealand

The eruption and formation of Kuwae caldera, Vanuatu, was inferred to have induced a major atmospheric impact and climate cooling event in the mid-15th century [1]. C^{14} dating of charcoal from non-welded ignimbrite deposits on the adjacent Tongoa Island, provided an age of AD 1425 [2], later recalculated to AD 1452 and linked to sulphur spikes of ice cores from Greenland and Antarctica [3]. Oral traditions [4] were linked to this catastrophic event, and more-recently tsunami deposits locally as well as on Futuna, Wallis and Efate Islands [5]. Volatile, halogen and sulphur analyses, along with assumptions of the eruption volume based on the caldera dimensions indicate that the Kuwae magma could have been strongly climate-forcing [1]. However, the interpretation of this caldera was formed in a single huge volcanic event may be too simple, based on its complex double-shape and deposit geometry and sedimentology [4]. New stratigraphy, along with whole rock, major element composition of juvenile pyroclasts from the eruptives of Kuwae caldera show evidence for multiple explosive events with very similar compositions, separated by soil-forming breaks. This implies that the caldera was formed in a series of eruptions of the same type of magma, some potentially submarine. The most recent of these events (the AD1452 event) produced a basal basaltic andesitic and capping dacitic ignimbrite in localised areas from multiple apparent vent locations at the edges of a complex caldera. Its volume was probably half to a quarter of whole-caldera estimates (c. f., 1), but its impact was clearly globally relevant in terms of atmospheric chemistry. Earlier explosive eruptions at this centre may also have been violent enough to also generate high eruption columns and a series of earlier atmospheric cooling events. Further dating and geochemical study of this volcano is required to evaluate its past climatic influences and evaluate its potential for future large-scale events of a similar nature.

Marine productivity: Impacts on aerosols and clouds

ATHANASIOS NENES[1,2]

[1]School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta, GA
[2]School of Chemical and Biomolecular Engineering, Georgia Institute of Technology, Atlanta, GA

Aerosols influence the planetary radiation balance directly by scattering and absorbing sunlight, and indirectly by modifying cloud microphysical properties. Marine aerosols are a particularly important class of particles, as they contribute considerably to the global aerosol load, are emitted from a large surface area, and are emitted in areas where cloud properties are especially sensitive to changes in aerosol concentration.

Aerosols over the remote oceans consist of a mixture of sea salt particles, organics, and sulfates from the oxidation of biogenic dimethyl sulfide, with additional contributions from mineral dust, biomass burning and anthropogenic sources. The biological sulfur cycle has long been thought a major source of oceanic cloud condensation nuclei. In recent years, significant abundances of organic carbon (OC) aerosols have been identified in marine environments and attributed to biological activity. The concentrations of marine-source OC aerosols are particularly high over regions of enhanced oceanic biological activity. Despite recognizing their crucial role, the source strength and chemical composition of biogenic marine aerosols remain highly uncertain.

This talk will give an overview of the state of knowledge of the links between marine productivity, aerosols and clouds.

Atmospheric acidification of mineral aerosols: A source of bioavailable phosphorus for the oceans

ATHANASIOS NENES[1,2,3], MICHAEL D. KROM[4], NIKOLAOS MIHALOPOULOS[5,3], PHILIPPE VAN CAPPELLEN[1], ZONBGO SHI[4], AIKATERINI BOUGIATIOTI[5], PAVLOS ZARMPAS[5] AND BARAK HERUT[6]

[6]Israel Oceanographic Limnological Research, Tel Shikmona, Haifa, Israel

Primary productivity of continental and marine ecosystems is often limited or co-limited by phosphorus. Deposition of atmospheric aerosols provides the major external source of phosphorus to surface waters. However, only a fraction of deposited aerosol phosphorus is water soluble and available for uptake by phytoplankton. We propose that atmospheric acidification of aerosols is a prime mechanism producing soluble phosphorus from soil-derived minerals. Acid mobilization is expected to be pronounced where polluted and dust-laden air masses mix. Our hypothesis is supported by the soluble compositions and reconstructed pH values for atmospheric particulate matter samples collected over a 5-year period at Finokalia, Crete. At least tenfold increase in soluble phosphorus is observed when Saharan soil and dust were acidified in laboratory experiments which simulate atmospheric conditions. Aerosol acidification links bioavailable phosphorus supply to anthropogenic and natural acidic gas emissions, and may be a key regulator of ocean biogeochemistry.

Crystallographic relationships between diamond and its olivine inclusions

F. NESTOLA[1], P. NIMIS[1] AND J.W. HARRIS[2]

[1]Dipartimento di Geoscienze, Università di Padova
[2]School of Geographical and Earth Sciences, University of Glasgow

Modern single-crystal X-ray analysis of minerals still encapsulated in diamond not only permits the determination of both the chemical composition of inclusions and of the residual internal pressures [1], but also provides a three dimensional analysis of the crystallographic relationships between inclusions and diamond hosts. Although the syngenicity of inclusions in diamonds is generally assumed on the basis of strong morphological criteria, the crystallographic relationships between inclusions and their host are rarely determined and a systematic survey of them for the different mineral species is lacking. We will present results of an on-going single-crystal X-ray diffraction study of olivines included in diamonds from the Udachnaya kimberlite (Russia). Implications on the syngenetic or protogenetic nature of the inclusions will be discussed.

Size dependent element interaction and speciation in environmental nanoparticles

E. NEUBAUER, F. VON DER KAMMER, S.M. KRAEMER AND T. HOFMANN*

Univ. of Vienna, Dept of Env. Geosciences, A-1090-Vienna, Austria (*correspondence: thilo.hofmann@univie.ac.at)

Environmental nanoparticles play an important role e.g. in the binding of trace metals [1]. Increasing evidence is found that material <20 nm, such as natural organic matter (NOM) and Fe-rich mineral-like nanophases, play a key role in the fixation of trace elements in many natural systems, including soil and peat bog systems.

Size Exclusion Chromatography (SEC) and Flow Field-Flow Fractionation (FlowFFF), both coupled to ICP-MS, are used as complementary high-resolution size separation techniques, providing size dependent element information. In the < 30 nm fraction of natural waters we observe NOM and Fe-rich mineral-like particles with significantly different affinities to trace elements. The presence of Fe-rich nanoparticles governs the binding of e.g. Pb, Ti, and Mn. Cu is predominantly associated with NOM.

While the complexation of inorganic As with NOM and Fe-minerals has been investigated previously, a particular focus of this work is their interaction with organic As species. We observe that substantial fractions of As are associated with low molecular weight NOM (Figure 1) despite the reported high affinity of Fe minerals for As binding [2].

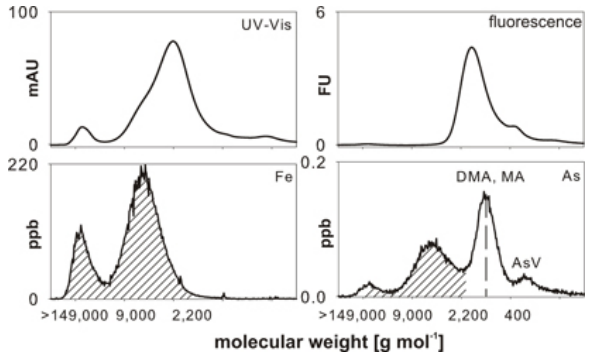

Figure 1: Size exclusion chromatogram of a peat bog drainage.

Combined FlowFFF/SEC size fractionation and IC speciation analysis can show, however, that some of the fractions are not colloid-bound but present as organic As species such as DMA and MA, as well as inorganic As (V).

Arsenic removal with composite iron matrix filters from Bangladesh

A. NEUMANN[1]*, R. KAEGI[1], A. VOEGELIN[1], A. HUSSAM[2], A.K.M. MUNIR[3] AND S.J. HUG[1]

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, Ueberlandstrasse 133, CH 8600 Duebendorf, Switzerland (*correspondence: anke.neumann@eawag.ch)
[2]Center for Clean Water and Sustainable Technologies, George Mason University, Fairfax, Virginia 22030, USA
[3]Sono Technology and Research Inc, Courtpara, Kushtia, Bangladesh

In Bangladesh, 30–50 million people are exposed to toxic levels of arsenic (As) in drinking water from shallow tube wells. With more than 50% of the affected population still exposed, inexpensive, reliable, and low-maintenance filters to remove As from well water could lead to a significant reduction of As exposure. The SONO water filter, which was developed in Bangladesh and is produced there from local materials, fulfills these criteria as well as the requirements for potable water. It has been used in large numbers in Bangladesh for years and was recently approved by the Bangladesh government.

The removal of As with SONO filters is based on the transformation of zero-valent iron (ZVI) to a porous solid matrix known as composite iron matrix (CIM) and subsequent reactions. Although some of the general pathways for the removal of As with ZVI are known, the complex chemistry within the CIM is not yet fully understood. In particular, a more detailed identification of formed solids and proper mass balances could improve the assessment of the filters' sustainability and environmental impact and would help in the development of a consistent model for As removal with ZVI-based filter systems.

In a combined long-term field and laboratory study, we investigated the chemical reactions involved in As removal with SONO filters. The effect of the water components Ca, P, Fe, and dissolved oxygen (DO) on the As removal efficiency has been investigated for 13 months in the field and was complemented with experiments with small-scale columns in the laboratory. The sampling of the percolating solution and of filter material at different depths enabled the detailed analysis of the chemical gradients within the filter. We identified the main components in the solid samples with X-ray based methods (XRF, XRD) and microscopy (Raman, ESEM) and investigated whether the mode of filtration and the influent DO content had an effect on the solids formed in these filters over time.

The hydrogeochemistry of pond and rice field recharge: Implications for the arsenic contaminated aquifers in Bangladesh

REBECCA B. NEUMANN[1]*, KHANDAKER N. ASHFAQUE[2], MATTHEW L. POLIZZOTTO[3], A. BORHAN M. BADRUZZAMAN[4], M. ASHRAF ALI[4] AND CHARLES F. HARVEY[5]

[4]Department of Civil Engineering, Bangladesh University of Engineering and Technology, Dhaka, Bangladesh
[5]Department of Civil and Environmental Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA

Researchers have puzzled over the origin of dissolved arsenic in the aquifers of the Ganges Delta since widespread arsenic poisoning from groundwater was publicized two decades ago. Previous work has concluded that biological oxidation of organic carbon drives geochemical transformations that mobilize arsenic from sediments; however, the source of the organic carbon that fuels these processes remains controversial. A combined hydrologic and biogeochemical analysis of a typical site in Bangladesh, where constructed ponds and groundwater-irrigated rice fields are the main sources of recharge, shows that only recharge through pond sediments provides the biologically degradable organic carbon that can drive arsenic mobilization. Chemical and isotopic indicators suggest that contaminated groundwater originates from excavated ponds and that water originating from rice fields is low in arsenic. In fact, rice fields act as an arsenic sink. Irrigation moves arsenic-rich groundwater from the aquifers and deposits it on the rice fields. Most of the deposited arsenic does not return to the aquifers; it is sorbed by the field's surface soil and bunds, and is swept away in the monsoon floods. The findings indicate that patterns of arsenic contamination in the shallow aquifer are due to recharge-source variation and complex three-dimensional flow.

'Ordering' in glasses and melts: Structural observations and their properties implications

DANIEL R. NEUVILLE[1]*, CHARLES LE LOSQ[1], FLORIAN PIERRE[2], ALAIN BARONNET[3] AND DOMINIQUE MASSIOT[2]

[1]CNRS-IPGP, 1 rue Jussieu, 75005 Paris
[2]CEHMTI-CNRS, 1d rue de la recherche scientifique, 45000 Orléans
[3]CINaM, Université de Marseille, Marseille

As the chemical and physical behavior of magmas dominates many geological processes, and as most technological glasses and glass ceramics start off in the molten state, understanding of the physical chemistry of silicate glasses and melts is important in both the earth and material sciences. Our present knowledge of these systems is limited, however, by the technical difficulties of working at high temperatures, and the theoretical complexities of materials whose structure and dynamics lie somewhere between the relatively well-understood field of organic polymers and that of molten salts. One of the most important questions concerns the link between macroscopic properties and structure at the nano-scales of the glassy state but also of the liquid and in the melts with changing intensive properties.

One of the more challenging and controversial idea is about middle and long range order in glass. Greaves *et al*. [1981] and Greaves [1985] proposed the *Modified Random Network* (MRN) model, where a glass can be a mixing of between rich domain in network former and rich domain with cation modifier that create some channels. This assumption can be used to explain alkali diffusion in glass [Roling *et al*. 2001; Sunyer *et al*. 2002; Meyer *et al*. 2004], and even if EXAFS experiments were over interpreted to build this original structural view, the channel idea works well to explain glass structure.

Following this idea, a glass is a non-random structure composed of two interpenetrated sub-networks: one rich in network former, surrounded by the other rich in network modifier or charge compensator, concentrated in channels already observed by Frischat *et al*. [2004] using high resolution AFM on Duran® borosilicate glass surface. These two different domains can be also interpret in term of low and high density region following Tanaka works to explain fracture, unmixing, polyamorphism and crystallization in glass [Kurita and Tanaka, 2004; Shintani and Tanaka, 2006; Patrick Royall *et al*. 2008; Furukawa and Tanaka, 2009].

We plan to discuss and complete this idea using some new rheological and structural investigation on alkali aluminosilicate glasses and melts. These considerations are of prime importance for glasses industry, earth sciences and more particular for explosive volcanos activity.

Volatile and major element zonation within melt inclusions: A natural diffusion experiment

M. NEWCOMBE[1]*, A. FABBRIZIO[2], YOUXUE ZHANG[3], Y. GUAN[1], C. MA[1], M. LE VOYER[1], J. EILER[1], A. SAAL[4] AND E. STOLPER[1]

[1]California Institute of Technology, Pasadena, CA 91125, USA (*correspondence: megan@gps.caltech.edu)
[2]Institut für Mineralogie und Petrographie, Universität Innsbruck, Innrain 52f, 6020 Innsbruck, Austria
[3]University of Michigan, Ann Arbor, MI 48109-1005, USA
[4]Brown University, Providence, RI 02912, USA

The diffusivities of volatile elements in silicate melts significantly impact petrological processes [e.g. 1, 2]. Although many studies of volatile diffusion in silicic melts have been undertaken, there have been few studies in basaltic melts [e.g. 3], and most of these have concentrated on the diffusion of only one or two elements in each experiment.

Significant zonation in volatile and major elements has been discovered in olivine-hosted melt inclusions from the Siqueiros Fracture Zone [samples previously studied in 4]. Elements that are compatible in olivine, such as Mg and Fe, are depleted at the edges of the zoned melt inclusions relative to their centers, whereas elements that are incompatible in olivine, such as Al, Ca, Si, Na and S, are enriched. Preservation of this zonation suggests that it formed during crystallization of olivine on the walls of the inclusions in response to cooling during or just prior to eruption. Although all melt inclusions from this sample suite exhibit zoning profiles, there are few previous reports [e.g. 5] of comparable concentration profiles in melt inclusions, so it is not known if this feature is widespread.

The MgO concentration profiles in two melt inclusions have been used to constrain the cooling history of the inclusions using the results of [6]. The profiles are consistent with an initial slow cooling rate followed by a period of more rapid cooling. For other components, their zoning profiles can be used to estimate their diffusivities relative to that of MgO. Of the volatile elements, we have demonstrated such profiles in S, and have preliminary results on Cl and F that allow constraints to be placed on their relative diffusivities in basaltic melt.

Theories of fluids at extreme conditions

I. NEZBEDA[1,2]

[1]Faculty of Science, J. E. Purkinje University, 40096 Usti n. L., Czech Republic
(*correspondence: IvoNez@icpf.cas.cz)
[2]E. Hala Lab. of Thermodyn., Acad. Sci., 16502 Prague, Czech Republic

Introduction

In this contribution two completely different methods to estimate by means of theory properties of fluids at conditions encountered in geochemical applications will be presented and discussed.

It is been well known that at these conditions most of compounds can be treated fairly well by a softly repulsive EXP6 potential. Consequently, common theories of fluids making use, either directly or indirectly, of the properties of the fluid of hard spheres (HS) are inapplicable in this case. Following the recently established idea of a uniform view of fluids [1] we have developed a theory, called augmented van der Waals theory [2], based on a Yukawa reference. Within this theory the EXP6 fluid may be described either directly by means of a 2-Yukawa model or by a simple Yukawa-based van der Waals equation, vdW (Y), with a simple mean field term. Both methods make use of the knowledge of theory-based analytic expressions for the thermodynamic properties of the Yukawa fluids.

The other method follows the common experimental setup, namely, to operate at fixed temperature, T, and pressure, P, and is based on P-explicit analytic equations of state for both pure HS fluids [3] and general hard-body fluid mixtures [4]. It is shown that the volume, as a function of T and P, estimated by means of the hard body equations captures extremely well the behavior of real fluids and that the additional mean field term is sufficient to bring theoretical results to agreement with experiment.

First-principles simulations of alkali aluminosilicate liquids

HUAIWEI NI* AND NICO DE KOKER

Bayerisches Geoinstitut, Universität Bayreuth, 95440 Bayreuth, Germany
(*correspndence: huaiwei.ni@uni-bayreuth.de)

We have investigated the thermodynamics, diffusion, and structure of alkali aluminosilicate liquids at mantle conditions using first-principles molecular dynamics. Results for $NaAlSi_2O_6$ and $NaAlSi_3O_8$ liquid have been obtained at temperatures of 3000-6000 K and pressures up to 150 GPa. We find that fourth order finite strain expansions are required to account for the pressure-volume equations of state. Thermodynamic properties derived from simulation results agree well with experimental measurements. Isochoric heat capacity decreases with pressure, but the Grüneisen parameter increases with pressure. Liquid structure changes continuously with pressure, showing trends in mean coordination numbers and relative abundances of distinct coordination species consistent with previous studies of other silicate liquids. Self-diffusivities for Si and O increase with pressure below 16 GPa at 3000 K, while low-pressure diffusivities of Na are 3–6 times higher than values for other components. Activation volume for Na diffusion is much larger than that for Al, Si, and O diffusion, so that Na diffusivities become comparable to those of the other components at lower mantle pressures. This disappearance of mobility contrast implies that alkali-rich silicate liquids associated with low degree melting in Earth's interior are unlikely to have high electrical conductivity and will be more difficult than previously expected to detect by magnetotelluric sounding.

Mineral sources of arsenic from glacial aquifer sediments to well water in Minnesota, USA

SARAH L. NICHOLAS[1], BRANDY M. TONER[1]*, MELINDA L. ERICKSON[2], LAUREL G. WOODRUFF[2], ALAN R. KNAEBLE[3] AND GARY N. MEYER[3]

[1]Department of Soil, Water and Climate, University of Minnesota, USA (nich0160@umn.edu) (*corespondence: toner@umn.edu)

[2]United States Geological Survey, Mounds View, Minnesota, USA (merickso@usgs.gov, woodruff@usgs.gov)

[3]Minnesota Geological Survey, St. Paul, Minnesota, USA (knaeb001@umn.edu)

In Minnesota, USA, domestic wells with arsenic concentrations exceeding 10μgL^{-1} are predominantly found within the footprint of the Des Moines Lobe glacial advance (12-14 kya). The arsenic concentrations in groundwater are variable over short distances. Although the exact mineral source of arsenic remains unknown, a frequent hypothesis is that arsenic-bearing pyrites in Cretaceous shale fragments common to these glacial sediments release arsenic to groundwater. The abundance of arsenic in reduced well-water and groundwaters suggests that the solid source of some of the arsenic may be oxidized, sorbed species.

The goals of this study are to identify the mineral and chemical species of the arsenic in the solid phase, and better understand the mechanisms liberating arsenic to well-water. This information may provide guidelines to well-drillers for future well construction.

In our analysis, we use sequential extractions to identify arsenic species operationally, and whole-rock chemistry to describe total elemental abundances of the strata. Bulk and microprobe X-ray absorption spectroscopy (XAS) is used to identify and quantify arsenic and iron species. Powder and microprobe X-ray diffraction (XRD) are used to describe the bulk and arsenic-bearing mineralogy of the glacial deposits. Nested analysis of resulting datasets across the landscape and as a function of depth is accomplished in a geographic information systems (GIS) and geostatistical framework.

Glacial sediments sampled from ten rotary-sonic drill cores (20-70m depth) were examined. Arsenic speciation in strata above, at, and below transitions between fine-grained glacial tills (confining layers) and sand-gravel deposits (aquifers) was measured. Arsenic is present in three distinct oxidation states: As^{5+}, As^{3+}, and As^{1-}. The presence of three arsenic species, with varying proportions in the solids, may explain some of the observed spatial heterogeneity in well-water arsenic concentrations These forms of arsenic will be labile under different redox conditions in waters.

Approaching a consistent set of cosmogenic ^{3}He, ^{21}Ne and ^{10}Be production rates

S. NIEDERMANN* AND C.R. FENTON

Helmholtz-Zentrum Potsdam – Deutsches GeoForschungs-Zentrum, Telegrafenberg, D-14473 Potsdam, Germany (*correspondence: nied@gfz-potsdam.de)

Cross-calibrations of production rates for cosmogenic ^{3}He, ^{21}Ne and ^{10}Be in olivine, pyroxene and quartz have revealed an inconsistency between earlier production rate calibrations, mainly because the ^{3}He (ol, px)/^{21}Ne (qz) ratio of 8.19 ± 0.19 was found to be considerably higher than the predicted ratio of ~6.1 [1]. Recently however, several new ^{3}He and ^{10}Be production rate determinations have indicated that the discrepancy may be less severe than anticipated. In particular, three regional studies in northeastern North America, New Zealand and Norway [2, 3, 4] have yielded ^{10}Be production rates that are consistently ~15% smaller than the earlier 'global mean' of Balco *et al*. [5]. It seems unlikely that all calibration sites, which are at latitudes from 42° to 70°N and ~44°S, are characterized by a uniform reduction in production rates due to untypical conditions of the atmosphere or the geomagnetic field. Rather, we believe that earlier work included in the 'global mean' [5] may have overestimated the ^{10}Be production rate. Similarly, a recent compilation [6] as well as an additional calibration study [7] indicate ~10% higher ^{3}He production rates in olivine and pyroxene than reported earlier [5]. Using these new production rate values, the discrepancy between direct production rate determinations and cross-calibrations is substantially reduced. In this respect, ^{3}He and ^{10}Be production rate values that have been scaled by the De, Du and Li methods [cf. 5 and references therein] perform distinctly better than those scaled by the St or Lm methods (11-12% vs. 19% remaining discrepancy). Indeed, the directly determined and cross-calibrated production rates overlap within error limits for the former three scaling methods. Therefore, the apparent inconsistency is largely resolved when the new set of production rates is used. ^{10}Be and ^{21}Ne exposure ages will however increase by ~15%.

Formation and inhibition of calcite, aragonite and vaterite

A. NIEDERMAYR[1,2], M. DIETZEL[2] AND S.J. KÖHLER[3]

[1]Institute of Geology, Mineralogy and Geophysics, Ruhr-University Bochum, Germany (andrea.niedermayr@rub.de)
[2]Institute of Applied Geosciences, TU Graz, Austria
[3]Swedish University of Agricultural Sciences, Uppsala, SE

Calcium carbonates ($CaCO_3$) are widespread in sediments and organisms and highly relevant materials for industrial applications. The formation of calcium carbonate is strongly affected by dissolved magnesium ions (Mg) and polyaspartic acid (Pasp). In the present study the formation of the anhydrous $CaCO_3$ polymorphs calcite, aragonite and vaterite were investigated at various temperatures ($6 < T < 40°C$), carbonate accumulation rates ($0.15 < R_{CO3} < 320$ μmol h^{-1}), concentrations of Mg (≤ 55 mmol l^{-1}) and Pasp (≤ 3.4 mg l^{-1}) by using the CO_2 diffusion technique at constant pH. Nucleation of $CaCO_3$ was retarded from few minutes up to several hours at $T \leq 10°C$, and up to several hundreds of hours at elevated [Mg] and [Pasp]. Distinct $CaCO_3$ polymorph formation is mainly controlled by [Mg], [Pasp], T and R_{CO3}. [Mg]/[Ca] > 0.2 (40°C) to [Mg]/[Ca] > 2 (6°C) promote the formation of aragonite and suppress the formation of vaterite. Pasp inhibits aragonite formation and favours vaterite formation, whereas combining both Pasp and Mg causes calcite formation. In the presence of Pasp, $CaCO_3$ nucleates only in case of supersaturation with respect to monohydrocalcite. The present study provides conditions to synthesize tailored $CaCO_3$ polymorphs. Moreover, the results can be used to obtain an advanced understanding for the mechanisms of $CaCO_3$ biomineralization and to evaluate $CaCO_3$ scaling mechanisms with special regard on inhibition of $CaCO_3$ polymorphs and nucleation times.

Conductive filaments and electric fields associated with electric currents in marine sediment

L.P. NIELSEN[1]*, N. RISGAARD-PETERSEN[1], Y. GORBY[2], A. REVIL[3], G. WANGER[4], M. EL-NAGGAR[5] AND T. YUZVINSKY[5]

[5]Dep. of Physics and Astronomy, Univ. of S. California, USA (mnaggar@usc.edu) (yuzvinsky@gmail.com)

Electric currents have been found to explain tightly coupled but spatially separated sulphide oxidation and oxygen reduction in marine sediment [1]. In the present study we searched for electron conductors and additional measures of electric activity in the sediment. Networks of filaments resembling bacterial conductive pili ('nanowires') were observed in the sediments and electron conductivity was documented with nanofabrication approaches [2]. Down-core measurements of self-potentials revealed an electric field that matched the geochemical evidence of electric circuits extending from the sediment surface to a depth of 2 cm. The upwards charge transfer by electrons was thus balanced by ion drift in the pore water.

The results suggest that sediment electric networks are engineered by microorganisms using nanowires as electron conductors.

Molecular model of kinetic isotope fractionation during surface-controlled growth of $CaCO_3$ from aqueous solution

LAURA C. NIELSEN*, DONALD J. DEPAOLO AND JAMES J. DE YOREO

Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA (*correspondence: lnielsen@berkeley.edu)

The attachment and detachment of cations and anions at the mineral-aqueous solution interface control rates of crystal growth and dissolution, and also affect isotope fractionation and trace element partitioning. Recent experimental work has begun to characterize kinetic isotope fractionation during precipitation of $CaCO_3$ and other di-ionic solids. Proposed models for isotopic and trace element effects deal only with macroscopic properties such as solution saturation state and solid state diffusivity. In this study, we apply molecular models of di-ionic crystal growth to deduce the dependence of kinetic isotope fractionation on growth mechanism, and both solution saturation state and stoichiometry. Recent theoretical advances have underscored the significance of solution stoichiometry—e.g. the ratio of Ca to CO_3 ion activities in solution—for controlling mineral surface kink density and composition and thus growth rate and growth mechanism. Our approach incorporates the effect of solution composition on microscopic mineral surface structure and composition, providing testable hypotheses for growth of sparingly soluble AB crystals such as calcite, namely:

1) Oversaturation and solution stoichiometry control growth rate and partitioning of A and B isotopes during precipitation;
2) For step growth, distinct rate laws describe dislocation- and 2D nucleation-driven growth, while the expression describing isotope fractionation requires no change;
3) Formation of amorphous precursors will generate isotope effects incompatible with ion-by-ion growth theory.

As observed during calcite growth, increasing oversaturation increases growth rate and drives isotope partitioning towards the kinetic limit. Also, increasing concentration of Ca^{2+} relative to CO_3^{2-} should drive new growth towards isotopic equilibrium. These competing effects, as well as the formation of an amorphous precursor, determine the observed magnitude of isotope fractionation. This model provides a clear mechanistic description of processes controlling the cross-over from the near-equilibrium to the kinetic limit of isotope fractionation, allowing us to relate trends in experimental data to environmental conditions of growth.

Large vanadium isotope difference between silicate Earth and meteorites

S.G. NIELSEN[1,2], J. PRYTULAK[1], B.J. WOOD[1] AND A.N. HALLIDAY[1]

[1]University of Oxford, Dept. of Earth Science, South Parks Rd, OX1 3AN, Oxford, UK
[2]WHOI, Dept. of Geology and Geophysics, 266 Woods Hole Rd, 02543 Woods Hole, MA, USA

We have recently developed a technique to measure precise and accurate vanadium (V) isotope ratios [1, 2]. All data are reported in parts per thousand as $\delta^{51}V$ relative to an Alfa Aesar (AA) standard. Processing multiple aliquots of the same sample, including dissolution and column chemistry, yields a long-term external reproducibility of about 0.15‰ (2sd) [2].

Here, we present the first high precision $^{51}V/^{50}V$ isotope composition data for a range of extraterrestrial materials. The sample set comprises CI, CO, CM, CV and CK carbonaceous chondrites, one ordinary chondrite, one ureilite, three HED parent body achondrites and the martian meteorite Nakhla. The data fall in a relatively narrow range about 1.5 to 2‰ lighter than AA.

If the meteorites are considered as one sample group then they are 0.5-0.8‰ lighter than our current best estimate for bulk silicate Earth [3]. The isotopic offset between Earth and meteorites may be explained by partitioning of isotopically light V into the Earth's core. This conclusion, however, is at odds with the insignificant V isotopic fractionation observed for three metal-silicate equilibration experiments.

Alternatively, the Earth does not have a V isotope composition identical to chondrites. The abundance of ^{50}V is sensitive to irradiation [4] and it is therefore conceivable that early solar system processes may have generated a V isotope gradient that could be preserved today in meteorites.

[3]Royal Netherland Institute for Sea Research (NIOZ), Texel
[4]Swiss Federal Institute of Aquatic Science and Technology (EAWAG), Dübendorf

Lake Cadagno is a relatively small glacial lake in southern Switzerland (1921 m altitude). We recovered a 10.5 m long composite core from the lake covering the sedimentary sequence of the last 11000 yrs. Our aim was to reconstruct past mean annual air temperature (MAAT) using a novel, lipid-based proxy, the MBT/CBT paleothermometer. The MBT/CBT ratios comprise fossilised methyl-branched and cyclic Glycerol Dialkyl Glycerol Tetraethers (GDGTs) of presumably soil bacterial origin that are preserved in the sediments. Our results stand in good agreement with instrumental MAAT values for Lake Cadagno (ca. 0°C, Swiss Meteo). Furthermore, temperature variations recorded by the MBT/CBT paleothermometer match published temperature reconstructions for the last two millennia at nearby locations in timing and magnitude. Major climate anomalies recorded by the independent proxies and by the MBT/CBT paleothermometer are, for instance, the Little Ice Age and the Medieval Warm Period. Furthermore, we detected a cold period lasting from about 2400 - 2000 yrs BP (-0.7°C), which correlates with the disappearance of the last lake dwellings in the European Alps. We also found a cold period during the Bronze Age (3500 - 4500 yrs BP; -0.5°C). In alpine regions, strong rain falls typically lead to increased erosion and flood activities, which are recorded in the sedimentary sequence (frequency and layer thickness of flood deposits). Similarly, pronounced precipitation can induce leaching of basic elements and thus acidification of soils, which has an impact on the CBT ratios. We found strongly enhanced flood activities concomitant with a decrease in soil pH during time periods of major cold spells, which also agrees with earlier reports on alpine lake level stands. Our results strongly emphasise the usefulness of the MBT/CBT paleothermometer for terrestrial climate reconstructions.

Soil carbon sequestration in olive grove with different soil management

O. NIETO[1], J. CASTRO[2] AND E. FERNÁNDEZ-ONDOÑO[1]*

[1]Dpto. Edafología y Química Agrícola. Facultad de Ciencias University of Granada (*correspondence: efernand@ugr.es)
[2]IFAPA Camino de Purchil. Junta de Andalucía

Introduction

We have simulated the dynamics of carbon (OC) under two soil management systems (tillage soil and cover plant soil) in a Mediterranean olive grove with the RothC model. We choose two soil management (tillage and cover crop) in three locations (L). The soil OC storage was calculate as difference between the content in both management. Carbon sequestration was calculated as difference between simulated RothC input and soil respiration.

Discussion of Results

	Clay	OC input	Carbon storage	Carbon sequestration
	%	Mg C ha^{-1} yr^{-1}		
L1	45	9.39	4.53	6.48
L2	50	5.51	2.18	3.63
L3	25	8.88	5.35	7.63

Table 1: clay content and carbon fluxes in the three locations for the first year after soil management change.

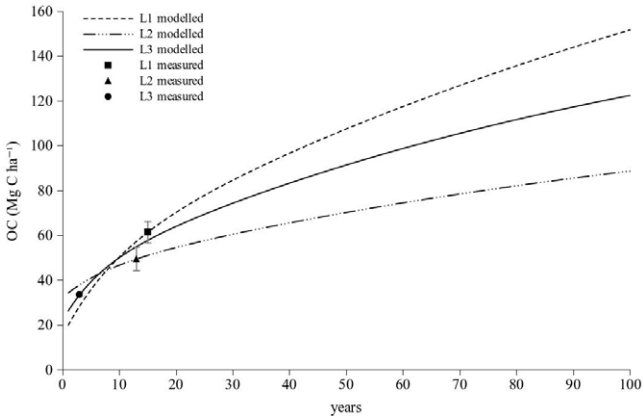

Figure 1: OC modelled for the three locations under cover crop.

Differences between the three locations were due to the amount of biomass generated by the cover crop and the clay content. L1 and L2, with high clay content but different carbon input, resulted in high OC for L1 after 100 years (Figure 1). The lower clay content whit high input (L3) was an intermediate position.

'Geo-metabolomics' — A key for understanding function and reactivity of dissolved organic matter

JUTTA NIGGEMANN[1]*, GUNNAR GERDTS[2] AND THORSTEN DITTMAR[1]

[1]Max Planck Research Group for Marine Geochemistry, ICBM, University of Oldenburg, Germany (*correspondence: jniggema@mpi-bremen.de) (tdittmar@mpi-bremen.de)

[2]Alfred Wegener Institute, Helgoland, Germany (Gunnar.Gerdts@awi.de)

Dissolved organic matter (DOM) in the ocean contains as much carbon as the earth atmosphere. This huge pool of energy- and nutrient-rich compounds provides an important base for microbial life in the water column. We hypothesize that the microbial community shapes DOM composition (and vice versa), thereby determining the dynamics of individual molecules and the entity of DOM. The entity of DOM is considered as a population of compounds, each characterized by a specific function and reactivity in the cycling of energy and elements. We propose 'geo-metabolomics' as the principle that a most comprehensive characterization of molecular DOM composition and its abiotic and biotic sources and sinks reveals a correlation of properties and behavior, ultimately allowing for the prediction of function and reactivity.

We present results from a long-term study of molecular DOM composition in the open North Sea. Ten-thousands of molecular formulae were identified in DOM by ultrahigh resolution mass spectrometry analysis (FT-ICR-MS, Fourier-Transform Ion Cyclotron Resonance Mass Spectrometry). For the 'geo-metabolomics' approach we include abiotic environmental factors and information on abundance and composition of phytoplankton and microbial communities.

The DOM pool in the North Sea is highly dynamic and influenced by a complex interplay of processes that produce, transform and degrade dissolved molecules. Phytoplankton blooms significantly change the molecular composition of DOM, strongly increasing the inherent molecular diversity. The temporal variability of individual molecular formulae in the 'geo-metabolome' provides novel information on their function and reactivity. This is a crucial step towards assigning structures to molecular formulae and finally the key for understanding DOM dynamics and interactions.

Near-source compositions of Italian kamafugite melt

I.K. NIKOGOSIAN* AND M.J. VAN BERGEN

Department of Earth Sciences, Utrecht University, The Netherlands (*correspondence: iniki@geo.uu.nl)

Within the wide compositional spectrum of K-rich magmatism in Central Italy, kamafugitic rocks in the Intra-Apennine Volcanic Province constitute the most alkalic, Si-undersaturated end-member, showing the highest enrichment in many incompatible trace elements. Longstanding debate concerning magmagenesis and geodynamic controls has been fuelled by questions concerning the extent to which crustal-interaction processes modified primary melt compositions. Here we present the results of a detailed study of melt-inclusions (MI) and host olivines from a representative kamafugite specimen from San Venanzo, that enabled us to constrain the primary composition (s) of mantle-derived melt.

Olivine phenocrysts show complex textures indicative of drastic late-stage changes in the crystallization regime. Pristine core parts, characterized by Fo_{93-90}, low CaO (0.2-0.3 wt.%) and Cr-spinel inclusions (Cr# ~ 0.7) are considered to to have crystallized from primary mantle-derived melt. Modified rim zones, showing a strong compositional gradient of decreasing forsterite (down to Fo_{70}) and increasing CaO (up to 1.8 wt.%), and hosting compositionally deviating MI, point to re-equilibration in response to drastic compositional changes induced by interaction with carbonate-rich rock types at shallow crustal levels.

Melt inclusions in the unmodified central parts of the olivines have compositional characteristics consistent with mantle derivation (8-12 wt.% MgO) but span a continuous range between 3 and 9 wt.% K_2O. The K-richest MI have compositions are relatively enriched in Na_2O, P_2O_5 and TiO_2. The K-poor end-member is characterized by very high CaO contents (up to 22 wt.%). From an average of the entire group of MI (n=25) the approximate volatile-free composition of the kamafugite parental magma is 43.0% SiO_2, 12.1% Al_2O_3, 2.15% TiO_2, 6.5% FeO, 0.11% MnO, 8.9% MgO, 17.6% CaO, 6.8% K_2O, 1.9% Na_2O, 0.95% P_2O_5.

We propose that this kamafugite composition represents an assembly of primary melts with differentiated compositions controlled by small-scale variations in the source. These would fit with different imprints by siliceous potassium-rich and carbonate-rich metasomatic agents derived from subducted carbonate-bearing metapelitic sediments.

Native iron in association with forsterite, experimental research

E.I. NIKOLENKO* AND E.I. ZHIMULEV

V.S. Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk 630090, Russia
(*correspondence: nevgeny@gmail.com)

Experimental research of zonal ilmenite formation in low oxygen fugacity conditions was spent on a high-pressure pressless 'split sphere' (BARS type). The investigated sample consisting of a haemoilmenite (Geik 10 mol. %, Ilm 44 mol. %, Hem 46 mol. %), powdered kimberlite and metal titanium was located in a platinum capsule which was placed in a high pressure cell. The longest experiment proceeded 5520 minutes at pressure 2.0±0.25 GPa and temperature 1100 ±20 °C. Highly reducing conditions in a capsule were supported at the expense of the metal titanium, which bonds oxidizing components. As a result of experiments a rim of Mg-rich ilmenite on a grain of haemoilmenite was obtained. It was formed by interaction of haemoilmenite with melt. Thus, the iron reduced from a haemoilmenite was accumulated in a native form in interstitial area, near to a titanium tablet. Native iron composition was estimated by EDS spectrometer (Oxford instruments): Fe 92.4-97.5, P up to 5.9, S up to 3.2, Ni up to 4.5, Ti up to 0.5 (wt.%). Olivine have the following composition near the titanium tablet (wt.%): SiO_2 - 41.06; Cr_2O_3 - 0.04; FeO - 7.67; MnO – 0.06; MgO - 50.27; CaO - 0.18; NiO - 0.41. With increasing distance from a titanium tablet iron content in olivine rises from 7.67 to 14.76 wt.% (Fo 92.1 - 84.5 mol. %).

In this case the dependence of olivine composition from redox conditions is clearly shown. At low values of oxygen fugacity native iron coexists with forsteritic olivine (Fo 92.1). Obtained data indicate the possibility of highly reducing conditions in a mantle at which some silicate phases could lose iron. These results are confirmed by finds of native iron together with Fe-poor silicate inclusions in natural diamonds [1, 2].

Fluid inclusion and stable isotope studies of the Kharape Epizonal Orogenic Gold Deposit, West Azerbaijan Province, Iran

S. NIROOMAND, R.J. GOLDFARB AND F. MOORE

(sh.niroomand@gmail.com, goldfarb@ usgs.gov, moore@geology.shirazu.ac.ir)

The Kharapeh epizonal orogenic gold deposit is located the Sanandaj-Sirjan Zone (SSZ) in the West Azerbaijan province, Iran. The deposit area is underlain by folded Cretaceous metamorphic rocks. The gold-bearing quartz veins are >1 km in length and average about 6 m in width; breccia zones are 10-50 m in length and ≤1 m in width. Four fluid inclusion types were recognized in cogenetic quartz: monophase aqueous inclusions, monophase carbonic inclusions, two-phase aqueous inclusions and three-phase carbonic-aqueous inclusions. Fluid inclusion data suggest mineral deposition at temperatures of at least 220 to 255°C, and depths of at least 1.4-1.8 km, from a H_2O-CO_2±CH_4 fluid of relatively high salinity (12-14 equiv. wt% NaCl). Ore fluid $\delta^{18}O$ values between about 7 and 9 per mil suggest no significant meteoric water input, despite gold deposition in a relatively shallow epizonal environment.

Cathodoluminescence of high-pressure feldspar minerals

H. NISHIDO[1]*, M. KAYAMA[1], T. SEKINE[2] AND K. NINAGAWA[3]

[1]Research Institute of Natural Sciences, Okayama University of Science, Japan (*correspondence: nishido@rins.ous.ac.jp)
[2]Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University
[3]Department of Applied Physics, Okayama University of Science, Japan

Cathodoluminescence (CL) of high-pressure silica minerals have been investigated, although high-pressure feldspar minerals such as $KAlSi_3O_8$-hollandite has not been studied from the perspective of CL spectroscopy. In this study, high-pressure feldspar minerals have been characterized by CL spectral analysis to clarify their emission mechanisms.

$KAlSi_3O_8$-hollandite ($Or_{97}Ab_3$) synthesized from adularia at a static condition of ~15 GPa and ~1200°C for 1 hour and experimentally shock-induced sanidine ($Or_{87}Ab_{13}$) from Eifel, Germany at pressure of 10 to 40 GPa by a propellant gun were selected for CL measurements. A scanning electron microscopy-cathodoluminescence (SEM-CL) was used to obtain CL spectra of these minerals.

CL spectrum of $KAlSi_3O_8$-hollandite consists of emission bands at 330 and 380 nm in UV-blue region. Similar UV-blue emission bands were detected in experimentally shocked sanidine above 20 GPa (diaplectic glass), but not observed in the samples below 20 GPa (diaplectic feldspar), where these emission intensities increase with increasing shock pressure. Diaplectic glasses in shergottites also exhibit UV-blue emissions at 330 and 380 nm. $KAlSi_3O_8$-hollandite has higher intensities of the UV-blue emissions than shocked samples at 40 GPa as well as diaplectic glasses in shergottite which might be responsible for completely octahedral coordination of Si (Al) in $KAlSi_3O_8$-hollandite and partially one in diaplectic glass. The UV emissions at 330 and 380 nm might be assigned to defect centers in Al and Si octahedral coordination produced by static and shock metamorphism. Furthermore, CL spectrum of $KAlSi_3O_8$-hollandite shows emissions at 550, 580, 660, 710 and 730 nm, which were undetectable in experimentally shocked sanidine above 20 GPa and diaplectic glasses in shergottite. These emission bands are characteristics of CL signals derived from $KAlSi_3O_8$-hollandite. Therefore, the CL signals can be used to identify high-pressure feldspar minerals and to observe its distribution in meteorite with high spatial resolution (~1 μm).

Long-term production rates of cosmogenic nuclides: Millions of years of rock exposure in Antarctica and the Atacama Desert

K. NISHIIZUMI[1]*, M.W. CAFFEE[2], S.A. BINNIE[1], R.C. FINKEL[3], J.J. OWEN[4], R. AMUNDSON[4], W.E. DIETRICH[5] AND G. FAURE[6]

Introduction

Production rates (PR) for terrestrial cosmogenic nuclides are typically estimated by measurements of independently dated samples, by exposure of artificial targets for a known duration or by coupling cross-sections with model-generated particle fluxes. The determination of PRs for extraterrestrial samples, on the other hand, utlizes samples that have achieved secular equilibrium during long exposure in a low erosion environment. Here we adopt this approach to derive terrestrial cosmogenic ^{10}Be and ^{26}Al production rates.

Results and Discussion

Sets of paired ^{10}Be-^{26}Al results were selected from our published and unpublished data (28 Antarctica, 45 Atacama Desert). All samples contain more than $4x10^6$ atoms ^{10}Be/g quartz, sea level at high latitude. The ^{10}Be concentrations were plotted against corresponding $^{26}Al/^{10}Be$ values, and a range of possible 'saturated' ^{10}Be production rates.

A ^{10}Be production rate (P_{10}) of 5.1-5.3 atom/yr g-quartz is the best fit to the measurements. This P_{10} is much higher than the recently proposed P_{10} of ~4.5. Known geologic processes cannot reconcile these two production rates. In fact, the P_{10} based on Atacama and Antarctic samples is a minimum production rate since: (1) samples must have experienced some erosion and even 5 cm/Myr erosion yields a 16 % P_{10} increase; (2) any soil, ash or snow cover would artificially depress our PR estimate; (3) saturation may not have been achieved, since for many samples ^{26}Al-^{21}Ne exposure ages do not show more than 8 Myr exposure age (98 % saturation for ^{10}Be); (4) uplift of the Transantarctic Mountains and Atacama Desert moves the samples into higher PR. The high P_{10} indicates that the long-term cosmic ray flux is higher than that of the last few tens of thousands of years, probably due to a higher GCR flux and lower geomagnetic field in the past.

Relationship between water saturation and mineral-water contact area of a sandstone

N. NISHIYAMA* AND T. YOKOYAMA

Department of Earth and Space Science, Osaka University, 1-1 Machikaneyama-cho, Toyonaka, Osaka, Japan (*correspondence: nnishiyama@ess.sci.osaka-u.ac.jp)

Mineral-water contact area (reactive surface area) of a rock is an essential parameter for quantitative treatment of water-rock interaction. Although mineral-water contact areas have been often estimated by the gas adsorption method and image analysis, pore spaces in rocks near the Earth's surface are not always filled only with water but also with air. In such unsaturated condition, only a portion of mineral surfaces may contact water. However, knowledge of the dependence of mineral-water contact area on water saturation (the proportion of pore water volume to total pore volume) has been very limited. In the present study, we performed the dissolution experiments using a sandstone under various water saturations. Fontainebleau sandstone from France, having a porosity of 7% and being composed of ~100% quartz, was used. In the experiments (Fig. 1), a constant water pressure was applied to the rock core whose water saturation was adjusted in advance, and volumetric flow rate Q [m^3 s^{-1}] and concentration of dissolved Si [mol m^{-3}] were measured. Mineral-water contact ratio α, the proportion of mineral-water contact area at the given water saturation to that at the saturated condition, can be calculated by the following relationship: $Q \times [Si] = k_{diss} \times A \times \alpha$, where k_{diss} [mol m^{-2} s^{-1}] is the dissoluton rate of quartz and A [m^2] mineral-water contact area at the saturated condition. It was found that the mineral-water contact ratio is almost unchanged even if water saturation decreases. We attribute this result to the existence of water films wetting mineral surfaces.

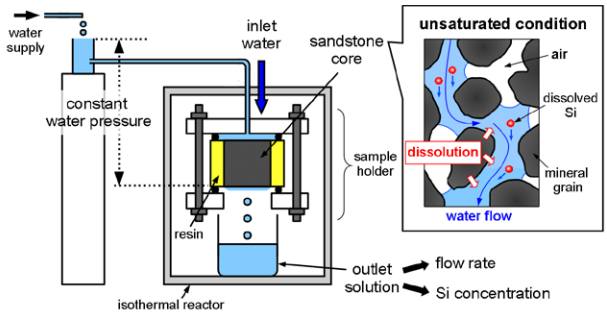

Figure 1: Experimental setup for measuring mineral-water contact area at various water saturations.

Linking nitrogen isotope systematics and microbiology in a subsurface geothermal water stream, Hishikari Gold mine, Japan

MANABU NISHIZAWA[1]*, KEISUKE KOBA[2], AKIKO MAKABE[2], NAOHIRO YOSHIDA[3], MIHO HIRAI[4], JUNICHI MIYAZAKI[1,4], TAKURO NUNOURA[4] AND KEN TAKAI[1,4]

[1]Precambrian Ecosystem Laboratory, JAMSTEC, 237-0061, Japan (*correspondence: m_nishizawa@jamstec.go.jp)
[2]Tokyo University of Agriculture and Technology, Japan
[3]Tokyo Institute of Technology, Japan
[4]Subsurface Geobiology Advanced Research Program, JAMSTEC, 237-0061, Japan

We report biogeochemistry of a subsurface geothermal water stream in the Hishikari gold mine, Japan. The stream, which is derived from a subsurface anaerobic aquifer containing plentiful CO_2, CH_4, H_2, and NH_4^+, emerges in a mine tunnel 320 m below the surface, providing nutrients for a lush microbial community that extends to a distance of approximately 10 m in the absence of sunlight-irradiation. 16S rRNA gene analyses showed a change of microbial community structure along the stream. In the upstream site (72°C), dominant phylotypes were methane-oxidizing bacteria, and hydrogen- and sulfur-oxidizing bacteria. In contrast, dominant phylotypes were closely related to ammonia-oxidizing archaea (AOA) and nitrite oxidizing bacteria (NOB) in the midstream and downstream sites (65 and 57°C). Abundance of archaeal *amoA* gene (10^9 copies/g mat) is much higher than that of bacterial *amoA* gene ($10^{5\sim6}$ copies/g mat). Water chemistry systematically changes along the stream. From the upstream to downstream sites, CH_4, H_2 and NH_4^+ contents decrease, while NO_2^- and NO_3^- contents increase, respectively. These results indicate a tight coupling of microbial community structure and chemical dynamics of C, H, and N in the subsurface hydrothermal ecosystem.

We extensively studied the nitrogen dynamics driven by thermophilic AOA and NOB. Contents and $\delta^{15}N$ values of inorganic N species in the geothermal water are as follows: NH_4^+: 166 to 255 μM, 0 to 7‰; NO_2^-: 0 to 27 μM, -25 to -27‰; NO_3^-: 0 to 67μM, -1.8 to -2.3‰. Importantly, content and $\delta^{15}N$ value of total fixed-N little change along the stream. By using two-step reactions model in a closed system, we have estimated apparent isotopic fractionations and relative ratio of reaction rate coefficients of ammonia oxidation and nitrite oxidation in the subsurface hydrothermal ecosystem.

Plutonium interactions with pure and substituted iron and manganese oxyhydroxide minerals

H. NITSCHE[1,2]*, Y.-J. HU[1,2], D.L. WANG[1,2] AND L.K. SCHWAIGER[1,2]

[1]Department of Chemistry, University of California, Berkeley, CA 94720-1460, USA (*correspondence: hnitsche@berkeley.edu)

[2]Nuclear Science Division, Lawrence Berkeley National Laboratory, Berkeley, CA, 94720-816, USA

Due to its long half live 239-Pu is a major concern for radioactive contaminated sites and risk assessment of high-level geologic nuclear waste repositories. Plutonium can co-exist in four stable oxidation states [Pu^{3+}, Pu^{4+}, $Pu(V)O_2^+$, and $Pu(VI)O_2^{2+}$] under environmental conditions. Solubility and speciation can vary widely depending on oxidation state and ultimately affect the transport properties. Oxidized plutonium is orders of magnitude more soluble than the reduced forms, Pu(III) and Pu(IV), and thus Pu(V) and Pu(VI) are more mobile in the environment. Plutonium is highly redox active; contact with the surrounding environment could potentially reduce the more soluble forms of plutonium, causing them to become more insoluble.

We studied the interaction iron oxyhydroxide minerals (ferrihydrite and goethite), as environmentally prevalent mineral phases with hexavalent plutonium. XAS analysis for the sorption of Pu(VI) to pure goethite, showed that Pu(VI) was reduced to Pu(V).

We also investigated the interaction of Pu(VI) with pure manganese oxyhydroxide minerals manganite (MnOOH) and hausmannite (Mn_3O_4). These are minor minerals that have been shown to be present at many current and potential geologic nuclear storage sites as coatings on iron minerals. XANES measurements showed that upon contact with the minerals, all the plutonium sorbed to the minerals was reduced to either Pu(V) or Pu(IV). Fits to the EXAFS imply that the Pu is sorbed to the manganite and hausmannite surfaces in an inner-sphere coordination.

We also studied the influence of manganese as a minor component with synthetic manganese-substituted goethite. Pu(VI) was reduced to Pu(V) or Pu(IV) upon contact with the mineral. The results suggest that manganese is the species responsible for the reduction of Pu(VI) to the more insoluble Pu(IV) oxidation state, and indicate the possibility of limited plutonium migration in the environment through interaction with Mn-containing minerals

Influence of oil price fluctuation to Chinese Economy

NIU JIANYING[1]*, ZHAO LIANRONG[1] AND ZHOU JINSHENG[2]

[1]School of Humanities and Economic Management, China University of Geosciences (Beijing), Xue Yuan Road 29#, Hai Dian District, Beijing, China (*correspondence: niujy@cugb.edu.cn)

[2]China University of Geosciences (Beijing)

Research aiming at relation between oil price and economic activities dated back to 1970's when economic depression happened in main oil consuming countries because of twice oil crisis. However, initial research took energy economy as one part of resources & environmental economics, afterwards research emphasis gradually turned to aspects such as how government policies affect energy consumption and improve efficiency of energy utilization. In recent years, by establishing models, each research conducted analysis, measurement and predict of affection to economic activity index by oil price fluctuation [1]. Research results indicate that large fluctuation of crude oil price caused a certain affects to OECD countries [2].

From the turn of this century up to the present, dramatic rise of oil price has caused a certain affect to Chinese economic operation. By following oil consumption material flow and value chain analysis principle, we have established oil price fluctuation and micro-economic growth related analysis model. We also calculated relative industrial departments oil consumption coefficient. We formed a model of affect by international oil price fluctuation to Chinese economy, overcoming shortage of previous research. We conducted sensitivity analysis and projection about oil price fluctuation affecting Chinese economy, providing scientific evidence to the nation for formulating early warming mechanism on guarding against oil price risk.

Intra-plate magmatism of the Al Haruj Volcanic Field, Libya

SARAH NIXON*, JOHN MACLENNAN AND NICKY WHITE

Department of Earth Sciences, University of Cambridge, Cambridge, CB2 3EQ, UK
(*correspondence: sn340@cam.ac.uk)

The Al Haruj volcanic field covers a 45,000 km^2 area in central Libya. The volcanic field is comprised of a sequence of 6 volcanic phases and a series of lava shields and scoria cones. The volcanic phases were distinguished using ASTER images and field observations. The age of the Al Haruj has been estimated to range from 5.27-0.1 Ma. New ^{3}He exposure dates on the youngest lava flow extend this age range, revealing recent activity with an age of 2.31±0.81 ka (1σ, n=5). Initial phases of volcanism 1-3, consist of both alkali and tholeiitic basalts which were erupted in close spatial proximity. The younger phases 4-6 can be attributed to better preserved continuous lava flows and show a more consistent geochemical signature evolving from transitional to sub-alkaline lavas.

The alkali basalts are incompatible trace element enriched and isotopically depleted relative to the tholeiitic samples. Fractional crystallisation occurred at depths of 25-39 km and temperatures between 1215-1360°C. 0-4% combined assimilation and fractional crystallisation introduced a heterogeneous crustal component to the mantle melts. Differentiation processes cannot account for all compositional variability. REE inversion modelling predicts generation of alkali and tholeiitic basalts can be accounted for by melting of a predominately anhydrous mixed mantle source in an upper mantle plume with a mantle Tp of ~1460-1480°C. The maximum melt fractions are 18.9 and 13.5%, extracted at depths of 70 and 74 km for tholeiitic and alkali basalts, respectively.

Across North Africa volcanism is predominately of alkaline affinity. The lithospheric thickness influences the melt fraction; small degree (0.5-2.2%), incompatible element enriched melts, are found beneath regions of thicker lithosphere at Hoggar and Air Massifs. These melts are also isotopically depleted. At the Jebel Marra and Tibesti volcanic provinces, values of Vs are lower and predicted melts fractions are larger (4.4-8.2%) and melts are enriched isotopically. The larger melt fractions estimated for the Al Haruj lavas and the abundance of tholeiitic basalts in comparison to other North African volcanic fields is attributed to a higher Tp in addition to the occurrence of thinner lithosphere (<80 km). North African Cenozoic volcanic provinces can be explained by diapiric upwellings or hot fingers originating in the upper mantle. Isotopic enrichment of larger melt fractions may represent a greater proportion of a lithospheric or plume component in the source.

Pb-Sr-Nd systematics of the early Mauna Kea Shield Phase and insight into the Pacific deep mantle

INÊS GARCIA NOBRE SILVA*, DOMINIQUE WEIS AND JAMES S. SCOATES

PCIGR, EOS, University of British Columbia, Canada
(*correspondence: inobre@eos.ubc.ca)

High-precision Pb, Sr and Nd isotopic compositions of 40 basalts from the bottom 408 metres of core recovered during the final phase of the Hawai'i Scientific Drilling Project (HSDP2-B and -C) reveal compositional continuity of the >650 ka stratigraphic record of Mauna Kea volcano, with the majority of the basalts plotting along the 'Kea-mid8' array [1]. Compared to the previous ~3099 m of drill core, the upper 210 m (3098.2 to 3308.2 m) of samples from this drilling phase show very restricted isotopic variations (e.g. 5x and 3x smaller variation for ^{206}Pb/^{204}Pb and ^{86}Sr/^{87}Sr, respectively). This indicates sampling of a more homogeneous source domain during the time interval represented by the eruption of these basalts. In contrast, samples from the deeper 170 metres show the largest range of ^{206}Pb/^{204}Pb (18.304–18.693) and ^{208}Pb/^{204}Pb (37.923–38.270). These older lavas extend the isotopic record of Mauna Kea both to significantly more radiogenic values, similar to the isotopic compositions shown by 'ancestral' Kilauea lavas [2], and to significantly less radiogenic values, similar to those observed in Mauna Kea and Kohala post-shield lavas [3]. Based on their older ages (> 650 kyr) and compositional characteristics, these basalts likely erupted in the very early shield phase of Mauna Kea, rather than representing part of the output of Kohala or another unknown volcano [4]. Similar to Mauna Loa [5], the earlier stages (older lavas) of Mauna Kea volcanism are isotopically more variable than subsequent stages. Overall, the isotopic heterogeneity in Mauna Kea shield lavas can be explained by mixing variable proportions of four isotopically distinct components intrinsic to the Hawaiian mantle plume: the more radiogenic 'Kea' component, a high ^{208}Pb*/^{206}Pb* (producing low-SiO_2 basalts) component similar to Loihi, and two components with less radiogenic Pb isotopic compositions. Besides being a common, long-lived component in the Hawaiian plume, 'Kea' has isotopic similarities to the common mantle component 'C'. The fact that it is positioned at the convergence between other Pacific Ocean island basalt groups suggests that 'Kea' is a common composition in the deep mantle beneath the Pacific Ocean basin.

Nucleation and growth of calcite particles: Comparing modelling and experimental approaches

C. NOGUERA[1]*, B. FRITZ[2] AND A. CLÉMENT[2] AND G. MONTES-HERNANDEZ[3]

[1]INSP, CNRS-UPMC, Paris, France (*correspondence: noguera@insp.jussieu.fr)
[2]LHYGES, Université de Strasbourg/EOST, CNRS, France
[3]ISTerre, Université J. Fourier, CNRS, Grenoble, France

The development of CO_2 storage projects stimulates an extensive use of geochemical models for the precipitation of mineral phases and particularly carbonate phases. A thorough modelling of the formation of secondary minerals in geochemical processes requires an account of nucleation and growth mechanisms in a generalized kinetic approach. We have developed the Nanokin code [1-3] which models kinetic dissolution of primary minerals and precipitation of secondary minerals, relating the nucleation and growth of precipitated particles to the saturation state of the aqueous solution. This model predicts the size evolution of created particles and the feedback effect on the aqueous composition.

We present an application of the Nanokin code to the formation of calcite from a supersaturated solution produced by the dissolution of portlandite at 30°C with a high pH value around 12. These conditions correspond to those selected by Montes *et al*. [4] in their recent experimental approach. The simulated calcite particles are produced by heterogeneous nucleation and tri-dimensional growth.

The results show that the nucleation of calcite occurs rapidly from the initial dissolution stages of portlandite as obtained experimentally during the first 5 hours of reaction. The nucleated particles grow over 24 hours, reaching sizes of about 70-75 nm which compare well to the sizes obtained experimentally (64 nm).

This modelling approach validated at 30°C may be extended to higher temperatures up to 90°C as in the experimental approach.

Spin crossover and iron-rich silicate melt in the Earth's deep mantle

R. NOMURA[1]*, H. OZAWA[1,2], S. TATENO[1], K. HIROSE[1,2], J. HERNLUND[3], S. MUTO[4], H. ISHII[5] AND N. HIRAOKA[5]

[5]National Synchrotron Radiation Research Center, Hsinchu 30076, Taiwan

The density crossover between melt and solid in the deep mantle has long been speculated with profound implications for chemical evolution of our planet[1]. Recent *ab-initio* calculations[2] suggested that melt-solid iron partitioning is the key to cause density crossover, which has been examined only at low pressures (25 GPa)[3].

In this study, we performed melting experiments on $(Mg_{0.89}Fe_{0.11})_2SiO_4$ olivine using laser-heated diamond anvil cell (LHDAC) and extended measurements of iron partitioning over the entire mantle pressure range.

The calculated Mg-Fe distribution coefficient K_D between melt and liquidus phase (Fig. 1) showed the sudden drop of K_D value at about 76 GPa, which could be explained by a Fe^{2+} spin crossover (from high-spin to low-spin) in melt suggested by additional X-ray emission spectroscopy (XES) measurements in $(Mg_{0.95}Fe_{0.05})SiO_3$ glass which observed the change of spin state at about 70 GPa and room temperature.

The culculated density of (Mg, Fe)SiO_3 liquid coexisting with $(Mg_{0.92}Fe_{0.08})SiO_3$ perovskite shows that melt is denser than solid below 1800 km depth in the Earth. These results suggest that dense basal magma ocean in the early Earth whose subsequent crystallization may have formed large low shear velocity provinces (LLSVPs) and ultra low velocity zone (ULVZ).

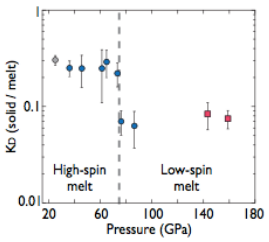

Figure 1: Change in Fe-Mg distribution coefficient K_D between perovskite (blue circle) or post-perovskite (red square) and melt. The datum of previous experiment is shown in grey circle [3].

Fractionation of $^{238}U/^{235}U$ during weathering and hydrothermal alteration

J. NOORDMANN[1]*, S. WEYER[1], M. SHARMA[2], R.B. GEORG[3], S. RAUSCH[4] AND W. BACH[4]

[1]Institute of Mineralogy, University of Hanover, Germany (*correspondence: j.noordmann@mineralogie.uni-hannover.de)
[2]Department of Earth Sciences, Dartmouth Collage, New Hampshire, USA
[3]Worsfold Water Quality Centre, Trent University, Canada
[4]Geosciences Department, University of Bremen, Germany

Recently, fractionation of $^{238}U/^{235}U$ has been observed between oxic and anoxic oceanic environments [1]. To use U isotopes as a proxy to constrain mass fluxes or the redox evolution of the oceans [2], we need detailed information on the U isotope mass balance. However, U isotope fractionation during continental weathering and transport to the oceans, as well as during hydrothermal alteration (the second most important sink for U) is yet unknown.

Here, we analysed $\delta^{238}U$ of water samples from rivers of different climatic conditions, granites of different localities, five different hydrothermal fluids from the Juan de Fuca Ridge and altered oceanic crust from the Bermuda Rise, Reykjanes Ridge and Pigafetta Basin

Large rivers display an average $\delta^{238}U$ of -0.24 ‰ (relative to CRM-112A) which is very similar to the average value of granites ($\delta^{238}U$ = -0.30 ‰) and basalts ($\delta^{238}U$ = -0.28 ‰), indicating that in average only minor U isotope fractionation occurs during weathering and transport. Only smaller rivers display larger U isotope variations (between 0.01 and -0.28 ‰) likely monitoring U isotope variations of their bed rocks. The hydrothermal waters display a tight range of $\delta^{238}U$ (-0.28 and -0.50 ‰) around the seawater value of $\delta^{238}U$= -0.37 ‰ (modified after [1]), however, at much lower U concentration levels (0.08 to 0.24 ppb) compared to that of seawater (3.3 ppb, [1]). Also, most of the analyzed altered basalts have $\delta^{238}U$ similar to that of fresh basalts ($\delta^{238}U$= -0.42 to -0.23 ‰), with two notable exceptions (0.18 and 0.31 ‰). Accordingly, removal of U from the ocean water during hydrothermal alteration of the oceanic crust appears not to result in significant U isotope fractionation in most cases.

Geochemistry in a boreal stream after a major forest fire — Implications for a changing climate

FREDRIK NORDBLAD[1], FRAUKE ECKE[1,2] AND JOHAN INGRI[1]

[1]Division of Geosciences, Luleå University of Technology, S-97187 Luleå, Sweden (*correspondence: fredrik.nordblad@ltu.se)
[2]Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences, Box 7050, S-750 07 Uppsala, Sweden

In August 2006, a major wildfire burned 15 km^2 of boreal forest land near Harads, a town in the north of Sweden. The purpose of this work was to examine wildfire effects on surface water geochemistry in a boreal catchment.

In 2007, increased dissolved output of major elements Ca, K, Mg, Na and elevated conductivity was measured in a stream draining the burnt area. Repeated measurements in 2009 showed a considerable decrease in conductivity and post-fire release of major elements from the burned catchment, which was interpreted as regression towards pre-fire conditions.

A nearby stream not draining the burned area was used as a reference. Conductivity and concentrations of Ca, K, Mg & Na were 1.5 – 7 times lower compared to the burnt creek in 2007. The 2009 re-measurements showed equivalent levels of Ca & Na concentrations and conductivity in both creeks but K & Mg concentrations were still higher in the burnt creek.

The elevated concentrations in the burnt creek in 2007 were interpreted to originate from leaching ash and remainders of burnt organic material on the forest floor. The maintained elevation of K & Mg concentrations in 2009 is likely to be caused by inhibited plant uptake as the biomass was severely reduced by the fire.

Diurnal specific transport rates ($\mu mol/m^2$) in the burnt creek were 1.8 – 2.6 times higher in 2007 compared to 2009. This implies there is a potential for increased transport of major elements from boreal areas since it is likely that wildfire frequency and the extent of burned area will increase according to current climate change scenarios [1].

Acid mine drainage and responsible mining

D.K. NORDSTROM

U.S. Geological Survey, Boulder, Colorado, 80303, USA (dkn@usgs.gov)

One of the most challenging environmental problems to mitigate or remediate is acid mine drainage (AMD) from metal and coal mining. Until relatively recently, planning for a new mine did not consider the production of AMD or even an accounting of the water cycle (recharge, flowpaths, and discharge). Environmental managers were not considered part of the mining work force and hydrogeologists, geochemists, land use planners, and socio-economic planners were mocked for being irrelevant. Fortunately, this situation has been reversed for many companies and today there are several industry consortiums whose goal is to prevent or mitigate AMD**.** Professionals in the hydrologic, geochemical, geological, and microbiological sciences are being asked more frequently to investigate and advise on water-quality issues and remediation scenarios related to mining and mineral processing. Unfortunately we still have a long ways to go. I suggest that even more fundamental changes are needed: (a) support environmental scientists in hydrology, environmental geology, and geochemistry and involve them in the initial planning stages, in background studies, and in testing of waste materials and modeling their environmental effects. (b) The word mine 'wastes' should be dropped from common usage. An attitude needs to be developed that every bit of earth removed but not economic for ore processing is economic and utilizable for something. (c) Contaminant water pathways can be anticipated beforehand with hydrogeochemical expertise and after waterways have been polluted, careful investigations through synoptic sampling and tracer-injection test can establish sources and sinks of AMD, simulate potential remediation scenarios, and determine the reasons for successes and failures of remediation from properly monitored sites.

Geochemical and physical characteriation of palaeo and contemporary redox interfaces within Late Palaeozoic sediment sequences in South Australia

VERITY NORMINGTON*, S.M. HILL AND ROBERT C. DART

Deep Exploration Technologies Cooperative Research Centre. School of Earth and Environmental Sciences. University of Adelaide. SA 5005 (*correspondence: verity.normington@adelaide.edu.au)

The record of Late Carboniferous to Permian glacial erosion and deposition in South Australia is part of the Late Palaeozoic Gondwanan glaciation. Although there have been many different sedimentological and palaeogeographical studies of these sediments, they have not been mutli-element, geochemically characterised. This study identifies and briefly characterises some of the redox interfaces within these sediments that have important attributes in accounting for the multi-element characteristics of these sediments from ICP-MS and XRF.

Lodgement tills, fluvial-glacial, lacustine-glacial and glacial-marine sediments are abundant within these sequences, with some of the larger and deeper depositional areas (e.g. Arckaringa Basin) also containing fluvial and coal swamp deposits. Some of the most extensive redox interfaces are associated with the interfaces between geochemically reduced lignite beds and geochemically oxidised sandstone beds. These interfaces are major repositories for a range of redox-sensitive elements, in particular U. Another important setting for redox interfaces is within the predominantly geochemically reduced clays and interbedded oxidised fine sands within the glacial marine sediments. These interfaces typically feature tabular sheets of calcareous and silicified sandstones, as well as silica-indurated, discoidal reduction spots and in some sites irregular masses of alunite concretions. The third major type of redox interface identified contains variably ferruginised and minor manganiferrous induration. This may be constrained by the hydromorphic attrubites of particular sediment lithologies (e.g. preferentially confined to sandstone or clay beds) or fractures sets within the sequence. Alternatively ferruginisation is associated with redox and weathering profiles associated with palaeosurfaces, with oxidation typically extending vertically downwards into otherwise geochemically reduced sediment.

Enhancing heavy metal immobilization in SuDS

M. NORRIS[1]*, V. PHOENIX[1], I. PULFORD[1], H. HAYNES[1] AND C. DOREA[2]

[1]University of Glasgow College of Science and Engineering, Glasgow, Scotland G12 8QQ (*correspondence: norris@civil.gla.ac.uk)
[2]Université Laval Département de génie civil et génie des eaux, Québec, QC, Canada G1V 0A6

Introduction

Diffuse water pollution from urban runoff has the potential to carry a variety of heavy metals and other pollutants throughout the environment. Sustainable urban drainage systems (SuDS) are increasingly being used as a first defence for stormwater-borne pollutant removal. One example of a SuDS system is a filter drain; a trench filled with gravel filter material intended to filter pollutants from road runoff and act as storage during high rainfall events.

Since a major component of stormwater runoff can include heavy metals such as Cd, Cu, Pb and Zn, the aim of this study is to increase the heavy metal immobilization of gravel filter media within filter drains. Chemical amendments (iron-oxide coatings) were made to typical filter drain gravel with the aim of increasing affinity for metals. These amendments have already been shown to enhance metal immobilization by finer media such as sand [1, 2] and polyethelyne beads [3].

Experimentation and Results

A process adapted from Liu *et al*. [3] was used to coat 10mm gravel with iron oxide. Initial batch experiments showed that heavy metal removal was pH dependent due to the coating method altering the pH buffering capacity of the gravel. Different coating proceedures generated gravels which buffered batch reaction solutions between pH 3 and 10, (despite repeated washing). Perfecting of the coating method is ongoing, as well as further amendments to gravel which include manganese oxide and clay.

In order to verify geochemical processes, the PHREEQC modelling program was used to determine metal speciation and saturation indices of the solutions. When increased metal removal is observed at higher pH, the solutions are shown to be supersaturated. This is corroborated in batch experiments which show that the immobilization process is non-reversible, and thus likely precipitation dominated.

Usefulness of stable isotopes in small catchment studies: Overview of results from the stressed ecosystems of Central Europe

M. NOVAK*, F. BUZEK, I. JACKOVA, V. CHRASTNY, J. FARKAS, D. FOTTOVA, P. VOLDRICHOVA, M. STEPANOVA AND E. PRECHOVA

Czech Geological Survey, Geologická 6, Prague 5, Czech Republic (*correspondence: martin.novak@geology.cz)

Over the past 20 years, a number of stable isotopes (C, N, S, O, Pb and Zn) have been used in Central European catchments as diagnostic tools in biogeochemical studies or tracers of dispersion pathways of pollutants. Here we summarize the main isotope success stories in a hydrochemical monitoring network of 13 headwater catchments in the Czech Republic. The network, known as GEOMON, has been supplying monthly hydrochemical input-output data since 1994. The monitoring has coincided with a major decrease in industrial emissions, that had peaked in the 1980s, and are now lower. We have documented linkages between the behaviour of C, N and S in ecosystems. Assimilation of all three elements by plants is associated with an isotope fractionation. Plant tissues tend to accumulate lighter isotopes. In soils, both in upland and wetland locations, degradation of organic molecules is associated with preferential release of the lighter isotopes of C, N and S. The residual vertical soil profiles exhibit isotopically heavier C, N and S with an increasing depth. In retrospective studies, comparing isotope data from emanating greenhouse gases and from organic soils can provide an insight into terminal C, N and S mineralization. Vertical stratification of S isotopes in soils has been used to calculate the proportion of organically cycled anthropogenic S in stream discharge. It appears that most acidifying S was stored in the topmost organic soil horizon and is now flushed out of the ecosystem. Soil solutions, taken by lysimeters, contain newly formed nitrate and sulfate, isotopically different from that in rainfall/canopy throughfall. Sulfate oxygen isotopes systematically show that throughfall sulfate was mainly formed by heterogeneous oxidation of SO_2, wherese sulfate deposited in open areas was mainly formed by homogeneous oxidation of SO_2. Lead isotopes in tree rings and peat profiles are useful as archives of past pollution rates and for apportionment of pollution sources (coal burning, traffic, ore smelting). Zinc isotope ratios, recently determined in ice accretions and snow, fingerprint pollution sources that are rarely situated upwind from the receptor sites.

Lithium isotope fractionation in pegmatites — Function of bond length

M. NOVÁK[1], T. MAGNA[2,3], J. CEMPÍREK[4], V. JANOUŠEK[3], C.V. ULLMANN[5] AND U. WIECHERT[5]

[1]Masaryk University Brno, Czech Republic
[2]Universität Münster, Germany (tomas.magna@geology.cz)
[3]Czech Geological Survey, Prague, Czech Republic
[4]Moravian Museum, Brno, Czech Republic
[5]Freie Universität Berlin, Germany

Large ranges in Li isotope compositions of pegmatites have recently been reported and δ^7Li variations variously ascribed to melt–exsolving fluid fractionation [1], source variations [2], the ^{7}Li affinity to occupy stronger (i.e. shorter) Li–O bonds [3] or extensive crystal–melt fractionation [4].

Petalite, spodumene, amblygonite, lepidolite, tourmaline, beryl, muscovite and secondary lithiophosphate and cookeite from two pegmatites with similar mineral assemblages but distinct ages (Nová Ves, Czech Republic, ~335 Ma; Tanco, Canada, ~2640 Ma), show large range in Li (770–154, 000 ppm) and δ^7Li (from -2 to +32‰). The Nová Ves pegmatite has δ^7Li comparable with crustal rocks from wider area [5, 6] while the Tanco pegmatite has uniformly high δ^7Li >9‰, indicative of distinct sources (melting of upper continental crust vs. ^{7}Li-rich brines) for the two localities. δ^7Li tends to increase with decreasing coordination number of Li in the crystal lattice (see also [3, 4]). More notably, tight negative δ^7Li correlation with the Li–O bond length is observed with nearly identical slopes for both localities, perhaps suggestive of general rule driving the Li isotope fractionation at moderate temperatures (500–250°C), overall confirming experimental results [3]. These observations are further tied by broadly similar order of crystallizing mineral phases but the crystallization sequence does not result in uni-directional evolution of δ^7Li. Thus, the Li–O bond length appears to be the key factor in fractionating Li isotopes, irrespective of genetic context (parental melt, sub-solidus or hydrothermal origin). Also, pegmatite zones crystallized from Na–Li-rich melts during the final phase of solidification are the most important carriers of Li, implying (i) behavior of the whole system as a near-infinite Li reservoir and (ii) high Li mobility in Na–Li–F-rich melts and hydrothermal fluids that impedes development of Li isotope heterogeneity.

Water contents of incipient partial melts in equilibrium with peridotite at upper mantle conditions

D. NOVELLA* AND D.J. FROST

Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany
(*correspondence: davide.novella@uni-bayreuth.de)

Beneath mid ocean ridges the onset of adiabatic melting in the mantle is thought to first occur through the formation of small degree melts likely rich in H_2O. Small degree melts produced from a mantle with a relatively low bulk H_2O content still have the potential to strip trace elements from larger regions of the mantle compared to dry melting processes. Also, the presence of such melts may be responsible for the low viscosity of the asthenospheric mantle and for the regular metasomatism of the lithospheric mantle. Therefore, the compositions of incipient melts in particular the H_2O content and H_2O partitioning between the melts and peridotite minerals are very important and need to be constrained.

The aim of this study is to determine the chemical composition and H_2O content of small degree partial melts that form by melting a hydrous peridotite at pressures and temperatures compatible to the upper mantle and to determine the H_2O mineral-melt partitioning.

Sandwich experiments have been performed at 6 GPa and 1400°C, the adiabatic temperature at this depth. In our experiments, an initial guess melt composition containing H_2O is sandwiched between layers of peridotite and equilibrated at high P and T. Changes in the melt composition during the equilibration result in a new melt composition, which is then used as a starting material in a second experiment. After several iterations a melt composition is found saturated in the same peridotite assemblage as found under anhydrous conditions at the same P and T. The water content of each experiment has to be assessed through mass balance. We then measure the mineral/melt partition coefficients. Our results have implications in terms of melt production in the Earth's upper mantle and observed anomalies in the propagation of seismic waves.

Cenozoic volcanic activity in North Sudetic Basin (Lower Silesia, SW Poland) —Possible evolution model based on combineded petrological, geochemical and isotopic investigation of litospheric xenoliths and volcanic host-rocks

M. NOWAK[1]*, A. MUSZYŃSKI[1] AND P. MICHALAK[1,2]

[1]Institute of Geology, Adam Mickiewicz University in Poznań (*correspondence:mnap@amu.edu.pl)
[2]Institut für Mineralogie, TU Bergakademie Freiberg

The Cenozoic volcanism in the North-Sudetic Basin (CEVP) took place ca. 30 to 18 Ma [1]. Throughout the basin (Złotoryja and Jawor area) there are about 26 outcrops on the surface, mostly in the form of necks, lava flows and veins [1, 2].

The model was based on considerate microscopic observations of all xenoliths (after excluding such effects as decompression melting, interaction with a host rock etc.), analysis of petrological, chemical and isotopic variation of the host-rocks and literature data [1, 2, 3].

As the orogenic movements and asthenospheric activity intensified, the lithospheric mantle was penetrated by melts that caused crystallization of pyroxenites and early cumulates. Subsequent uplift of the asthenospheric mantle resulted in partial melting of the lithospheric mantle and first significant peak of volcanic activity in the area (Oligocene). The material supplied form deeper parts of the lithosphere/asthenosphere caused an increase in metasomatism of the lithospheric mantle, mainly cryptic metasomatism and locally modal metasomatism [4, 5].

The supply of deeper melts (garnet stability field) in the last phase of the volcanic activity (Miocene) along with partial melting of the metasomatized lithospheric mantle resulted in changes in chemical and isotopic composition of the studied rocks.

The work was support by MNiSW grant No. NN307040736.

[5]Dept. of Geological Sciences, Brown University, USA

The evolution of $^{187}Os/^{188}Os$ in residual mantle effectively ceases after large-degree mantle melting events, due to almost complete depletion of Re in the residue. Thus, Os isotopes in mantle rocks can be used to constrain the timing of major melting episodes, by comparison with a chondritic evolution curve, and to investigate the scale of such events through time (e.g. [1]). Platinum-group minerals (PGM) are formed in the mantle and in mantle-derived ultramafic rocks rich in platinum-group elements (PGE). Although difficult to locate and extract directly, PGM are sampled and preconcentrated by fluvial systems. The Os isotope compositions of detrital PGM retain a record of mantle depletion events, owing to their high Os and low Re contents and their resistance to alteration [2]. Laser ablation MC-ICPMS provides a rapid, accurate and precise method for the analysis of large suites of PGM.

Osmium isotope analyses of over 300 PGM from the Witwatersrand Supergroup, the largest recognised Archaean sedimentary basin, indicate major mantle melting in the region at around 3.0 Ga to 3.2 Ga, with the oldest ages (~3.5 Ga). The range of Os isotope values in Wits detrital PGM may reflect multiple ultramafic sources. Unlike Phanerozoic ophiolite-derived suites [2], the Wits PGM do not have a pronounced skew towards older ages, confirming that Archean mantle is less heterogeneous than modern day mantle.

Suites of PGM from a Philippine ophiolite and the Rhine river system, the latter sampling various ultramafic bodies of the Alps, have major modes in $^{187}Os/^{188}Os$ corresponding to a depletion age of ~0.5 Ga, but also display subsidiary peaks at ~1.2 Ga and possibly around ~2 Ga, similar to ages found in other global ophiolites [2]. This confirms the global nature of the 1.2 Ga event and indicates a significant mantle to crust mass flux at that time, as documented in the zircon record.

Re-Os ages of Besshi-type massive sulfide deposits associated with *in situ* basalt as a new age constraint for ridge subduction

T. NOZAKI[1,2], Y. KATO[2], K. SUZUKI[1], Y. TAKAYA[2] AND K. NAKAYAMA[3]

[3]Nittetsu Mining Consultants Co. Ltd., 4-2-3 Shiba, Minato-ku, Tokyo 108-0014, Japan (nakayama@nmconsults.co.jp)

Introduction

We report two Re-Os ages for the Makimine and Shimokawa (Kyusyu and Hokkaido area, southwestern and northeastern parts of Japan, respectively) Besshi-type massive sulfide deposits in the Northern Shimanto Belt. These Besshi-type deposits are characterized by close association with an *in situ* basalt whose geochemical composition is similar to those of mid-ocean ridge basalts. Terrigenous clastic materials such as sandstone and mudstone directly overlie massive sulfide layers, indicating that the Makimine and Shimokawa deposits were formed in the marginal sea.

Results and Discussions

The Re-Os ages obtained for the Makimine and Shimokawa deposits are ca. 89 Ma and 48 Ma, respectively. Based on the stratigraphic and geochemical features of two Besshi-type deposits, we interpret these Re-Os ages as a timing of sulfide deposition on a paleo-seafloor when the Kula-Ridge subducted to the paleo Japanese island arc in the Late Cretaceous. The Re-Os age of the Makimine deposit (89 Ma) is generally consistent with the timing of the ridge subduction determined by microfossils in the sedimentary rocks. The plate motion model has documented the the northeastward migration of ridge subduction occurred at the Late Cretaceous Japanese island arc. Considering that the distance between two Besshi-type deposits is about 1, 600 km, this migration speed is estimated to be 4 cm/yr, which is very consistent with the model estimation.

Asthenospheric signature in mantle xenoliths from Enmelen, NE-Russia?

TH. NTAFLOS[1]*, C. TSCHEGG[1], M. BIZIMIS[2] AND V.V. AKININ[3]

[1]Dept. of Lithospheric Research, Univ. Vienna, Austria (*correspondence: theodoros.ntaflos@univie.ac.at)
[2]Dept. Earth and Ocean Sciences, Univ. S. Carolina, USA
[3]NE Interdisciplinary Science Research Institute, Russia

The late Cenozoic intra-plate Bering Sea Basalt Province (BSBP) comprise 17 volcanic fields that occur on islands in the Bering Sea, on the west coast of Alaska and on the northeast cost of Russia. The lavas are mainly tholeiitic and alkaline olivine basalts with subordinate basanites and nephelinites. The Enmelen volcanic field in east Chukotka, NE Russia, differs from the other volcanic fields in that the majority of the lavas are strongly undersaturated (nephelinites, olivine melanephelinites and basanites) and carry abundant mantle xenoliths. The sampled xenoliths hosted by the lavas are mainly fertile spinel lherzolites but few depleted spinel lherzolites occur as well.

Based on the bulk rock and clinopyroxene trace element analyses the Enmelen spinel lherzolites can be divided into three groups. Group A represents non-metasomatized xenoliths that have experienced 3-4% fractional melting. Group B is represented by spinel lherzolites that have whole-rock chondrite-normalized REE patterns with strongly enriched LREE relative to HREE (La_N/Yb_N=9). Their clinopyroxenes are also enriched in LREE and plot sub-parallel to the whole-rock REE patterns (La_N/Yb_N=7). The lack of hydrous phases suggests that group B has experienced cryptic metasomatism. Group C is characterized by the presence of amphibole. Chondrite-normalized REE from the core of clinopyroxenes have patterns with depleted LREE similar to those of group A. However, their rims show, relative to the core, an increase of the LREE (La_N/Sm_N = 0.21 and 2.44 for core and rim respectively). The introduction of fluids, rich in H_2O, LREE, Sr and Ti and the formation of amphibole must have taken place shortly prior to the incorporation of the rocks into the host lavas and before re-equilibration could be achieved.

The clinopyroxene Sr, Nd, and Hf isotope systematics generally overalap the range of MORBs $^{86}Sr/^{87}Sr$= 0.70222-0.7310, $^{143}Nd/^{144}Nd$=0.51303-0.51333 $^{176}Hf/^{177}Hf$=0.28303-0.28363). These depleted isotopic compositions coupled with the trace element enrichements suggests that any metasomatc overprint must have been relatively recent. These data colectively suggest that the Enmelen peridotite xenoliths most likely originate from the convective asthenosphere.

Basaltic volcanism in NE-Russia; Evidence for metasomatized depleted mantle underneath Bering Sea Basalt Province

TH. NTAFLOS[1]*, C. TSCHEGG[1], M. BIZIMIS[2] AND V.V. AKININ[3]

[1]Dept. of Lithospheric Research, Univ. Vienna, AUSTRIA (*correspondence: theodoros.ntaflos@univie.ac.at)
[2]Dept. Earth and Ocean Sciences, Univ. S. Carolina, USA
[3]NE Interdisciplinary Science Research Institute, RUSSIA

Small volcanic fields, which are diffuse and widespread in the Bering Sea and in NE-Russia and Alaska define the Bering Sea Basalt Province (BSBP). The Late Neogene Enmelen volcanoes on Chukotka Peninsula, NE-Russia, belong to the BSBP and consist of nephelinites, olivine-melanephelintes and basanites that are relatively MgO-rich with average 1ooxMg# 58, 65 and 64, respectively. The nephelinites have the highest total alkalis (7.5 wt.%) and basanites the lowest (5 wt.%). The high concentrations of REE in the lavas indicate that they have been formed after low degrees of partial melting, whereas the high $(Dy/Yb)_N$ ratios (1.9-2.6) suggest melting in the garnet peridotite field, leaving garnet in the residue.

While the nephelinites have Ba/Ce ratio that vary around the Primitive Mantle value of 4.5, the olivine melanephelinites and basanites have considerably higher ratios ranging from 9 and 10 that point to LILE enrichments in their source.

Radiogenic Sr, Nd, Hf and Pb isotopic ratios aproach MORB-values, with $^{87}Sr/^{86}Sr$ ranging from 0.703094 to 0.703225, $^{143}Nd/^{144}Nd$ from 0.512990 to 0.513031, $^{176}Hf/^{177}Hf$ from 0.283069 to 0.2830907 and $^{208}Pb/^{204}Pb$ vs. $^{206}Pb/^{204}Pb$ values that lie on the NHRL line within the MORB field. Calculated melt segregation T and P vary around 1400 °C and 3.5 GPa respectivevely. For the estimated 0.15 % melt fraction, a Tp of 1450 °C can be inferred precluding any plume activity beneath BSBP. Similar geochemical characteristics have been described for the Pribilof Island, Alaska [1] suggesting that lavas along the BSBP reflect common petrogenetic conditions. Lithospheric extention with addition of LILE-rich fluids to the source could account for the magma generation.

The elevated LILE and high LREE/HREE all support an enriched source, while the radiogenic isotope ratios suggest recent enrichment of a long lived depleted source by fluids from the depleted upper mantle.

The Barbados Cloud Observatory: Controls on precipitating shallow cumulus convection

L. NUIJENS*, I. SERIKOV, L.HIRSCH AND K. LONITZ

Max-Planck Institute for Meteorology, Bundesstrasse 53, 20146 Hamburg, Germany (*correspondence: louise.nuijens@zmaw.de)

Shallow cumulus clouds are ubiquitous over the subtropical oceans in regions called the “trades”, after the steady surface winds that once made foreign commerce flourish. These clouds help regulate the transport of moisture and heat between the ocean and the free troposphere and are therefore crucial to the climate system. Their small footprint and limited vertical extent, however, make it challenging to observe them from space or to simulate them accurately in coarse resolution models. Important questions regarding the statistical properties of trade-wind cumuli and what controls their aggregate behavior are therefore still left unanswered.

The cloud observatory on Barbados, an island exposed to the relatively undisturbed trade winds, is a collaborative initiative of the Max-Planck Institute for Meteorology and the Caribbean Institute for Meteorology and Hydrology, and strives to improve our understanding of the interplay between clouds, precipitation, the aerosol and large-scale meteorology. The instrument platform includes a scanning cloud radar and microwave radiometer, as well as a vertically-pointing Raman lidar, water vapor lidar, micro-rain radar and ceilometer, and is operational since April 2010 for a duration of at least three years.

We shall present one year of data from the observatory to indicate the large variability present in cloudiness, even within this meteorological regime (the undisturbed trades). Relationships between cloudiness and rainfall are explored in comparison with the humidity structure derived from Raman lidar water vapor profiles. The presence of features such as a well-defined inversion height and a transition layer near cloud base, and the extent to which they regulate convection, is discussed.

Unravelling P-T-t paths: Pseudo-sections versus classical phase petrology

P.J. O'BRIEN

Institute für Erd- und Umweltwissenschaften, Universität Potsdam, Germany (obrien@geo.uni-potsdam.de)

Crystalline rocks record critical information about the magnitude and rates of geodynamic processes. Important factors such as: how deep; how hot; how fast; and for how long are all in some way encoded in the mineral assemblages, mineral compositions and microstructures. Our ability to estimate metamorphic pressure–temperature (*P-T*) conditions has improved markedly with the increased availability of thermodynamic data for both simple and complex solid-solution phases, internally-consistent thermodynamic datasets and powerful computer programs to manipulate this data for a variety of equilibrium calculations. An increasingly popular tool is the single composition *P-T* section (commonly termed pseudosection) which allows rapid determination of mineral assemblages, compositions and their modal amounts for a given bulk composition within a specified *P-T* window. Unfortunately, with the increasing popularity has come an increasing disregard for the fact that a rock in equilibrium can only define a single point on such a diagram and that *P-T* paths, interpreted due to compositional zoning, inclusion suites and reaction textures, cannot be reliably indicated on the same, single pseudosection. Fortunately, the solution to this dilemma already exists. It is possible to model the consequences of bulk compositional fractionation along a P-T-path and even to define local bulk chemical sub-domains (e.g. for a single inclusion or between two specific grains). Conventional geothermobarometry, typically utilising standardised formulations of exchange, net transfer or solvus reactions, is only of limited, indicative use. However, if one is confident of having identified a preserved equilibrium assemblage, and assuming that the compositions of the phases have not been subsequently modified, the same conventional thermobarometric reactions can be determined with thorough consideration of the *P*- and *T*- dependence of thermodynamic parameters, including activities, with the internally consistent data. Rocks in perfect (metastable) equilibrium are ideal for studying by a single pseudosection but of zero use for determining *P-T*-time paths. It is only by the combination of petrography, careful microanalysis and thoughtful application of various equilibrium thermodynamic tools, including pseudosections, that we will advance to a better quantification of, and thus also ability to model and predict, geodynamic processes.

Mercury distribution and speciation in a seasonal wetland impacted by mine waste

P.A. O'DAY[1]*, S. SERRANO[1], T. STILSON[1] AND D. VLASSOPOULOUS[2]

[1]University of California, Merced, CA 95343 USA (*correspondence: poday@ucmerced.edu)
[2]Anchor QEA, LLC, Portland OR 97224 USA (dvlassopoulos@anchorqea.com)

Ephemeral pond waters and surface sediments were studied in a seasonal wetland adjacent to the former Sulphur Bank Mercury Mine and Clear Lake (CA, USA) in order to evaluate *in situ* stabilization treatments as a remedial option for Hg-contaminated sediments. Surface ponds fed during winter by acidic groundwater seepage from a pit lake on the adjacent mine site have high and variable total dissolved Hg concentrations ($[Hg]_{tot}$ = 70-2300 ng l^{-1}), but low methyl-mercury (Me-Hg) (<0.1% of $[Hg]_{tot}$). Higher dissolved Me-Hg concentrations, comprising 22-41% of total Hg, are correlated with pond waters influenced by groundwater flux from Clear Lake with circum-neutral pH (~6.6-8.6) and relatively high dissolved organic carbon (~30 mg l^{-1}). Characterization by X-ray diffraction and X-ray absorption spectroscopy (XAS) showed sulfate-rich (gypsum, jarosite) and clay alteration phases in surface sediments influenced by acidic groundwater, and less altered primary minerals and the presence of calcite in neutral pH sediments. Results from bulk and micro-focused Hg XAS of sediments indicated the presence of metacinnabar (HgS (s)), most likely as residual mine waste particles, nearest the former mine with high sediment $[Hg]_{tot}$ concentrations (100-500 mg kg^{-1}). Sediments from weakly acidic and neutral pH ponds had lower $[Hg]_{tot}$ (3-15 mg kg^{-1}), but a higher fraction of Hg associated with extractable organic matter. There was no evidence in sediment Fe or S XANES spectra for the presence of reduced Fe-sulfide minerals, and all surface pond waters were oxidized, with measureable dissolved oxygen and low dissolved Fe. The lack of evidence for active sulfate or Fe reduction in neutral pH ponds with high dissolved Me-Hg suggests that Hg methylation is occurring in the subsurface, with possible transport of Me-Hg by organic matter complexation. Thus, remediation strategies must consider both (1) stabilization of residual HgS (s) particles, but limiting bacterial sulfate reduction and Hg methylation as pond water pH increases with remediation of the pit lake, and (2) transport of Me-Hg in groundwater to surface biological receptors where Hg bioaccumulation may occur.

Effects of microbial activity and electron shuttles on the reduction of U(VI) under sulfidogenic conditions

E.J. O'Loughlin[1]*, M.I. Boyanov[1] M.J. Kwon[1], P.E. Long[2], K.H. Williams[3] and K.M. Kemner[1]

[1]Argonne National Laboratory, Argonne, IL, 60439, USA (*correspondence: oloughlin@anl.gov)
[2]Pacific Northwest National Laboratory, Richland, WA, 99352, USA
[3]Lawrence Berkeley National Laboratory, Berkeley, CA, 94720, USA

Introduction

Recent studies suggest that electron shuttles such as low molecular mass quinones and humic substances may play a role in many redox reactions involved in contaminant transformations and the biogeochemical cycling of redox active elements. This study investigates the effects of 9, 10-anthraquinone-2, 6-disulfonate (AQDS), a synthetic electron shuttle often used as a surrogate for quinone moieties in humic substances, on transformations of Fe, S, and U under reducing conditions.

Experimental Methodology

Experiments were conducted in defined mineral medium containing 30 mM Fe (III), 5 mM sulfate, and 10 mM acetate, with and without 100 μM AQDS and inoculated with sediment from the Rifle, CO, USA, Integrated Field Research Challenge (IFRC) Site. After the system reached steady state with respect to Fe (III) and sulfate reduction, aliquots of suspension were collected from each system and one set was pasteurized at 70 °C for 1 hr. The suspensions were then spiked with 500 µM U (VI).

Discussion of Results

After 48 h, 100% of the added U was removed from solution in the non-pasteurized AQDS system. However, only 58%, 25%, and 11% of added U was removed in the no AQDS non-pasteurized, AQDS pasteurized, and no AQDS pasteurized systems, respectively. U XANES analysis of the hydrated solids indicated that, with the exception of the pasteurized system without AQDS, the majority (85-95%) of the U associated with the solids was reduced to U (IV). The results of the EXAFS analysis of U (IV) in the systems with and without AQDS (not pasteurized) are consistent with the formation of nanoparticulate uraninite. The results of this study suggest that microbial reduction was the dominant process contributing to the reduction of U (VI) over the timescale of this experiment and that the presence of AQDS enhanced both biotic and abtiotic/microbially mediated U (VI) reduction.

Age and origin of the Nuvvuagittuq Greenstone Belt

J. O'Neil[1], R.W. Carlson[1], D.E. Moser[2], L.M. Heaman[3]and D. Francis[4]

[1]Carnegie Institution of Washington, DC, USA, 20015
[2]University of Western Ontario, London, Canada, N6A 3K7
[3]University of Alberta, Edmonton, Canada, T6G 2E3
[4]McGill University, Montreal, Qc, Canada, H3A 2A7

The Nuvvuagittuq belt is dominated by mafic and ultramafic rocks metamorphosed to at least upper amphibolite facies. Primary U-rich minerals that might provide reliable dates for rock formation have yet to be found in the dominant lithology called the Ujaraaluk unit. Metamorphic zircons, rutiles and monazites are, however, present in the unit locally and give variably discordant results with $^{207}Pb/^{206}Pb$ ages ranging from 2.8 Ga to 2.5 Ga. The younger ages overlap 2686±4 Ma zircon ages for intruding pegmatites and Sm-Nd ages for garnet formation in the Ujaraaluk rocks suggesting this era as the time of peak metamorphism and metasomatism in the Nuvvuagittuq belt, coeval with regional metamorphism of the Superior craton. ^{147}Sm-^{143}Nd data for Ujaraaluk whole rocks provide a statistically poor isochron of 3814±300 Ma, but when separated by compositional groups, this 'isochron' is seen to consist of a series of ~2.7 Ga slopes emanating from a baseline distribution older than 4 Ga. Metamorphism at 2.7 Ga will have less effect on the ^{146}Sm-^{142}Nd chronometer because of ^{146}Sm extinction prior to ~4 Ga. Expansion of the ^{142}Nd dataset for the Ujaraaluk rocks and associated ultramafic cumulates continues to show a good correlation between Sm/Nd and $^{142}Nd/^{144}Nd$ that corresponds to an age of 4.359^{+45}_{-67} Ga. The dataset now includes samples with superchondritic Sm/Nd ratios that extend the correlation to values of $^{142}Nd/^{144}Nd$ slightly higher than the terrestrial standard with a total range in $\varepsilon^{142}Nd$ of more than 24 ppm. The upper Sm/Nd end of this correlation is defined by rocks that are interpreted as cumulates to compositionally related extrusive rocks indicating that this crystal fractionation had to occur while ^{146}Sm decay was active, i.e. well before 4 Ga. Intruding gabbros give ^{143}Nd and ^{142}Nd isochron ages overlapping within error at 4.16 Ga also supporting an Hadean age for the belt. Eoarchean tonalites surrounding the Nuvvuagittuq belt show a deficit in ^{142}Nd compared to the terrestrial standard, but plot to the low Sm/Nd side of the Ujaraaluk isochron suggesting that they are remelts of this type of mafic basement. The Nuvvuagittuq belt thus preserves over 1.6 billion years of early Earth history including an expanse of mafic crust formed only ~200Ma after Earth formation.

The punctuated evolution of the Earth: Geodynamic constraints and model predictions

CRAIG O'NEILL[1],
ADRIAN LENARDIC[2] AND KENT CONDIE[3]

[1]CCFS Centre of Excellence, Macquarie University, Sydney, NSW, Australia
[2]Rice University, USA
[3]New Mexico Tech, USA

The preserved Precambrian crustal record is strongly episodic, and observation that has been attributed to preservational effects or episodic crustal production. These age peaks are associated with juvenile crustal production, voluminous high-temperature volcanism, massive mantle depletion, widespread orogeny and mineralisation, large apparent polar wander velocity spikes, and subsequent paleointensity increases. The impact of these events impinged on the glaciation record, atmospheric and ocean chemistry, and on the rise of oxygen. Here we assess a variety of geodynamic models for Precambrian dynamics against the swath of observational constraints available. We find that episodic behaviour from non-linear slab-driven models - such as mantle avalanches or episodic subduction events - are best able to simultaneously satisfy the majority of geological constraints. In such models, rapid descent of subducted material into the mantle drives fast plate motions and convergence at the surface. This is accompanied by large-scale upwellings of deep hot mantle which contribute to voluminous volcanism. Currently, it is not possible to differentiate the ultimate cause of non-linear plate behaviour solely from the geological record, however, dynamic simulations under Earth-like conditions may be able to secern.

Redox variable trace elements

HUGH ST.C. O'NEILL[1],
ANDREW J. BERRY[2] AND GUILHERME MALLMANN[3]

[1]Research School of Earth Sciences, ANU, Canberra, Australia (hugh.oneill@anu.edu.au)
[2] Department of Earth Science and Engineering, Imperial College London, London SW7 2AZ, UK
[3] Institute of Geosciences, University of São Paulo, São Paulo SP, 05508-080, Brazil

As a change in the oxidation state of an element is usually accompanied by a profound change in its geochemical properties, redox variable elements are potentially sensitive indicators of mantle differentiation processes. Prominent redox variable elements include V, Cr, Mo, the PGEs, Re and U, as well as the volatiles C, H, and S. While Fe is the most abundant redox variable element, likely amounts of Cr, C and S are enough to affect the complex interactions between oxygen content and oxygen chemical potential (or oxygen fugacity, fO_2) that must be understood to quantify the redox state of a system. The presence of abundant Fe^{3+} and Fe^{2+} may obscure the redox state of a trace element in glasses quenched from natural silicate melts because electron exchange reactions (e.g. $Cr^{2+} + Fe^{3+} = Cr^{3+} + Fe^{2+}$) can be too fast for the high temperature speciation to be preserved. Hence spectroscopic measurements on natural materials at room temperature may be misleading.

V occurs in three oxidation states under terrestrial mantle conditions, V^{3+}, V^{4+} and V^{5+}, with a huge variation in incompatibility, making this element a good monitor of mantle redox processes. Its properties may be utilized either through whole-rock abundances to deduce redox conditions during partial melting, or from phenocryst/matrix partitioning, to study magma crystallization. When applied to arc basalts, the two methods show disconcertingly disparate results, crystallization mostly being under oxidized conditions (long known from Fe^{3+}/Fe^{2+} ratios), but from a source of similar redox character to MORB source. Mo systematics show promise for further investigation of this conundrum. U is of particular interest because of the importance of U-Th-Pb systematics in evaluating mantle evolution, and of U series disequilibria in understanding rate processes. While U^{4+} is slightly less incompatible than Th, U^{5+} and U^{6+} are much more incompatible. Significant fractions of U^{6+} are expected at natural fO_2s, with U^{5+} making an unexpected but intriguing appearance at low pressures.

Petrogenesis of the oceanic crust from trace elements in basalt glasses

HUGH ST.C. O'NEILL* AND FRANCES E. JENNER

Research School of Earth Sciences, ANU,Australia
(*correspondence: hugh.oneill@anu.edu.au)

Laser-ablation ICP-MS gives precise trace-element analyses on small areas of basaltic glasses, not only for the traditionally analysed trace elements (REE, HFSE, LILE and first-row transition elements), but also elements such as Be, Ga, Ge, As, Se, Ag, Cd, In, Sn, Sb, W, Tl and Bi. We have analysed >350 Ocean Floor Basaltic (OFB) glass samples from the Smithsonian collection [1] covering a global range in OFB from the Atlantic, Pacific and Indian oceans, for 53 trace elements, plus sulfur by electron microprobe. EMP analyses of the major elements are given in [1]. Principal Component Analysis of a set of 29 precisely determined (±2%) highly incompatible trace elements (HICE: here, all 26 Refractory Lithophile trace elements plus P, K and Pb) shows that 96% of their variance is contained in the first two PCs (93% with PCA on the correlation matrix). The further statistical treatment of this large data set uncovers a highly systematic variation of HICE with degree of low pressure evolution from beneath the variability due to source heterogeneity and melting processes. This cannot be explained by simple fractional crystallization but reflects magma eruption/discharge processes [2, 3], not evident from major elements, which are buffered along the olivine-plagioclase-clinopyroxene cotectic. This evolution systematically fractionates the HICE among themselves in a way that is not consistent with simple fractional crystallization, e.g. mean Th/U increses from 2.3 at 9.5% MgO to 3.3 at 5.5% MgO. Inverting the parental OFB composition allows average mantle source composition and degree of melting to be calculated independently of assumptions about ocean crust recycling. The result shows that OFBs are a product of a high degree of melting (20 to 25 %), from a source that is too depleted to be balanced by estimates of the composition of the continental crust. This seems to require a non-chondritic Earth [4].

Coupling, decoupling and metasomatism: A saga of crust-mantle relationships beneath NW Spitsbergen (Arctic Norway)

SUZANNE Y. O'REILLY*, N. NICOLIC, W.L. GRIFFIN AND N.J. PEARSON

GEMOC/CCFS, Earth and Planetary Sciences, Macquarie University, NSW 2109 Australia
(*correspondence: sue.oreilly@mq.edu.au)

Recent studies integrating mantle and lower crustal geochronology on xenolith samples, isotopic information from crustal zircons worldwide, and seismic tomographic imaging of deep lithosphere domains, suggest that over 70% of the present deep lithosphere formed by about 3 Ga. Subsequent tectonism has modified the lithospheric mantle and caused crustal reworking. The Bockfjord area of NW Spitsbergen (Norwegian Arctic) provides an ideal natural laboratory to track crust/mantle evolution and tectonism over >3.2Ga. Quaternary alkali-basalt volcanism provides abundant xenoliths of mantle and crustal rocks from both sides of a major translithospheric N-S fault. Zircons from lower-crustal xenoliths (from both sides of the fault) have mainly Neoarchean/ Paleoproterozoic or Paleozoic U-Pb ages; several show ages and/or Hf model ages >3.2 Ga. Mantle-derived peridotite xenoliths east of the fault contain common metasomatic minerals rare in those west of the fault. Re-Os analysis of sulfides in xenoliths west of the fault show T_{RD} model ages to 3.3 Ga; major populations are 2.4-2.6 Ga, 1.6-1.8 Ga and 1.2-1.3 Ga, with rare Caledonian ages. However, sulfides in xenoliths east of the fault show maximum T_{RD} of 2.3 Ga with major peaks at 900-1100 and 400-500 Ma, identical to the spectrum of zircon ages of protoliths for exposed gneisses and schists east of the fault

These data demonstrate a major disjunct, on both sides of the B-B fault, between the Archean lower crust and a Proterozoic-Paleozoic upper crust; this suggests that the original Archean upper (and middle?) crust was detached from the lower crust and replaced by thrust sheets of younger material, probably during the major overthrusting of the Caledonian orogeny. The striking differences in the SCLM on either side of the B-B fault suggest major transcurrent movement, juxtaposing lithospheric sections that evolved discretely at some distance from one another. West of the B-B fault, the presence of Archean lower crust overlying Archean SCLM suggests coupling of the crust and mantle for ≥3 Ga

In situ U-Pb dating of rutile in UHT granulites from the Gruf Complex, European Central Alps

JEFFREY OALMANN[1]*, ANDREAS MÖLLER[1] AND ROMAIN BOUSQUET[2]

[1]Department of Geology, Univ. of Kansas, 1475 Jayhawk Blvd, Rm. 120, Lawrence, KS 66045, USA (*correspondence: joalmann@ku.edu)

[2]Géosciences Rennes, Université de Rennes 1, Campus Beaulieu, 35042 Rennes Cedex, France (romain.bousquet@univ-rennes1.fr)

In situ U-Pb dating of rutile directly in thin sections preserves textural information including inclusion relationships. Grains included in some minerals such as garnet may preserve older U-Pb ages than matrix grains due to sluggish Pb diffusion through the host mineral and can provide additional constraints on P-T-t evolution.

The Gruf Complex of the Central Alps consists of amphibolite migmatitic gneisses and relict ultra high temperature (UHT) charnockite and sapphirine-bearing granulites. Whether the UHT event occurred during the Permian Variscan orogeny or the Tertiary Alpine orogeny is a matter of debate [e.g. 1, 2, 3]. Amphibolite facies metamorphism and migmatization began at ~32 Ma in the Central Alps, and temperature may have remained >640°C until 22 Ma [4, 5]. The Gruf Complex lies structurally below the Bergell pluton, which crystallized between 32 and 30 Ma [6], and was intruded by the Novate granite at 24 Ma [7].

Rutile in the Gruf granulites was analyzed using laser ablation inductively coupled mass spectrometry. Inclusions in garnet, orthopyroxene, biotite, and sapphirine as well as grains in the matrix and leucosomes were dated to determine if included grains preserve older ages than matrix grains. Average $^{206}Pb/^{238}U$ ages uncorrected for common Pb range from 21-25 Ma for different samples. There is no clear correlation between age and textural setting; however, the oldest concordant date of ~30 Ma is from a grain included in garnet. These ages suggest that cooling from 640°C to below the closure temperature of Pb diffusion in rutile was rapid and possibly occurred as early as 25 Ma in the Gruf Complex.

Is mineral precipitation the reverse of dissolution?

E.H. OELKERS[1]* G.D. SALDI[2] AND J. SCHOTT[1]

[1]Geoscience and Environment Toulouse (GET), CNRS, UMR 5563, OMP, 14 Avenue Edouard Belin, 31400 Toulouse, France (*correspondence: oelkers@get.obs-mip.fr)

[2]Earth Science Division, Lawrence Berkeley Laboratory, 1 Cyclotron Rd. Berkeley CA 94720, United States

Mineral precipitation and dissolution are fundamental processes governing fluid-solid reactions in nature and chemical mass transfer in the crust; the accurate description of the rates of these reactions within geochemical modelling codes holds the promise to quantify in real time the fate and consequences of processes ranging from radioactive waste disposal and carbon storage to the formation of hydrothermal ore deposits. Based, on the principle of detailed balancing, it has been commonly been assumed that mineral precipitation can be described as the reverse of dissolution; transition state theory rate expressions that successfully describe mineral dissolution as a function of degree of fluid saturation state have been adopted to predict corresponding precipitation rates.

Surface sensitive microscopy suggests similar mechanisms at near to equilibrium; both dissolution and precipitation adds or removes material to existing active sites resulting in a linear dependence of rates on chemical affinity. At far from equilibrium etch pits form on dissolving surfaces, and analogous nuclei form on precipitating surfaces. The differences between dissolution and precipitation, however, stem from the existence of grain edges, which are active sites for dissolution but not precipitation. Moreover, the removal of material from edge sites creates additional active sites for dissolution, but precipitation fills active sites. As a consequence, steady state precipitation is dominated by nucleation in contrast to dissolution which removes material from continuously renewed active sites. This conclusion is supported by our recent measurement of quartz and magnesite dissolution and precipitation rates [1, 2]. Precipitation on grains having pre-existing active sites is consistent with the reversibility of dissolution whereas precipitation on pristine crystals is inconsistent and following independent rate equations.

Si isotope fractionation during precipitation of silica by cyclic freezing and adsorption of monosilicic acid on gibbsite

M. OELZE[1], F. VON BLANCKENBURG[1], D. HÖLLEN[2] AND M. DIETZEL[2]

[1]Earth Surface Geochemistry at GFZ German Centre for Geosciences, Potsdam, Germany (Oelze@gfz-potsdam.de)
[2]Institute of Applied Geosciences, Graz University of Technology, Austria

Cyclic freezing of aqueous solutions containing silicic acid can be used to precipitate amorphous silica through complex precipitation-dissolution reactions. In such a dynamic system kinetic isotope effects during an unidirectional transfer from silicic acid to a solid may be equalized by cyclic dissolution of the previous precipitated silica and slow isotopic equilibrium between solutions and solids is potentially attained.

We performed several sets of freeze-thawing experiments to decipher the silicon isotope fractionation during precipitation of amorphous silica at pH 4.5 and 7. The initial solutions contain 1.6 mmol L^{-1} of Si and 0.1 or 1 mmol L^{-1} of Al (TEOS and $AlNO_3 \cdot 9H_2O$). The solutions were frozen and thawed within 24 hours by up to 130 cycles and sampled at regular intervals.

Experiments with high initial Al concentration ([Al] = 1mmolL^{-1}) show changing $\delta^{30}Si$ values with time. The $\delta^{30}Si$ solution values increased during the first 20 freeze-thaw cycles to up to 2.4‰ and then showed a decline to almost starting values of 0‰ after 130 days. Experiments with low Al concentrations ([Al] = 0.1mmolL^{-1}) remained at the value of the initial solution throughout.

Supplementary adsorption experiments, with monosilicic acid (0.36 mmol L^{-1} Si) and gibbsite (55 m^2 L^{-1}) were carried out at pH 7. Adsorption of silicic acid results in an increase of $\delta^{30}Si$ values and a quasi isotopic/chemical steady state is reached at ~ 300 h.

We developed a mass balance approach and applied time-dependent fractionation factors consisting of $\alpha 1_{precipitate\text{-}solution}$ and $\alpha 2_{precipitate\text{-}solution}$ to the freeze-thaw system. Model results predict that during the first 20 freeze-thaw cycles presumably kinetic fractionation was dominant with a 1000ln (α1) = -4.5‰. This value is close to what is observed by adsorption of silicic acid onto gibbsite. Once the system reaches a steady-state the modeled fractionation factor changes to 1000ln (α2) = 0‰. α2 = 1 possibly represents the equilibrium isotope fractionation factor and indicates no discrimination of silicon isotopes between dissolved silicic acid and newly formed amorphous silica or hydroxyalumosilicate.

A profile of multiple Sulfur isotopes for the Oman ophiolite

M. OESER[1,2,*], H. STRAUSS[1], M. PETERS[1], P.E. WOLFF[2], J. KOEPKE[2], D. GARBE-SCHÖNBERG[3] AND M. DIETRICH[2]

[1]Westfälische Wilhelms-Universität, Institut für Geologie und Paläontologie, 48149 Münster, Germany (*correspondence: m.oeser@mineralogie.uni-hannover.de)
[2]Leibniz Universität Hannover, Institut für Mineralogie, 30167 Hannover, Germany
[3]Christian-Albrechts-Universität zu Kiel, Institut für Geowissenschaften, 24118 Kiel, Germany

The Oman ophiolite is regarded to represent the best example of fast-spreading oceanic lithosphere on land. Here, we present the first multiple sulfur isotope profile through all components of the (ancient) oceanic lithosphere (Fig. 1), together with sulfur abundances and a petrographic study.

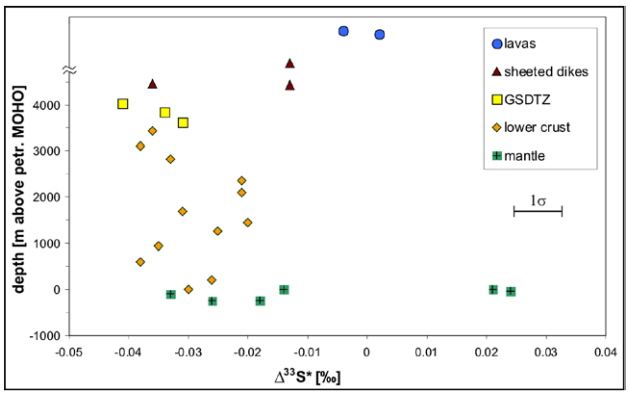

Figure 1: $\Delta^{33}S^*$ values of Cr-reducible sulfur versus depth for a composite section through the Oman ophiolite; $\Delta^{33}S^* = \delta^{33}S - 1000 \times ((1 + \delta^{34}S / 1000)^{0.515} - 1)$ [1]; GSDTZ represents the gabbro/sheeted dike transition zone.

Our results indicate that upper crustal rocks of the Oman ophiolite (lavas and sheeted dikes) exhibit: (i) pervasive alteration due to intense circulation of seawater; and (ii) microbial reduction of seawater sulfate occurring within the lavas during low-temperature alteration. Samples from the gabbro/sheeted dike transition zone and lower crustal rocks are affected by a high-temperature alteration resulting in leaching and redistribution of sulfide-S. $\Delta^{33}S^*$ values of Cr-reducible sulfur (CRS) between -0.020‰ and -0.038‰ clearly differ from those of upper crustal rocks (Fig. 1). This could either suggest that intense sulfur leaching processes operate in those units, or that oceanic lower crust has a primary multiple sulfur isotopic composition that deviates from the postulated mantle value ($\Delta^{33}S^* = 0.0$‰; [1]). Samples from the mantle portion of the Oman ophiolite display the widest ranges in $\delta^{34}S$ and $\Delta^{33}S^*$ reflecting multi-stage serpentinization processes.

Geochemical behavior of As originated from acidic thermal water during river transport and sedimentation mechanism

Y. OGAWA[1]*, N. SHIKAZONO[2], K. IWANE[2], Y. TAKAHASHI[3], K. SUTO[1] AND C. INOUE[1]

[1]Graduate School of Environmental Stidies, Tohoku University, Miyagi 980-8579, Japan (*correspondence: ogawa@geo.kankyo.tohoku.ac.jp)
[2]Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Kanagawa 223-8522, Japan
[3]Marine Microbiology, Atomosphere and Ocean Research Institute, University of Tokyo, Chiba 277-8564, Japan

We investigated change in the physico-chemical and redox status of As originated from the acidic Tamagawa thermal waters during transport in Shibukuro and Tama Rivers and sedimentation mechanism in the watershed.

The predominant dissolved As species in the thermal water was arsenite. However, this specie was rapidly oxidized. Thus, the geochemical mobility of arsenate was mainly controlled by the sorption onto hydrous ferric oxides (HFO). Most HFO sorbing As was transported and effectively settled onto the downstream man-made lake.

Most of As in riverbed and shallow part of lake sediments were extracted as reducible phase, indicating that they are originated from the Tamagawa hot spring area transported as HFO sorbates. Furthermore, XANES spectra reveal that As existed as As (V). On the other hand, As in deep part of lake sediments could not be extracted by reducing agent and XANES spectra reveal the conversion to As (III). The arsenite and ferrous ion was also detected in the interstitial water. These results indicate that HFO sorbing As was reduced during the sedimentation process.

The iron-oxidizing bacteria inhabited in acidic river water. The inhabitations of several microorganism including sulfate-reducing bacteria in deep part of lake sediment were also confirmed. Taking these facts into consideration, the As mobility in this river system would be possibly controlled by the bacterial activities.

Development of the modern-style geochemical cycle of uranium by 3.5 Ga: A solution to the 'lead paradox'

H. OHMOTO[1], Y. WATANABE[1], K.E. YAMAGUCHI[2], D.C. BEVACQUA[1], I. JOHNSON[1] AND T. RUSHTON[1]

[1]NASA Astrobiology Institute and Dept. of Geosience, Penn State University, University Park, PA 16802, USA and hqo@psu.edu
[2]Department of Chemistry, Toho University, Funabashi, Chiba, 274-8510, Japan

From analyses of redox-sensitive elements in many paleosol-, shale-, and submarine basalt- sections 3.5-2.5 Ga in age, we have recognized: (1) depletions of S and C, and depletions/enrichments of U, Mo, Fe, Mn, Cr and Cu in the paleosols; (2) enrichments of U and Mo in many of the black shales; (3) enrichments of U, Fe^{III} and Mo in the basalts that were affected by submarine alteration; and (4) Ce anomalies in many of the paleosols and submarine basalts. Therefore, the behaviours of redox-sensitive elements in these Archean rocks are essentially the same as those in Phanerozoic rocks. This suggests that the Archean oceans were poor in Fe, but rich in U and Mo, and that the modern-style geochemical cycles of redox-sensitive elements through the continental crust, oceans, oceanic crust, and mantle reservoirs have operated since at least ~3.5 Ga. The presence of highly radiogenic Pb in many Archean-age submarine basalts also supports this suggestion. The atmospheric pO_2 >0.5 PAL is necessary to operate the modern-style geochemical cycle of U. Subduction of Fe^{III}- and U-enriched oceanic crust may have created a large-scale heterogeneity of the mantle since ~3.5 Ga, including: (a) the Fe^{III}/Fe^{II} ratio, and (b) the 'lead paradox' where the Pb in the mantle, especially in the source regions of OIBs and MORBs, is more radiogenic than in the chondrite-modeled bulk Earth. Therefore, through the creation of the oxygenated oceans and atmosphere, microbes have influenced the geochemistry of the deep Earth and the nature of volcanism since ~3.5 Ga.

Trace element composition of size-fractionated particulates in the Mauritanian upwelling zone of the Eastern North Atlantic U.S. GEOTRACES section

DANIEL C. OHNEMUS[1,2] AND PHOEBE J. LAM[2]*

[1]MIT/WHOI Joint Program in Chemical Oceanography, Woods Hole, MA (*correspondence: dan@whoi.edu)
[2]Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Inst., Woods Hole MA (pjlam@whoi.edu)

Sinking (>51μm) and suspended (<51μm) particulates were collected via *in situ* filtration during the first US GEOTRACES North Atlantic Zonal Transect on the *R/V Knorr* in October-November, 2010. Total and acetic-acid leachable compositional profiles for key trace elements and isotopes (TEIs—Fe, Al, Zn, Mn, Cd, Cu) and other TEIs of interest (Co, Ti, Ba, V, Ni, Mo) are presented from four stations along the eastern tropical North Atlantic oxygen minimum zone (OMZ) extending from the coast of Mauritania to the Cape Verde Islands.

This dataset provides the first look at full (16-point) ocean-depth profiles of size-fractionated particulate trace elements in this productive and biogeochemically complex region. Particulate inputs, including mineral dust deposition from the Sahara, resuspended particles from the African margin, and in bottom nepheloid layers, are examined via bulk compositional data. Acetic acid-leachable phases are used to examine scavenging and remineralization processes of redox-sensitive and surface-active TEIs, especially within the Mauritanian OMZ and along upwelling-driven transport pathways away from the African continent.

Information from these particulate analyses, and soon the full particulate section of the US GEOTRACES North Atlantic zonal transect, will provide critical insights into TEI remineralization length and depth scales, elemental scavenging behavior in the OMZ and benthic nepheloid zones, and trace nutrient recycling rates within and below the euphotic zone.

Isotopic fractionation of Mg, Ca and Sr in calcite and aragonite

TAKESHI OHNO[1], TAKAHIRO WAKABAYASHI[2], TAKAFUMI HIRATA[3], EDWARD TIPPER[4] AND ALBERT GALY[4]

[1]Department of Chemistry, Gakushuin University, Mejiro 1-5-1, Toshima-ku, Tokyo, Japan (takeshi.ohno@gakushuin.ac.jp)
[2]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Japan
[3]Department of Earth and Planetary Sciences, University of Kyoto, Japan
[4]Department of Earth Sciences, The University of Cambridge, UK

The alkaline earth metals such as magnesium, calcium and strontium play an important role in a variety of geochemical and biological processes. The element ratios (Mg/Ca and Sr/Ca) in marine carbonates have been used as proxies for reconstruction of the past environment. Recently several studies suggested that the study for the isotopic fractionation of the alkaline earth metals in marine carbonates has a potentially significant influence in geochemical research fields (e.g. Eisenhauer *et al*. 2009). However there are few studies for possible correlations between the level of isotopic fractionation of Ca and that of other alkaline earth metals during carbonate precipitation.

The purpose of this study is to see if there are any correlations between the isotope fractionation factor of Ca during carbonate precipitation and that of Mg and Sr. Moreover, we investigated whether fractionations of Mg, Ca and Sr isotopes could differ between calcium carbonate polymorphs (Calcite and Aragonite). In order to examine the isotope fractionation factor of Mg, Ca and Sr during carbonate precipitation, calcite and aragonite were synthesized from calcium bicarbonate solution in which the amount of magnesium was controlled based on Kitano method (Kitano, 1962). Calcium carbonates were also prepared from the mixture of calcium chlorite and sodium hydrogen carbonate solutions for the purpose of comparison among the methods. The isotope fractionation factors were measured by MC-ICPMS (Nu plasma).

Results suggested that the level of isotopic fractionation of Mg during carbonate precipitation was correlated with that of Sr and that the change of the carbonate crystal structure could make differences of isotopic fractionations of Mg and Ca, however no difference was found in the case of Sr. In this presentation, the possible mechanism will be discussed.

Biotransformation Rare Earth Elements

T. OHNUKI

Advanced Science Research Center, Japan Atomic Energy Agency (JAEA), Tokai, Ibaraki, 319-1195 Japan (ohnuki.toshihiko@jaea.go.jp)

Geochemical behaviors of rare earth elements (REEs of La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu) are important to understand the migration of trivalent actinides fission genic REEs from nuclear power plants and high level radioactive waste. When REEs migrates in environemnts, their chemical states may change by the interaction with inorganic and organic materials. Many researchers have studied the interaction of REEs with inorganic materials. However, the biotransformation of REEs have not fully understood. We have conducted the research on the effects of microorganisms on chemical states change of REEs.

The REEs patterns of the distribution coefficients (K_d) for hyphae of *Acremonium* sp. showed no Ce anomaly. On the contrary, the REEs pattern of K_d for biogenic Mn oxides with *Acremonium* sp. showed positive Ce anomaly at pH 3.7 by oxidization of Ce (III) to Ce (IV) by Mn oxides. With increase of pH in solution positive Ce anomaly became smaller, and the polarity of Ce anomaly shifted from positive to negative around pH 6.5. This anomaly shift is probably caused by organic molecules released from the hyphae.

Presence of desferrioxamine B (DFO) showed negative anomaly of Ce in the REEs patterns of K_d for *Pseudomonas fluorescens*. Negative Ce anomaly came smaller with increasing contact time, caused by oxidaton states change of Ce (IV) in the Ce-DFO complex to Ce (III).

We found that Ce (III) phosphate nano minerals were formed on the cells surface of yeast *Saccharomyces serevisiae* after exposure of Ce (III) solution with the resting cells, even though no phosphate is added. Ce (III) ions were first adsorbed by the functional groups of cells surface, followed by the chemical states change by the reaction with phosphate ions released from inside the yeast cells.

These findings indicate that microorganisms affect geochemical behavior of REEs.

Carbonate dissolution at oceanic atolls: A CO_2 sequestration option

T. OHSUMI

CRIEPI, Abiko, Chiba 270-1194, Japan (*correspondence: ohsumitk@ohsumi-jp.com)

Carbon dioxide storage in the ocean will eventually bring about the dissolution of carbonate in the ocean floor. Ohsumi [1] suggested the purposeful *in situ* reaction of CO_2 with the ocean-floor carbonate as a storage option of captured CO_2. However, the carbonate dissolution method [2, 3] proposed and discussed technically and geochemically so far has put the focus on siting the reactor vessel on land near emission sources of CO_2. The ocean bottom covered with carbonate sediments may not be suitable in applying the carbonate-dissolution method, because of high implementation cost as revealed by the research and development effort of the deep-sea Mn nodule mining and also of the associated environmental impacts on the open ocean. If the partial pressure of CO_2 is raised up more above one atmosphere by selecting the site of the dissolution underground, the volume of water required for the reaction to proceed could be saved, the reaction being:

$$CO_2\,(g) + CaCO_3\,(s) + H_2O\,(l) \Rightarrow Ca^{2+}(aq) + 2HCO_3^-(aq).$$

Large scale coral atolls found typically in the Pacific ocean give an appropriate example of the installation site of the reaction system. When several hundreds tonnes H_2O coexisting with one tonne CO_2 are to be reacted with the ambient carbonate rocks at depths of a few hundred meters inside the atoll, *ca*. 20% of the injected CO_2 would be transformed into bicarbonate, reaching to the equilibrium where the pH value is above 6 and the CO_2 partial pressure is below one atmosphere. The drainage waste water containing the residual CO_2 (aq) and the reaction products, *i.e*. calcium bicarbonate solution would be discharged directly to the deep ocean for further dilution of CO_2 (aq). The discharge operation offers an opportunity for the measurement of CO_2 inventory, and more importantly contributes avoidance of the long term possible erosion of the atoll and its consequent impacts to the island surface.

The presented storage concept of captured CO_2 is essentially the ocean storage by dissolution of carbonate minerals, but eliminates the large-scale surface reaction plant.

Natural analogue study on long-term reaction of bentonite and highly alkaline groundwater

MASAYA OI[1], NAOTATSU SHIKAZONO, MINORU YAMAKAWA[2] AND NAOKI FUJII[3]

[1]3-14-1, Hiyoshi, Kouhokuku,Yokohamashi, Kanagawa, Japan (ooimasaya@gmail.com, sikazono@applc.keio.ac.jp)
[2]1-15-7, Tsukishima, tyuoku,Tokyo, Japan (amakawa_ytmy@ybb.ne.jp, fujii@rwmc.or.jp)

Geological disposal of high-level nuclear waste has been planned and developed in many countries worldwide. In Japan, it is to be vitrified and an overpack enclosing metallic containers that contain the vitrified waste is to be placed in a deep geological repository with the multibarrier system consisting of an engineered barrier and a natural barrier by geological formations. One of the possible buffer materials for the engineered barrier is bentonite, which should possess the property of long-term stability, although the functions required for it depend on the method of disposal of the waste. When used with cement materials as reinforcing agents, however, the functions required for the bentonite-based barrier material may deteriorate due to such phenomena as dissolution and change of properties by highly alkaline groundwater formed by reactions of the cement materials with groundwater. Since it takes hundreds of thousands of years for the radioactivity of high-level nuclear waste to decrease to the natural background level, it is impossible to clarify the reaction mechanism of bentonite and highly alkaline groundwater in the laboratory for such a long time. An appropriate method to examine such a long-term system is natural analogue study that is an investigation of a natural system that has some similarities with a radioactive waste repository and its surrounding environment.

The Mangatarem district, in the Philippines, was chosen as a study area in this natural analogue study. Through the investigation of the Mangatarem district, we tried to elucidate the long-term interaction of bentonite with highly alkaline groundwater

Analytical results reveal some differences between the trench and outcrop samples. Assuming that the source rock of bentonite and zeolite is common for the rock samples of the two sampling points, those differences are probably attributable to the difference in the reaction of the source rock with the highly alkaline groundwater that had come up along faults.

Iron isotopic signature for weathered ordinary chondrites: Application of the LAL sampling-ICP-MS technique for cosmochemical sample

S. OKABAYASHI[1]*, T.D. YOKOYAMA[1], T. YOKOYAMA[2] AND T. HIRATA[1]

[1]Laboratory for Planetary Sciences, Kyoto University, Kitashirakawa Oiwakecho, Kyoto, 606-0582, Japan (*correspondence: okabayashi-s-aa@kueps.kyoto-u.ac.jp)
[2]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, O-okayama 2-12-1, Meguro, Tokyo, 152-8551, Japan

The laser ablation in liquid (LAL) is one of the most versatile techniques to produce the nanoparticles of the solid materials. Our recent research revealed the LAL can be also applied for the sampling technique of the solid samples to measure the elemental and isotopic composition using the mass spectrometer [1, 2]. The LAL sampling technique provides the micro scale sampling, sample integration, and the elimination of the coexistent elements through the ion exchange chromatography. These advantages enable the high-precision measurement of the micro region on the solid samples.

In this study, we have measured the δ^{56}Fe and δ^{57}Fe values of the Fe-Ni grains and the related weathering products in the ordinary chondrites. The cut pipette tip filled with deionized water was placed on the polished meteorite surface and the laser ablation was performed through the water layer. After the LAL procedure, the sample suspension was collected using the micropipette. The resulting sample suspension was decomposed and dissolved in conc. HCl, then the resulting solution was used for the ^{56}Fe/^{54}Fe and ^{57}Fe/^{54}Fe ratio measurements using the multiple collector-ICP-MS technique. The measured $\delta^{56, 57}$Fe values of metal grains showed good agreement with the previously reported values [3]. In contrast, the iron isotopic signature for weathering products found in the identical meteorite samples revealed that the measured $\delta^{56, 57}$Fe values were significantly higher than those for the inherent metal grains. It should be noted that the inherent part of the metallic grains were commonly surrounded by the weathered parts. Possible cause of the present large difference in the measured iron isotope ratios between the fresh and weathered metal grains will be discussed in this presentation.

Water and ethanol reactivity on chalk from water- and gas-saturated zones

D. OKHRIMENKO*, K.N. DALBY, N. BOVET AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*correspondence: denisokr@nano.ku.dk)

Adsorption and wettability properties of chalk in oil-reservoirs are highly affected by many factors. These factors include: the presence of inorganic, polymeric, and especially, organic additives on the surface.

To compare the behavior of samples with different levels of surface coatings, we analyzed the solid surfaces of chalk sampled from a water and a gas zone. We also examined how the adsorbed organic material affects the ability of chalk to interact with polar molecules such as water and ethanol. The changes in adsorption energy of water can be used to predict the changes in surface wettability, while ethanol adsorption studies can help in understanding adsorption mechanisms for polar organic compounds. For investigating porous solids such as chalk, vapour adsorption isotherm determination is an appropriate alternative technique to the methods usually used for adsorption studies.

Isosteric enthalpies of water and ethanol adsorption were examined on chalk samples before and after liquid (chloroform) – solid extraction of the organic matter and compared with the results for synthetic calcite. The chemical composition of the extracted organic fraction was established by chromato-mass-spectrometry and qualitative changes on chalk before and after the extraction procedure were monitored with X-ray photoelectron spectroscopy (XPS).

The XPS spectra show that extraction with chloroform leads to a relative increase in concentration of polar groups on the chalk surface. This is consistent with the extraction experiments, which show that the liquid extract from both chalk samples contains mainly nonpolar long-chain alkanes.

We observed a difference in water and ethanol adsorption behaviour caused by the nature of the solid and the adsorbate. Water adsorption depends on the presence of adsorbed polar groups and enthalpy of asorption increases with decrease in amount of preadsorbed nonpolar organic matter, while ethanol adsorption is not influenced by amount of polar groups on the chalk surface. At the same time, ethanol bonds specifically to synthetic calcite with an energy of ~200 kJ/mol, which is 3-4 times higher than on chalk. The results can be used in interpretating the adsorption mechanisms for organic matter on natural oil reservoir materials and for modifying surface properties.

Low temperature alteration of serpentinized dunite; A case study from the Leka ophiolite complex

INGEBORG ØKLAND, INGUNN THORSETH, SHANSHAN HUANG AND ROLF B. PEDERSEN

Centre for Geobiology and Department of Earth Science, University of Bergen, Allegaten 41, 5007 Bergen, Norway (Ingeborg.Okland@geo.uib.no)

Ecosystems based on water-rock interactions independent of photosynthesis have been known for the last decades. Systems where processes like serpentinization produce H_2 and simple hydrocarbons supports the hypothesis of a H_2 based subsurface biosphere. Such environments could be important analogues to systems where life originated. The low temperature water-rock interactions in ultramafic rock is poorly constrained. In this study we try to understand ongoing low-temperature reactions through textural, mineralogical and geochemical characterisation of a 50 m long rock core from the dunitic part of the Leka ophiolite complex, mid-Norway, in combination with geochemical analyses of groundwater emanating from this drill hole, and rainwater. Geochemical modelling has been used to describe ongoing processes in this system.

The core show different degrees of alteration from olivine-dominated, near unaltered dunite to nearly completely altered dunite consisting mainly of blocky serpentine with partly open veins lined with fibrous serpentine and brucite. Groundwater infiltration is thought to take mainly place in three major fracture zones in the most altered parts. Analysis of the groundwater show that the pH increases and the Mg and Si decrease as the groundwater evolves. The most evolved groundwater also has elevated levels of H_2 and traces of CH_4.

Since the main part of the water-rock reactions take place in the serpentine dominated part of the rock it is suggested that the H_2 is a result of the reduction? of water due to oxidation of ferrous iron from dissolving serpentine and brucite.

[4]Dept. of Mineralogy, Natural History Museum, Cromwell Road, London, SW7 5BD, UK

The goal was to study interphase partitioning of trace elements in high-pressure melted eclogite-carbonatite $[[CPx_{40-64}Grt_{16-40}(SiO_2)_{20}]_{59.3}Carb_{39.3}]_{98.6}RE_{1.4}$ and peridotite-carbonatite $[[Ol_{36-60}OPx_{16}CPx_{12-24}Grt_{12-24}]_{30}Carb_{70}]_{99}RE_1$ systems doped with a set of trace elements: Li, Rb, Cs, Ba, Th, U, Ta, Nb, La, Ce, Pb, Pr, Sr, Nd, Zr, Hf, Sm, Eu, Gd, Tb, Dy, Y, Ho, Er, Tm, Yb, Lu, Sc, and Zn. Concentrations of trace elements in coexisting phases were determined using LAICPMS and the mineral-melt partitioning coefficients were calculated. The main feature of the trace element partitioning in high-pressure experiments is the different behaviour of light REE (La, Ce, Pr) in relation to medium and heavy REE (Nd, Zr, Hf, Sm, Eu, Gd, Tb, Dy, Y, Ho, Er, Tm, Yb, Lu). Light REE are partitioned favourably into the melt phase, and the rest REE go into garnet, when the last is presenting. Comparison of the new experimental and published data for partitioning between garnet, clinopyroxene and carbonatite melt, as well as for garnet, clinopyroxene and silicate melt [1-4] shows a similarity in respect of trace element distribution of diamond-forming homogeneous carbonate-silicate melts studied and carbonatite or silicate melts equilibrated with the mantle silicate minerals.

REE geochemistry, mineralogy and origin of manganese mineralization in the Derbent (Mahkeme Hill), Yozgat (Turkey)

N. OKSUZ[1]*, A. KARAKUŞ[2] AND C. YURTERI[3]

[1]Bozok University, Department of Geology, Yozgat, Turkey (*correspondence: nursel.oksuz@gmail.com)
[2]Ankara University, Department of Geology, Ankara, Turkey(karakusalpay@hotmail.com)
[3]Hacettepe University, Department of Geology, Ankara, Turkey (cansu.yurteri@hotmail.com)

Artova ophiolite complex is located along the North western and east margin in Yozgat (Turkey). The Mn-deposits in the Derbent area is part of this ophiolite complex. This deposit banded and lenticular forms, is hosted by radiolarite and is generally overlying volcanics. Manyetite, manganite, pyrolusite and goethite are main constituents of the manganese ores in Mahkeme Hill (Derbent-Yozgat) area. The gang minerals in Derbent are quartz and calcite.

In chondrite normalized REE graphics samples are characterized by highly negative and positive Ce anomalies in area. Europium shows negative anomaly in all samples. The negative Ce anomaly is typical to submarine hydrothermal deposits and positive Ce anomaly is indicative of hydrogenous deposits [1]. The negative Eu anomaly shows contamination from the continental crust and/or sediment contribution via dehydration [2].

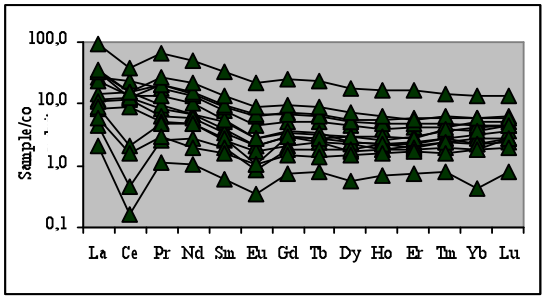

Figure 1: Chondrite normalized REE diagram for ore samples

Ce values in the Mahkeme Hill mineralization were computed and the anomalies were found as $Ce_{anom} < -0.1$ in 9 samples and $Ce_{anom} > -0.1$ in 5 samples. These values are indicative of both oxic and anoxic sedimentation conditions. Chemically, the studied manganese deposit and associated radiolarite are very similar to these formed by hydrothermal – hydrogenous processes.

Beyond petroleomics – Petroleum geochemistry for the 21st Century

THOMAS B.P. OLDENBURG*, NORKA MARCANO, HAIPING HUANG, BEN HSIEH AND STEVE R. LARTER

Petroleum Reservoir Group (prg), Department of Geoscience, University of Calgary, Calgary, AB, Canada (*correspondence: toldenbu@ucalgary.ca)

Petroleum geochemistry has been driven by analytical developments since the development of gas chromatography in the 1950's and practical computerized GCMS technologies in the 1970's heralding, in the 70's and 80's, the development of practical biomarker technologies and most of the source rock facies and maturity molecular concepts that we still use today. Recent advances in Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FT-ICR-MS) technology now allow a more comprehensive analysis of polar constituents of fossil fuels. This new technology allows for the first time routine analysis of the broad range of complex polar compound mixtures that dominate source rock extracts and heavy oils.

In this study we will show the use of FTMS derived high molecular weight multi hetero component (HMWMH) complex compound class distributions to discriminate biodegraded oils from different source rocks from marine versus lacustrine systems and also differentiate oil charges from mixed facies marine source rocks. These new proxies are independent of microbial biodegradation alteration levels from Peters & Moldowan levels 0 to 8 (Peters and Moldowan, 1994) and show that it is likely that FTMS techniques and parameters may offer substantial advances over conventional GCMS based approaches to petroleum system characterisation. In addition, new insights into the compositional changes during *in situ* thermal recovery processes simulated in the lab under aquathermolysis and hydrotreating conditions will be shown.

The environmental impact of sewage effluent discharges in the Pracana River - Portugal

N. OLIVEIRA, P. ALMEIDA, N. CARVALHO, A. SILVA, I.M.H.R. ANTUNES, A. FERREIRA AND T. ALBUQUERQUE

Polytechnic Institute of Castelo Branco, 6000-243 Castelo Branco, Portugal (teresal@ipcb.pt)

The Pracana River is an important tributary of the Ocreza River. The Ocreza River is located in Central Portugal and has it source in an important Alpine chain called Gardunha. It starts at 1160 m altitude and stretches for 80 km until draining into the Tagus River. It has several creeks and tributaries along which there are several rural villages. The Pracana's waters has an important role by being abundantly used in agriculture, the main economic activity of these communities, and for human consumption. Characterization, monitorization and control of the impact due to several wastewaters treatment plants discharges on water quality is of crucial importance.

This paper focuses on the Proença-a-Nova wastewaters treatment plant, which discharges directly into the Freixada River, a Pracana's tributary. Twelve georeferenced water samples were collected between the sewage effluent discharge and the Pracana river confluence. Secondary inflows were identified and water samples collected downstream at approximately equal distances. The core of our study is the hydrological year of 2010. Sampling campaigns were conducted during three different periods: rainy winter (January), intermediate conditions (March) and dry season (June). The following chemical parameters were analyzed: biochemical oxygen demand (BOD), dissolved oxygen concentration (DO), dry residue, P_{total}, N_{total}; pH, temperature and microbiological parameters. The dissolved oxygen concentration (DO), biochemical oxygen demand (BOD) and the microbiological parameters were used as indicators for the presence of organic matter in the body of water, and as parameters for evaluating the environmental pollution.

The pollution simulation in the Pracana river was performed by a coupled hydrodynamic and water dispersion model. A water quality model was constructed applying to QUAL2kw software. The simulation results are consistent with field observations and demonstrate that the model has been correctly calibrated. The model is suitable for evaluating the environmental impact of wastewaters plant discharges on the Pracana River, allowing feasibility studies of different treatment schemes and the development of specific monitoring activities.

U-Pb dating of very low-grade metamorphic titanite

V. Oliveros[1]*, A. Simonetti[2] and D. Morata[3]

[1]Departamento Ciencias de la Tierra, Universidad de Concepción, Casilla 160-C, Concepción, Chile (*correspondence: voliveros@udec.cl)
[2]Civil Engineering and Geological Sciences, University of Notre Dame, Notre Dame, IN 46556, USA
[3]Departamento de Geología, Universidad de Chile, Plaza Ercilla 803, Santiago, Chile

Titanite is a common secondary mineral present in metabasites in the Chilean Andes. Its rather high closure temperature (<550°C) renders it very suitable for dating sub-to-low-grade metamorphism or hydrothermal alteration. In this study we tested the feasibility of dating very small grains of secondary titanite. Thirteen standard petrographic thin sections of Mesozoic volcanic rocks outcropping in the Main and Coastal cordilleras of central Chile (33-35°S) were selected for U-Pb dating by LA-MC-ICP-MS. The analyzed titanites occur as four different varieties: infilling amygdales or veins, within the groundmass, and replacing both former pyroxene and magnetite phenocrysts. The radiogenic Pb content is generally low and correlates with the type of titanite, i.e. the large titanites within amygdales (~200 μm) contain the most radiogenic Pb. The mean ages range from 48.5±6.5 to 147±22 Ma, with three distinct groups at 102-108 Ma, 80-85 Ma, and 49-62 Ma. One sample from the Coastal Cordillera yielded an age of 119.8±3.6 Ma (Fig. 1). The U-Pb ages do not correlate with either the amount of common Pb, or with the varietal type of titanite (Fig. 1). The U-Pb ages overlap with those previously obtained by K-Ar and Ar-Ar methods, which have been attributed to either very low-grade metamorphism, or approach the age of volcanism; however, several samples yield Cenozoic ages, which may represent a geologic event or related to secondary Pb loss.

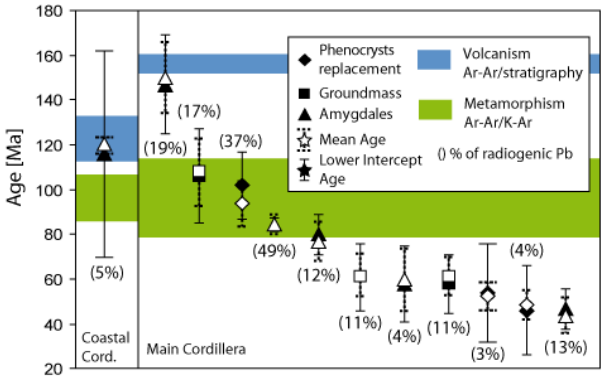

Figure 1: Titanite U-Pb ages.

Low biodiversity tropics in a high CO_2 median Mesozoic world

Paul E. Olsen[1], Jessica H. Whiteside[2] and Morgan F. Schaller[3]

[1]Lamont-Doherty Earth Observatory, Palisades, NY 10968, USA (*correspondence: polsen@ldeo.columbia.edu)
[2]Dept. of Geological Sciences, Brown Univ., Providence, RI 02912, USA (jessica_whiteside@brown.edu)
[3]Dept. of Earth and Planetary Sciences, Rutgers Univ., Piscataway, NJ 08854, USA (schaller@rci.rutgers.edu)

A strong latitudinal gradient in biodiversity, increasing to the tropics, is one of the most striking of modern ecological patterns. Late Triassic to Early Cretaceous tropical assemblages do not show this pattern, however. Most tropical and subtropical floral records from this time are characterized by low diversity and are overwhelmingly dominated by cheirolepidaceous conifers and their pollen, *Classopollis*. These conifers have been traditionally described as arid-adapted with features such as microphyllus leaves and thickened cuticle with sunken or papillate stomata. While some subtropical occurrences of cheirolepidaceous conifers are indeed associated with sedimentological evidence for aridity such as evaporites, many from the tropics are not and instead are found in settings incompatible with aridity. In contrast, the temporal distribution of these low-diversity assemblages tracks Mesozoic CO_2, rising through the Triassic and falling through the Cretaceous as angiosperms become more prevalent. We suggest that these conifers were not so much arid-adapted, but rather specialized in extraordinarily hot, high-CO_2 environments, regardless of precipitation.

The same pattern maintains at finer time scales. The end-Triassic extinction (ETE) exhibits a dramatic drop in biodiversity at pulsed 2-3X increases in CO_2 associated with Central Atlantic Magmatic Province (CAMP) basaltic eruptions. *Classopollis* massively increased in the tropics and subtropics as generic diversity of other pollen and spores dropped in direct association with the eruptions. However, perennial lake sediments and other indications of an enhanced hydrological cycle increased dramatically at the same time consistent with high CO_2 and extremely hot temperatures, being the main drivers of cheirolepidaceous dominance and low biodiversity, not the lack of water.

High latitudes had dramatically higher diversity. At the ETE, these assemblages also suffered a huge drop in diversity among broader leaf forms consistent with thermal damage, but they never became as skewed as the tropics. Thus, relative to now, latitudinal diversity gradients were reversed at all temporal scales during times of very high CO_2, plausibly because of near lethal temperatures.

Incorporation of heavy metals into recent travertine formations at the Eyjafjallajökull volcano

J. OLSSON[1,2]*, S.L. S. STIPP[2], K.N. DALBY[2] AND S.R. GISLASON[1]

[1]Nordic Volcanological Institute, Institute of Earth Sciences, University of Iceland, Iceland (*correspondence: jolsson@hi.is) (sigrg@raunvis.hi.is)

[2]Nano-Science Center, Chemistry Department, University of Copenhagen, Denmark (stipp@nano.ku.dk, kdalby@nano.ku.dk)

The release of heavy metals from water-volcanic rock-gas interaction and pristine volcanic ash-water interactions pose a serious environmental problem for water supplies. Thus it is interesting that the concentrations of waterborne pollutants monitored in the vicinity of active volcanoes are often much lower than predicted. Released heavy metals from the iniaial water-rock interactions are probably scavanged by and/or reincorporated into secondary precipitates including aluminium silicates, iron (hydr)oxides and carbonates. The purpose of this study was to investigate the capacity of naturally formed travertine to immobilise heavy metals.

Following the eruption of the Eyjafalljökull Iceland volcano in the spring 2010, a new strong outlet of riverine CO_2 was observed via the river Hvanná, which indicates deep degassing into the water. A white mineral layer; at some places several cm thick, for hundreds of meters downstream was observed. The precipitation was identified solely as calcite with X-ray diffraction. Low concentrations of riverine Al and Fe provide a unique opportunity to examine the scavenging role of the precipitating carbonates exclusively. A gradual decrease of: conductivity from 1.8 to 1.1 mS/cm, alkalinity from 20.8 to 8.8 meq/kg, concentration of Ca, Mg, Cd, Cu, Mn, Sr, Ba and CO_2, and increase in the pH from 6.5 to 8.5, strongly correlated with the amount of precipitated travertine. Dissolution experiments show that bulk travertine incorporates the same metals. The water temperature was below 5 °C and an elevated atmospheric CO_2 partial pressure was detected near the river. The river water degassed downstream and pH increased, resulting in calcite supersaturation and precipitation. Our thermodynamic models suggest that, in addition to $CaCO_3$, Mg-, Sr- and Ba-carbonates and two phyllosilicate phases were supersaturated.

Our study provides valuable information for assessing environmental impacts for, e.g. volcanic eruptions or carbon capture and storage (CCS) projects in basaltic rock, such as the Icelandic multi-collaborator project 'Carbfix'.

Enzymatic and abiotic hydrolysis of glucose phosphate adsorbed on goethite

R. OLSSON[1]*, R. GIESLER[2], J.S. LORING[3] AND P. PERSSON[1]

[2]Climate Impacts Research Centre, Department of Ecology and Environmental Science, Umeå University, 901 87 Umeå, Sweden (reiner.giesler@emg.umu.se)

[3]Pacific Northwest National Laboratory, Richland,Washington 99352, USA

Organophosphates constitute a substantial part of the total phosphorus in soil. However, hydrolysis of the phosphate ester bond may be required in order to produce bioavailable phosphate. Adsorption on mineral surfaces can facilitate abiotic hydrolysis, but has also been suggested to block enzymatic hydrolysis. In this study we have investigated the enzymatic and abiotic hydrolysis of glucose-1-phosphate and glucose-6-phosphate adsorbed at the water-goethite interface. Sugar monoesters such as these have been indicated to occur at significant concentrations in soils.

To study the kinetics and molecular mechanisms of the abiotic and enzymatic hydrolysis we have used wet-chemical and spectroscopic techniques. Ion chromatography was used to obtain quantitative data, while a setup for simultaneous infrared and potentiometric titrations was used to investigate *in situ* the goethite-water interface reactions. We found that glucose phosphate forms three surface complexes on goethite in the pH range 3 – 10 differing in protonation states and hydrogen bonding interactions with neighboring surface groups. Below pH 7 the glucose-1-phosphate complexes are stable with respect to hydrolysis whereas at higher pH values a small extent of hydrolysis is detected. With glucose-6-phosphate the trend is reversed, i.e. hydrolysis occurs at low pH values. When an enzyme (acid phosphatase) is added the hydrolysis increases considerably. This increase coincides with adsorption of enzyme, and all experimental data indicate that the enzymatic hydrolysis is a strictly interfacial process. Furthermore, the enzymatic hydrolysis is strongly dependent on the amount of glucose phosphate adsorbed since the properties of the surface affect the enzyme's mode of adsorption and hence it's activity.

A study on the beach sediments of The Gulf of Fethiye (SW Turkey), focus on geochemical data

Z. ONAL, B. ESER-DOGDU*, M. ERGIN, Z.S. KARAKAS, K. SOZER AND E.S. DURMUS

Ankara University, Department of Geological Engineering, 06100, Tandoğan, Ankara (*correspondence: edogdu@eng.ankara.edu.tr)

This study is carried out to investigate sedimentary transport and depositional processes, heavy mineral distribution and possible economically important placer potentials of coastal beaches of the Fethiye Gulf. Investigation also forms part of a Project supported by the Ankara University Scientific Research Projects Office. To perform this, in September 2009, a large number of sediment samples were collected along the shoreline (A) and backshore (B) parts of coastal beaches of Fethiye and subjected to well-known sedimentary petrographic methods.

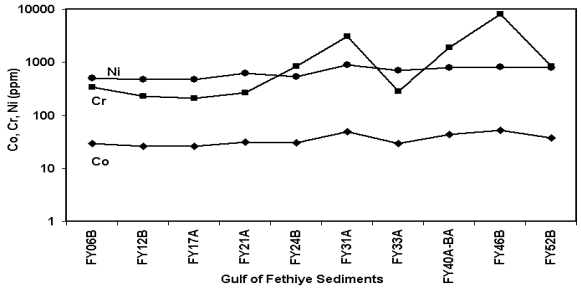

Figure 1: The distribution of Co, Cr and Ni concentrations in the beach sediments of Fethiye.

According to multielement analysis of sediments, Ni (657 ppm), Co (35, 5 ppm) and Cr (1605 ppm) contents are found to be higher than average values of Earth's crust and sandstones values. Earth' s crust averages (ppm) for Co 25, Cr 100 and Ni are also given for comparison [1]. High concentrations of the elements can be related to the occurrences of ophiolites and bearing chromites on the coastal hinterland of the Fethiye Gulf. The total heavy mineral contents of the sediments showed parallel trend with an some element contents.

Experimental tests for the origin of Archean sulfur mass-independent fractionation during SO_2 photolysis

SHUHEI ONO* AND ANDREW WHITEHILL

Earth, Atmospheric, and Planetary Sciences, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, MA 02139 (*correspondence: sono@mit.edu)

The signatures of Archean sulfur isotope mass-independent fractionation (S-MIF) provide critical constraints on the redox evolution of the early Earth's atmosphere. Although S-MIF is likely to be sourced from SO_2 photolysis, the physical origin of this unique isotope effect is yet to be identified. Recent studies suggest 1) selfshielding [1] or 2) isotopologue specific photoexcitation [2, 3] as the origin of observed S-MIF signatures. These two models imply the pattern of S-MIF is sensitive to the UV spectrum, and thus, the atmospheric components that absorb UV region between 190 to 220 nm, potentially providing significant new constraints on the chemical compositions of early atmosphere.

A series of laboratory experiments are in progress to test above two hypotheses during UV photolysis of SO_2 ($3SO_2 + h\nu \rightarrow 2SO_3 + S$). A flow-though photochemical reactor is used to examine S-MIF as a function of SO_2 mixing ratio. Two broad band light souces (D and Xe arc lamp), with or without 200 nm bandpass filter, are used to test the effect of light spectrum. Detailed photohemial model using available rate constants suggests that S is formed by SO bimolecular collision ($SO+SO \rightarrow SO_2 + S$), and the photolysis of SO ($SO + h\nu \rightarrow S + O$) is a minor channel.

Experiments with D and Xe lamp produced similar MIF patterns ($\delta^{33}S/\delta^{34}S$ and $\Delta^{36}S/\Delta^{33}S$ ratios), suggesting S-MIF is not sensitive to the detailed shape of the UV spectrum. Although large $\delta^{34}S$ isotope effect is consistent with [2], their cross section predicts the opposite signs of $\Delta^{33}S$ for D and Xe lamp experiments. This suggests that the photoexcitation step itself may contribute relatively little to S-MIF. Instead, S-MIF may be originating from the isotope-sensitive quantum yield, such as curve crossing among various excited states SO_2. We will also report the results from a newly constructed dual-flow cell system designed to test the SO_2 selfshielding model at optically thin condisions.

The role of hydroxyl group (OH) in forming minerals

V.V. ONUFRIENOK*, A.M. SAZONOV, A.V. TEREHOVA AND A.G. NIKIFOROV

Siberian Federal University, Krasnoyarsk, Russia (*correspondence: VOnufriynok@sfu-kras.ru)

There was studied the changes of the pyrrhotites structure when hydroxyl group (OH) is introduced into it. After synthesis (1273 K) the samples were maintained at the room temperature (~ 25°C) for 29 years in atmospheric conditions.

The X-ray and chemical analysis analysis of the samples, which were maintained, showed that there are compounds containing hydroxyl group (OH) in the crystal structure. The samples contained parabutlerite, goethite, szomolnokite, rozenite, rhomboclase, pyrite and pyrrhotite.

For example the influence of hydroxyl group (OH) on the content of the formed szomolnokite was considered on the basis of calculating the thermodynamic potentials using the Bose-Einstein statistics. The theoretical calculations were compared with X-ray phase analysis data (table 1).

S/Fe ratio	Percentage hydroxyl group (OH)	Szomolnokite percentage	
		X-ray	As calculated
1.710	4.25	21.21	16.779
1.684	2.72	12.92	18.533
1.670	4.42	23.70	19.553
1.660	2.38	11.65	20.315
1.580	5.11	25.61	27.586
1.571	5.27	17.36	28.552
1.497	7.99	41.55	41.127
1.382	4.25	26.60	21.780
1.380	9.35	21.04	21.540
1.250	0.85	5.07	10.499
1.158	2.03	6.19	6.314
1.157	1.70	3.29	6.279
1.052	0.34	2.07	3.514

Table 1. The szomolnokite percentage in the samples

As it is shown in the table, tendency to decreasing both with increasing of szomolnokite content with decreasing S/Fe ratio is observed both X-ray data and the theoretical calculation results.

Seasonal magnesium isotope variations in soil solutions reflecting physico-chemical processes controlling soil weathering fluxes

S. OPFERGELT[1,2], R.B. GEORG[3], K.W. BURTON[1], R. GUICHARNAUD[4], C. SIEBERT[1], S.R. GISLASON[5] AND A.N. HALLIDAY[1]

[4]Agricultural University of Iceland, Reykjavik, Iceland

[5]Institute of Earth Sciences, University of Iceland, Reykjavík, Iceland

Chemical weathering supplies base cations controlling the long-term availability of nutrients. Base cations, including magnesium, lost by plant uptake or leaching, are replaced by mineral weathering and partly retained on the soil exchange complex. Despite Mg isotopes being used as a weathering proxy, the fractionation mechanisms in the critical zone are still unclear. Here we report the first look into the seasonal variability of Mg isotope compositions in soil solutions derived from a well-defined protolith, Icelandic basalt, which was exposed to seasonal freeze-thaw cycles. Less weathered freely drained Brown and Gleyic Andosol (BA-GA) are compared with more weathered poorly drained Histosol and Histic Andosol (H-HA). The difference in clay content (35 and 48%) and proportions of exchangeable Mg (2 and 7%) in BA-GA and H-HA, respectively, allow for a direct assessment of the processes controlling Mg isotope ratios (δ^{26}Mg relative to DSM-3). Vegetation (-0.30 to -0.18‰) is heavier than parental basalt (-0.31‰) and bulk soils (-0.79 to -0.25‰). Soil solutions (-1.16 to -0.53‰) are relatively lighter than the basalt. Magnesium retention on the soil exchange complex is larger in neutral than in acid soils and discriminates against light Mg isotopes (-0.88 to -0.51‰) contributing towards isotopically lighter soil solutions in BA-GA. Seasonal variations (from June to September) of Mg isotope ratios in soil solutions from organic-rich H-HA are likely to reflect the release of heavier Mg isotopes from the decomposition of plant material during thaw. Our results show that Mg isotopes have a great potential as a proxy for seasonal soil processes, especially in sub-arctic soils where environmental changes would potentially affect vegetation decomposition, CO_2 release, and associated nutrient delivery to the hydrosphere.

Erebus, the only presently erupting phonolite volcano, offers an exceptional opportunity to examine the complexities that accompany degassing and the evolution of magmas from deep to shallow levels. These include aspects of magmatic differentiation, redox chemistry and eruptive transitions widely relevant to understanding other volcanoes. Its long-lived anorthoclase phonolite lava lake, sustained degassing and hyperarid environment provide uncommonly favourable circumstances for direct measurement of the lava lake – the uppermost portion of the magmatic system.

Several features distinguish Erebus: the decadal persistence of the lava lake; evidence for continuous fractionation (the Erebus Lineage) from basanite to phonolite; episodic Strombolian activity at the lava lake (which provides samples for analysis); and the abundance of megacrysts (up to 10-cm-long) of anorthoclase feldspar in the lava lake. The longevity of the lava lake implies counterflow of vesicular and degassed magma within the (<10 m) feeder conduit. Flow instabilities and diffusional processes allow complex transfers of gas, melt and crystals up and down the conduit.

This contribution focuses on integration of field measurements of volcanic gas emissions (composition and flux) and the vigour of lava lake motion, and how the observations map to characteristics of magma flow and degassing. It aims to showcase key findings of recent annual field seasons on Erebus, to review some of the challenges of volcano surveillance in the extreme Antarctic environment, and to stimulate comparative studies of Erebus and volcanoes such as Vesuvio, Stromboli, Nyiragongo, and others, with shared characteristics.

Halophilic microorganisms: Modern and ancient, on Earth and in Space

AHARON OREN

Department of Plant and Environmental Sciences, The Alexander Silberman Institute of Life Sciences, The Hebrew University of Jerusalem, 91904 Jerusalem, Israel

Salt-saturated environments on Earth are inhabited by a great diversity of halophilic microorganisms. They are found in all three domains of life: Bacteria, Archaea, and Eucarya. Many can thrive not only at low water activities, but are also adapted to high divalent cations concentrations (the Dead Sea) and to extremes of pH and temperature. Different groups of halophiles can be detected using biomarkers such as the archaeal isoprenoid ether lipids, pigments (the archaeal C-50 bacterioruberins, β-carotene from the alga *Dunaliella salina*), and osmotic solutes such as glycine betaine and ectoine in Bacteria, glycerol in *Dunaliella*.

When halite crystallizes from salt-saturated brines, microorganisms are often trapped within fluid inclusions in the crystals, where they can survive for prolonged periods. Live microorganisms have been recovered from ancient halite, e.g. *Virgibacillus marismortui* from Permian salts of New Mexico, Archaea (*Halobacterium*, *Natronobacterium*) from Cretaceous halite crystals from Brazil. DNA encoding bacterial and archaeal rRNA genes was recovered from Cretaceous (Brazil) and Silurian (Michigan) salt. Salt crystals deposited 35,000 years ago in Death Valley, CA, contained microscopically recognizable prokaryotes, as well as *Dunaliella*, which may have provided the prokaryotes with glycerol and other organic compounds as a source of energy for survival. In spite of the earlier scepticism, compelling evidence for long-term survival of halophilic microorganisms within salt crystals has accumulated in the past decade.

Some species of halophilic Archaea can survive large doses of UV radiation, desiccation and exposure to low temperatures, but not all halophiles are equally adapted. Some strains of halophiles have survived flights on the Biopan facility of the space shuttle, including a species named *Halorubrum chaoviator*, 'the traveller of the void'.

Halite has been detected on Mars and in meteorites. In view of the ability of some halophiles to survive in salt at low water activity, high radiation levels, and in a broad range of pH, salt crystals are promising material to search for life elsewhere in the universe, using a combination of techniques: microscopy, gene-based approaches, and detection of specific biomarkers. Model systems on Earth – recent and ancient – provide plentiful material to evaluate the different methods.

Numerical study of weathering fluxes at the catchment scale in a boreal watershed: A coupled thermo-hydro-geochemical mechanistic approach

L. ORGOGOZO[1]*, Y. GODDÉRIS[1], O.S. POKROVSKI[1], J. VIERS[1], D. LABAT[1], A.S. PROKUSHKIN[2] AND B. DUPRÉ[1]

[1]GET, 31400, Toulouse, France (*correspondence: laurent.orgogozo@get.obs-mip.fr) (yves.godderis@get.obs-mip.fr, oleg.pokrovsky@get.obs-mip.fr, jerome.viers@get.obs-mip.fr, david.labat@get.obs-mip.fr, bernard.dupre@get.obs-mip.fr)

[2]V.N. Sukachev Institute of Forest, SB RAS, Akademgorodok, Russia (prokushkin@ksc.krasn.ru)

This work deals with the assessment of the impact of the climatic changes on weathering processes in boreal catchments which are characterized by the occurrence of a continuous permafrost. The two main goals of this study are : (i) to quantify the influence of seasonal cycles of freezing and thawing of the active layer on the fluxes of chemical elements generated by the weathering processes and (ii) to estimate the effect on the weathering fluxes of possible interannual variations of these cycles caused by climatic changes. Our approach is based on the development and the validation of a coupled thermo-hydrological mechanistic modelling at the catchment scale for current climatic conditions. This thermo-hydrological model is designed to give the entrance data (the seasonal evolutions of the average thickness and of the average water content of the active layer) for the computation of weathering fluxes with the WHITCH geochemical model (e.g. [1]). This modelling approach at the catchment scale is established on the basis of the data available in the International Research Group CAR WET SIB ([2], [3]). In further studies, the model developed here will allow to forecast the impact of various scenarios of climatic changes on the weathering fluxes.

[6]Kanagawa Prefecture Museum of Natural History, Kanagawa 250-0031, Japan

We reports the results of U-Pb dating for 282 zircon crystals separated from a Middle Miocene adakite in Cerro Pampa, southern Argentine Patagonia, using LA-ICP-MS. With the exception of 3 spot ages, 140 of the concordia ages are significantly older (> 94 Ma) than the cooling ages of the adakite magma (~ 12 Ma). Kay *et al*. [1] attributed the origin of adakite magmas to partial melting of subducted slab of the Nasca plate. Presence of exotic zircon crystals clearly indicates crustal contaminations to produce the adakitic magma in Cerro Pampa. The obtained concordia ages of exotic zircons range from 94 Ma to 1441 Ma and could be divided into five groups having distinctive peaks on a population diagram. The first (100-125 Ma) and second age groups (125 to 145 Ma) correspond to the age of plutonic activities that formed main body of the South Patagonian Batholith [2]. The third to fifth groups correspond to activities of El Qumado-Ibañez volcanic complex (145-170 Ma) [2], gabbroic rocks scarcely distributed in Central Patagonia (170-200 Ma), and the Eastern Andean metamorphic complex of Late Paleozoic to Early Mesozoic ages (200-380 Ma) [3], respectively.

Our data suggests that the crust underneath Cerro Pampa were mostly formed after 380 Ma and majority of the upper crust was formed during early Cretaceous to middle Jurassic. The processes of crustal development ceased ~ 94 Ma until the activity of the Cerro Pampa adakite in ~ 12 Ma. There was no evidence for Archean-Paleoproterozoic crust.

The ability to decipher the metabolic roles of microorganisms within living microbial ecosystems and to connect microbial metabolism with biosignatures preserved in the rock record represents some of the grand challenges in the field of Microbial Geobiology. The combination of molecular methods with stable isotope analysis (both natural abundance and as tracers) in modern environments represents a multidisciplinary approach that has been used successfully to characterize links between specific microorganisms and their ecophysiology in situ. In particular, the introduction of micron-scale isotopic analyses by secondary ion mass spectrometry (SIMS and nanoSIMS) [1] to the study of microorganisms has enabled an unprecedented level of inquiry into the inner workings of microbial ecosystems. Integrating SIMS-based stable isotope analysis with microscopy and culture-independent metagenomics techniques, we have been investigating carbon and nutrient utilization by deep-sea microorganisms and symbiotic microbial consortia fuelled by methane in sediments and associated authigenic carbonates. Single cell characterization of methane-cycling archaea and sulphate-reducing bacteria have revealed significant inter and intra-group heterogeneity in both stable carbon isotopic signatures and nitrogen utilization, including differences in nitrogen fixation [2] and assimilatory nitrate reduction. These cell-specific analyses have yielded new information regarding the isotopic variability, metabolic potential and interactions between individual microorganisms and the greater biological community in methane-based ecosystems.

Combining electrochemical and spectroscopic methods to obtain speciation of quinones

S. ORSETTI*, S. SPAHR, C. LASKOV AND S. HADERLEIN

Center for Applied Geosciences, University of Tübingen, Sigwartstrasse 10, D-72076 Tübingen, Germany (*correspondence: silvia.orsetti@uni-tuebingen.de)

In anoxic aquifers, the presence of goethite-Fe(II) systems plays a major role in electron transfer processes, such as degradation of organic pollutants [1]. To investigate the role of organic matter as potential electron shuttles commonly model quinones such as AQDS, juglone and lawsone were used [2, 3]. To address this question we studied interactions with iron minerals and the speciation of model quinones.

Defined redox and acid-base species of the model quinones were obtained by electrochemical methods, varying systematically the reduction potential, pH and ionic strength. The UV-visible spectra of these species were used as reference to obtain the redox speciation of quinones in goethite-Fe(II) systems. From these data information on electron transfer processes, redox potential and equilibrium states of the redox sensitive quinone and iron species can be derived.

PGE distribution in base-metal sulfides from the Merensky Reef of the Bushveld Complex, South Africa

I. OSBAHR[1]*, T. OBERTHÜR[2] AND R. KLEMD[1]

[1]GeoZentrum Nordbayern, University of Erlangen, Schlossgarten 5a, 91054 Erlangen, Germany (*correspondence: osbahr@geol.uni-erlangen.de)
[2]Federal Institute for Geoscience and Natural Resources (BGR), Stilleweg 2, 30655 Hannover, Germany

Introduction

Several studies were undertaken to elucidate the distribution of PGE between various sulfides such as pentlandite, pyrrhotite or chalcopyrite [1, 2]. This present study concentrates on the PGE distribution in BMS in profiles of the Merensky Reef of the Bushveld Complex using whloe-rock, electron microprobe and LA-ICP-MS analysis.

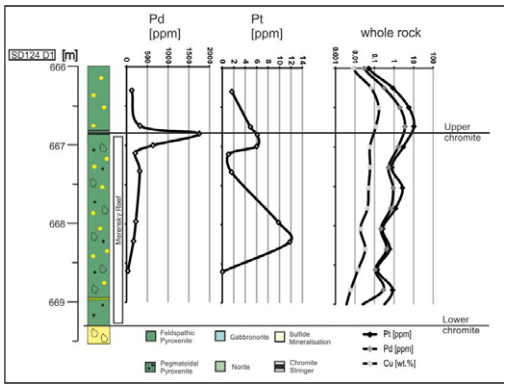

Figure 1: Pd and Pt distribution in pentlandite and whole-rock.

Results

Pentlandite is a principal host of Pd (and Rh) whereas Pt is mainly hosted by PGM. The distribution of Pt and Pd in two profiles from the western Bushveld reveals a top-loaded mineralization – max. concentrations of Pd and Pt occur in the area of the upper chromite stringer in the whole-rock, coinciding with max. concentrations of Pd in pentlandite (Fig. 1). Two profiles from the eastern Bushveld reveal 'offset patterns' – max. concentration of Pd in pentlandite is displaced ny 0.5 – 1 m below the max. concentration of whole-rock Pd and Pt. Downward percolation of sulfides or post-magmatic processes such as selective diffusion may be responsible for the observed offset feature.

The evolution of surface, intermediate and deep water connections during the closure of the Central American Seaway

A. OSBORNE[1]* M. FRANK[1] AND R. TIEDEMANN[2]

[1]IFM-GEOMAR, Leibniz Institute of Marine Sciences at the University of Kiel, Wischhofstrasse 1-3, 24148 Kiel, Germany (*correspondence: aosborne@ifm-geomar.de)
[2]AWI, Alfred Wegener Institute for Polar and Marine Research, Am Alten Hafen 26, 27568 Bremerhaven, Germany

The progressive closure of the Central American Seaway and the associated reorganisation of deep-ocean circulation have been controversially reported as contributing to a warming and a cooling of global climate, as well as increasing moisture supply to the northern hemisphere and hence preconditioning the inception of Northern Hemisphere Glaciation. Here we use radiogenic isotopes of Nd and Pb to reconstruct the history of shallow, intermediate and deep water connections between the Caribbean Sea and the eastern Equatorial Pacific Ocean from 5.0 to 2.0 million years ago. Surface water exchange and mixing is characterised using the Nd isotope composition of planktonic foraminiferal calcite. The Nd and Pb isotope compositions of early diagenetic ferromanganese coatings of the same sediment samples are employed to determine intermediate and deep water exchange.

A core-top survey compares ε_{Nd} in surface sediments, with the expected water mass signature. Leaches of core-top sediments taken from intermediate water depths (~1000m) in the central Caribbean Sea give values between ε_{Nd} = -7.5 and -10.2. Planktic foraminifera from the same samples have ε_{Nd} between -8 and -10.8. Around a deeper central Caribbean site (~3000m), leaches give between -5.9 and -8.2 in ε_{Nd}, which is 2 to 6 ε_{Nd} units more radiogenic than published data from ferromanganese crusts in the Lesser Antilles[1, 2], but still significantly less radiogenic than core-top leaches from the Eastern Equatorial Pacific (EEP), which have ε_{Nd} between 2 and 0. These latter measurements are broadly consistent with data from an EEP ferromanganese crust [3]. These findings form the basis for the down-core survey and the reconstruction of the exact timing of the closure of the seaway and corresponding water mass exchange at different water depths.

3 stages of Earth evolution — Core formation, ocean emergence and the 2.3 Ga rise of atmospheric oxygen: How are they linked?

MILES F. OSMASTON

The White Cottage, Sendmarsh, Ripley, Woking, Surrey GU23 6JT, UK (miles@osmaston.demon.co.uk)

Recognized nearly a century ago [1], the mean specific angular momentum (a. m.) of SS planetary materials is $>10^5$ times the Sun's, so it is an important constraint upon how the planets were built. Nebula is the only conceivable agent for this partition. And it must do this for both the protoplanet and all of its feedstock, so planetary growth must be essentially complete before it departs (<5 Ma?). This rules out the post-nebula growth in cores-by-Fe-percolation models, for which isotopic (Hf-W, etc) data have been interpreted as needing upwards of 30 Ma for completion, though this interval may actually relate to post-core-completion exchange at the CMB.

Those models also do nothing for the origin of SS water. Ringwood's model (1960-1978) invokes a cool nebula, achievable with other advantages [2-4], to give high-*f*O2 accretion. It then uses the nebula to reduce hot erupted FeO at the protoplanet's surface; the Fe then being 'subducted' to form the core. Nebular departure halted this, leaving some FeO in the mantle. Incorporation into its mineral structure of a few of the >400 Earth-ocean volumes of reaction water thus generated greatly water-weakened it, facilitating convective loss of early heating.

But at ~2.49Ga, ocean production caused parts of the upper mantle to reach a critical loss of water-weakening in the presence of interstitial melt [5], halting convective motion for ~270Ma [6, 7]. MOR collapse lowered sea-level by >3km, exposing cratons to erosion, unroofing TTG, lowering atmospheric CO2 and causing Huronian glaciation (2.4 Ga). During this hiatus, oxygenic life, previously confined to the top 200m of oceans, won its battle against MOR effusions, depositing BIF and oxygenating the atmosphere, which is why we are here [5, 7]. The restart after 2.22Ga left cratons with the deep-keeled tectospheres of stiffened mantle, manifest in plate dynamics behaviour for at least the past 90Ma [8].

Experimental study of nucleation and phase stability of calcium sulfate

M. OSSORIO[1]*, A.E.S. VAN DRIESSCHE AND J.M. GARCÍA-RUIZ

LEC, IACT, CSIC - U.Granada, 18100 Granada, Spain (*correspondence: mercedes@lec.csic.es)

Calcium sulfate presents three common phases when precipitated from aqueous solution in nature or in the laboratory: gypsum ($CaSO_4{\cdot}2H_2O$), bassanite ($CaSO_4{\cdot}0.5H_2O$) and anhydrite ($CaSO_4$) [1]. The conversion of these phases into each other takes place in nature but also represents the basis of gypsum-based building materials. Therefore many studies have been performed on the phase stability of calcium sulfate in solution, as a function of temperature but, at present, the mechanisms by which precipitation, phase transition and phase stability occur in solution are not well defined [2].

We performed an experimental study in order to identify the factors that influence the nucleation, growth and phase stability of calcium sulfate at laboratory scale. The crystallization was carried out by chemical reaction by varying temperature (40°C-120ºC), salinity (0.8, 2.8, 4.3 M NaCl) and duration of the experiments (2 min – 3 months). The reaction products were characterized by Powder X-Ray Diffraction, SEM and TEM.

Our results show a clear dependence on temperature and salinity of the precipitated phase of calcium sulfate; at low temperatures, gypsum is the most stable phase (<60°C). As temperature increases, direct precipitation of bassanite (80-110°C) and anhydrite (120°C) occurs. The temperature at which primary bassanite appears decreases with increasing salinity (110-80°C) while anhydrite shows a more complex dependence. Besides primary precipitation phase transition of calcium sulfate in contact with the mother solution occurs over time (>days). With time the temperature at which bassanite and anhydrite appear decreases. This behavior is generalized for the three salinities studied but at the highest salinity this phase transition occurs faster.

A plausible explanation for the mechanism of phase transition is the dissolution of the phase that precipitates first (less stable) and subsequent 'recrystallization' of the more stable phases with passing time. The kinetics of dissolution/precipitation of these compounds plays a decisive role in the transition rates of calcium sulfate phases and are mainly controlled by temperature and solution salinity.

Petrogenesis of syn-orogenic leucogranites (Damara orogen, Namibia)

J. OSTENDORF[1] AND S. JUNG[2]

[1]Institut für Mineralogie, TU Bergakademie Freiberg, 09596 Freiberg, Germany (joerg.ostendorf@mineral.tu-freiberg.de)
[2]Mineralogisch-Petrographisches Institut, Universität Hamburg, 20146 Hamburg, Germany

The granite-dominated part of the Central Damara Orogen (Namibia) consists of basement gneisses, high-grade metamorphic metasedimentary rocks, and crust-derived granites. Granites that crop out in the Kubas area fall into two groups; 553±8 Ma-old grey granites and 513±6 Ma-old red leucogranites. The grey granites have a common granitic composition but the red leucogranites are highly fractionated melts shown by extremely high Rb/Sr ratios, fractionated REE patterns and the presence of euhedral Mn-rich garnet. Digested remnants of upper crustal pelites are clusters of biotite, sillimanite and cordierite indicating some crustal contamination. The grey granites have less evolved isotopic compositions (init. $^{87}Sr/^{86}Sr$: 0.720; init. ε Nd: -16; large variation in $^{207}Pb/^{204}Pb$ (15.55-15.61) at $^{206}Pb/^{204}Pb$ ratios lower than the red leucogranites). The red leucogranites have more evolved isotopic compositions (init. $^{87}Sr/^{86}Sr$: 0.725-0.750; init. ε Nd: -16; large variation in $^{206}Pb/^{204}Pb$ trending towards the composition of common pelitic metasediments from the Damara orogen). These isotopic features indicate that both granite types represent melts from a similar source (Proterozoic/Archaean basement?) but have undergone different processes. The grey granites appear to be uncontaminated and hence, their composition mirror their sources. The red leucogranites have apparently interacted with upper crustal rocks via AFC processes (digested xenoliths, fractionated REE patterns, large variation in Sr and Pb isotopes), probably during stagnation within the crust. Such lower crustal melts are apparently confined to the pre-to syn-collisional phase of the orogeny and it is therefore likely that they have also contributed to the heat budget that controlled high-temperature metamorphism. Even in complex terranes granites can preserve a record of their sources and can be used to place limits on possible compositions of the unexposed sources of the granites and thus on the nature of the terranes through which the melts ascended.

Level of ^{129}I and ^{127}I in terrestrial environment of Slovenia: A two-year study of background areas

A. OSTERC AND V. STIBILJ*

Institute Jožef Stefan, Jamova 39, 1000, Ljubljana, Slovenia (*correspondence: vekoslava.stibilj@ijs.si)

Introduction

Iodine has two natural isotopes – ^{127}I is a stable isotope, while ^{129}I is a radioactive isotope formed naturally by spallation of cosmic rays on atmospheric Xe and spontaneous fission of ^{238}U. However, the main sources of ^{129}I in the environment are anthropogenic from nuclear fuel reprocessing plants (NFRP). Current levels of ^{129}I do not represent any radiological hazard to humans, but the discharges of ^{129}I from NFRP can be used as an environmental tracer [1]. Our aim was to investigate levels of ^{129}I in environment of Slovenia, because no data exist.

Experimental

Samples of precipitation, soil from opened field and forest, and pine needles were collected three times at four various locations in period 2009–2010. Total concentrations of ^{127}I and ^{129}I were determined with radiochemical neutron activation analysis [2].

Results

Sample	**^{127}I** ($\mu g\ g^{-1}$)	**$^{129}I/^{127}I$** (10^{-8})
precipitation (n = 10)	0.0017–0.0065	<2.3–91.0
soil		
opened field (n = 12)	2.4–22.2	0.7–7.1
forest (n = 12)	3.9–35.2	0.7–7.4
pine needles (n = 12)	0.058–0.413	15–189

Table 1: Range of concentration levels and $^{129}I/^{127}I$ ratios

Discussion

The highest concentrations of ^{127}I and ^{129}I were found in soil samples. Soil samples collected in forest, where more organic matter is present; contained more ^{129}I and ^{127}I than soil from opened field, although the $^{129}I/^{127}I$ isotopic ratio is the same. The highest $^{129}I/^{127}I$ isotopic ratio was found for pine needles. Obtained results are the first for terrestrial environment of South Europe and are comparable to values found in literature for background areas.

Transformation of nitrogen during sediment burial history

CHRISTIAN OSTERTAG-HENNING[1] AND CHRISTIAN ILLING[2]

[1]Bundesanstalt für Geowissenschaften und Rohstoffe, Stilleweg 2, D-30655 Hannover, Germany (*correspondence: Christian.Ostertag-Henning@bgr.de)
[2]Westfälische Wilhelms-Universität, Institut für Geologie, Corrensstr. 24, D-48149 Münster, Germany

Many gas reservoirs contain appreciable percentages of gaseous dinitrogen besides the commercial valuable hydrocarbon gases. The source of this nitrogen and its transformation path to gaseous dinitrogen is still a matter of ongoing research (cf. [1], [2]).

To follow the transformation of nitrogen in organic rich sediments and sedimentary rocks during burial history with increasing pressure and temperature different approaches have been followed in this study: (1) Two sets of natural maturity series of type II or type III kerogen containing sediments and sedimentary rocks have been analysed with respect to several forms of nitrogen: exchangeable NH_4^+, N in the bitumen, HCl-hydrolysable N (amino-N in kerogen and N in clay minerals), kerogen bound N and N fixed in feldspars and other acid-stable minerals. In addition to the concentrations of the different nitrogen forms the nitrogen isotopic composition was investigated. (2) For the low maturity sediment and sedimentary rock samples artificial heating experiments in closed gold capsules as well as in flexible gold-titanium cells at high pressures and temperatures have been conducted to simulate the natural maturation process.

The results clearly document the release of organically bound nitrogen during early maturation – and a concomittant increase in dissolved inorganic nitrogen concentrations. With elevated ammonium concentrations in the pore water the incorporation of ammonium into authigenic minerals increases. This mineral-bound nitrogen is fixed until the mineral phase is destabilised by higher p-T-conditions or changing aqueous fluid compositions. The final transformation of ammonium released from minerals to gaseous dinitrogen might be a consequence of redox reactions involving mineral surfaces. At very high temperatures dinitrogen might be formed from organically bound nitrogen in type III kerogen.

U-Pb and Pb-Pb dating of phosphates in Martian meteorites

YOSHI. OTA[1]*, N. TAKAHATA[2], Y. SANO[3] AND N. SUGIURA[4]

[1]School of Sci., Univ. of Tokyo, Tokyo 113-0033 Japan (*correspondence: y_ohta@aori.u-tokyo.ac.jp)
[2]AORI. Univ. of Tokyo, Kashiwa 277-8564 Japan (ntaka@aori.u-tokyo.ac.jp)
[3]AORI. Univ. of Tokyo (ysano@aori.u-tokyo.ac.jp)
[4]Sch.of Sci., Univ. of Tokyo (sugiura@eps.s.u-tokyo.ac.jp)

There are many studies that measured U-Pb and Pb-Pb ages in phosphates of Martian meteorites. The ages of Shergottites are controversial, ranging from 4 billion years [1] to 200 million years [2] and are not well constrained. The ages are very important for understanding Martian evolution.

Here we show the U-Pb and Pb-Pb ages in several Martian meteorites. ALH84001, Zagami, DaG476 and some other Martian meteorites were investigated. For U-Pb and Pb-Pb dating by NanoSIMS, primary O- ions with a beam intensity of 10nA were used in a spot diameter of about 10-20 micrometer. An apatite from Prairie Lake called PRAP with a known age [3] was used as a standard for Pb/UO-UO/UO_2 calibration. The age of ALH84001 is about 4 billion years and it is consistent with those of the previous studies [4] within the experimental error. Our U-Pb age of phosphate minerals in Zagami are very young, suggesting that it was reset by some recent metamorphism. However the Pb-Pb isochron age at the same spots of U-Pb dating is about 4 billion years. This age is derived from two grains. Our data suggest that Zagami crystallized at 4 billion years ago, and it experienced some recent metamorphism to reset the U-Pb age. At the poster session I will discuss the implication of the U-Pb and Pb-Pb ages of ALH84001, Zagami and other Martian meteorites.

Origins of chromite found in chemical and clastic sedimentary rocks of the 3.2 Ga Moodies Group, South Afirica

T. OTAKE[1]*, Y. SAKAMOTO AND T. KAKEGAWA

Department of Earth Science, Tohoku University, Aoba 6-3, Aramaki, Aoba-ku, Sendai, 980-8578, Japan (*correspondance : totake@m.tohoku.ac.jp) (y-sakamoto@m.tains.tohoku.ac.jp, kakegawa@m.tohoku.ac.jp

The timing of the emergence of oxygenic photoautotrophs (e.g. cyanobacteria) is critical for understanding the evolution of life and the earth's surface environments. Yet, no palaeontological or geochemical signature in sedimentary rocks has provided unequivocal evidence for the emergence of cyanobacteria in the Archean era. The objective of this study was to find mineralogical and geochemical signatures that mark the emergence of cyanobacteria in a shallow ocean environment from the the Moodies Group, South Africa (~3.2 Gyr), in which Javaux *et al*. (2010) [1] discovered large, well-preserved microfossils, possibly the remnants of eukaryotes. We were particularly focused on the origins of chromite ($FeCr_2O_4$) and magnetite (Fe_3O_4), which contain the redox-sensitive elements, iron (Fe) and chromium (Cr), found in the chemical and clastic sedimentary rocks.

Our samples collected from underground mines (e.g. Sheba gold mine) were divided into 3 groups, based on the dominant iron-bearing mineral: the Siderite ($FeCO_3$), Mgnetite, and Hematite (Fe_2O_3) groups. While fine-grained (<5 μm in diameter) hematite, or ferric hydroxide ($Fe(OH)_3$) as its precuror, was interpreted to have been directly precipitated from seawater, large-grained (>50 μm in diameter) magnetite and siderite were interpreted to have formed during early diagenesis. We identified two types of chromite: eudheral and unhedral chromite. All eudheral chromite, which was observed in the Magnetite group, was overgrown by magnetite. This suggests that both euhderal chromite and magnetite in the Magnetite group were formed during diagenesis. On the other hand, unhedral chromite in the Siderite group was often included in silicate minerals (e.g. chlorite and biotite), indicating that it is detrital in origin. A positive correaltion between the Cr/Ti ratio and the U/Th ratio in the bulk chemical composition of the Magnetite group may suggest that both Cr and U were transported to the ocean through oxidative chemical weathering, and therefore that cyanobacteria was emerged before 3.2Ga.

Uranium speciation in opals from the Nopal I deposit (Mexico)

G. OTHMANE[1]*, T. ALLARD[1], N. MENGUY[1], T. VERCOUTER[2], G. MORIN[1], G. CALAS[1] AND M. FAYEK[3]

[1]IMPMC, CNRS UMR 7590, UPMC, Paris, France (*correspondence: guillaume.othmane@impmc.upmc.fr)

[3]University of Manitoba, Canada

The study of uranium migration and trapping in the environment is relevant to assess the safety of potential high-level nuclear waste repositories (HLNWR). The Nopal I uranium deposit (Sierra Peña Blanca, Mexico) is a natural analogue of HLNWR located in volcanic tuff. Secondary uranyl minerals such as uranophane and weeksite occur in the deposit and are coated by opal [1], [2].

The aim of this study is to determine the uranium speciation in these opals to reveal the low temperature conditions of trapping of this element, from the micrometer scale of electron microscopy to the molecular scale provided by fluorescence spectroscopy.

Uranium speciation was found to be various and complex. We evidenced by scanning electron microscopy (SEM) microparticles of ß-uranophane Ca $[(UO_2)(SiO_3OH)]_2$ $(H_2O)_5$ and apatite Ca_5 $(PO_4)_3$ (OH, Cl, F) containing small amounts of uranium. However the major part of uranium is concentrated in Ca-U-enriched zones with a Ca:U ratio of 1:1 and displaying spherical features (Fig. 1).

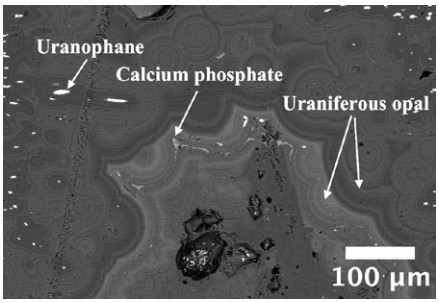

Figure 1: SEM back-scattered electron picture of a yellow opal cross-section from the Nopal I uranium deposit, Mexico.

The exact nature of Ca-U species in these zones was not determined but transmission electron microscopy (TEM), cathodoluminescence and time-resolved laser fluorescence spectrocopy (TRLFS) analyses suggest the presence of Ca_m-$(UO_2)_m$-$(O/OH/H_2O)_n$ complexes adsorbed or incorporated in opal. These results will be discussed in terms of chemical conditions that prevailed during U incorporation.

Density functional theory study of the interaction of arsenic complexes with FeOOH surfaces

KATRIN OTTE*, WOLFGANG W. SCHMAHL AND ROSSITZA PENTCHEVA

Department of Earth and Environmental Sciences, University of Munich, Theresienstr. 41, 80333 Munich, Germany (*correspondence: Katrin.Otte@lrz.uni-muenchen.de, Pentcheva@lrz.uni-muenchen.de)

Iron oxyhydroxides (FeOOH) possess high surface areas which are relevant for cycling and retention in a series of environmental and technological processes [1]. Using density functional theory (DFT), we explore the stability and electronic properties of the goethite (101), akaganeite (100), and lepidocrocite (010) surfaces under different environmental conditions. The GGA+*U* calculations reveal that the termination impacts the oxidation state of the surface iron ions, providing a possibility to tune the catalytic activity. The energetics and bonding mechanisms of arsenic complexes in different adsorption geometries (e.g. mono- and bidentate) on the surfaces are investigated.

Funding by the BMBF programme Geotechnologies: Mineral Surfaces (Project SURFTRAP) and Elitenetzwerk Bayern is acknowledged.

[3]Aerodyne Research, Inc., Billerica, Massachusetts, USA

[4]Physics Department, University of Helsinki, Helsinki, Finland

Marine aerosol has a strong impact on both the Earth's albedo and climate; however, its inherently complex composition ranging from inorganic components (sea salt, nss sulfate) to complex organic carbon mixtures of water soluble and insoluble components [1, 2] and bio - aerosol components [3] complicates the quantification of those impacts. In recent years, the dominant organic matter (OM) contribution (in particular, the primary organic matter) to submicron marine aerosol during periods of high biological activity over N.E. Atlantic has been quantified on a seasonal basis [1] as well as in real-time [4]. However, the character of its influence on cloud formation is still undergoing an intense discussion. Here, we present the comprehensive long term real time ambient aersol measurements which reveal the important role of marine organics to cloud formation: the recurrent enhancement of cloud formation activity (cloud condensation nuclei) under aerosol enrichment by primary organics with low hygroscopic growth factor is reported for the first time. Moreover, the complexity of organic matter identified by high resolution time of flight aerosol mass spectrometry (HR-ToF-AMS) and its interpretation from HR-PMF (Positive matrix factorization) revealed a dominant contribution of primary sources to marine organic aerosol, with unique marine organic aerosol fingerprint, when compared to anthropogenic organic aerosol.

First principles investigation of manganese oxide surface chemistry

GLORIA A.E. OXFORD* AND ANNE M. CHAKA

National Institute of Standards and Technology, Gaithersburg, MD 20899, USA
(*correspondence: gloria.oxford@nist.gov)

Manganese oxides, which are ubiquitous in geological settings, play an important role in heavy metal adsorption and oxidation in the environment. In particular, the ability of manganese oxides to oxidize trivalent chromium to hexavalent chromium has garnered considerable attention, but questions remain concerning the mechanim of oxidation. To accurately model hexavalent chromium transport and its fate in the environment, the specific interactions between chromium ions and manganese oxide surfaces must be ascertained. Because structure, composition, and chemical properties of surfaces are intimately related to reactivity, a fundamental understanding of manganese oxide surface reconstructions and redox behavior lays the foundation for investigating oxidation mechanisms involving manganese oxides. However, detailed structural analyses of manganese oxide surfaces under environmentally relevant conditions are scarce.

We have combined periodic density functional theory calculations and *ab initio* thermodynamics to identify stable surface terminations of the β-MnO_2 (110) and γ-MnOOH (010) surfaces and to determine their redox behavior in response to varying oxygen and water chemical potentials. Reduction of the surfaces produces interesting surface reconstructions driven by the competition between lattice constraints and optimal *d*-orbital occupation and manganese coordination geometry. Multiple oxidation states are found at the surfaces due to Jahn-Teller effects. Under ambient conditions, oxidation of the γ-MnOOH (010) surfaces is predicted to be favorable, while the reduced β-MnO_2 (110) and γ-MnOOH (010) surfaces are not stable but may become relevant during heavy metal oxidation processes at the surface. Molecular and dissociative adsorption of water on the clean surfaces significantly lower the surface free energies. Binding sites for trivalent chromium on the hydrated surfaces will be presented with a focus on the effect of manganese oxidation state on adsorption geometry.

Modeling oceanic anoxia/euxinia induced by massive CO_2 injection

K. OZAKI[1]* AND E. TAJIKA[2]

[1]University of Tokyo, Tokyo, 113-0033, Japan
(*correspondence: ozaki@eps.s.u-tokyo.ac.jp)
[2]University of Tokyo, Chiba-ken, 277-8561, Japan

Atmosphere-ocean biogeochemical cycle model

Rapid global warming caused by large igneous provinces (LIPs) has been suggested as the cause of ocean anoxia. To constrain the required conditions for the occurrence of oceanic anoxic event (OAE) and investigate the climate change during OAE, we constructed the atmosphere-ocean biogeochemical cycle model. The ocean model [1] can reproduce the vertical distribution of several dissolved components (e.g. PO_4, O_2, H_2S, DIC, Alk) in the water column. We also consider the kinetic treatment of carbonate dissolution in the ocean. Hence, carbonate compensation depth (CCD) can also be calculated. The simplified chemical (carbonate and silicate) weatheriing on land and air-sea exchange of CO_2 were also included.

Results and discussions

We conducted the sensitivity analyses of CO_2 injection event systematically with several initial conditions (we especially focused on pCO_2, pO_2, SST, and shelf area) because climate and geographical setting would affect the required amount of CO_2 and behaviour of climate change. Simulations indicate that (1) enhanced nutrient (phosphorus) input to ocean effectively promote the oceanic productivity, resulting in an expantion of oxygen minimum zone and nutrient efflux from the surface sediments to the bottom waters, (2) global eutrophication (and anoxia) can be induced by a positive feedback loop among anoxia, phosphorus regeneration, and surface productivity, (3) once global anoxia achieve, enhanced accumulation of organic carbon in marine sediments acts as a buffer against global warming, resulting in climate cooling during OAE in some cases.

In this presentation, we will also discuss the effect of initial conditions on the required amount of CO_2 for the occurrence of global anoxia. We conclude that historical background has an important role in the required conditions for OAEs.

Petrographic and geochemicial characteristics of dolomites in the Golbogazı Formation (Upper Devonian) at SW of Hadim, (Konya - Turkey)

ALI MUJDAT OZKAN AND EMRE BICER

Selcuk University, Engineering Faculty, Department of Geological Engineering, Konya – Turkey (mujdatozkan@selcuk.edu.tr)

Upper Devonian units, locating Central Taurus composed of thick dolomite with massive limestones layers and thinner dolomite layers with intercalated limestone are described. Various dolomite types include: Type I) dolomite formed as dolomicrite as mimic replacement, Type II) the planar-e texture dolomites are scattered in a micritic matrix, Type III) fracture and void filling dolomite (zoned dolomite, overgrowth and saddle), Type IV) brecciated dolomite, and V) polymodal dolomite.

The Sr content in the Golbogazı Formation (184 to 74 ppm in the early dolomites, and 105 to 78 ppm in the late dolomites, respectively) is compatible with the Sr concentration mixing-zone dolomites. The Na content in the Golbogazı Formation (593 to 148 ppm in the early dolomites, and 519 to 297 ppm in the late dolomites, respectively) is compatible with the Na concentration mixing-zone dolomites. The investigated dolomites exhibit -1.95 to -3.46 PDB in $\delta^{18}O$ values relative to their $\delta^{13}C$ values (1.33 to -1.33 PDB) in the early diagenetic dolomites. The late diagenetic dolomites display -3.96 to -9.44 PDB in $\delta^{18}O$ values relative to their $\delta^{13}C$ values (2.52 to -1.58 PDB).

REE	Samples		Normalized values			
	Rocks	Str. Sed.	Chondrite	Peridotite	MORB	NASC
La	22,1	24,1	67,0	22,3	6,0	0,7
Ce	44,8	49,2	52,1	17,0	3,9	0,6
Pr	5,4	5,3	44,8	15,8	3,0	0,6
Nd	20,7	20,3	33,3	11,5	2,1	0,7
Sm	4,1	4,1	20,3	7,5	1,2	0,7
$\sum_{LREE}$	97,1	103				
Eu	0,8	0,9	11,4	3,8	0,6	0,6

Tb	0,7	0,7	13,7	4,9	0,8	0,7
Dy	3,8	4	11,6	4,0	0,7	0,7
Ho	0,7	0,8	10,3	3,4	0,6	0,6
Er	2,4	2,5	11,0	4,0	0,7	0,7
Tm	0,4	0,4	12,0	4,0	1,1	0,7
Yb	2,4	2,5	10,8	4,0	1,1	0,8
Lu	0,3	0,4	12,3	3,7	1,0	0,8
$\sum_{HREE}$	15,2	16				
$\sum_{REE}$	112,3	119				

As a result, the Golbogazı Formation dolomites have been formed as early diagenetic at the shallow marine environment and as the late diagenetic at the shallow-deep burial depths.

Comparison of REE concentrations between the Bozkir ophiolitic rocks and stream sediments derived from these rocks in the Bozkır Region (Konya – Turkey)

A. ÖZTÜRK*, F. ARIK AND M. KARADAG

Selcuk University, Geological Engineering Department, Konya, Turkey (*correspondence: acan@selcuk.edu.tr)

The study area located in south and east of Bozkır (Konya-TURKEY), covers approximately 250 km^2. The units cropped out in the study area are Geyikdağı (slightly metamorphic detricious and carbonaceous rock), Bozkır (ophiolitic rocks such as serpentinite, pyroxenite, gabbro, radiolarite, chert, limestone) and Bolkardağ (generally limestones) tectonic units from bottom to top. This study aims investigation of REE concentration of the rocks and stream sediment samples derived from Bozkir Ophiolitic Melange and comparison between the two mentioned groups [1, 2].

REE contents of the rock samples higher than those of the chondrite and peridotite while lower than that of NASC. $\sum$REE, HREE $_{(La-Sm)}$ and LREE $_{(Gd-Lu)}$ of the rocks are 112.2, 97 and 15.2 ppm respectively. REE contents of stream sediments higher than that of the rock samples (Table 1).

Table 1. REE contents of the rock and stream sediment and normalized values to the some reference rocks.

Some normalized values of the rock samples to the chondrite such as La/Lu, Gd/Yb, Eu/Eu* and Ce/Ce* are 5.44, 1.27, 0.68 and 0.93.

Mineralogy and geochemistry of the Yellice magnetite occurrences of Sivas-Central Anatolia, Turkey

C. OZTURK*, T. UNLU AND İ.S. SAYILI

Ankara University, Department of Geological Engineering, 06100, Tandoğan, Ankara
(*correspondence: cozturk@eng.ankara.edu.tr)

Ophiolitic rocks, trusted tectonically over Munzur limestones of Taurus platform and emplaced during Maastrichtian form the basement of the study area.

The primary ore mineral at Yellice is magnetite in serpentinized ultramaphic rocks of ophiolites. Other ore minerals are chromite, machinavite inclusions bearing pentlandite, pyrrhotite, cubanite lamellae bearing chalcopyrite and pyrite characterizing a liquid magmatic phase. Secondary magnetites of a subsequent phase are formed from ferromagnesian minerals during serpentinization processes.

XRD studies carried on post-tectonic basin deposits (e.g. basalts) indicate albite, calcite, augite, chlorite, olivine and lizardite minerals which point out to minerals occurred by ocean floor metamorphism [1]. Two different mineral assemblages occur in serpentinites. The first paragenesis is antigorite, talc, magnetite, magnezite and chlorite which indicate nearly 400-500 °C temperature conditions [2]. The second paragenesis represented by chrysotile, lizardite, diopside, augite, tremolite, actinolite, calcite, quartz, chromite, magnetite, olivine and talc characterize approximately 350-400°C temperatures and suggests an ocean floor (or hydrothermal) metamorphism [3].

Raman studies revealed that the plagioclases of basaltic rocks are albitized by the affects of sea water. Some pyroxenes are replaced by actinolites due to uralitization.

Consequently, lens shaped magnetite ores with an average grade of 18-20 % Fe_3O_4 and 125 millions tons of tonnages in serpentinites suggest an assemblage of primary minerals formed in upper mantle conditions and a further element association by serpentinization processes.

Arsenic and its compounds in plants growing in soils contaminated by mining activities

I. PACÁKOVÁ[1], J. SZÁKOVÁ[1]*, W. GOESSLER[2] AND P. TLUSTOŠ[1]

[1]Czech University of Life Sciences, CZ-165 21 Prague 6, Czech Republic (*correspondence: szakova@af.czu.cz)
[2]Karl-Franzens-University Graz, Universitaetsplatz 1, A-8010 Graz, Austria (walter.goessler@uni-graz.at)

Areas of silver and gold ore deposits associated with elevated concentrations of arsenic-bearing elements of the Bohemian Massif were investigated to assess uptake of arsenic species by individual plant species growing at these sites. The areas of the interest were: i) Kaňk near Kutná Hora, Central Bohemia, where the plant species were collected at dump remaining after medieval silver mining. The total arsenic contents in the soil ranged from 100 to 450 mg kg^{-1}. ii) Spoil close to former gold mine in Roudný, Central Bohemia, where the mining activities were stopped in 1930's. The total arsenic contents in the soil ranged from 50 to 1100 mg kg^{-1}. iii) Former mining area Nalžovské Hory, Western Bohemia, where silver was mined till the beginning of 17th century with total As concentrationsin the soil between 70 and 75 mg kg^{-1}.

Results and Discussion

Arsenite, arsenate, dimethylarsinic acid (DMA), methylarsonic acid (MA), trimethylarsine oxide (TMAO), the tetramethylarsonium ion (TETRA), arsenocholine (AC), and arsenobetaine (AB) were commonly found in the plant species. Among the species determined, high arsenobetaine concentrations represent the most interesting finding. Among the plant families, AB was identified in the species representing *Poaceae, Cyperaceae*, and *Plantaginaceae families*. *Similar findings were already published by* Geiszinger *et al*. [1] where arsenocholine and arsenobetaine were detected in *Trifolium pratense*, *Dactylis glomerata*, and *Plantago lanceolata* collected at an arsenic containing ore vein. The results showed the ability of higher plants to produce and/or accumulate a wide spectrum of arsenic species. Their fate and transformations in plant tissues needs intensive research especially when elevated total As concentrations are in the plant biomass.

The $\delta^{18}O$ fingerprint of spring water pathways with evaporating recharge areas

F.A.L. PACHECO [1] AND C.H. VAN DER WEIJDEN[2]

[1]Department of Geology and Centre for Chemistry, UTAD, Vila Real, Portugal (fpacheco@utad.pt)
[2]Utrecht University, The Netherlands (chvdw@geo.uu.nl)

Evaluation of the mean recharge elevation of a spring in a mountainous area by extrapolation using the vertical isotopic gradient of local precipitation assumes that evaporation is limited during the period of recharge. Usually, this assumption fails when recharge takes place in low permeability rocks (e.g. granites). In these cases, water remains variable periods of time in the recharge cells to ensure replenishment of local, intermediate and regional flow circuits. Preservation in the recharge area potentiates evaporation and therefore the enrichment of recharge water in ^{18}O. Resulting from evaporation, an isotopic gradient develops for spring waters, represented by a negative correlation between $\delta^{18}O$ in spring water and elevation. The lines representing the isotopic gradients of precipitation and spring water are expected to converge towards the recharge area and diverge in the opposite direction. The recharge area will be defined by the sectors of the catchment where $\delta^{18}O$ (precipitation) - $\delta^{18}O$ (spring) = 0. A result corroborating this approach is illustrated in Fig. 1 for the Sordo River basin (North of Portugal).

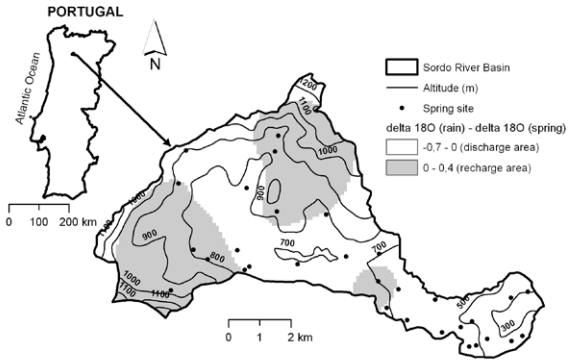

Figure 1: Recharge areas of Sordo River basin

Holographic interferometry study of the inhibition of gypsum dissolution

E.A. PACHON-RODRIGUEZ AND J. COLOMBANI

Laboratoire de Physique de la Matière Condensée et Nanostructures, Université de Lyon, Université Claude Bernard Lyon 1 and CNRS, 69622 Villerbanne, France (Jean.Colombani@univ-lyon1.fr)

The knowledge of the dissolution properties of gypsum in aqueous solutions is of primary importance in many situations, among which the weathering of rocks, the gypsum karst formation, the quality of drinking water, the scale formation in the oil and gas industry, and the liberation of calcium ions, useful for the geological storage of CO_2.

In standard dissolution experiments, the mineral is dissolving in stirred water. So the dissolution kinetics is blurred by diffusive and convective contributions. For hard minerals, dissolution is so slow that it drives the whole kinetics and the convection contribution can be neglected. But for softer minerals like gypsum, dissolution, diffusion and convection timescales are of the same order of magnitude and their respective contribution can be difficult to distinguish.

We have collected dissolution rates of gypsum in water measured by various methods found in the literature. The deduced dissolution rate constants span over several decades. Therefore we have analysed the hydrodynamics of the experimental setups, eliminated the convective contribution and deduced from them the pure surface reaction rate constant of gypsum in water. It appears to be much smaller than expected from the literature results. An holographic interferometry experiment, performed in still water, is carried out and enables to measure directly this rate constant. Both values agree within experimental uncertainty.

We have made use of this methodology to investigate the influence of various salts, known for their calcium-complexing influence, on the dissolution rate of gypsum. These agents provoke a decrease of the surface reaction rate constant of gypsum of up to more than one order of magnitude (cf. Fig. 1).

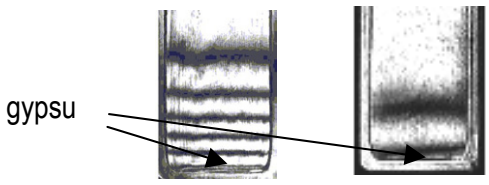

Figure 1: Holointerferograms of the dissolution of a gypsum sample in pure water (left) and in a phosphate salt aqueous solution (right) at rest.

Viruses: A key role in microbial mat mineralization

MURIEL PACTON[1]*, DAVID WACEY[2,3], MATT R. KILBURN[2], GEORGES E. GORIN[4] AND CRISOGONO VASCONCELOS[1]

[1]ETH Zurich, Geological Institute, Zurich, Switzerland (*correspondence: muriel.pacton@erdw.ethz.ch)

[2]Centre for Microscopy, Characterisation and Analysis, The University of Western Australia, Crawley, WA, Australia

[3]School of Earth and Environment, The University of Western Australia, Crawley, WA, Australia

[4]Earth Science Section, University of Geneva, Geneva, Switzerland

In microbial mats, microbes mediate the formation of mineral layers, most commonly carbonates, through the process of organomineralisation, and in doing so enhance their preservation potential in the geological record; Cell walls, sheaths and extracellular polymeric substances (EPS) matrix are currently thought to be the main templates for such mineral precipitation. Nanometer-scale spheroids (20-200 nm) have been widely found in the geological record and are thought to initiate precipitation. Previously, these nano-spheres have been interpreted as fossilised bacterial remains [1] such as nannobacteria, proteins and, more recently, EPS [2].

This study focuses on organomineralisation in a living, hypersaline, non-lithifying microbial mat from Lagoa Vermelha, Brazil, where mineralized nano-scale spheroids have been found. Correlative NanoSIMS and TEM analyses of the same sample area show a one-to-one correlation of nano-scale spheroid morphology, organic material and mineralogy. These results indicate that viruses, which cause the death of the bacteria and then become mineralized upon release, are the most likely origin of these spheroids. The infection of microbial mats by viruses appears to be significant in preserving one of Earth's most primitive and enduring ecosystems in the fossil record.

[3]Instituto Andaluz de Ciencias de la Tierra (IACT), CSIC & UGR, Facultad de Ciencias. 18002 Granada, Spain

Dehydration fronts in metamorphic terrains are mechanically distinct zones where fluids and grain-scale porosity are generatated. Their temporal evolution is a complex interelationship between metamorphic and compactation timescales leading to several mechanisms of fluid expulsion and kinetic fluctuations [1]. An exceptionally well preserved dehydration front, corresponding to the high-pressure (680-710°C and 1.6-1.9 GPa) antigorite breakdown reaction (Atg-out), crops out in Cerro del Almirez (Betic Cordillera, Spain), which displays a complete sequence of metamorphic reactions and allied textures [2, 3]. Detailed mapping of the Atg-out front shows that, between Atg-serpentinite and prograde Chl-harzburgite, a narrow band (up to 8 m thick) occurs of transitional lithologies consisting of chlorite-antigorite-olivine-serpentinite (Chl-serpentinite), grading through antigorite-chlorite-orthopyroxene-olivine (Atg-Chl-Opx-Ol) rocks to Chl-harzburgite (Ol-Opx-Chl). Mass balance calculations and phase diagram considerations indicate that HP Atg breakdown occurred by the sequential formation of: Chl-serpentinite through the reaction,

$$\text{Atg (Al-rich)} + \text{Ol} = \text{Atg (Al-poor)} + \text{Chl} + \text{fluid} \quad (1)$$

and Atg-Chl-Opx-Ol assemblage through the reaction,

$$\text{Atg} = \text{Ol} + \text{Opx} + \text{Chl} + \text{fluid} \quad (2)$$

Observed continuous chemical changes and progresive grain coarsening suggest that these reactions took place at near equilibrium conditions. These observations are important to unravel the kinetics and fluid expulsion mechanisms of this natural dehydrating system.

Methane and the PETM: All good things must come to an end?

M. PAGANI[1], R. DECONTO[2], S. GALEOTTI[3] AND D. BEERLING[4]

[1]Yale University, Deptartment of Geology and Geophysics, New Haven, CT, 06520 USA (mark.pagani@yale.edu)

[4]Department of Animal and Plant Sciences, University of Sheffield, Sheffield S10 2TN, UK (d.j.beerling@sheffield.ac.uk)

Global warming during the Paleocene Eocene Thermal Maximum is often explained by a massive release of methane hydrates. However, modeled methane hydrate abundances during warm climates are lower than required to explain the carbon isotope shift that characterizes the PETM. Even if ancient hydrate abundances were greater than model predictions, a very high climate sensitivity to CO_2 would be required to explain the magnitude of warming during the event. While some portion of this high apparent climate sensitivity could be related to an assumed pre-warming that triggered hydrate instability, evidence for that warming is weak at best, and why this warming occurred repeatedly to trigger successive hyperthermals has never been adequately addressed.

In contrast to the methane paradigm, an emerging supposition involving the storage and orbitally controlled release of terrestrial carbon from the arguably vast permafrost reservoirs of Antarctica and the high Arctic region readily explains the warming characteristics of the early Cenozoic hyperthermals. Modeled permafrost carbon estimates and simulations accounting for rising background greenhouse gas concentrations and orbital variability demonstrate terrestrial permafrost thawed during high eccentricity and obliquity orbital nodes once a long-term warming threshold was reached. This new supposition allows for the massive amount of carbon necessary to explain the magnitude of carbon isotope shifts, a reasonable climate sensitivity to CO_2, and the mechanistic basis for repeated warming events during an ever-warming planet.

Oxidized organic aerosol components in Cabauw, Netherlands, during the May 2008 EUCAARI IOP: NMR spectroscopic characterization and factor analysis

M. PAGLIONE[1], E. FINESSI[1], S. DECESARI[1], A. KIENDLER-SCHARR[2], A. MENSAH[2], M. STOCCHERO[3] AND M.C. FACCHINI[1]

[1]National Research Council (CNR), Institute of Atmospheric Sciences and Climate (ISAC), Bologna, Italy, +39-051-6399578 (m.paglione@isac.cnr.it)
[2]Forschungzentrum Jülich (ICG), Germany
[3]S-IN Soluzioni Informatiche, Vicenza, Italy

Outside urban areas, oxidized organic aerosols (OOA) dominate the composition of the organic atmospheric particulate matter. In the frame of the EUCAARI (European integrated project on Aerosol Cloud Climate Air Quality Interactions) project, the submicron aerosol chemical composition in Cabauw, Netherlands, was characterized by means of proton-Nuclear Magnetic Resonance (^{1}H-NMR) spectroscopy with aim of organic aerosol characterization and source apportionment. The analysis was applied to water-soluble organic aerosols (WSOA), which is a proxy for OOA.

A set of 25 PM1 filter samples, collected in a period of prolonged stable anticyclonic conditions and of accumulation of pollutants, were analysed by ^{1}H-NMR spectroscopy and the resulting collection of spectra was processed using a suite of chemometric techniques, including PCA, cluster analysis and factor analysis (PMF, NMF, MCR) aiming to identify recurrent spectral profiles, to quantify their relative contributions and so to identify different prevalent sources.

Factor analysis identified three factors with characteristic spectral profile: (a) OOA associated to metanesulphonic acid (MSA), (b) humic-like substances (HULIS) and (c) other complex OOA enriched in aliphatic acids. The analysis of metadata (meteorological variables, concentrations of nitrate, sulfate, ammonium, potassium, black carbon, and air masses origin), shows that the MSA-containing OOA factor is associated to northerly marine air masses, the HULIS are carried by polluted continental air masses, whereas the aliphatic-rich OOA have no clear dependence on wind direction.

The comparison of these results with those of Positive Matrix Factorization (PMF) applied to a parallel AMS dataset showed a good agreement between NMR 'HULIS'-factor and one type of AMS 'LV-OOA' (a-type).

Volatile loss via outgassing of the lunar magma ocean

KAVEH PAHLEVAN* AND SHUN-ICHIRO KARATO

Department of Geology and Geophysics, Yale University, New Haven, CT 06520
(*correspondence: kaveh.pahlevan@yale.edu)

Among the most striking observations made of the Apollo samples is the depletion of trace elements in lunar materials [1] including moderately volatile elements (i.e. potassium) that condense from the solar nebula at relatively high temperature (T > 1000 K). While initially thought to be a feature of the degassing of lunar magmas into vacuum, the depletion of volatile elements in lunar samples has since been established as a feature of interior reservoirs [2] and therefore potentially diagnostic of the processes of lunar formation. While this observation is generally thought to be consistent with the high energy events associated with a giant impact, no quantitative scenario has been put forward to explain it. In particular, the settings and processes relevant to the volatile loss episode(s) have not been identified, and the isotopic signatures expected for the various scenarios have not been developed.

The energy released in the Moon-forming giant impact is sufficient to melt and partially vaporize both the Earth and the impactor. The timescale to eliminate this heat by radiation is ~10^3 years [3]. Hence, the Earth-Moon system is expected to be in a melt-vapor state for the first thousand years after the giant impact. Moreover, the Moon-forming material may revaporize during the process of lunar accretion from a disk if the process is sufficiently rapid [4]. Previous work has shown that silicate vapors are gravitationally bound to the gravity field of the Earth, even at the high temperatures encountered after a giant impact [5]. We have investigated the conditions necessary for the efficient outgassing of the lunar magma ocean and hydrodynamic escape of the resulting transient atmosphere from the weak lunar gravity field. We will present predictions for isotopic signatures that can test and constrain such a scenairo experimentally.

Benthic fluxes of iron and manganese under various redox conditions

S. PAKHOMOVA

P.P.Shirshov Institute of Oceanology RAS, Moscow, Russia (s-pakhomova@yandex.ru)

Fluxes of dissolved forms of iron and manganese across the sediment-water interface were studied *in situ* in the Gulf of Finland and the Vistula Lagoon (Baltic Sea), and in the Golubaya Bay (Black Sea) from 2001 to 2005. Fluxes were measured using chamber incubations (Jch), and sediment cores were collected to assess the porewater and solid phase metal distribution at different depths to calculate diffusive flux (Jpw). Measured and calculated benthic fluxes of manganese and iron were directed out of sediment for all sites and were found to vary between 70–4450 and 5–1000 μmole m^{-2} day^{-1} for manganese and iron, respectively. Benthic fluxes of manganese were found to correlate with manganese concentration in the porewater of the top sediment layer positively. The manganese fluxes were not influenced by redox conditions in the near-bottom water. On a large timescale manganese fluxes depend on redox conditions in bottom water, because a change of redox conditions would lead to a change of dissolved manganese content of the porewater. However, on a timescale of a single chamber incubation manganese fluxes did not depend on oxygen concentration (redox conditions), because for dissolved manganese the rate of oxidation is much lower than the rate of release from sediment. Diffusive flux of manganese constitutes 25–70% of the measured flux determined with the chamber incubation (on average Jch/Jpw=3). This indicates that another processes such as bacterial dissolution or bio-irrigation also play an important role in manganese benthic flux formation. Our results showed the importance of bottom water redox conditions for benthic iron fluxes. We measured no fluxes at oxic conditions, intermediate fluxes at anoxic conditions and high fluxes at suboxic conditions. Oxidation of released dissolved iron occurred very rapidly under oxic conditions right after its release from the sediment. Under suboxic and anoxic conditions in the bottom water, the iron flux was dependent both on its concentration in porewater of the surface sediment and on the content of iron in the solid phase of sediment. The chamber measured and diffusive fluxes of total iron differed much more than for manganese, 0.01<Jch/Jpw<50. Thus, bio-irrigation, sediment resuspension and chemical processes at the interface are much more important for iron fluxes than for manganese fluxes.

Peformance characteristics of an enhanced Daly ion counting system for TIMS

ZENON PALACZ*, TONY JONES, DAMIAN TOOTELL, ROBERT GUEST AND STEVE LOCKE

Isotopx Ltd, Middlewich, Cheshire CW10 0GE,UK (*correspondence: Zenon.Palacz@isotopx.com)

We have developed matched and close-coupled pulse amplification electronics for the ion-counting Daly detector used on Phoenix and IsoProbe-T thermal ionization mass spectrometers. These developments have largely eliminated post pulse ringing and permit the use of very low discrimination thresholds resulting in a new ion-counting Daly detector system which is linear (within ~0.05%) from zero to 3.5e6cps (~50-60mV) using a single deadtime correction.

The large dynamic range of the new Daly provides a significant overlap with the range of the Faraday detectors. This provides an exciting opportunity to obtain high precision measurements of minor isotopes such as ^{234}U and ^{230}Th using a combination of Faraday and ion-counting Daly. It also extends the range of large ratios that can be measured by peak jumping on the Daly alone, eliminating the requirement for a Daly/Faraday gain calibration. The large dynamic range also provides the ability to resolve small differences in deadtime (<0.1ns) to allow accurate and precise measurements of Pb isotopes by peak jumping i.e. for high resolution geochronological applications.

A further benefit of the large dynamic range is the ability to measure 20-30mV ion signals with zero noise. This will be of real benefit for the measurement of sub-ng levels of e.g. Nd by peak jumping. It could also offer an alternative to the use of $1e^{12}\Omega$ gain resistors on Faraday detectors since noise, linearity and signal decay times are significantly better than can be attained using these resistors.

Examples of different applications will be presented with indications of the level of precision that can be attained using different analytical combinations.

Red Sea detritus provenance during MIS 6/5 and MIS 2/1 transitions

D. PALCHAN[1,2], M. STEIN[2], A. ALMOGI-LABIN[2], Y. EREL[1] AND S.L. GOLDSTEIN[3]

[1]Institute of Earth Science, The Hebrew University, Jerusalem, Israel (Pdanielos@gmail.com, yerel@vms.huji.ac.il)

[3]Lamont-Doherty Earth Observatory and Columbia University, 10964 Palisade, NY, USA (steveg@ldeo.columbia.edu)

The Red Sea (RS), located in the midst of the Arabian-Sahara desert belt, comprises a sedimentray trap for fine-grain detritus that is transported from its neigbouring continental terrains. Interpreting the fine detritus as desert dust we explored the mineralogy, grain-size, major and trace elements chemistry and Sr-Nd-Hf isotope composition of silicate material (insolbule in acetic acid) recovered from the sedimentary core KL-23, which was drilled in the northern RS (25°44' 88N 35°03' 28E). Core chronology is based on the SPECMAP $\delta^{18}O$ age model indicating that the core spans over 370 ka. We focused on two glacial interglacial transitions: MIS 6 to 5 and MIS 2 to 1 (~160-110 kyr BP and ~20-8 kyr BP, respectively) and analyzed the <63μm fraction of the insoluble material. The Nd-Sr-Hf isotopic ratios indicate contribution from two main lithological sources: 'granitic' material, which is common over the Arabian and Sahara crustal terrains and a 'basaltic' material, which possibly originated from the Cenozoic basaltic terrains at the southern margins of the RS. The 'granitic' source was more dominant during glacials while the 'basaltic' source contributes fine detritus immediately after glacial terminations and transitions to interglacials. Major elements reveal different effects of diagenetic–alteration processes reflecting possibly enhanced alteration during wetter periods in the basaltic source regions during interglacials.

Ti-in-quartz thermometry of siliciclastic metasedimentary rocks of the Otago Schist, New Zealand

J.M. PALIN*, C.L. KING, A. WILSON AND C.E. MARTIN

Department of Geology, University of Otago, P.O. Box 56, Dunedin 9054 New Zealand (*correspondence: michael.palin@otago.ac.nz)

We have used exposures of silicilcastic metasedimentary rocks of increasing grade from the margins to the core of the Otago Schist belt of New Zealand to examine changes in quartz Ti concentration due to re-equilibration and new crystallization at increasing P-T [1, 2]. Samples were taken across three well-documented metamorphic field gradients: Dansey Pass [3], Lindis Pass [4], and Lake Hawea/Haast River [5]. Quartz in thin sections and mineral separates was analyzed using LA-ICP-MS. Raw intensity data were normalized via the NIST 610 standard to obtain trace element concentrations.

There are systematic changes in the concentrations of Ti in quartz: (a) variability is greatest at low grade where re-equilibration of primary igneous signatures of detrital quartz is incomplete; and (b) quartz Ti concentrations increase systematically from moderate to high metamorphic grade. The latter provide metamorphic P-T constraints that agree with previous geothermometry for the rocks [6] for a reduced a (TiO_2) appropriate for textural equilibrium of quartz with titanite at low metamorphic grade and ilmenite at higher grades (Fig. 1).

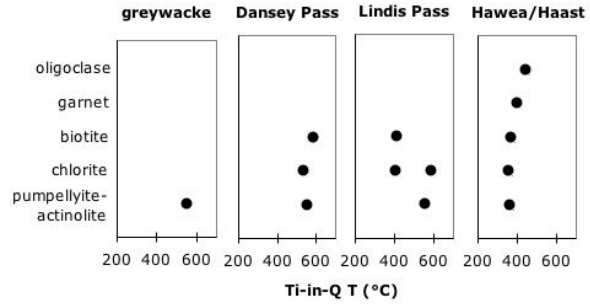

Figure 1: Ti-in-quartz temperatures calculated for P = 5 kb and $a(TiO_2)$ of 0.8 ± 0.2.

Al and Fe substitution in $MgSiO_3$ perovskite: An ^{27}Al and ^{29}Si NMR study

A.C. PALKE[1]*, J.F. STEBBINS[1], D.J. FROST[2] AND C.A. MCCAMMON[2]

[1]Department of Geological and Environmental Sciences, Stanford University, Stanford, CA 94305, USA (*correspondence: apalke@stanford.edu)
[2]Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany

This study involves ^{27}Al and ^{29}Si NMR spectroscopy on ^{29}Si- and ^{57}Fe-enriched, Al- and Fe-bearing $MgSiO_3$ perovskite of nominal composition $(Mg_{1-x}Fe_x)(Si_{1-x}Al_x)O_3$ ($x < 0.05$) in order to elucidate the substitutional mechanisms of Al and Fe. Previous ^{27}Al NMR studies have focused on Fe-free, Al-bearing $MgSiO_3$ perovskite; however, it is known that Fe has a dramatic impact on the incorporation of Al due to a coupled substitution of Al^{3+} and Fe^{3+} [1]. Nonetheless, the exact nature of Al substitution in the presence of iron (i.e. site occupancy of Al^{3+} and Fe^{3+}, order/disorder and distribution of the substituting cations, etc…) is incompletely understood. Mössbauer spectroscopy of our samples found bulk sample Fe^{3+}/Fe_{total} = 40-60%, indicating that coupled substitution of Fe^{3+} and Al^{3+} occurs to a significant extent. An analysis of ^{27}Al and ^{29}Si signal losses and peak widths with increasing Al and Fe content suggests a strong ordering of Fe^{3+} occurring in Mg^{2+} sites with Al^{3+} occupying adjacent Si^{4+} sites. However, particularly at higher concentrations of Al and Fe, it is clear that this coupled substitution is not the only mechanism operating in these samples. This study is an extension of previous work involving natural Fe-bearing pyrope garnet [2] and rare earth orthophosphates and builds on the insights obtained therein.

[4]School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta, GA 30332, USA (pvc@eas.gatech.edu)

Nitrate and sulfate are two important terminal electron acceptors for anaerobic respiration in littoral sediments. We investigated the environmental factors controlling potential rates of nitrate reduction and sulfate reduction (NRR and SRR) in a range of aquatic sediments. Reaction rates were determined on intact surface sediment slices sampled at 14 sites using flow-through reactors. Nitrate and sulfate were added separately or simultaneously. We used redundancy analysis to assess how environmental factors might control the variability of these rates.

On average, NRR exceeded SRR by one order of magnitude and 9% of the NRR can be accounted for by nitrate-mediated sulfide oxidation to sulfate in the studied sediments. When nitrate and sulfate were supplied simultaneously, the effect of nitrate on SRR was variable, ranging from near complete inhibition to 25% enhancement. Redundancy analysis showed that overlying water pH and salinity were the two most important predictors of variability of sediment potential NRR and SRR under all conditions. However, when nitrate and sulfate were added separately, sulfate concentration in the overlying water and sediment N content were additional factors explaining the variations of potential NRR and SRR. Furthermore, when the two electron acceptors were both present, the potential NRR and SRR were also controlled by sediment arsenic content besides pH and salinity. It suggests that different biogeochemical processes are involved in the N and S cycles in response to separate and simultaneous addition of nitrate and sulfate. These results indicate that controls on elemental cycling in systems subject to S and N pollution are more complex than formerly thought and point to the need to critically reassess the representation of anaerobic respiration kinetics and their interactions in diagenetic models.

Combining spot samples and continuous sampling to study small catchment storm runoff

M.R. PALMER[1]*, A. GKRITZALIS-PAPADOPOULOS[2] AND M.C. MOWLEM[2]

[1]School of Ocean & Earth Science, University of Southampton, Southampton SO14 3ZH, UK (*correspondence: pmrp@noc.soton.ac.uk)
[2]National Oceanography Centre, Southampton SO14 3ZH, UK

We have used two different sampling techniques to study the geochemical response of a small lowland rural catchment to episodic storm run off. The first method involves traditional daily spot sampling and has been used to develop a standard end member mixing analysis (EMMA) of the relative contributions of ground water flow and surface run off to the total stream flow. The second method utilises a continuous sampling device, powered by an osmotic pump, to produce an integrated 24-hour sample of the stream flow.

There is generally very good agreement between the patterns of solute chemistry measured from both sampling methods. The spot sample data can be used to construct a hydrograph separation model for the river chemistry that indicates the export chemistry is dominated by groundwater flow during low flow conditions and surface runoff during high flow conditions, but that the groundwater flux also increased during periods of high flow. Comparison between the chemistry predicted from the hydrograph separation model and the concentrations recorded by the continuous sampler are generally very good for most solutes. For NO_3, however, data from the continuous sampler indicates that there is a stored soil water reservoir that contains high NO_3 concentrations and is flushed during the rising hydrograph limb of a storm event. The continuous sampler data also indicates that the NO_3 concentration of this reservoir takes >7 days before it is replenished to pre-flushing event levels. Combined use of spot sample and continuous sample data can yield insights into the behaviour of nitrate during storm events, that are not apparent from spot sample data alone.

The elasticity of hydrous minerals in the lower mantle

M.G. PAMATO*, T. BOFFA BALLARAN, D.J. FROST, A. KURNOSOV AND D.M. TROTS

Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany (*correspondence: martha.pamato@uni-bayreuth.de)

Water is recycled into the Earth's interior by hydrous minerals in descending slabs and the amount of water that is transported into the deep mantle depends on the stability of high-pressure hydrous phases. As water plays an important role in mantle dynamics and planetary evolution, the study of the structure, elastic properties and stability of possible hydrous high-pressure phases in subducting slabs is of crucial importance.

A number of hydrous phases have been experimentally synthesized at pressures and temperatures compatible with subduction zone conditions. Very recently, a super aluminous version of the dense hydrous magnesium phase D (Al-phase D), was synthesized in a simplified basaltic bulk composition at lower mantle conditions [1]. The high temperature stability of this new form of phase D, which is stable up to 1600°C at 26 GPa, suggests that this phase may be an important host for water within portions of subducted oceanic crust in the Earth's lower mantle. Given the importance of such a hydrous aluminous phase and the fact that no similar phases have been previously reported, we investigated its elasticity.

High-pressure single crystal X-ray diffraction measurements were performed using a diamond anvil cell. Simultaneously S and P elastic wave velocities were measured using Brillouin spectroscopy. Preliminary results indicate that although Al-phase D can contain up to 16 wt% H_2O, the measured Vs and Vp are similar to that expected for an anhydrous lower mantle assemblage. Consequently if larger amounts of H_2O were present in this phase within the lower mantle it would have an undetectable seismic signature.

Interfacial thermodynamics: Inherent limitations of classical adsorption theories

G. PAN

Research Center for Eco-environmental Sciences, Chinese Academy of Sciences, Beijing, China (gpan@rcees.ac.cn)

Equilibrium adsorption properties defined by macroscopic parameters of adsorption densities (mol/m^2) are inherently ambiguous and do not obey conventional thermodynamic adsorption theories, because the energy states for different microscopic metastable-equilibrium adsorption (MEA) modes that construct real equilibrium state cannot be described by the macroscopic methodology such as adsorption density [1-2]. An initial concentration (C_0) effect, i.e. the dependence of equilibrium adsorption isotherms on the initial adsorbate concentration, was first found to be a fundamental macroscopic adsorption phenomenon [3-5]. A multi-batch adsorption experiment was designed to test this phenomenon in arsenate-TiO_2 system. Under the same thermodynamic conditions, when the initial adsorbate was added by multiple batches, adsorption isotherms declined as the multi-batch increased. Microscopic EXAFS analysis showed that at least two MEA states co-existed in the equilibrium samples: monodentate mononuclear (MM) and bidentate binuclear (BB) modes. The ratio of BB:MM increased as the multi-batch increased or as the C_0 decreased. Experimentally measured equilibrium isotherms/constants therefore fundamentally depend on the initial reactant concentrations (e.g. initial absorbate concentration and/or adsorbent concentration) and kinetic pathways since the surface molecular structures of different MEA states are generally affected by the kinetic/danamic processes [6-10]. Failure in recognizing this principle has greatly hindered our understanding and interpretation on many interfacial processes in earth, environmental, and engineering sciences.

Studying on tectono-geochemistry and rock ore specimens appraisal of Bangwei copper mine

PAN PING[1,2]*, HAN RUNSHENG[1] AND CHANG HE[1]

[1]Kunming University of Science and Technology, Southwest Institute of Geological Survey, Geological Survey Center for Non-ferrous Mineral Resources, Kunming, China (*correspondence: panping0815@vip.qq.com)

[2]Scientific Research Department, Kunming Metallurgy college, Kunming 650033,China

Bangwei copper mine is located in the east of Wendong-Fubang folded bundle, the copper-bearing limonite-quartz vein penetrate north-south fracture and 50 meters width fractured zone which along the Huimin group of Lancang of Proterozoic. The Occurrence is 300∠600, The thickness of single vein is about 1meter, mineralized zone extend 3 kilometers spasmodically. Mineral is mainly copper-bearing limonite. The gangue is composed of quartz and sericite, with a Honeycomb structure.The spectrum of ore contains: Cu-7000ppm, As-600ppm, Y-100ppm. It can be determined that the background value of ore-forming element by the statistical analysis of obtained data. It shows that the content changes of element of Sn, W, Cu, Pb, Zn focus on the rock mass of Indosinian and fracture of metamorphic rock nearby. There is significantly positive correlation between the content of element.

This paper studies on tectono-geochemistry of Bangwei copper and rock ore specimens appraisal, the results of ICP-AES is that the higher copper content reach 350ppm, 198ppm, and doesn't discover copper metallic minerals in rock ore appraisal. Based on previous work this paper considers that the metallogenic province is Cu, Fe abnormal of mineralization.

Response of continental biogeochemical processes to short- and long-term global warming

R.D. PANCOST[1]*, K. TAYLOR[1], C. HOLLIS[2], L. HANDLEY[1], R. REES-OWEN[1], E.M. CROUCH[2] AND S. SCHOUTEN[3]

[1]Organic Geochemistry Unit, School of Chemistry, University of Bristol, UK (*correspondence: r.d.pancost@bris.ac.uk, kyle.taylor@bris.ac.uk, luke.handley@gmail.com)
[2]Geological and Nuclear Sciences, P.O Box30-368, Lower Hutt, NZ (c.hollis@gns.cri.nz, e.crouch@gns.cri.nz)
[3]Royal Netherlands Institute for Sea Research, Texel, The Netherlands (schouten@nioz.nl)

Much work on past hyperthermals, and especially the Paleocene-EoceneThermal Maximum (PETM), illustrates that rapid global warming caused dramatic changes in the continental hydrological, erosional and weathering regime. Evidence for such changes include higher plant δD records indicative of increased moisture transport to the poles, lithlogical and organic geochemical evidence for increased erosion and transport of sediments to marginal marine settings, and osmium isotopic evidence for increased chemical weathering. Here we compare the impact of these transient events to that of the longer term global warming that occurred from the mid-Paleocene to mid-Eocene.

New short-term records from Tanzania and NZ provide further evidence for a reorganisation of the global hydrological cycle coinciding with the onset of the PETM. They also document increased inputs of terrigenous biomarkers into marginal sediments, complementing previous work from, for example, the North American margin, the Arctic Ocean and the Tethyan realm.

In contrast, longer term terrigenous biomarker records document no difference between relatively cooler (Late Paleocene, Middle Eocene) and warmer (Early Eocene) intervals. Where the records do exhibit variability, they do not inidcate elevated terrigenous inputs during warm intervals. This is expected as the long-term control on erosion will be dictated by the temperature-mediated balance between uplift and denudation. By comparison, the dramatic perturbations at the PETM must reflect the consequence of temporary but dramatic deviations from this steady state due either directly to elevated temperatures or consequential changes in hydrology. This highlights the importance of examining the rapid climate change events of the past if we wish to understand the consequences of comparably rapid Anthropocene climate change.

Chlorine and CO_2 rich Fluids in 2.5 Ga amphibolite-granulite facies basement below the Killari earthquake region, India and seismogenesis

O.P. PANDEY[1], G. PARTHASARATHY[1], PRIYANKA TRIPATHI[1], V. RAJAGOPALAN[2] AND B. SREEDHAR[3]

[1]National Geophysical Research Institute (CSIR),Hyderabad-500606, India (om_pandey@rediffmail.com)

Halogens form an important component in the upper mantle fluids and play a significant role in understanding the evolutionary processes of the earth's crust and upper mantle. Killari-Latur earthquake (M 6.2) region of Maharashtra (central India), concealed below a thick suite of Deccan volcanics, is one such region where massive exhumation of mafic crust has taken place [1]. In order to understand the role of mantle fluids in the seismogenesis, we have carried out a detailed mineralogical investigation on the 2.5 Ga Archean basement core samples from a 617m deep Killari borehole, drilled in the epicentral region for seismotectonic studies. Our study indicates that the crystalline basement, covered by a 338m thick Deccan volcanics, is made up of CO_2, Cl, FeO and CaO-rich, high density (2.82 g/cm^3) - high velocity (avg. Vp: 6.20 km/s) amphibolite-granulite facies rocks, which underwent pervasive Ca-metasomatism due to infiltration of mantle fluids. Primary source of such fluids apparently existed in the upper mantle, from where it moved to lower crust due to thermal remobilization. Input of mantle heat flow in this region is estimated to be quite high at about 32 mW/m^2. Present study reveals an interesting possibility that nucleation of large intraplate earthquakes may be related to the regional metasomatism, which is also fluid controlled and alters the basic fabric and composition of the rocks considerably due to recrystallisation.

[4]UMR-CNRS 5805 EPOC, Avenue des Facultés, Université Bordeaux I, 33405 Talence Cedex, France

Coastal and continental shelf zones are among the most productive ecological provinces of the Southern Ocean and account for c.76% and 3.5% of the total primary productivity of the marginal ice zone and southern ocean respectively [1]. Diatoms account for a large proportion of primary productivity in these regions. Piston core MD03-2601 was recovered in 2003 off the coast of Adélie Land, east Antarctica (66°03.07′S, 138°33.43′E, 746 m water depth) and $\delta^{30}Si_{diatom}$ as analysed by MC-ICP-MS were conducted on a total of 29 samples at regular intervals across a total 2700 cm (c.1000-8000 years BP) of the core to reconstruct productivity changes. $\delta^{30}Si_{diatom}$ is reported as delta values relative to the NBS28 standard. $\delta^{30}Si_{diatom}$ values fluctuate between -0.01 and +0.82‰, with analytical standard errors less than ±0.08, over the duration of the record, with higher values indicating increased utilisation. Increasing $\delta^{30}Si_{diatom}$ values are concomitant with increases in *Chaetoceros* resting spores, reflecting periods of higher diatom productivity associated with longer periods of surface water stratification. These correspond with millennial periodicities of increased productivity [1]. Main trends in the percentage abundance of summer diatom species (predominantly *Fragilariopsis kerguelensis*) show a decline after c.3500 years BP and a change to the dominance of spring diatom assemblages (e.g. *Fragilariopsis curta*), reflecting prolonged sea ice cover [2]. Overall results show that after the Hypsithermal period (c.3500 years BP), during the late Holocene Neoglacial, productivity is reduced.

Isotopically heavy sulfur in banded iron formations from the Eoarchean Nuvvuagittuq Supracrustal Belt

DOMINIC PAPINEAU[1,2] AND ERIK HAURI[3]

[1]Department of Earth and Environmental Sciences, Boston College, United States (dominic.papineau@bc.edu)

[2]Geophysical Laboratory, Carnegie Institution of Washington, United States

[3]Department of Terrestrial Magnetism, Carnegie Institution of Washington, United States

All known Eoarchean (*c*. 3.85–3.60 Ga) volcano-sedimentary successions (i.e. supracrustal rocks) are restricted to high-grade gneissic terranes where biological signatures are challenging to recognize. Although they can be complicated by metamorphic overprinting, sulfur isotopes from Archean supracrustal rocks have the potential to preserve signatures of atmospheric redox chemistry and metabolic fractionation from the original depositional environment. Such sulfur isotope signatures have pushed the record of microbial sulfur metabolism back to 3.49 Ga (Shen *et al*. 2001; Philippot *et al*. 2007) and that of the anoxic atmosphere to 3.8 Ga (e.g. Papineau and Mojzsis, 2006). In order to further extend the Eoarchean sulfur isotope record, we undertook a study of multiple sulfur isotopes from various types of banded iron formations (BIFs) and associated rocks in the 3.77 to 4.28 Ga Nuvvuagittuq Supracrustal Belt (NSB). NanoSIMS was used to analyze sulfides with spot sizes of 15x15 μm for ^{32}S, ^{33}S, and ^{34}S. Analytical conditions yield a 2σ reproducibility for $\delta^{34}S$ and $\delta^{33}S$ better than 0.6 and 0.4‰, respectively, for a combined $\Delta^{33}S$ reproducibility better than 0.3‰. In sulfides from NSB BIFs, we measured the largest range of $\delta^{34}S$ values between -5.7 and +14.6‰ so far reported in Eoarchean rocks, along with a range of $\Delta^{33}S$ values between -0.9 to +3.3‰, that point to an anoxic sulfur cycle. The heaviest $\delta^{34}S$ values were of chalcopyrite grains, up to 2 mm in size, randomly distributed in jaspilitic BIFs in the southwestern part of the NSB. Associated metavolcanic rocks had a comparatively small range of $\delta^{34}S$ values between -2.8 to +1.1‰ along with a range of MIF $\Delta^{33}S$ values between -2.6 to +1.7‰, that suggest that some sedimentary sulfur was remobilized in volcanic rocks. The heavy $\delta^{34}S$ values in NSB BIFs may be an indication of biological metabolic fractionation, but alteration of isotope compositions by post-depositional isotope diffusion cannot be excluded. To independently verify the ranges measured by NanoSIMS, we are currently performing continuous flow isotope ratio mass spectrometric analyses of multiple sulfur isotopes in microdrilled sulfides from polished slabs from these rocks.

Geology and geochemistry of carbonate-hosted nonsulphide Zn-Pb mineralization in Southern and Central British Columbia, Canada

S. PARADIS[1], G.J. SIMANDL[2], H. KEEVIL[3] AND M. RAUDSEPP[3]

[1]Geological Survey of Canada, Box 6000, Sidney, BC, V8L 4B2, Canana (*correspondence: suparadi@NRCan.gc.ca)
[2]British Columbia Ministry of Energy, Mines and Petroleum Resources, British Columbia, Canada
[3]Earth and Ocean Sciences, University of British Columbia, Vancouver, British Columbia, Canada

Carbonate-hosted, nonsulphide base metal deposits are derived from sulphide mineralization (i.e. MVT, SEDEX, Irish-type, vein-type deposits and skarns) by supergene processes. Several carbonate-hosted sulphide deposits in BC have near-surface Zn- and Pb-bearing iron oxide-rich gossans. Such gossans form when carbonate-hosted, base-metal sulphide mineralization is subject to intense weathering and metals are liberated by the oxidation of sulphide minerals. The metals can be trapped locally, forming direct replacement, nonsulphide ore deposits (‘red ores’) or they can be transported by percolating waters down and away from the sulphide protore, forming wallrock replacement nonsulphide deposits (‘white ores’). The direct replacement nonsulphide deposits consist predominantly of Fe-oxyhydroxides, goethite, hematite, hemimorphite, and minor smithsonite, hydrozincite, cerussite, and anglesite; they contain 0.8-23 wt.% Zn, 0.7-5 wt.% Pb, and >20 wt.% Fe. Zinc content of sphalerite ranges from 56.6 to 67.3 wt.%, and iron content of sphalerite ranges from 0.03 to 9.4 wt.%; both show a negative correlation with a general increase in Fe from the southern to the northern deposits. The wallrock replacement deposits consist mainly of hemimorphite, smithsonite and hydrozincite, and minor Fe-oxyhydroxides and carbonates. No remnants of sulphides were observed. They contain 31.5-49.8% Zn, 0.13-0.19% Pb and <3% Fe.

Effects of municipal solid waste compost amendments on carbon and nitrogen cycling in a clayey soil

N.V. PARANYCHIANAKIS*, G. GIANNAKIS, N.P. NIKOLAIDIS AND N. KALOGERAKIS

Dept of Environmental Engineering, Technical University of Crete, 73100

The decline of organic matter is currently recognized as an important threat to soil quality. Land application of biosolids has been employed as a common management practice worldwide to restore soil C content. In this work, we provide findings from a six-month study investigating the effects of various compost amendments (0, 50, 100 t/ha) on the kinetics of carbon (C) and nitrogen (N) mineralization in soil microcosms either spiked or not with inorganic N. N application at rates of 50 kg/ha further stimulated CO_2 evolution at compost application rates of 50 t/ha, but it did not at the higher application dose (100 t/ha). N addition in compost-treated microcosms also increased potential nitrification rates compared to the treatments not spiked with N. In addition, the application of compost up-regulated enzyme activities involved in C and N cycling, including proteases, β-glucosaminidase, arginase and glutamine. Finally, data regarding genes copy number variation, involved in the N cycling (bacterial-*amoA*, archaeal-*amoA* and *nir*S), throughout the study are discussed and interpreted with enzyme activities and N-forms availability.

Crystal-rich basaltic andesites of the current Arenal eruption in light of experiments with crystal-poor basalt

F. PARAT[1,2]*, M.J. STRECK[3], F. HOLTZ[4] AND R. ALMEEV[4]

[1]Géosciences Montpellier, Univ. Montpellier, France (*correspondence: Fleurice.Parat@gm.univ-montp2.fr)
[2]Mineralogie-Geochemie, Univ. Freiburg, Germany
[3]Department of Geology, Portland State Univ., Portland, OR 97207, USA (streckm@pdx.edu)
[4]Institute of Mineralogy, Univ Hannover, Germany (f.holtz@mineralogie.uni-hannover.de)

Arenal volcano is nearly unique with its 43 year long continuous activity erupting remarkably monotonous basaltic andesites but mineral zoning records indicate complex open-system processes including the episodic injections of basalt. The condition of the mafic input as well as the evolution to the currently erupting basaltic andesite were addressed by an experimental study on a phenocryst-poor (~3%) Arenal-type basalt (50.5 wt% SiO_2) from a nearby scoria cone containing olivine (ol, Fo_{92}), plagioclase (pl, An_{86}), clinopyroxene (cpx, mg#=82) and magnetite (mag, X_{ulvo}=0.13).

Our experiments (200 MPa, 900-1050°C, oxidizing and fluid-saturated conditions with various water activities, XH_2O_{fluid}=0.3 to 1) produced at 1050°C and water-saturated conditions (H_2O_{melt}=5 wt%), only magnetite, whereas mag+cpx+ol crystallized at low water activity. Plagioclase and cpx crystallized at water-saturated conditions with olivine at 1000°C and with amphibole at 950-900°C, whereas they crystallized with opx at low water activity (for T=1000-900°C). The mineral assemblage as well as the mineral compositions of the natural basalt were reproduced at 1000°C with basaltic andesitic melt (55 wt% SiO_2) with 5 wt% H_2O.

Our results can be used to substantiate previously envisioned crystallization environments beneath Arenal. Basaltic magma inputs are water-rich at relatively high pressure and high temperature. Evolution to more evolved magmas would have happened under fluid-saturated conditions but variably water activities. A decrease of water activity (degassing?) induces the change of the mineral assemblage pl+ol+cpx to pl+cpx+opx observed in basalt (e.g. ET3-1) to andesitic tephras (e.g. Ar7/68). On the other hand, the lack of opx and the presence of amphibole also in basaltic andesitic tephra units of earlier eruptive phases (e.g. ET3-2) indicate water-saturated conditions at temperature lower than 950°C. Continuous degassing may contribute to persistent small-scale explosive activity - so characteristic for the current eruption-, likely prevailed during crystallization of the water-rich magmas at Arenal. Mixing of magma batches (with subtle but distinct compositional and mineralogical differences) plus the occasional process of concentrating mineral contents by melt expulsion will do the rest to make crystal-rich basaltic andesites of the current eruption.

Iron reduction by a *Clostridia* consortium

MADHAVI PARIKH, CHU-CHING LIN, TAMAR BARKAY AND NATHAN YEE*

School of Environmental and Biological Sciences, Rutgers University, New Brunswick, NJ, USA (*correspondence: nyee@envsci.rutgers.edu)

Background

One of the major pathways of inorganic contaminant (e.g. Cr, Hg, Pu and U) transformation in Earth's critical zone is through redox reactions with Fe (II). Reactive Fe (II)-bearing minerals are known to form during microbial respiration of ferrihydrite. However, the common crystalline iron oxide phases in the critical zone are notoriously recalcitrant towards microbial reduction. Here we report the cultivation of a microbial consortium, enriched from subsurface sediments, that rapidly reduces crystalline goethite (α-FeOOH) and hematite (Fe_3O_2), and produces highly reactive Fe (II)-bearing particles.

Materials and Methods

A sediment core collected from the United States Department of Energy Field Research Center (FRC) in Oak Ridge Tennessee was used as inoculum for anaerobic enrichment cultures. The media were initially amended with acetate and citrate as the electron donors, and active cultures were eventually tranferred to media containing fumarate as the carbon source. After a purified consortium was obtained, the genomic DNA was extracted and DGGE analysis was performed to determine the microbial community composition. Iron reduction experiments were conducted to evaluate the ability of this consortium to reduce goethite and hematite when provided with alternate electron donors. Periodically, samples were collected and the mineral transformation products were analyzed using powder X-ray diffraction (XRD).

Results and Discussion

Enrichment cultures Oak Ridge FRC resulted in the cultivation of a microbial consortium that exhibited robust iron reducing activity. This consortium consisted of two strictly anaeorbic spore-forming microorganisms. 16S rRNA gene sequences indicated that both organisms belong to the class *Clostridia* in the *Firmicutes* phylum. When given peptone, the consortium was able to reduce goethite and hematite at rates an order of magnitude faster than any pure culture reported to date. The biogenic ferrous iron produced by this consortium was largely retained in the solid phase. The Fe (II) precipitates exhibited distinct coloration and were highly reactive towards oxygen. Notably, these secondary ferrous iron phases were not detectable by XRD, suggesting that the Fe (II)-bearing solids were amorphous.

In-diffusion of some chemical species in a weathered granite

C.K. PARK*, M.H. BAEK AND JT. JEONG

Atomic Energy Research Institute, Yousung-gu Daedukdaero 1045, Daejin, Korea
(*correspondence: ckpark@kaeri.re.kr)

An in-diffusion experiment for some chemical species onto a weathered granite core of Φ5x 20 (cm) was carried out in a glove box under a reducing condition. After nine months, the rock samples was recovered, cut into two parts along its axis. The one part was scanned with a cyclone, a kind of autoradiographe, to identy the distrubution of radionuclide on the rock surface with the diffusional direction. The other part cut into several slices of 1cm thickness. In order to identify sorption types of the species, a sequential chemical extraction was carried out on the slices. The considered sorption types are physiosorption, ion exchange, association with ferro-manganese oxides, and incorporation into mineral structure.

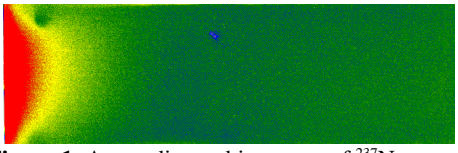

Figure 1: Autoradiographic amage of ^{237}Np

Fig.1. shows the concentration distribution of ^{237}Np on the rock surface. Np sorbed mainly within 2`3 cm and penetrated about 6 cm. Sr and Co penetrated more deeply than the other species. And some species such as Th, Cs and Eu were sorbed mainly on the contacting surface and their diffusion depth were within 3 cm.

The most interesting finding in this experiment is that the sorption mechanisms of some species were changed along their penetration depth. For examples, at the contacting surface U and Co sorbed mainly by ion exchange but association with ferro-manganese oxides became important with going into the inside of the rock. On the other hand, Np mainly associated with ferro-manganes oxides on the contacting surface and ion exchange becomes main sorption type in the deeper region.

Study for the geochemical reaction of Bukpyong CO_2 sequestration site, Korea

JINYOUNG PARK*, HYUNMIN KANG, MINHO PARK AND MINHEE LEE

Deprtment of Environmental Geosciences, Pukyong National University, 599-1 Daeyon 3 Dong, Namgu, Busan, 608-737, Republic of Korea (pjy9614@naver.com)

The objective of this study is to investigate the geochemical reaction of rock in Bukpyong CO_2 sequestration site, Korea. Target formations were mostly composed of porous sandstone and conglomerate beds. For the experiment, the high pressurized cell system (100 bar and 50 ºC) was designed to create supercritical CO_2 in the cell. The dissolution and precipitation of sandstone and mudstone were observed while the rock reacted with supercritical CO_2 and saline water in the cell for 30 days. Ten g of rock powder type and 50 ml of saline water were contacted with supercritical CO_2 in the cell. For the experiment, saline water was sampled from a hot-spring well (800 m in depth) in Busan. SEM-EDS analysis was conducted to measure the precipitated minerals and ICP/OES was used to quantify main compounds dissoved in solution of the high pressure cell. The mineral surface was observed by using a reflection microscope. Three locations were randomly selected on the surface and the average roughness value of those locations was measured by SPM (Scanning Probe Microscope) to investigate the change of mineral surface.

For the mudstone, concentrations of Ca^{2+}, Fe^{2+}, Mg^{2+}, Na^{2+} and K^{+} in solution increased to 348.9 mg/L, 185.2 mg/L, 134.1 mg/L, 66.9 mg/L and 7.5 mg/L, respectively, after 30 days. For the sandstone, concetrations of Ca^{2+}, Fe^{2+}, Mg^{2+}, Na^{2+} and K^{+} in solution increased to 3895.9 mg/L, 378 mg/L, 23.8 mg/L, 63.1 mg/L and 9.9 mg/L, respectively. These results suggested that ions such as Ca^{2+}, Fe^{2+}, Mg^{2+} and Na^{2+} would be significantly dissolved when it contact with the supercritical CO_2 and saline water in Bukpyong CO_2 sequestration site. The average roughness value of the plagioclase surface was 1.04 nm before the reaction, but it considerably increased to 11.26 nm after 30 days. For the orthoclase, the average roughness increased from 2.74 nm to 18.56 nm, suggesting that the dissolution of plagioclase and orthoclase occurs in active when the feldspars contact with supercritical CO_2 and saline water at Bukpyong CO_2 sequestration site.

Study for TPH removal efficiency of landfarming process using indigenous microorganisms to diesel contaminated site

MINHO PARK* AND MINHEE LEE

Department of Earth Environmental Sciences, Pukyong National University, Daeyon 3 Dong, Namgu, Busan, 608-737, Republic of Korea
(*correspondence: minhop1008@gmail.com)

Landfarming is the representative process to use the biodegradation by using microorganisms and it is considered to be more economical and pre-environmental than other process to remediate fuel-contaminated sites. The feasibility of landfarming process using indigenous microorganisms, living in diesel contaminated soils of a military camp was investigated by batch experiment. Initial TPH concentration of soil sample in the study was 3, 819 mg/kg and the soil was classified to 'Sand' for USDA soil texture group. The average water content was 1.19 % and soil pH was 8.29. For the experiment using indigenous microorganisms, total four microorganisms (*Arthrobacter* sp., *Burkhoderia* sp., *Cupriavidus* sp. and *Bacillus* sp.) were isolated from two diesel contaminated soils from a military camp, Korea. Batch experiments were performed to investigate the TPH removal efficiency with different conditions for 1 month. In the petri dish (15 cm in diameter x 2 cm in depth), 300 g of soil were mixed with each isolated microorganism solutions (0.3 ml and 0.6 ml) and nutrient (0.3 ml). The ratio of C:N:P in the nutrient was 100:10:1. Various water contents (10 % and 20 %) and temperature (20 ℃, 30 ℃ and 40 ℃) were applied to the experiments. The humidity of batch soil decreased due to the vaporization and the distilled water was added into the batch soil every 48 hours to maintain a constant humidity.

After 31 days of experiment, the greatest TPH removal efficiency was 95 % by using *bacillus* sp.. The average TPH removal efficiency of four microorganisms was 76.5 %, suggesting that the landfarming process using indigenous microorganisms is successful to remove TPH from diesel contaminated soils.

Microstructure of Yuka eclogite, North Qaidam HP/UHP terrane, Northwestern China

M. PARK AND H. JUNG*

School of Earth and Environmental Sciences, Seoul National University, Seoul, Republic of Korea
(*correspondence: hjung@snu.ac.kr)

This study aims at further understanding of the mechanisms how lattice-preferred orientation (LPO) developed during the HP-UHP metamorphism in the eclogites. Microstructures of Yuka eclogites from North Qaidam HP/UHP terrane, northwestern China were analyzed using optical microscopy and electron backscattered diffraction (EBSD) in order to determine the LPOs of minerals and deformation mechanisms. The LPOs of omphacite showed that [001] axes are alligned parallel to lineation and [010] axes distributed within a girdle normal to lineation which is known as the L-type fabric, while the garnets showed a week LPO. The fabrics of quartz showed a weak rhomb <a> slip system which the C{0001} axis pole figures present patterns which form a girdle in the plane normal to the lineation. To determine water content of minerals we used the Nicolete 6700 FTIR with a Continuum IR microcroscope in the Tectonophysics Laboratory in SEES in Seoul National University. Unpolarized FTIR analysis of samples showed that two hydroxyl absorption bands at 3430 – 3530 cm^{-1} and 3600 – 3620 cm^{-1} exist in the omphacite grains indicating the deforrmation of omphacite in a wet condition, while there was no O-H peak observed in garnet and quartz minerals indicating deformation of the minerals in a dry condition. The presence of strong LPOs in omphacite suggests that dislocation creep was a dominant deformation mechanism of omphacite, but the garnet grains appear to be deformed by other mechanisms (e.g. grain boundary sliding). Quartz grains appear to be deformed by the dislocation creep mechanism in a dry condition, and the weak LPOs of quartz may have been caused by the later stage deformation and metamorphisms.

Effects of future climate change on air quality over East Asia

ROKJIN J. PARK[1]*, MINJOONG KIM[1], JAEIN JEONG[1] AND CHANG-KEUN SONG[2]

[1]School of Earth and Environmental Sciences, Seoul National University, Seoul, Korea (*correspondence: rjpark@snu.ac.kr)

[2]Global Environment Research Center, National Institute of Environmental Research, Incheon, Korea

Air pollutant concentrations such as troposheric ozone and aerosols are affected by meteorological variables including temperature, mixing depth, precipitation, and so on. Future climate is expected to be different from the present and so are those meteorological variables due to human perturbation to the atmospheric levels of the long-lived greenhouse gases and aerosols. East Asia is one of important source regions of both anthropogenic and natural greenhouse gases and air pollutant precursors. Therefore, significant environmental changes are expected in the future. We here use an offline coupling of a 3-D chemical transport model (GEOS-Chem) and a climate model (CAM3) to examine the effects of future climate change on air pollutatnt concentrations over East Asia. We conduct several model simulations with the IPCC SRES emission scenarions. Simulated air pollutant concentrations over East Asia in the future are found to be sensitively perturbed relative to the present depending on the different emission scenarios. Important meteorological factors affecting air pollutant concentrations include temperature, cloud covers, and precipitation over the continent. Changes in synoptic meteorological patterns induce different transport pathways of air pollutatns. Future climate changes may in general exacerbate air quality degradation that requires more stringent emission reductions over East Asia.

Column experiments for biosorption by immobilized carrier beads using *Bacillus* sp. and polysulfone to remove Pb from aqueous solution

SANGHEE PARK, INSU KIM, HAJUNG LEE AND MINHEE LEE

Department of Earth Environmnetal Sciences, Pukyong National University, Daeyon 3 dong, Namgu, Busan, 608-737, Republic of Korea (sthico0911@gmail.com)

Biosorption of Pb from aqueous solution has been investigated in column experiments. Sorption column experiments were used the immobilized carrier beads with dead biomass and polysulfone. *Bacillus* sp. was isolated from soil contaminated with oil and heavy metals at a military site in Repubilic of Korea. Dead biomass prepared by freeze-drying and autoclaving at 121 ℃ was mixed with 10 % polysulfone in DMF (*N, N*-dimethyl formamide) solution to produce the immobilized carrier beads which were spherical and porous beads (1 mm in diameter).

The column was designed with an internal diameter 2.5 cm and 100 cm height. Experiments were carried out in glass column filled with 5 % of dead biomass in carrier beads which were investigated to Pb removal efficiency in batch experiments. The initial concentration of Pb in the synthetic aqueous solution was titrated as 10 mg/L. Pb solution was pumped through peristaltic pump connected to the bottom of the column at a flow rate of 2.2 ml/min. From the top of the column, water samples were collected at regular time intavals (1, 2, 3, 4, 5, 6, 7, 8, 12, 15, 18, 24, 30, 36, 42, 48, 54, 60, 66, 78 pore volume). Samples were analyzed on ICP-OES for residual Pb concentrations in solution.

From the results of the column experiments, the Pb removal efficiency of immobilized carrier beads was kept over 98 % until the Pb solution was injected quantity of 30 pore volume. The amount of Pb adsorbed per unit weight of beads was 12.78 mg/g. A small quantity of immobilized beads could remove a lot of Pb in aqueous solution, therefore immobilized beads have a great passibility to clean up the heavy metal contaminated groundwater at the field.

Evaluation of anthropogenic contamination of bedrock groundwater using hydrochemical data: An example from suburban areas in Korea

SEONG-SOOK PARK[1,2], SEONG-TAEK YUN[1]*, KYOUNG-HO KIM[1], HYANG MI KIM[3] AND EUN-SEON JANG[1]

[1]Department of Earth and Environmental Sciences, Korea University, Seoul 136-701, South Korea (*correspondence: styun@korea.ac.kr)
[2]Department of Natural Resources and Environmental Engineering, Hanyang University, Seoul, South Korea
[3]Department of Mathmatics and Statistics, University of Calgary, Calgary, Alberta, Canada T2N1N4

A better evaluation of the relative contribution from natural versus anthropogenic sources to the observed groundwater quality is highly needed for better groundwater management. In this work, we evaluated hydrochemical data of 102 bedrock groundwater samples from two suburban areas using multivariate statistical techniques, in order to distinguish between anthropogenic contamination and natural process. The hydrochemistry of groundwater changed gradually from Ca-Na-HCO_3 to Ca-HCO_3-Cl type, concomitantly with the general increase of nitrate. The estimation of the distribution using the non-parametric kernel algorithm showed the bimodality for F and NO_3. The collected samples could be divided into natural versus anthropogenic groups via multivariate hierarchical, k-means, and fuzzy c-means clustering methods. The results from those multivariate clustering showed a drawback in terms of definite classification. On the other hand, the model-based clustering with a mixture model was a preferred method for identifying the two groups. Careful examination of hydrochemistry data for the two clustered groups suggests that the formation of Ca-Na-HCO_3 type groundwater is mainly controlled by plagioclase hydrolysis accompanying subordinate cation exchange (between Ca and Na) and calcite precipitation, while Ca-HCO_3-Cl type groundwater with noticeable NO_3 reflects varying degrees of anthropogenic contamination by agrochemicals and sewage/manure. This study provides an example of the successful application of the model-based clustering with mixture model to the regional groundwater quality evaluation.

Preliminary results of a recent expedition to the Australian-Antartic Ridge

S.H. PARK[1]*, C.H. LANGMUIR[2], J. LIN[3], D. HAHM[1], S.S. KIM[4], S.G. HONG[1], Y.M. LEE[1] AND P. MICHAEL[5]

[4]Seoul National University, Seoul, Korea
[5]University of Tulsa, Tulsa, OK, USA

The Australian-Antarctic Ridge (AAR) is the largest unexplored expanse of the global mid-ocean ridge system. In early 2011, the Korea Polar Research Institute conducted a short survey of two segments at 160°E (K1) and 152.5°E (K2) using the icebreaker Araon. As a result, we have a multi-beam map and 16 rock core samples from the two segments. Also, we found strong signals of hydrothermal venting using MAPR (Miniature Autonomous Plume Recorder) profiles from the ridge. The AAR is intermediate spreading ridge and its axial depth is relatively shallow (~2100m). The axial morphology varies from an axial high to well-developed rift valley in the K1 segment, suggesting magma supply has varied on short spatial scales. The K1 western end abuts a transform with a strike towards the Balleny Islands, providing a possible source of excess magma supply and the shallow axial depth. MgO varies from 1.72 to 7.63 wt.%, mostly between 6~7wt.%. Fe-Ti basalt and dacite are at the western end of the K1 segment where magma supply appears most robust. The K2 segment samples are more primitive, and include E-MORB with 0.65% K_2O. Na_8 (2.5) is lower than the EPR but slightly high in the context of the global correlation with axial depth. It falls on trend with the slightly higher Na of Indian Ocean ridges. Trace elements and isotopes will be analyzed to characterize the mantle source. It appears that hydrothermal vents are distributed in the central part of the K1 segment. In the K2 segment, hydrothermal vent signals were mainly found in the western part of the segment.

Structure and stability of mineral interfaces

S.C. PARKER[1]*, M. MOLINARI[1], R ZHU[1], W SMITH[2] AND C. NOGUERA[3]

[1]Department of Chemistry, University of Bath, Bath BA2 7AY, United Kingdom (*correspondence: s.c.parker@bath.ac.uk)
[2]STFC Daresbury Laboratory, Warrington WA4 4AD, United Kingdom
[3]INSP, Université Pierre et Marie Curie, Paris, France

The aim of this presentation is to describe some recent applications of atomistic simulation studies for extending the range of applications to mineral interfaces. Two main themes will be addressed. The first is to describe our recent work on using Path Integral Molecular Dynamics. The approach is to provide quantum treatment of nuclear motion and particularly improve the description of proton motion. As a way of disentangling the electronic from nuclear motions we begin by presenting preliminary results for a number of mineral water interfaces using PIMD in the DL_POLY [1] code and employing interatomic potentials.

The second area is the application of both potential-based and DFT simulations towards modelling increasingly complex mineral interfaces. Two areas where we have investigating ways of improving the mineral surface description are (i) the simulation of polar surfaces and (ii) the interaction of nanoparticles with mineral surfaces.

A number of strategies in which the mineral can remove a surface dipole will be discussed and illustrated with several examples including the layered mineral: lizardite, where each layer is comprised of a silica sheet linked to brucite.

Finally, modelling the nanoparticle-surface interaction will be discussed. The release of nanoparticles into the environment could cause adverse ecological problems, and thus the transport of nanoparticles in the environment and the interaction of nanoparticles with the geosorbents are of concern. There are currently few studies that have addressed the interactions of nanoparticles with soil minerals, although numerous reports already showed that soil minerals such as clays can have strong interactions with organic contaminants. Here we will report our current work on these interactions. One example where all techniques can be applied is the interaction and transport of fullerene and its interaction with clay surfaces. Our results indicate that adsorption of fullerene on soil clay minerals could significantly influence its transport in the environment.

Mine water geochemistry and biogeochemical modeling

MARC PARMENTIER, NOLWENN CROISET, FABIENNE BATTAGLIA-BRUNET AND MOHAMED AZAROUAL

BRGM – Water Division, Hydrogeological and Hydrogeochemical Modelling, 3 av. C. Guillemin, BP 36009, 45060 France (m.parmentier@brgm.fr)

In mine tailings sites, where sulfide minerals are in contact with atmospheric humidity and meteoritic water, oxidation of sulfides generate acidity leading to mobilization of metals and metalloids through the soil to surface and underground waters. The resulting acid mine drainage can impair dramatic environmental problems (i.e. toxicity of arsenic III, etc.). In the old gold mine of Chéni (France), large physical, chemical and microbiological datasets are available: mineralogical compositions of the tailings [1], long-term survey of drainage waters chemistry [2] and microbiological characterizations [3]. The pH/Eh of sampled waters through the tailing column (unsaturated and saturated zones) is in the range of 2.9–7.6 and 0-700mV respectively. Analysis of these data permitted to identify the key processes of mine water behavior. Numerical simulations, using the geochemical software PHREEQC [4], were performed aiming to identify the key mechanisms and understand those coupling processes.

First analysis of geochemistry show different redox potentials for each element (Fe, As, O_2, N, S). Such redox disequilibrium, known in natural waters [5] is rarely take into account in modeling. In our work, redox decoupling of the thermodynamical database is used to model redox behavior of mine water.

Biological oxidation of arsenic was identified as an active and sustained process in such systems. Experimental results of biological As oxidation was used to develop a thermokinetic model coupling geochemistry and biologic activity [6] and reproducing the pH-dependant activity of bacterial population.

Finally, we elaborate a mixed biogeochemical model to reproduce the behavior of an acid mine drainage, which takes into account major processes including bacterial activities, precipitation of Fe-containing minerals (Schwertmannite, ferrihydrite, jarosite) and surface complexation.

Modelling methyl halide emissions from plants: From cytosol to the atmosphere

L. PARSHOTAM[1], D. CHRISTOPOULOU[2] AND K.R. REDEKER[1]*

[1]University of York, Department of Mathematics (lep506@york.ac.uk)
[2]University of York, Department of Mathematics (dc685@york.ac.uk)
[3]University of York, Department of Biology, *correspondance:(kelly.redeker@york.ac.uk)

Methyl halides affect climate through a number of important atmsopheric chemical processes, from ozone depletion to reduction of the cleansing capacity of the lower atmosphere to enhancing regional aerosol formation potentials. Despite these recognized concerns global budgets for methyl halides, including methyl chloride, methyl bromide and methyl iodide, remain poorly quantified. One major source of uncertainty within methyl halide budgets is the terrestrial biosphere. Only a few ecosystems have been quantitatively measured over full season life-cycles and our understanding of environmental parameter effects on plant emissions remains limited.

Here we present a 'from the ground up' model which predicts methyl halide emissions from plant tissues based upon estimated production rates within leaf mesophyll cell cytosol and diffusional transport through stomata, cuticle, leaf boundary layer and into the free atmosphere. This is the first model that the authors are aware of that follows trace gas transport from within plant cell tissues through diffusion to the free atmosphere.

Modelled results are compared to observational data from several plant systems to establish critical knowledge gaps within the methyl halide plant-atmosphere system. An inverse approach has also been performed to answer one of the persistent questions regarding the terrestrial biosphere and methyl halides: 'Do plants produce methyl halides as a defense mechanism'?

The effect of flood-induced redox oscillations on arsenic mobility in a calcareous fluvisol

C. PARSONS[1]*, R.-M. COUTURE[2], E. OMEREGIE[3], F. BARDELLI[1], G.ROMAN-ROSS[4] AND L. CHARLET[1]

[4]Department of Chemistry, Faculty of Sciences, University of Girona, Campus de Montilivi, 17071 Girona, Spain

Contamination of floodplain soils with metals and metalloids is widespread, particularly in areas with a legacy of intense industrial activities [1], as is the case for much of Western Europe. It is well established that arsenic associated with metal oxides in soils and sediments can be released under reducing conditions experienced during flooding [2], due to desorption processes, speciation changes or mineral dissolution [3].

We show, through a combination of batch experiments, spectroscopy and thermodynamic and kinetic modelling, that the cumulative effects of redox cycling, often neglected in floodplain studies, also control arsenic mobility and that repetitive cycling in a closed system can help to attenuate arsenic mobilized during reducing conditions after a severe contamination event.

We demonstrate that this attenuation is due to a combination of fast reversible surface complexation of As to iron oxide minerals and slow irreversible adsorption/co-precipitation. This has implications for management of contaminated floodplains and suggests that controlled flooding and draining may help reduce the risk posed by arsenic in soils.

Establishing baseline geochemical conditions at historic gold mines for risk assessment and remediation

M.B. PARSONS[1]*, T.A. GOODWIN[2] AND M.E. LITTLE[1]

[1]Natural Resources Canada, Geological Survey of Canada (Atlantic), Dartmouth, Nova Scotia, Canada (*correspondence: Michael.Parsons@NRCan.gc.ca)
[2]Nova Scotia Department of Natural Resources, Mineral Resources Branch, Halifax, Nova Scotia, Canada

The mining and milling of Au from orogenic lode Au deposits can result in risks to the environment and human health without appropriate mine planning, environmental management, and monitoring programs. These deposits are the main source of Au in Canada, and are presently the focus of considerable exploration and development. Arsenopyrite occurs naturally in the ore and surrounding bedrock in these deposits, and As is generally present at high concentrations in mine wastes and drainage waters. Historically, Hg amalgamation was often used to extract Au from the ore, and high Hg concentrations are common in mine tailings and near abandoned mill sites. The recent surge in global Au prices has generated renewed interest in many former mining districts, and in the possibility of reprocessing historic Au mine wastes. To develop appropriate environmental management plans for these sites, it is essential to characterize both the pre-mining concentrations of metal (oid)s in waters, sediments and soils, as well as the impact from previous mining operations.

This presentation will summarize recent studies of geochemical baselines at lode gold deposits in Nova Scotia and British Columbia, Canada. In Nova Scotia, we determined the vertical distribution of As and Hg in forest soils surrounding two abandoned gold mines to evaluate pre-mining baseline conditions, and the extent of historical mine wastes. In general, the concentrations of As are highest in B and C horizon soils, whereas Hg concentrations are highest in the organic-rich humus (H) layer. Arsenic concentrations in naturally mineralized soils range from 2-270 mg/kg, and are generally greater than the 12 mg/kg Canadian Soil Quality Guideline for As. In British Columbia, samples of stream water and sediment were collected around the past-producing Bralorne, King, and Pioneer Au mines. Background concentrations of As, Hg, and Sb commonly exceed environmental guidelines in sediments, but impacts on water quality were restricted to the immediate vicinity of former mine sites. The results of these studies are being used to inform environmental site assessments and to develop suitable monitoring and remediation strategies for orogenic lode gold deposits across Canada.

Major ion chemistry of subsurface water samples around waste disposal sites of Hyderabad city, India

VANDANA PARTH[1] *, N.N. MURTHY[1] AND PRAVEEN RAJ SAXENA[2]

[1]National Geophysical Research Institute, Council of Scientific and Industrial Research, Hyderabad, India (*correspondence: vandana.parth@gmail.com)
[2]Department of Applied Geochemistry, Osmania University, Hyderabad, India

The present study deals with hydrogeochemistry of groundwater around dumpsites, Hyderabad city, India. The city witness ~4000 tons of solid waste per day dumped in low-lying areas as landfills, affecting groundwater quality. Three waste dumpsites namely; Jawaharnagar, Autonagar and Dundigal were chosen for major ions study in the groundwater. The samples were collected from sixty location points around dumpsites covering entire area and were precisely analysed for physicochemical characters using the standard procedures recommended by APHA [1]. F^- and NO_3^- were determined by double junction electrode at 25°C. The type of water that predominated in the study area was assessed based on hydro-chemical facies. Suitability of groundwater for irrigation was evaluated based on sodium adsorption ratio, per cent sodium, residual sodium carbonate and the US salinity diagram. High concentrations of major ions (Ca^{++}, Mg^{++}, Na^+, F^-) observed in bore wells can be attributed to differential weathering of minerals such as pyroxenes, plagioclase feldspars, and apatite together with dissolution/precipitation reactions along fractures and joints in the granites. The high NO_3^- level >50 mg/l is ascribed to consequence of the oxidation of ammonia and similar sources from leachate emanating from waste. Although the water in the study area is not potable, it is found to be suitable for irrigation purposes with little risk in the development of detrimental level of exchangeable sodium. Based on piper diagram, the groundwater is being classified into Ca-HCO_3^- type, Ca-Cl^- type, Mg-HCO_3^- type and Mg-Cl^- type. The carbonate hardness exceeds 50% of the total ionic composition, which signifies that the chemical properties are dominated by alkaline earth (Ca^{2+}+Mg^{2+}) and week acids (CO_3^{2-}+HCO_3^-). Though the suitability of water for irrigation in the present study is determined based on SAR, RSC, %Na and USSL diagram, it is only an experimental conclusion. In addition to water quality, other factors like soil type, crop pattern, frequency and recharge (precipitation), climatic conditions, etc. have a vital role in determining the suitability of water.

Pressure dependence of electrical resistivity of cummingtonite from the world's deepest Kola super deep-borehole (KSDB-3), Russia

G. PARTHASARATHY[1] AND F.F. GORBATSEVICH[2]

[1]National Geophysical Research Institute (CSIR), Hyderabad-7, India (gpngri@rediffmail.com)
[2]Geological Institute Russian Academy of Sciences, Apatity, Murmansk 184209, Russia

We present here for first time the temperature and pressure dependence of the electrical resistivity of cummingtonite from the Kola super-deep borehole (KSDB-3) up to 700 K and 4 GPa. The Kola super-deep borehole near Zapolyarny, Kola Peninsula, Russia is the deepest borehole in the world (12261 m deep) that has penetrated Proterozoic complex from the surface to 6840 meters, with mafic meta-volcanic on the top 1000m, metasedimentary rocks from 2800m to 4500 m, and intermediate metavolcanics dominating from down to 6800 m depth, further in the depth region 6800 m to 12261 meters the KSDB-3 intersects an Archaean gneiss-migmatite complex with ubiquitous amphibolites bodies up to 30 meters thickness. About 1/3 of the total cross section of the borehole consists of amphibolites [1]. High-pressure electrical resistivity measurements were carried out in a Bridgman opposed anvil system, up to 9 GPa [2]. We have observed a distinct slope change in the Arrhenius plot of the electrical conductivity of cummingtonite at 455 K, which can be explained as a $Mg^{2+} \rightarrow Fe^{2+}$ cation order-disorder phase transition, which is due to the migration of Fe^{2+} from M4 to M1, M2, M3 sites at 683 K [3]. The conductivity activation energy has been measured at different pressures, and found to be decreasing from 065 eV at room pressure to 0.35 eV at 6GPa.

Spectroscopic investigations on natural stichtite and synthetic hydrotalcites

G. PARTHASARATHY[1] AND CH.VENKAT REDDY[2]

[1]National Geophysical Research Institute(CSIR) Hyderabad-500606, India (gpsarathy@ngri.res.in)
[2]Indian Institute of Chemical Technology (CSIR), Hyderabad-500607, India Presently Dept of Chemsitry, Iowa state university, Ames, IA-50011,USA
E-mail: chvekatreddy@gmail.com

We present here structural and thermal properties of synthetic hydrotalcites and natural stichtite. Stichtite, a rare hydrated carbonate-hydroxide of Mg and Cr with ideal formula $Mg_6Cr_2(OH)_{16}CO_3 \cdot 4H_2O$, occurs in chromite bearing serpentenites of Nuggihalli Archaean greenstone belt, India.[1]. The efficiency of CO_2 adsorption based separation is based on the structural and thermal characteristics of the adsorbent. There are several naturally occurring minerals like zeolites, in the Deccan Trap area with high CO_2 adsorption capacity. However, most of these adsorbents suffer from low capacity at high temperature (seen in the combustion processes). Hydrotalcite is one of the few minerals with significant anion exchange capacity, and stands in contrasts to the more common mesoporous clay minerals, which have cation exchange properties. Carbon-dioxide adsorbing capacity has been investigated by using hydrotalcites as high temperature adsorbents. We present here the compositional and structural characteristics of the naturally occurring stichtite and synthetic hydrotalcites by using spectroscopic methods, and the potential applications of synthetic hydrotalcites and naturally occurring stichtite in the study of the adsorption of carbon dioxide are discussed. Infrared spectroscopic studies on the stichtite shown several absorbtion bands at 1460, 1380, 745 and 685 cm-1, all of them are assigned as per the standard vibrational modes described by Frost and Erickson [2]. High temperature DTA/TG studies showed a thermal dehydration reaction at about 530 K and decarbonation reaction at 825 K, similar to Al based synthetic hydrotalcites.

We thank PLANEX, ISRO Govt. of India, for funding.

Re-Os geochemistry and geochronology of the Ransko gabbro-peridotite massif, Czech Republic

JAN PAŠAVA[1], LUKÁŠ ACKERMAN[1,2]* AND VOJTĚCH ERBAN[1]

[1]Czech Geological Survey, Geologická 6, 152 00 Praha 5, Czech Republic

[2]Institute of Geology v.v.i., Academy of Sciences of the Czech Republic, Rozvojová 269, 165 00 Praha 6, Czech Republic (*correspondence: ackerman@gli.cas.cz)

The Ransko gabbro-peridotite massif is located in a transition zone between Moldabian and Kutná Hora crystalline unit of Bohemian Massif, Czech Republic. It represents a strongly differentiated intrusive complex with zoned structure which hosts low grade Ni-Cu-(PGE) ores. This mineralization is mainly developed close to the contact of olivine-rich rocks with gabbros, in troctolites, and to a much lesser extent in both pyroxene and olivine gabbros and plagioclase-rich peridotites [1].

We analyzed eleven samples of gabbro, troctolite, peridotite and Ni-Cu ore for Re-Os concentrations and Os isotopic ratios. Barren gabbro and troctolite have very low Os concentrations (0.02 to 0.1 ppb), high Re contents (0.6 to 2.4 ppb) and corresponding high Re/Os ratios. Their $^{187}Os/^{188}Os$ ratios display very variable strongly radiogenic values ranging from 0.4358 to 2.1372. This heterogeneity in Os isotopic ratios is most likely connected with different degrees of crustal contamination involved in the parent basaltic melt. The Ni-Cu low mineralized rock (peridotite, troctolite) and massive Ni-Cu-(PGE) ores have high Re (from 1.67 to 121.2 ppb) and Os (0.81 to 206.8 ppb) contents and consequently low Re/Os ratios (0.5 až 5.1). The subchondtritic to superchondritic $^{187}Os/^{188}Os$ ratios (from 0.1264 to 2.1372) show variable contribution of mantle- and crustal-derived ^{187}Os in Ni-Cu-(PGE) mineralization.

Four selected samples with suggested closure of the Re-Os system after emplacement of Ni-Cu mineralization have similar Os model ages and yield the Re-Os isochron age of 550 ± 49 Ma. This is in agreement with the results of [2] who suggested Lower Cambrian age of the Ransko massif based on geological and paleomagnetic studies.

Cryptoendolithic colonization in the hydrating mantle along mid ocean ridges

V. PASINI[1,2]*, B. MÉNEZ[1] AND D. BRUNELLI[13]

[1]Dipartimento di Scienze della Terra, Università di Modena e Reggio Emilia, L.go St. Eufemia 19, 41100 Modena, Italy (*correspondence: valerio.pasini@unimore.it)

[2]IPGP, UMR CNRS 7154, 1 rue Jussieu, 75005 Paris, France

[3]Istituto di Scienze del Mare – CNR, Via Gobetti 101, 49100 Bologna, Italy

The basaltic oceanic crust and associated sediments are recognized to harbor an active microbial life involved in the geochemical fluxes between geosphere and hydrosphere while the underlying mantle-derived peridotitic lithosphere remains until now underexplored. Nonetheless, the progressive hydration of peridotite-forming minerals (i.e. serpentinization) releases great amount of molecular hydrogen, that constitutes a valuable source of metabolic energy for chemiolithoautotrophic microorganisms. Although recent studies have demonstrated the presence of extremophile microbial life at hydrothermal vents related to oceanic serpentinization, as illustrated at Lost City (Mid Atlantic Ridge, 13° N), the presence and the level of activity of hydrogen-driven subseafloor communities inside the hydrating mantle rocks are still under debate.

By implementing a suite of microspectroscopic and microimaging techniques (i.e. coupled confocal laser scanning microscopy and Raman spectroscopy, transmission and scanning electron microscopies on focused-ion-beam ultrathin sections) we evidenced the presence of deep endogenic organic-carbon accumulations that sign a past mineralizing bioactivity in deeply serpentinized mantle rocks collected along the Mid-Atlantic Ridge (6°03.3'N-33°25.4'W). These niches are constituted by chains of porous hydroandraditic garnets harboring polyhedral/polygonal serpentines and iron oxides. Their strict association with remnants of multiple organic polymers carrying biological functionalities and thermally-evolved carbonaceous matter, proves that cryptoendolithic life drives hydrogarnet dissolution and concomitantly serpentine ± iron oxides formation while sequestrating carbon through primary production. Mass balance shows these activities to be local source for Ca and a sink for Mg. Our results support the existence of deep ecosystems within the low-temperature hydrating mantle sustained by the process of serpentinization that mediate chemical fluxes from the Earth's lithosphere to oceans and potentially impact the overall chemical transfer between the Earth's mantle and the exosphere.

Mesoarchaean tectono-metamorphic event from Bundelkhand craton, central India

J.K. PATI[1]* AND L. SAHA[2]

[1]Department of Earth and Planetary Sciences, UA, Allahabad, India (*correspondence: jkpati@yahoo.co.in)
[2]School of Geological Sciences, UKZN, Durban, SA

Bundelkhand craton is exposed over ~29, 000km^2 area in north-central India. The craton consists of slivers of Archaean greenstone successions within granitoids and gneisses, latter containing components with ages: 3.5 Ga [1], 3.3 Ga, 2.7 Ga and 2.56-2.49 Ga [2]. The amphibolites from the greenstone slivers yield depleted mantle ages clustering around 4.9-4.2 Ga and 3.4-3.3 Ga [3]. While the older age range may correspond to protolith formation, the younger cluster may indicate age of metamorphism.

Our study concentrates on a greenstone sequence SW of Mauranipur. The sequence consists of interlayered amphibolite-calc silicate-biotite schist-quartzite and have steeply dipping foliation. Amphibolites are of two types: Type-1, retrogressed amphibolites with garnet porphyroblasts in a matrix of chlorite-quartz, Type-2 amphibolites with hornblende-defined foliation and cross-cutting quartzo-feldspathic veins. Garnet porphyroblasts are extensively replaced by chlorite in Type-1 amphibolite. The Type-1 amphibolite is interbanded with a calc-silicate, latter consisting of alternate bands of garnet-amphibole-calcite-quartz and clinopyroxene-epidote-calcite-quartz. Garnets in the Type-1 amphibolite and in calc-silicate have compositions: $Prp_{11-14}Grs_{13-15}Alm_{65-69}Sps_{5-9}$ and $Grs_{30-50}Alm_{15-32}Sps_{34-37,}$ respectively. The P-T condition of metamorphism is ~5.7 kbar, 425-450°C and this has been obtained from the garnet-bearing layer of calc-silicate by determining the intersection of stable reactions by using THERMOCALC.

We conclude that the age of this metamorphic event from Bundelkhand craton was probably ~3.3 Ga, as obtained from the Nd isotope systematics of the amphibolites. The P-T conditions of metamorphism indicates a high geothermal gradient of ~30°C/km in contrast to ~ 12°C/km recorded during Neoarchean [5] from the craton.

C, O, Sr isotope compositions of sediments of the Mesozoic Kutch basin, NW India

D.J. PATIL[1], B. SREENIVAS[1], C. SRIKARNI[2], P.B. RAMAMURTHY[1], E.V.S.S.K. BABU[1], B. VIJAYA GOPAL[1] AND A.M. DAYAL[1]

[1]National Geophysical Research Institute (CSIR), Hyderabad 500007, India (djpatil@ngri.res.in)
[2]Geological Survey of India, Itanagar, Arunachal Pradesh, India

The Mesozoic period of earth history is known for the preservation of bulk of global hydrocarbon reservoirs. It is also known that this period is marked by global scale anoxic events reflecting in the C, O and Sr isotope records of marine carbonates [1]. In this work we report C, O and Sr isotope compositions of marine carbonate rocks belonging to the Mesozoic Kutch sedimentary basin of NW India. The sediments of the Kutch basin range in age from Bathonian stage (169.2 Ma) of Middle Jurasssic to the Albian (98.9 Ma) of the Cretaceous. Carbonate sediments belonging to the lower Jhurio (Bathonian to Callovian) and Jumara (Callovian to Oxfordian) Formations have been analyzed for their $\delta^{13}C$, $\delta^{18}O$ and $^{87}Sr/^{86}Sr$ values showing wide ranges mainly due to the effect of later diagenesis. Using the proxies such as Mn/Sr, $\delta^{18}O$ and $^{87}Sr/^{86}Sr$ the best-preserved C, O and Sr isotope compositons of ambient seawater compositions has been estimated (Table 1).

Formation	$\delta^{13}C_{Carb}$	$\delta^{18}O$	$\delta^{13}C_{Org}$	$^{87}Sr/^{86}Sr$
Jumara	-1.5 to 1.6 (n = 15)	-10.7 to -5.8 (n = 15)	-29.4 to -24.6 (n = 12)	0.707080 to 0.707441 (n = 15)
Jhurio	-1.0 to -1.6 (n = 2)	-6.4 to -9.4 (n = 2)	-30.9 to -26.9 (n = 2)	

Table 1: Best-preserved C, O and Sr isotope compositions of Mesozoic Kutch carbonates

While the best-preserved $\delta^{13}C$ and $^{87}Sr/^{86}Sr$ values of Kutch carbonates are well in agreement with the global curves, the $\delta^{18}O$ values show large depletion up to 5‰ when compared to the ambient global mean. The observed diagenetic trends indicate possible thermal maturity of organic matter and hence generation of hydrocarbon reservoirs as also corroborated by surface geochemical prospecting methods.

Improved $^{27}Al/^{24}Mg$ ratio measurement using a modified isotope-dilution approach

C. PATON*, M. SCHILLER, D. ULFBECK AND M. BIZZARRO

Center for Star and Planet Formation, Natural History Museum, University of Copenhagen, Øster Voldgade 5–7, 1350, Copenhagen, Denmark (*correspondence: cpaton@snm.ku.dk)

With its half-life of ~0.73 Myr, the decay of (now extinct) ^{26}Al to ^{26}Mg is capable of providing extremely precise relative ages, and as a result the ^{26}Al–^{26}Mg system is widely employed in constraining the timing of events in the early solar system. The popularity of ^{26}Al as a chronometer has stimulated a continual refinement in the analytical methods of Mg-isotope determination, resulting in a present day reproducibility for $^{26}Mg^*$ values of better than 3 ppm [1]. However, methods for the measurement of $^{27}Al/^{24}Mg$ ratios (as a proxy for parent/daughter ratios) have seen little improvement, and the present accuracy of ±2% [2] is no better than it was a decade ago [3]. As a result, the uncertainties in Al/Mg isochrons are now dominated by uncertainties in the measured $^{27}Al/^{24}Mg$ ratio.

By modifying conventional mixed-spike isotope-dilution methods we have developed a technique using a spike consisting of isotopically enriched ^{25}Mg and isotopically normal Al, which incorporates an approach analogous to standard-sample bracketing. The method employs isotope dilution to determine the spike to sample ratio for magnesium, but utilises bracketing of spiked and unspiked sample solutions to obtain the spike to sample ratio for aluminium. A typical run consists of four spiked measurements, bracketed by five unspiked measurements, and consumes < 2 μg of Mg.

This technique overcomes the problem of aluminium being monoisotopic, and measurements of international rock standards, as well as a gravimetric calibrant solution, indicate a reproducibility approaching conventional mixed-spike isotope dilution (i.e. 2 s. d. of <0.5%). Measurements are made on a single unpurified aliquot of the sample, so no chromatographic separation is required, and the method is less susceptible to biases generated by differences in sample matrix composition.

Concentration of chalcophile and siderophile elements in MORB sulphide droplets: New sulphide melt-silicate melt partition coefficients

C. PATTEN[1], S.-J. BARNES[2] AND E.A. MATHEZ[3]

[1]Sciences de la Terre, Université du Québec à Chicoutimi (clifford.patten@uqac.ca)

[2]Sciences de la Terre, Université du Québec à Chicoutimi (Sarah-Jane_Barnes@uqac.ca)

[3]Department of Earth and Planetary Sciences, American Museum of Natural History, New York (mathez@amnh.org)

We have determined the concentrations of chalcophile and siderophile elements by LA-ICP-MS from sulphide droplets and fresh glass in contact with them from MORB pillow rims. MORBs play an important role in the understanding of mantle petrogenesis, providing information on chemical fractionation of elements in the mantle. However, chalcophile element behaviour is not completely understood, partly due to the lack of data for partition coefficients between sulphide and silicate melts.

Some droplets present homogenous textures and others portions rich in monosulphide solid solution (Mss) and intermediate solid solution (Iss) indicating that they have undergone crystal fractionation. For homogenous droplets, concentrations of Ni and Cu are 10 to 1%; Co and Zn 1000 to 100 ppm; Se, Te, Ag and Pb 100 to 10 ppm; Cd, Sn, Pd, Bi and Pt 10 to 1 ppm; Au, Ru and Re 1 to 0.1 ppm. For some of these elements it was also possible to obtain data in fresh glass allowing the calculation of partition coefficients. These were calculated for Ni (745± 252), Cu (1219 ± 381), Co (42 ± 5.5), Zn (3.4 ± 0.9), Sn (10.4 ± 1.8) and Pb (55.6 ± 9.3). Values for Ni, Cu and Co are in agreement with literature [1], suggesting that values for Zn, Sn and Pb are realistic.

Radiation damage in biotite: Defined by Micro XAS and XRD

RICHARD PATTRICK[1], TINA GERAKI[2], JOHN CHARNOCK[1], CAROLYN PEARCE[3], SIMON PIMBLOTT[1] AND GILES DROOP[1]

[1]RCRD, University of Manchester, Manchester, UK, M13 9PL
[2]Diamond Light Source, Harwell, Oxfordshire, OX11 0DE
[3]PNNL, Richland, WA 99352, USA

Radiation damage in mineral structures is of interest because of their consideration as radioactive waste forms. Examples of damage occuring on geological timescales are available in nature. Alpha particle damage around actinide-bearing inclusions in silicates is best observed in the mineral biotite where a *ca* 35 micron damage halo is seen. By using combined synchrotron XAS and XRD at the Diamond Light Source, UK, the changes across the damaged zone around a U/Th-bearing monazite inclusion was investigated. Fe K-edge XANES from a traverse shows that within the damaged zone the biotite Fe^{3+} is reduced, perhaps as a consequence of radiolysis of the OH groups in the octahedral layers. The Fe K-edge EXAFS show an increase in disorder in the damaged zone. The micro XRD showed major changes in the biotite lattice as the U/Th containing inclusion was approached. The use of a single crystal positioned perpendicular to (001) enhanced the a, b plane reflections. The diffraction spots representing 110 and other sub-parallel planes show evidence of amorphisation of the biotite lattice. Also new reflections appear at d-spacings close to the main reflections, indicating local changes to the structure as a result of atomic displacements during the development of Frenkel pairs.

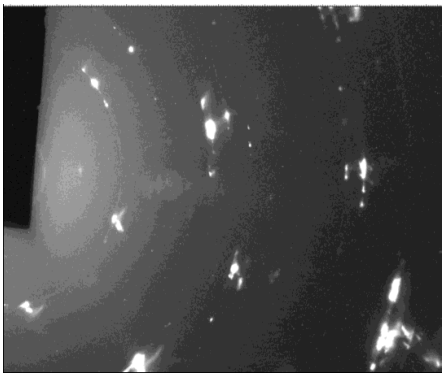

Figure. 1. Synchrotron diffraction image of biotite adjacent to an alpha particle emitting inclusion.

Melt inclusion Pb-isotope analysis by LA-MC-ICPMS: Assessment of analytical performance and application to OIB genesis

BENCE PAUL[1,2]*, JON D WOODHEAD[1], JANET HERGT[1] AND LEONID DANYUSHEVSKY[2]

[1]School of Earth Sciences, The University of Melbourne, Victoria, Australia (*correspondence: bpaul@unimelb.edu.au)
[2]CODES ARC Centre of Excellence in Ore Deposits, University of Tasmania, Tasmania, Australia (L.Dan@utas.edu.au)

We present laser ablation MC-ICPMS lead isotope measurements of olivine-hosted melt inclusions, analyses that include the low abundance Pb-isotope, ^{204}Pb, measured on an ion counter. These data were collected using a unique parallel ion counter-faraday cup method, developed for melt inclusion isotope analysis [1]. We tested this technique on an isotopically homogeneous sample from Tonga to provide constraints on both precision and accuracy. Using the variability of these data we then re-investigate two OIB inclusion suites. These new data demonstrate that greater variability than would be expected from analytical errors alone can be discerned in the two OIB suites.

Our data suggest that melt inclusions are not biased towards grain-scale phenomena and thus may indeed be representative of geologically significant processes in magma chambers. In the case of the Pitcairn Seamounts, we find that each sample contains melt inclusion compositions with the same variablity as the entire whole-rock sample population for these seamounts. Similarly, melt inclusion data from the island Mangaia show the same degree of compositional variability as defined by all lavas on the island.

In addition, our Pb isotope measurements of individual samples suggest that discrete batches of isotopically distinct melt exist to high levels in magmatic plumbing systems.

We also present two preliminary combined trace element/Pb isotope measurements for two inclusions, which we believe demonstrate the potential of such an approach for future studies. Results from the Pitcairn Seamounts suggest that isotopic variability is inherited from the mantle source and not necessarily from late stage crustal contamination.

Fe(II) exchange at titanomagnetite-water interfaces

C.I. PEARCE[1]*, J. LIU[1], O. QAFOKU[1], E. ARENHOLZ[2], S.M. HEALD[3] AND K.M. ROSSO[1]

[1]Pacific Northwest National Laboratory, Richland WA, USA (*correspondence: carolyn.pearce@pnl.gov)
[2]Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA
[3]Argonne National Laboratory, Argonne, IL 60439, USA

Spinel-type iron oxides such as magnetite are an important source of solid-state Fe (II) that can affect the transport of redox-active contaminants, such as ^{99}Tc (VII), in the subsurface. Natural magnetites present in sediments are typically highly impure with titanium, and structural Fe (III) replacement by Ti (IV) yields a proportional increase in the relative Fe (II) content in the metal sublattice to maintain bulk charge neutrality. Titanomagnetite ($Fe_{3-x}Ti_xO_4$) nanoparticles provide a high surface area pristine material for batch studies to evaluate the availability and reactivity of Fe (II) at the mineral surface. $Fe_{3-x}Ti_xO_4$ nanoparticles accept structural Ti (IV) into the octahedral metal sublattice up to $x = 0.4$; higher values up to $x = 0.6$ yield discrete amorphous Fe (II)/Ti (IV) phases on particle exteriors. In aqueous suspension, there is a net driving force for the movement of Fe (II) from the bulk $Fe_{3-x}Ti_xO_4$ structure to the nanoparticle surface with subsequent release of Fe (II) into solution to reach an equilibrium distribution between interior structural Fe (II)/Fe (III), near-surface Fe (II)/Fe (III), and aqueous Fe (II). Consumption of structural Fe (II) through both dissolution and redox reactions results in the replacement of octahedral cations with vacancies to form an Fe (II)-deficient titanomaghemitized surface. Spontaneous Fe (II) release from the solid into solution increases in extent systematically with both Ti-content and decreasing pH. The presence of Tc (VII) in solution, as an electron accepting probe molecule, also increases this driving force as Fe (II) at the surface reacts with the Tc (VII) to form of a mixed Fe (III)-Tc (IV) co-precipitate. In principle, this titanomaghemitization process is reversible and, under reducing conditions, structural reducing equivalents can be restored by an external Fe (II) source. Pre-oxidized $Fe_{3-x}Ti_xO_4$ nanoparticles were found to be systematically restorable to Tc (VII) reduction rate behavior of pristine titanomagnetites by exposure to various concentrations of aqueous Fe (II). The findings demonstrate that the reactive structural Fe (II) pool can be resupplied in these $Fe_{3-x}Ti_xO_4$ phases and suggest that the mechanism involves facile coupled electron/ion transport across the mineral-water interface.

Stable strontium (δ^{88}Sr) isotopic fractionation during hydrological cycling

CHRISTOPHER R. PEARCE[1]*, IAN J. PARKINSON[1], KEVIN W. BURTON[2] AND JEROME GAILLARDET[3]

[1]Department of Earth and Environmental Sciences, CEPSAR, The Open Universtiy, Walton Hall, Milton Keynes, MK7 6AA, UK (*correspondence: c.pearce@open.ac.uk)
[2]Department of Earth Sciences, Oxford University, Parks Road, Oxford, OX1 3PR, UK
[3]Laboratoire de Geochimie-Cosmochimie, Institute de Physique du Globe de Paris, 7 Place Jussieu 75252, Paris, Cedex 05, France

The stable strontium (δ^{88}Sr) isotope system has considerable promise for resolving source and flux variations during elemental transfer to the oceans by continental weathering. In combination with radiogenic Sr isotope ratios (^{87}Sr/^{86}Sr), δ^{88}Sr provides an additional compositional space in which the riverine source and weathering flux effects can be distinguished.

Analysis of >40 % of the global Sr flux to the oceans has revealed an average riverine δ^{88}Sr composition of 0.34 ‰ [1], similar to the mean seawater value of 0.36 ‰ [2]. Most continental rivers vary about this mean (between 0.2 ‰ and 0.5 ‰), although a broader range of values (0.1–0.9 ‰) is observed in rivers draining basaltic and carbonate terrains where fractionation processes relating to carbonate precipitation and dissolution are thought to occur [1].

The largest δ^{88}Sr offset in the modern hydrological cycle is observed in continental ice, with Langjökull glacier in west Iceland having a value of -0.24 ‰. The δ^{88}Sr composition of Parisian rainwater, 0.26 ‰, is also significantly lighter than seawater, and similar offsets have been previously reported in glacial meltwaters from Switzerland [3]. This evidence for the compositional differentiation of stable Sr isotopes between seawater and precipitation contrasts with results from other isotope systems (such as Li, Mg, Mo and Si), and implies that Sr-specific fractionation may be occurring during the evaporation-precipitation and/or freeze-thaw processes. This study explores the potential mechanisms responsible for this isotopic fractionation and the possibilities for using δ^{88}Sr as a monitor of the hydrological cycle.

Newly-discovered abyssal peridotite mantle xenoliths constrain mid-ocean ridge melting models

JULIAN A. PEARCE[1], PHILIP T. LEAT[2], TIFFANY L. BARRY[3] AND ANDREW G. TINDLE[4]

[1]School of Earth and Ocean Sciences, Cardiff University, Cardiff CF10 3YE, UK (PearceJA@cf.ac.uk)
[2]British Antarctic Survey, Cambridge CB3 0ET, UK (ptle@bas.ac.uk)
[3]Dept. of Geology, University of Leicester, Leicester LE1 7RH, UK (tbl2@leicester.ac.uk)
[4]Dept. of Earth Sciences, The Open University, Milton Keynes MK7 6AA, UK (a.g.tindle@open.ac.uk)

Much of our knowledge of mantle melting beneath mid-ocean ridges comes from modelling based on the composition of MORB and of variably-serpentinized abyssal peridotites tectonically exposed on the ocean floor. Here, we report a unique occurrence of fresh nodules of young, deep, sub-ridge oceanic lithosphere with the potential to test these melting models. The setting is the West Scotia Ridge spreading centre which actively spread at intermediate-slow rates for c.25Ma. Following the cessation of spreading at c.5.5Ma (Ar-Ar and magnetic anomaly dating), a final pulse of alkali basalt erupted at c.0.3Ma carrying the peridotite nodules to the sea-floor. Thermobarometry places these nodules at an original depth of c.1±0.3 GPa (Ca-in-olivine) and a temperature of c.1050°±35C (olivine-spinel and Ca-in-orthopyroxene), the latter consistent with c.6Ma of cooling of oceanic lithosphere at c.25-30km depth. Geochemical interpretation of the nodules (spinel Cr# and clinopyroxene REE) indicates that they have experienced c.12% of fractional melting, c.5% in garnet facies and c.7% in spinel facies, so supporting models for initiation of ridge melting in garnet facies and supporting some estimates for melt production rates (dF/dP). The host alkali basalt has REE concentrations and MREE-HREE gradients consistent with formation by a small degree of mainly garnet facies melting and so supports models requiring a contribution to MORB of a deep, small-volume melt with high incompatible element concentrations. The Nd isotope ratio of the alkali basalt is less than that of the MORB/nodule (0.513015 cf. 0.513095), which may result from sources of different compositions but could also be explained by fractional melting of a heterogeneous mantle. Thus the dying ridge setting provides a useful opportunity to sample the small melt fractions and deep near-ridge lithosphere normally unavailable during active spreading and facilitates the ground-truthing of ridge melting models.

Crust-mantle links in cratons

D.G. PEARSON[1]*, S. TAPPE[1], K.A. SMART[1], K.A. MATHER[2], C.W. DALE[2] AND B.A. KJARSGAARD[3]

[1]University of Alberta, Edmonton AB, T6G 2E3, Canada (*correspondence: gdpearso@ualberta.ca)
[2]Durham University, Durham, DH1 3LE, UK
[3]Geological Survey of Canada, Ottawa, Canada

Cratonic crust and its underlying mantle root are both bouyant survivors of the Archean tectonic regime. A central issue in constraining the formation of continents in this Eon is the genetic relationship between these two 'stable' units. Peridotite and eclogite xenoliths erupted by kimberlites provide vital clues that can be matched to a growing database of crustal geochemistry and geochronology. We illustrate the diverse relations between crust and mantle in three different cratons over Gyr periods.

(i) *Crust mantle coupling:-* In the North Atlantic Craton, West Greenland, newly discovered eclogite xenoliths are of similar age to the main peridotitic lithosphere. Their elemental geochemistry shows a clear genetic relationship to the TTG crust in that region [1], providing compelling support for craton root construction via tectonic stacking.

(ii) *Crust-mantle decoupling:-* Detrital Pt-alloy grains from late Archean sedimentary basins provide robust age data to compare with depletion ages from the underlying peridotitic root. These ages are generally distinct from the main craton-building events and appear to document earlier differentiation of oceanic mantle prior to craton formation.

(iii) *Major magmatic modification of lithosphere:-*

The Slave and Kaapvaal cratons both show evidence of major magmatic crustal addition and lithospheric mantle modification/growth due to the impact of some of the planet's largest igneous events. The entire lithosphere beneath the N. Slave craton is modified by the 1.3 Ga McKenzie LIP, with significant mass addition into the deeper cratonic crust that may go undetected in zircon studies of crustal evolution.

The Kaapvaal craton has been extensively modified by the 2.0 Ga Bushveld/Malopo Farms event that left a clear compositional imprint in the Kaapvaal lithospheric mantle. In contrast, the major 1.1-1.3 Ga Namaqua-Natal crustal event left a more subtle record on the root of the central craton but more strongly affected peri-cratonic lithospheric mantle to the SW of the craton margin. In detail, multiple linked crust-mantle events are evident over the 3.5 Gyr history of this and other cratons indicating that cratonic roots are more dynamic than usually assumed.

Matrix effects and Hf isotope analysis of zircon by laser ablation MC-ICP-MS

NORMAN J. PEARSON[1], JUSTIN L. PAYNE[2] AND KEVIN J. GRANT[1]

[1]GEMOC/CCFS, Earth and Planetary Sciences, Macquarie University, NSW 2109 Australia (norman.pearson@mq.edu.au, kevin.grant@mq.edu.au)
[2]Centre for Tectonics, Resources and Exploration, University of Adelaide, SA Australia 5005 (justin.payne@adelaide.edu.au)

In the last decade there have been significant advances made in the *in situ* measurement of Hf isotopes in zircon and the application of the Lu-Hf isotopic system to help constrain the sources that contributed to zircon formation. The information obtained from the *in situ* Hf analysis of zircon has been used to monitor magmatic processes, to identify inherited and juvenile components in magmatic sources, and to evaluate models of crustal evolution. Despite the success of the technique, its application is still limited by the contribution to the total uncertainty by corrections for isobaric interferences, especially for zircons with high REE/Hf ratios. A significant effort has been devoted to demonstrating the robustness of correction methods for isobaric interferences of ^{176}Yb and ^{176}Lu on ^{176}Hf but little attention has been paid to the contribution of molecular interferences.

In this study the accuracy and precision of isobaric corrections and the contribution of REE-oxides on Hf isotopes are evaluated using a suite of synthetic glass beads doped with the JMC475 Hf standard and varying concentrations of Yb, Gd and Dy. The results demonstrate the robustness of the isobaric interference correction procedures for ^{176}Yb/^{177}Hf ratios greater than 0.8 (i.e. approx. three times that of ^{176}Hf/^{177}Hf ratio).

Theoretical calculations and measurement of Gd- and Dy-doped glass beads demonstrate that REE-oxides are also able to bias Hf-isotope data. Gd oxides can produce interferences on a number of Yb isotopes and Dy oxides overlap several Hf isotopes. The significance of these interferences depends on the oxide production of the mass spectrometer as well as the slope of the REE patterns (Gd/Yb) and REE/Hf ratios (Dy/Hf). The results can potentially explain a number of observed correlations between REE content of zircon and measured Hf isotope ratios. These 'matrix-effects' are most apparent in high REE zircons and in zircons with high Gd/Yb ratios and leads us to recommend monitoring of REE levels and oxide interference corrections.

Assimilation of lithospheric mantle melts by West Greenland tholeiitic magmas recorded by melt inclusions

D.W. PEATE[1]*, I. UKSTINS PEATE[1], A.J.R. KENT[2] AND M.C. ROWE[1,3]

[1]University of Iowa, Iowa City, IA 52242, USA (*correspondence: david-peate@uiowa.edu)
[2]Oregon State University, Corvallis, OR 97331, USA
[3]Washington State University, Pullman, WA 99164, USA

An issue in many flood basalt provinces is how to distinguish crustal assimilation from lithospheric mantle inputs. We have studied olivine-hosted melt inclusions in five high MgO samples (olivine separates from [1]) from the Paleocene picrite-dominated Vaigat Formation in West Greenland [2]. Melt inclusions can preserve a diversity of compositions that record petrogenetic processes taking place within the magmatic plumbing system. Inclusions were rehomogenized to glass in a 1-atm gas-mixing furnace prior to EPMA and LA-ICP-MS analysis. One sample (332788) has lower ^{143}Nd/^{144}Nd and higher ^{206}Pb/^{204}Pb than the other samples. Inclusions from the other four samples show limited compositional variability, limiting any role for crustal assimilation, and inclusions in rare high Fo% (~92) olivines are similar to inclusions in less forsteritic olivines in terms of incompatible element ratios, indicating that the high Fo% olivines are not xenocrystic. Whole rock data on more evolved flows [1] show isotopic evidence for assimilation by crust with low ^{143}Nd/^{144}Nd and low ^{206}Pb/^{204}Pb, different to the displacement trend of sample 332788. Inclusions in sample 332788 show significant compositional variability, with K/Ti varying from 0.14 to 0.33 (compared to 0.12 to 0.19 in inclusions from the other samples). Trace element data show that K/Ti in inclusions from sample 332788 correlates with incompatible element ratios such as Zr/Y and Zr/Nb but not with La/Nb and Ba/Nb that might have been expected for crustal assimilation. Small-volume, incompatible-element-enriched, alkali picrite flows, interpreted as melts of old metasomatized lithospheric mantle, are found at a similar stratigraphic level elsewhere in the province [3]. Their isotopic composition is consistent with the displacement of sample 332788 from the other samples, and their trace element composition can explain the variations in the inclusions. The presence of these melts near the surface suggests a shallow-level magma mixing model rather than assimilation during ascent through the lithosphere.

D/H composition of leaf waxes from C_3 plants along a transect from the UK to central Siberia, Russia

N. PEDENTCHOUK[1]* AND K. FISHER[2]

[1]School of Environmental Sciences, the University of East Anglia, Norwich, NR4 7TJ, UK (*correspondence: n.pedentchouk@uea.ac.uk)
[2]Department of Georgraphy, the University of Leicester, UK

The δD values of individual organic compounds from leaf waxes are being increasingly used in environmental sciences. Extracting palaeoecological and palaeoclimatological information from the organic D/H signal requires a clear understanding of hydrogen isotope fractionation between the source water and biosynthates. The purpose of this work is to investigate differences in hydrogen apparent fractionation factor (ε) among several common deciduous and conifer plant species in northern Eurasia.

We determined the D/H composition of *n*-alkanes derived from leaf waxes extracted from several extant plants representing conifer (*Pinus*) and deciduous angiosperm (*Betula* and *Salix*) genera along a longitudinal transect from the UK to central Siberia in 11 locations. We also measured the δD values of tap waters collected at the same locations. The *n*-alkane and leaf water data were then used to calculate ε values. Our initial results show the following.

The δD values of *n*-C_{27} alkane from individual genera correlate with the δD values of tap water along the transect. The R^2 values for *Betula* (9 locations), *Salix* (5 locations) and *Pinus* (6 locations) are 0.95, 0.97, and 0.82, respectively. However, the ε values calculated between *n*-C_{27} alkane and tap water differ significantly among the genera: *Betula* -84‰, *Salix* -142‰, and *Pinus* -119‰. We suggest that there are at least two possible explanation that could account for such large difference in the ε values. Because of the differences in tree morphology and habitat, the plants could be using isotopically different soil water, so that *Betula* consumed soil water that underwent a larger D-enrichement than *Pinus* and *Salix*. Additionally, or alternatively, plants could vary in terms of their leaf morphology and biochemistry of photosynthesis so that the differences in biosynthate D/H composition – and thus in the ε values – arise during the processes that take place at the leaf level.

Further research involving analysis of the δD values of soil and leaf water as well as plant physiological variables at individual locations will help clarify which factors and to what extent control D/H fractionation between the individual compounds in leaf waxes and the source water.

Desorption of quinoline from clay: An investigation of the LoSal™ mechanism

C.S. PEDERSEN*, C.P. HEM AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*correspondence: cspe@nano.ku.dk)

Oil recovery from reservoirs is often less than 30%; increasing this would be an efficient way of increasing the available global oil resources. In traditional water flooding, recycled reservoir brine or sea water is injected to flush out interstitial oil. When this high salinity water is substituted with low salinity water (LoSal™), oil recovery from sandstone reservoirs has been shown to increase by 5 to 15% [1]. We have investigated the interaction between aromatic base compounds, as models for crude oil, and clay to gain understanding about the mechanism behind the LoSal™ effect.

Quinoline, a model for aromatic bases in oil, was adsorbed from aqueous solution onto kaolinite and Ca-montmorillonite. The clay samples were subsequently rinsed with high (36000 ppm) or low salinity water (1400 ppm). We found that high salinity water was more than 50% more effective in removing quinoline from both kaolinite and Ca-montmorillonite. Quinoline is adsorbed as a cation and therefore increased desorption can be explained by cation exchange. These results contrast with the LoSal™ effect, suggesting that the LoSal™ effect is not associated with the adsorption of aromatic bases on clays. We are currently investigating the interaction of other functional groups and minerals in an attempt to mimic the LoSal™ effect. This is the first step toward improving understanding of oil-water-mineral interactions in reservoirs at the molecular level.

[3]Cornell University, Ithaca, New York, USA

Injection of seawater in 130°C offshore chalk oil fields will induce chemical alterations as the seawater is not in equilibrium with the formation. This has been confirmed by core experiments. Furthermore, the core experiments reveal that the chemical alteration induces enhanced compaction and enhanced oil production. Many conceptual models have been suggested for this phenomenon, but quantitative geochemical simulations on the pore scale is missing. We investigate the spatial distribution of the chemical alterations induced by seawater and $MgCl_2$ flooding at 130°C; the net chemical change in the pore space is compared with the net chemical change observed in the core experiments.

A full geochemical solver integrated with a lattice Boltzmann (LB) model is used to model the pore scale reactive flow. The LB model solves the fluid flow and the advection-diffusion of the chemical species, while the geochemical model gives the interaction between the aqua chemical species and the pore mineral-surfaces. The geochemical solver has been compared successfully with PHREEQC and effluent from core experiments. A simulation on a carbonate sample is shown in Fig.1.

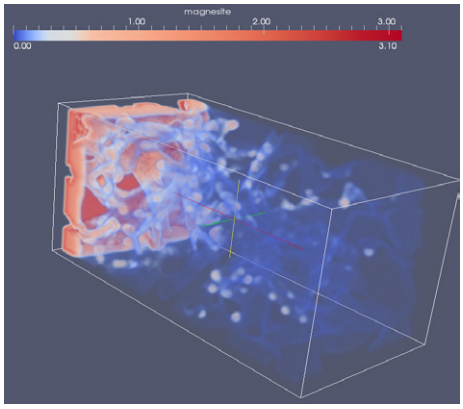

Figure 1: 0.219M $MgCl_2$ is flooded from the left at 130°C, the pore space is initial in equilibrium with distilled water. After 2 pore volumes of flooding magnesite is precipitated non-uniformly in the pore space (blue (opaque) to red (solid) colours). Only calcite is present initially.

Key impact of soil (Fe/organic C) ratio on REE shallow groundwater patterns

M. PÉDROT*, A. DIA, M. DAVRANCHE AND G. GRUAU

CNRS - UMR 6118 Géosciences Rennes, 35042 Rennes cedex, France (*correspondence: mathieu.pedrot@univ-rennes1.fr)

A number of studies have been carried out over the last two decades on the chemistry of rare earth elements (REE) in stream waters and groundwaters. They occur usually as simple REE (III) species, with the exception of Ce. Indeed, among the REE, Ce is the only element that can be oxidized to the (+IV) state, modifying its behaviour. REE are potentially used as tracers of rock/water interaction processes, groundwater flow and mixing, soil genesis, and notably, as proxies for evaluating paleoceanographic and paleoclimatic change by using Ce anomaly development.

Previous investigations of the REE geochemistry in groundwaters of the Kervidy/Coët-Dan catchment (Brittany, France) showed a systematic, topography related variation of REE signatures, notably a large negative Ce anomaly in the upper part which decreases from top to bottom of the transect. These studies also showed that REE are carried by organic colloids in these waters. A recent study showed that the strong spatial variation of negative Ce anomaly would be due to the input into the aquifer of REE-rich, Ce anomaly-free, organic colloids located in the uppermost, organic-rich soil horizons. Consequently, one major question arises: why organic colloids show a large negative Ce anomaly at the top and Ce anomaly-free at the bottom?

In this context, soil/water interactions performed through soil column experiments, were carried out with several soil samples recovered from top to bottom of two toposequences to understand the origin of the variability of REE patterns in the Kervidy/Coët-Dan catchment. The major carriers phases of the REE pools were determined. Moreover, batch experiments were carried out to investigate the role of organic molecules in the development of Ce anomaly in solution.

The results showed: (i) a strong Ce sequestration in oxidized phases such as secondary minerals formed at the frond of altered shale, (ii) a close relationship between soil Fe/Organic C ratio and Ce anomaly in soil solution. Moreover, this study showed (iii) the strong influence of organic molecules in the lack of Ce anomaly in waters by Fe oxyhydroxide dissolution. Furthermore, the REE signature in the Kervidy/Coët-Dan groundwaters appears to be provided in major part by the upper horizon of soil.

Analysis of oxygen isotopes in minerals is increasingly performed by Secondary Ionisation Mass Spectrometry (SIMS) [1, 2, 3, 4]. However, the application of SIMS to analyse $\delta^{18}O$ values in silicate glasses has been limited due to calibration difficulties related to the highly variable chemical composition of different glasses. In response to this problem, we have initiated the synthesis of a set of glass standards, selected natural samples and other existing experimental glasses [5] for a large-scale calibration program. To date we have fused a series of natural rhyolitic and phonolitic rock powders to produce the first experimental glasses, which have been tested for homogeneity by Electron Microprobe (EMP). We subsequently determined their $\delta^{18}O$ values using: a) a conventional silicate oxygen extraction line, b) laser fluorination and c) SIMS. The data we present here complements other recent SIMS studies of silicate glasses [6] and represent the first stage in our long-term efforts to develop a new SIMS analytical protocol. We plan to expand our glass standards to encompass intermediate to mafic glass compositions. Ultimately this work will significantly contribute to the fields of oxygen isotope geochemistry by SIMS, which can be used not only to study glasses in natural and synthetic systems [e.g. 7, 8], but will have a wide utility for geochemistry and geology in general.

Early Cretaceous bimodal magmatism in Tonghua area, Jilin province, China: Implications for the destruction of the North China Craton

F.P. PEI, W.L. XU, F. WANG, H.H. CAO AND S.M. LU

College of Earth Sciences, Jilin University, Changchun 130061, China (peifp@jlu.edu.cn,xuwl@jlu.edu.cn)

Chronological, geochemical and zircon Hf isotopic data of the Early Cretaceous granitoids, diabases, and gabbros in the Tonghua area, Jilin province, China, provide insights into the spatial extent of the destruction of the North China Craton (NCC). LA-ICP-MS zircon U-Pb dating results indicate that the granitoids, disbases, and gabbros emplaced in the Early Cretaceous (115-134 Ma), consistent with the timing of the intensive magmatism in eastern China in the Mesozoic [1].

The Early Cretaceous granitoids consist chiefly of granite-porphyry. Chemically, they display high SiO_2, and rich in alkali and are characterized by enrichment in LREEs and LILEs, and depletion in HREE, and Ba, P, Ti and Eu, smilar to A-type granite. ε_{Hf} (t) values and Hf model ages of zircons from the granitoids range from -10.8 to -20.8 and from 1.9Ga to 2.5Ga, respectively, indicating that they were mainly derived from the partial melting of the Neoarchean-Paleoproterozoic basement rocks within the NCC.

In contrast, the Early Cretaceous diabases and gabbros exhibit low SiO_2 and high Mg#, and high Cr, Ni and Sc contents, and are characterized by enrichment in LILEs, depletion in HFSEs and P, and no Eu anomaly. They belong chemically to tholeiitic series. The above-mentioned geochemical data indicate that these mafic igneous rocks could be derived from partial melting of the metasomatized lithospheric mantle.

The Early Cretaceous granitoids, diabase, and gabbro in the Tonghua area consititute a bimodal igneous rock association, implying an extensional setting. Combined with the researches on the coeval granitoids and mafic-ultramafic rocks in eastern Liaoning Peninsula [1, 2], we propose that the spatial extent of the NCC destruction should include the northeastern segment of the NCC.

Hydrological constraints for biogeochemical processes in acidic mining lakes

STEFAN PEIFFER

Department of Hydrology, University of Bayreuth, Germany (s.peiffer@uni-bayreuth.de)

Recovery or remediation of acidic mining lakes (AML) is severly impeded through the occurrence of schwertmannite, its transformation and an associated acidity-driven iron cycle that prevents generation of alkalinity [1]

This concept was derived based on evaluuation of sediment pore water data using a diffusion-controlled reactive-transport approach. It has, however, been demonstrated that ground water dynamics may have severe effects on the biogeochemical processes in sediments [2]. In this presentation I will therefore discuss some general aspects as to how hydrological processes interfere with biogeochemical process. Examples that will be discussed are

- The inflow of sulfate load on acidity formation from percolated sedimentary schwertmannite.

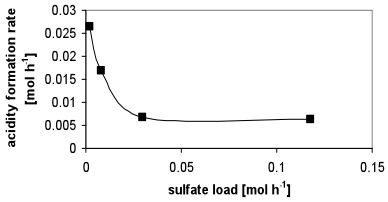

Figure 1: Acidity formation rate as a function of sulfate load measured in column experiments with schwertmannite (data from [3].

- The effect of flow rate on competition between chemical (through sulfide leading to fixation of iron sulfides) and microbial (amplifying the acidity driven iron cycle) reductive dissolution of iron oxides.

- The spatial decoupling between oxidaton of ground-water borne Fe(II) in lake water and and the precipitation of schwertmannite through lake-water travel-path controlled reaction kinetics.

Implications of ground-water flow on biogeochemical processes in an AML will be discussed in a companion paper [4].

High resolution sulfur isotope analyses across sulphate-methane transition zone

A. PEKETI AND A. MAZUMDAR*

Geological Oceanography, National Institute of Oceanography, Donapaula, Goa, 403004, India (*correspondence: maninda@nio.org)

We report here for the first time high resolution pyrite sulfur isotope ratios from Bay of Bengal. Pyrite from the sediment samples was extracted following chromium reduction method. Prior to CRS extraction, elemental sulfur and acid volatile sulphide were extracted using acetone and 6N HCl respectively. Two 30m long sediment cores, MD161-13 and MD161-8 were recovered at water depths of 647m and 1033 m respectively on-board *Marion Dufresne*. The cores were collected as part of our on going methane hydrate exploration program in the Krishna-Godavari basin. The CRS content at MD161-13 increases from 0.005 to 0.26 wt% down depth. CRS content varies from 0.04 to 0.41 wt% in the top 7.3 m at MD161-8. Below this depth CRS content shows marked fluctuations. Figure-1 shows the sulfur isotope ratios observed at the two locations. In both the cores $\delta^{34}S_{CRS}$ values increases with depth below seafloor. Highly depleted sulfur isotope ratios (-36 to -44‰ VCDT) at MD161-8 are attributed to sulfide oxidation and disproportionation of intermediate sulfur compounds. Sulfate limitation due to burial diagenesis resulted in enrichment in sulfur isotope ratios above SMTZ. Across SMTZ, $\delta^{34}S_{CRS}$ increases sharply due to sulfate reduction by anaerobic methane oxidation. AMO cause rapid sulfate limitation.

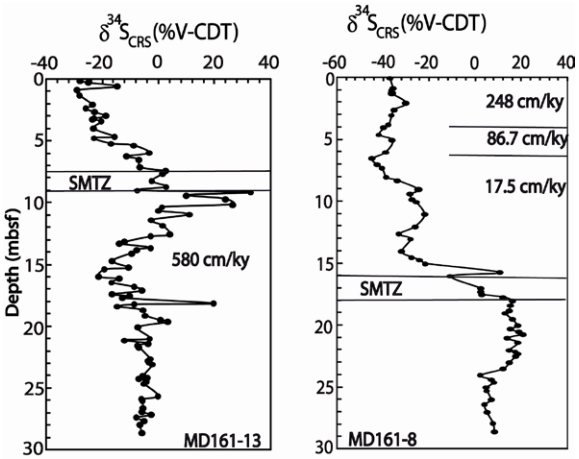

Figure 1: $\delta^{34}S$ of CRS in MD161-8 and MD161-13.

The anthropogenic rise in atmospheric CO_2 is driving fundamental and unprecedented changes in the chemistry of the world's oceans, with detrimental consequences for a wide variety of marine organisms. In this presentation I will review recent advances in our understanding of ocean acidification, with a focus on the Mediterranean Sea, from an integration of new data on high frequency variability of seawater chemistry and on the outputs from a suite of pH manipulative experiments in aquaria. Over the last centuries, paleoreconstructions of seawater pH in coral reefs have shown a certain degree of interdecadal variability. In coastal sites of the Mediterranean, from data measured using autonomous systems, we have also detected significant changes in seawater pH on the order of hours to days, possibly linked to vertical mixing and movement of water masses. To complement this information on natural variability, we have undertaken several experiments of pH manipulation, some of which are currently underway. I will show results from a first experiment of several months of duration on two species of Mediterranean corals, *Cladocora caespitosa* and *Oculina patagonica*, which have confirmed the expected decrease in skeletal growth with decreasing pH. In addition, a second experiment with the Mediterranean sponges *Chondrosia reniformis*, *Agelas oroides* and *Dysidea avara* has shown a varying species response. In this last experiment, changes in the abundance and diversity of sponge associated bacteria are being assessed, to seek for clues on possible groups that may be benefitted from ocean acidification.

Fe-poor and sulfide-rich: Mangrove Lake as a Precambrian analogue?

ANDRÉ PELLERIN[1]*, BOSWELL WING[1], THI HAO BUI[1], ALFONSO MUCCI[1], MIKAELLA ROUGH[1] AND DONALD E. CANFIELD[2]

[1]Departement of Earth and Planetary Sciences, McGill University, Montreal, Quebec, H3A 2A7, Canada (*correspondence: andrepellerin@gmail.com)

Minor sulfur (S) isotopes produce an integrated picture of biogeochemical S cycling through metabolism-specific deviations from reference isotope fractionations, and have become a recent tool in investigating the biogeochemical state of Precambrian oceans. We used this tool to investigate the S cycle of Mangrove Lake, Bermuda: a permanently stratified lake characterized by high levels of algal-derived organic matter (up to 32mM) and high sulfide concentrations (>15mM) below a wind-mixed layer. The sulfate concentration in the mixed layer is controlled by infiltration of seawater from the nearby ocean (~400 m), and is characterized by a $\delta^{34}S$ ~22‰, and $\Delta^{33}S$ ~0.04‰. Sulfate is nearly depleted 30 cm below the mixed layer, with $\delta^{34}S$ values approaching 80‰ and $\Delta^{33}S$ values of ~0.11‰. Proxies for sulfate in the Precambrian oceans that exhibit similar isotopic characteristics have been taken as evidence for a microbially complex marine S cycle, with active S re-oxidation and disproportionation. Nevertheless, we can nearly reproduce our $\Delta^{33}S$- $\delta^{34}S$ trajectories with a simple 1-D diffusion-reaction model that only considers microbial sulfate reduction. We will explore whether this apparent discrepancy represents the peculiar mechanisms of sulfide removal in Mangrove Lake, the inappropriate application of model parsimony, or limitations of retrodicting Precambrian oceanic conditions from modern analogue environments.

Influence of dust deposits to the budget of U-series nuclides in mount Cameroon basaltic soils

E. PELT[1], F. CHABAUX[1], C. INNOCENT[2], B. GHALEB[3] AND P. STILLE[1]

[1]LHYGES Strasbourg, UDS/CNRS, France
[2]BRGM Orléans, France
[3]GEOTOP Montréal, Canada

The timescale of soil formation can be inferred from U-series disequilibria. This requires a complete comprehension of sources and fractionation of U-series nuclides during soil formation processes [1]. Usually, aeolian inputs are not considered to be an important source of U-series nuclides in soils. We therefore propose to evaluate the impact of dust deposition on U-series nuclides in soils, by working on present and paleo-soils from the mount Cameroon volcano. Sr-Nd-Pb isotopic data for these samples have documented significant inputs of Saharan dusts in these soils [2]. Comparison of ^{238}U-^{234}U-^{230}Th isotopic data with Sr-Nd-Pb isotopic ratios indicates a significant impact of the dust inputs onto U-Th budget of the soils, with a mean value of 15% dust contribution for both U and Th. The dust pool estimate for both U-Th concentrations and U-Th isotope ratios is compatible with data obtained on Saharan dusts collected in Barbados [3]. However, according to U/Th elemental ratios, a secondary uranium migration associated with chemical weathering has affected both soils and paleo-soils. The quantification of this small U mobile pool (~10%) highlights that in this context the effect of dust accretion onto U-Th budget in soils can be as important as chemical weathering effect. This conclusion means that atmospheric dust cannot be systematically neglected in chemical weathering studies using U-series nuclides. Nevertheless, in basaltic terrains of mount Cameroon large dust inputs from continental crust of Sahara with high U-Th content contaminate soils with low U-Th contents. In other contexts where dust inputs are lower, or the soils more concentrated in U and Th, the dust contribution might not significantly influence U-series chronometry.

Organic geochemistry of mudstones in the Upper Permian Linxi Formation, NE China: Implications for hydrocarbon-forming potential in the Late Paleozoic strata

X.L. PENG*, L. LIU, N. LIU AND X.P. ZENG

College of Earth Sciences, Jilin University, Changchun, 130061, China (*correspondence: Pengxl@jlu.edu.cn)

It has been a hotly discussed issue whether the Late Paleozoic strata in the Xing-Meng orogenic belt (NE China) have hydrocarbon-forming potential or not. However, organic geochemical data of the mudstones from the Upper Permian Linxi Formation in northeastern Inner Mongolia provide insights for that. The Upper Permian Linxi Formation consists mainly of dark mudstone, shale, siltstone, fine sandstone. The thickness of the mudstones in the Formation is about 276 m in Solon. Organic geochemical analytical results for 30 mudstone samples indicate that their residual organic carbon contents range from 0.45~3.55% (average 1.09%). TOC values for about 87% samples are over threshold of the organic matter abundance (0.5%), and TOC values for about 73% samples are more than 0.6%, suggesting that the source rocks are of the midium-good hydrocarbon-forming potential. The organic matter includes sapropelinite and vitrinite, with a typical kerogen type of II_1-II_2. The Ro values range from 1.57% to 2.71%, and the maximum pyrolysis temperature is 475~507°C (average 488°C). Taken together, it is suggested that the source rocks are high maturity. Combined with the high-evolutionary hydrocarbon source rocks from the Tarim and Sichuan basins, we consider that the Upper Permian Linxi Formation could have the gas-forming potential, and that the marine source rocks from the Late Paleozoic strata in NE China could be of a good hydrocarbon -forming prospects.

[5]Institute of Geology, China Earthquake Administration

Dashui Gold Deposit in Maqu, Gansu found in west Qinling mountain area is a gold deposit with extra unique mineralization characteristics. Ore bodies mainly outcrop in the hematitization silicified limestone, hematitization silicified granodiorite and their contact zone. The ores are red, brown and very poor in sulfides.

Hydrothermal calcite veins within the mining area are well developed. They are closely associated with gold mineralization temporally and spatially, and often constituting the roof and floor of ore bodies. According to the calcite veins' spatial output form, crystal habits and the relationship with gold mineralization, the process can be divided into three stages, and the calcite from second stage is closely related to mineralization. In this research there were total 12 inclusion samples collected, two calcite samples from first stage, seven from second stage and three from the third stage.

The inclusion characteristics of Dashui Gold Deposit indicate that ore-forming temperature is bounded up with metallogenic depth. The maximum metallogenic depth in 3490m middle section is 0.59km with a maximum ore-forming temperature 370.1°C. The metallogenic depth of 3530m middle section is low. There are two samples collected from 0.29km and 0.30km separately with low ore-forming temperatures 168.2°C and 168.3°C of each other. This indicates that the the ore-forming fluid was upward migrating from the depth.

Regnonally the ore-forming temperature of fluid is decreasing from east to west. The average homogeneous temperature of east zone is 240.66°C, the general temperature are 217.4°C, 243.7°C and 276.3°C. The west zone's is decreasing to 174°C, showing that the migration of ore-forming fluid was from east to west. The ore-forming temperature can be divided into three intervals: 370.1°C, 217.4°C-276.3°C and 168.2°C-174°C, which can also stand for three metallogenic stages

The solubilities and phase diagram of the aqueous system containing with vanadate at 298 K

Y. PENG[1,2] AND Y. ZENG[1,2]*

[1]College of Materials and Chemistry & Chemical Engineering, Chengdu University of Technology, Chengdu, Sichuan, P. R. China.
[2]Mineral Resources Chemistry Key Laboratory of Sichuan Higher Education Institutions, P. R. China (*correspondence: zengyster@gmail.com)

The solubility of vanadium in soil solution is effected by coexisting ions in soil, such as potassium, sodium, phosphorus and so on. In this article, the solubility of the metavanadate coexists with them has been determined. The phase equilibria of the quaternary system Na^+, K^+// VO_3^-, $H_2PO_4^-$ - H_2O were studied at 298 K using an isothermal dissolution equilibrium method.

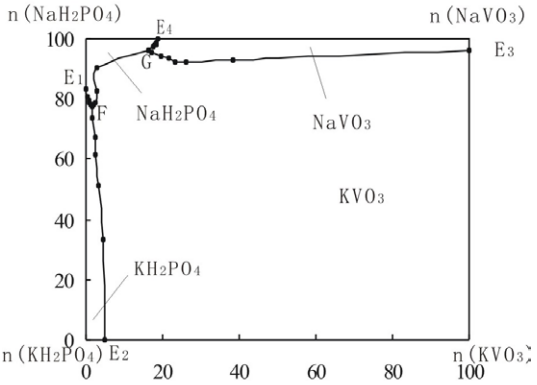

Figure 1: The solubility isotherms of the quaternary system Na^+, K^+// VO_3^-, $H_2PO_4^-$ - H_2O at 298 K

The phase diagram, as shown in Figure 1, is consists of four crystallization fields, five univariant curves, and two invariant points. No double salt or solid solution was formed at research temperature. The crystallizing field of KVO_3 is larger than that of $NaVO_3$, which indicates the solubility of KVO_3 is smaller than that of $NaVO_3$. In this weakly acid system, the crystallization form of metavanadate is polyoxovanadate. The dissolution and migration of vanadium in aqueous solution has negative correlation with dihydrogen phosphate ion.

[3]Research School of Earth Sciences, ANU, Canberra 0200, ACT, Australia
[4]Dept. of Oceanography, University of Hawaii at Manoa, Honolulu, HI 96822 USA

The Paleocene-Eocene Thermal Maximum (~55Ma) is recognized as a rapid (<10ka) input of a large mass (~4500-6000 GtC) of ^{12}C-enriched carbon into the ocean-atmosphere system. Patterns of $CaCO_3$ dissolution at the suggest that this was accompanied by a rapid decrease in ocean pH, followed by a gradual recovery phase. A further result of such modeling studies is the suggestion of an 'overshoot' or supersaturated ocean phase after the recovery, when the carbonate lysocline deepened to below its Paleocene depth and surface water carbonate saturation states rose to above pre-excursion levels. In an effort to quantify changes in the carbonate chemistry of surface waters and infer potential effects on calcifying organisms and Mg/Ca and $\delta^{18}O$-based temperature estimates, we have measured B/Ca and Mg/Ca in mixed-layer planktic foraminifers from IODP site 1209 in the Pacific and sites 1262 and 1263 in the Atlantic. Previous work at these sites has documented large increases (~50%) in Mg/Ca ratios in the mixed-layer planktic foraminifer species *M. velascoensis* and *A. soldadoensis* consistent with 5 to 6°C of sea surface warming. Our B/Ca measurements in both species suggest a large drop in surface water pH and $[CO_3^=]$ coincident with the rise in temperature at the onset of the carbon isotope excursion, followed by a gradual recovery to pre-excursion levels. The latter feature, coupled with the rise in total alkalinity caused by the dissolution of $CaCO_3$ is taken as evidence of an overshoot phase starting ~100ka after the onset of the event. We are currently measuring boron isotopes in the same taxa in order to quantify the pH changes suggested by the B/Ca data. Additionally, we plan to measure B/Ca and $\delta^{11}B$ in thermocline-dwelling planktic species in order to examine the depth-dependence of the pH changes. Estimating the magnitude of the pH drop at the onset of the event will facilitate calculations of the mass and rate of carbon input that triggered the PETM, as well as the magnitude of change in atmospheric pCO_2 levels and Paleogene climate sensitivity.

Can multiple sulfur isotopes be used as a tracer of sub-continental lithospheric mantle in the Bushveld?

S.C. PENNISTON-DORLAND[1]*, J. FARQUHAR[2], G.J. POLLEY[1], E.A. MATHEZ[3] AND J.A. KINNAIRD[4]

[4]Department of Geological Sciences, University of the Witwatersrand, Private Bag 3, Johannesburg, Wits, 2050, South Africa

The Bushveld Complex (BC) is the world's largest layered intrusion and contains most of its reserves of platinum group elements. The ultimate source of BC magma is thought to have been the mantle. Strontium, Nd and Os isotopic compositions of BC rocks are heterogeneous, however, and along with O isotopes indicate a source contaminated by sedimentary-derived material. Sub-continental lithospheric mantle (SCLM) has been proposed as a source of some of these anomalies. The multiple S isotopic composition of primitive mantle is thought to be $\Delta^{33}S = 0 \pm 0.01‰$ (1σ). Thirty whole-rock and sulfide separate analyses from a variety of locations within the BC have positive $\Delta^{33}S$ values, with an average $\Delta^{33}S = 0.13 \pm 0.05‰$(1σ). Since high-temperature processes are not thought to produce significant change in $\Delta^{33}S$, this high $\Delta^{33}S$ indicates that the BC sulfur contains a sedimentary or surface-derived component. There are geographic and stratigraphic variations in $\delta^{34}S$ and $\Delta^{33}S$ possibly reflecting hydrothermal alteration and/or localized wall rock interaction. Platreef $\delta^{34}S$=+2.7 to +9.2‰, $\Delta^{33}S$=0.03 to 0.26‰; Main Zone $\delta^{34}S$=-3.5 to -1.6‰, $\Delta^{33}S$=0.1 to 0.2‰; UG2 and Merensky Reef $\delta^{34}S$=-6.2 to +3.2‰, $\Delta^{33}S$=0.05 to 0.15‰. We are measuring the $\Delta^{33}S$ of Premier kimberlite mantle xenoliths to evaluate the hypothesis that SCLM has a non-zero $\Delta^{33}S$.

Besides being a potential spintronics material magnetite plays an important role in a number of environmental processes. As the surface reactivity depends critically on the electronic state of the mineral surface, we explore the interaction of water and hydrogen with the Fe_3O_4 (001)-surface using density functional theory (DFT) calculations with an on-site Coulomb repulsion term (GGA+*U*). The surface phase diagram compiled in the framework of *ab -initio* thermodynamics shows dissociation of isolated water molecules especially at oxygen vacancies and a crossover to a partial dissociation with chains of alternating H_2O and OH groups stabilised by hydrogen bonding with increasing oxygen and water pressures [1]. The DFT results reveal that defects and adsorbates induce a unique charge and orbital order at the Fe_3O_4 (001) surface: While the clean, water and OH-covered surfaces exhibit an exclusively Fe^{3+} surface layer with Fe^{2+}, Fe^{3+} ordering in the deeper layers [1], hydrogen adsorption can be used to reduce the surface layer to Fe^{2+} [2] with implications for the catalytic activity of the mineral surface, as well as the spin-polarization of carriers.

Decarbonation of subducting slab at subarc depth: Experimental modeling

A.L. PERCHUK[1,2]*, O.S. KOREPANOVA[2] AND V.O. YAPASKURT[1]

[1]Lomonosov Moscow State University, Geological Faculty, Moscow, Russia (*correspondence: alp@geol.msu.ru)
[2]Institute of Experimental Mineralogy, RAS, Chernogolovka, Moscow DC, Russia

We present UHP experimental results that model H_2O-CO_2 fluid release from the natural analogues of the oceanic crust and the mantle wedge. The experiments were conducted with two layer 'sandwich' materials consisting of calcite-bearing blueschist (BS) and olivine (OL) and three layer 'sandwich' with siliceous marble layer in between BS and OL. The experiments were carried out at 2.7 GPa under the conditions of imposed temperature gradient of ac. 40-50 ºC/mm so that to keep GS at the lower temperatures conditions than the OL [1]. The maximum temperature at the top of the capsules was 1000 °C. P-T conditions at the bottom of the capsules were corresponded to so-called 'hot' subduction zones.

The experiments reveal crucial role of hyrous fluid on decarbonation of calcite (the only carbonate in the starting materials) and contrasting behaviour of CO_2 in different types of sandwich materials. Aqueous fluid was produced mainly by the reaction of glaucophane breakdown: glaucophane => omphacite+quartz±Ca-Na amphibole+H_2O operated in the both types of sandwiches. Flux of H_2O (and solutes like Si, Al etc) in the OL zone of the two layer sandwich was resulted in the development of the Al-bearing orthopyroxene layer at contact with the glaucophane zone. Some of the released CO_2 was stored within abundant vermicular magnesite randomly distributed among olivine crystals above the orthopyroxene layer. Such magnesite occurrences are rare in the olivine from the three layer sandwich. However, upward migration of the H_2O-bearing fluid through the marble in this sandwich was resulted in the formation of ultrahigh pressure metasomatic column which consists of 4 zones: Fe-Mg-Ca carbonate| dolomite | diopside | magnesite in between the marble and OL, respectively. Multiple clinochlore flakes in lower part of the OL zone also witnesses migration of the hydrous fluid.

Storage of CO_2 in the mantle wedge minerals at the subarc depth may have valuable effect on an imbalance in the carbon budget in subduction zones. Further investigation of the slab-mantle interaction is necessary to explain existing discrepancies.

Impact of water sources and flow paths on carbon in streams of seasonally snow-covered catchments

JULIA PERDRIAL[1]*, PAUL BROOKS[2], JON CHOROVER[1], ADRIAN HARPOLD[2], INGO HEIDBUECHEL[2], JENNIFER MCINTOSH[2], JAMES RAY[3] AND XAVIER ZAPATA-RIOS[2]

[1]University of Arizona, SWES, Tucson, AZ, USA (*correspondence: jnperdri@email.arizona.edu)
[2]University of Arizona, HWR, Tucson, AZ, USA
[3]University of Puget Sound, Tacoma, WA, USA

Stream waters from seasonally snow-covered catchments of the Jemez River Basin Critical Zone Observatory in northern New Mexico are characterized by two distinct main water sources. While groundwater from deeper flow paths dominates the streams throughout the year, snowmelt and monsoon inputs additionally enter the streams through shallow soil flow paths. To investigate how changes in water sources influences dissolved carbon characteristics, 5 flumed streams at catchment outlets located around Redondo peak were sampled 10 times between March and October 2010 to analyze for total dissolved organic and inorganic carbon (DOC and DIC), DOC quality and stable isotopes of DIC. Stream water DOC showed a flushing pattern in all catchments, with highest concentrations during peak snowmelt and low concentrations during the dry season. $SUVA_{254}$ confirms presence of organic soil constituents of lignin based precursors during snow melt and monsoon season. Preliminary results of organic matter (OM) PARAFAC quantification identified a component with fluorescence in region II that dominates when shallow flow paths are activated. DIC concentrations show a dilution pattern with low concentrations during snowmelt. $\delta^{13}C$ values of DIC progressively increase with time since snowmelt, suggesting increasing inputs of groundwater enriched in ^{13}C, possibly from microbial cycling of carbon in long transit time reservoirs. In waters from deeper flow paths, low $SUVA_{254}$ values and a PARAFAC component with fluorescence in region I dominate. Those results indicate that differences in source waters, flow paths and residence times have important impacts on stream water carbon characteristics.

Predicting the fate of radionuclides at the Hanford tank farm using analog sediments

N. PERDRIAL[1]*, A. THOMPSON[2], N.A. RIVERA[3], Y.-T. DENG[2], P.A. O'DAY[3] AND J. CHOROVER[1]

[1]SWES, University of Arizona, Tucson, AZ 85721, USA (*correspondence: perdrial@email.arizona.edu)
[2]Crop and Soil Science, University of Georgia, Athens, GA 30602, USA
[3]School of Natural Sciences, University of California, Merced, CA 95343, USA

Due to challenges in studying *in situ* samples induced by the extreme conditions encountered at the USDOE facility at Hanford (WA, USA) and in order to predict the impact of the cleanup strategy on contaminant transfer, we investigated the geochemical behavior of Hanford sediments impacted by a synthetic tank waste (i.e. 'analog contaminated sediments') before and after removal of the waste source.

The reaction of pristine Hanford sediments with synthetic waste containing Sr, Cs and I led to the producion of 8 analog sediments reflecting different contamination scenarios. Amongst the variables tested (contaminant concentrations, pCO_2, reaction time), the level of trace contaminant had the greatest effect on the mineral transformation reactions that gave rise to sequestration of Sr and Cs. Reaction product formation was correlated with trace contaminant (mM vs. μM) concentration. Sodalite/cancrinite formation at μM levels and chabazite formation at mM levels affected the binding environment of incorporated Sr and Cs.

The effect of source removal was investigated by infiltrating the sediments with a synthetic porewater solution that reflected aquifer recharge, and monitoring elemental release in dissolved and colloidal pools, as well as solid phase transformation, over time. The observed release mechanisms helped constrain a contaminant transport model used as a predictive tool for contaminant release at Hanford. Contaminant stability differed according to the reaction time and contaminant levels, consistent with neophase ripening and structural modifications occuring during desorption. Cs and Sr release depended on neophase stability, whereas I was rapidly desorbed Elemental release monitored during wet-dry cycling did not significantly modify desorption rates. Sr particulate ($Ø < 20\mu m$) transport was observed in some cases.

The observation of contaminant dynamics in analog Hanford sediments helps predict the fate of contaminants, and highlights the strong potential for long-term natural sequestration of Sr and Cs (not I) after retrieval of the sources.

Uranium mobility in the Beiras granite (Central Portugal): Implications for radon exhalation

A.J.S.C. PEREIRA AND L.J.P.F. NEVES

IMAR-CMA, Department of Earth Sciences, University of Coimbra (apereira@dct.uc.pt, luisneves@dct.uc.pt)

The medium to coarse grained porphyritc biotite granite of the Beiras region is the dominant facies of a late Hercynian batholith outcroping in Central Portugal, associated with a large number of secondary uranium mineralizations exploited in the past (*ca*. 60). Geochemical and isotopic data indicates that it is a moderately evolved rock, slightly peraluminous, and likely originated from a heterogeneous portion of the lower crust. It's accessory mineralogy includes uraninite, which is a likely primary source for the thousands of local uranium anomalies detected in the region, usually associated with fault filling materials and metasedimentary rocks of the contact aureole and enclaves.

A total of 18 representative samples from the batholith were collected, 16 of granite and 2 of hornfelses. Granitic samples include fresh rock, some stages of slight and moderate weathering and also specimens showing hydrothermal alteration, characterized by the development of pink/red feldspars and strong chloritization; some of these last samples were colected in the vicinity of the Cunha Baixa old uranium mine. Thin sections coupled with mica detectors were prepared and irradiated with fast neutrons in a nuclear reactor. The study of fission tracks produced by ^{235}U decay and recorded in the mica detectors allowed to study the mineralogical distribution of U. In parallel, ^{226}Ra activity and total U concentration was estimated for all samples using a 3x3" Ortec NaI(Tl) gamma ray spectrometer; radon exhalation rate was determined placing the same samples inside sealed containers of known volume and measuring the radon activity in the air of the container after equilibrium being achieved (*ca*. 4 weeks) with an Alphaguard monitor.

Uranium concentration in the samples shows a wide range of variation, from 6 to 29 ppm, with a median of 13 ppm. Accordingly, exhalation rates are in the range 0.7 up to 7.3 $Bq.kg^{-1}.h^{-1}$, with a median of 1.4 $Bq.kg^{-1}.h^{-1}$. Fission-track observations indicate a generalized secondary uranium mobilization, even in fresh samples, with a large proportion of this element related with mineral borders, alteration surfaces and oxi-hydroxide fillings of microfractures; this is in good agreement with the very high exhalation rates measured.

IMS 1280-HR: A versatile SIMS instrument for Geosciences

P. PERES, F. FERNANDES, M. SCHUHMACHER AND P. SALIOT

CAMECA, 29 quai des Grésillons, 92622 Gennevilliers Cedex, France (peres@cameca.com)

SIMS (Secondary Ion Mass Spectrometry) is applied to a variety of applications in Geosciences, because it provides *in situ* measurement of elemental and isotopic composition in selected µm-size areas of the sample.

The CAMECA IMS 1280-HR large geometry SIMS offers outstanding capabilities for a wide range of geological applications, thanks to its very high transmission mass spectrometer combined to a versatile multicollection system. The IMS 1280-HR is also able to map the lateral distribution of major, minor, and trace elements, both in microscope and microprobe mode.

Hundreds of scientific papers have been published covering major application fields in geo- and cosmochemistry, geochronology, environmental studies,...:

- stable isotope ratio measurements on different systems: Hydrogen [1], Lithium [2], Carbon [3-5], Oxygen [6-10], Magnesium [11], Silicon [12], Sulfur [13-14],...
- U-Pb dating in Zircon [10, 15-18],
- trace element analyses [10, 19-20],

A review of recent analytical data obtained with the IMS 1280-HR on different domains will be presented.

Modeling of ultramafic-hosted hydrothermal systems using CAST3M

F. PEREZ[1]*, C. MUGLER[1], P. JEAN-BAPTISTE[1] AND J.L. CHARLOU[2]

[1]LSCE, CEA-CNRS-UVSQ, Gif-Sur-Yvette, France (*correspondence: florian.perez@lsce.ipsl.fr)
[2]Géosciences Marines, IFREMER, Brest, France

Along the Mid-Atlantic Ridge, ultramafic-hosted active hydrothermal sites such as Rainbow and Ashaze release unusual high fluxes of methane and hydrogen relatively to the hydrothermal sites in basaltic environments [1, 2]. This has been interpretated as the result of serpentinization processes. The purpose of this ongoing work is to simulate the hydrothermal circulation and fluid-rock interactions in such ultramafic environments with a thermo-hydraulic model in order to investigate hydrogen fluxes. We thus developed a two-dimensional numerical model of the ridge using a Finite Volume method to simulate heat driven fluid flows in the framework of the CAST3M code [3]. This thermo-hydrogeological model was then coupled with a geochemistry module to simulate the serpentinization reaction. The latter was built thanks to laboratory experiments [4, 5] and speciation calculations performed with the EQ3/6 code.

Preliminary results for the Rainbow site show that the model produces realistic temperatures for the exiting fluids (Fig. 1).

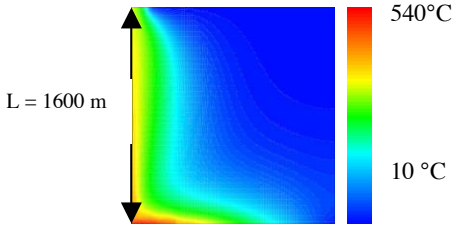

Figure 1: Simulated temperature field.

The next step will be to simulate hydrogen production and to compare it to available field data [1, 2] to gain further insight into the ongoing serpentinization process at Rainbow.

Controls on microbes in an actively venting chimney and in low-temperature hydrothermal fluids

M. PERNER[1]* AND J. LAROCHE[2]

[1]Microbiology and Biotechnology, University of Hamburg, D-22609 Hamburg, Germany
[2]Marine Biogeochemistry, Leibniz Institute of Marine Science, IFM-GEOMAR, Düsternbrooker Weg 20, 24105 Kiel, Germany

Two types of venting are recognised in hydrothermal habitats: hot and low-temperature emissions. Hot venting is commonly accompanied by formation of chimneys, which precipitate when ascending hot, reduced liquids come into contact with cold, oxygenated, ambient seawater. Alternatively, low-temperature emissions exist. These areas are often covered by microbial mats or symbiotic mussels. Besides the possibility of the type of host rock contributing to the chemical signature, the degree of seawater admixed to endmembers defines temperature and fluid chemistry in these liquids/habitats.

To understand the feedbacks of temperature and chemistry on the indigenous microbial community of hydrothermal biotopes, we collected a flank from an actively venting chimney and low-temperature hydrothermal emissions from two basalt-hosted sites on the southern Mid-Atlantic Ridge. As anticipated, measured sulfide (~6 mM), and hydrogen (~50 μM) is considerably higher in the hot chimney fluids (375°C) than in the low-temperature (9°C) emissions (47 μM, and 0, 9 μM, respectively). Oxygen was below detection limit in the former and around 71 μM in the latter fluids. The metagenomes of the chimney and the diffuse fluids clearly reflect the thermal and anoxic/oxic conditions of the two environments. From the metagenomic data, the importance of different pathways and enzymes for sulfur, nitrogen and carbon cycling can be deduced for the two biotopes. However, while microbial hydrogen and sulfide consumption rates were similar for both sites, hydrogen and sulfide only stimulated microbial CO_2 fixation considerably in the low-temperature fluids. Besides chemical controls, alternative factors may govern the microbial community structure. For example, more divergent transposases were in the chimney, but a higher divergence and abundance of phages, plasmid-related-functions as well as virulence, defense and disease strategies were found in the low-temperature liquids. Since conditions in the hot chimney are already highly selective for specific lifestyles, these type of defense/transfer strategies may be of profound importance for survival in low-temeprature venting habitats.

Magmatic plumbing dynamics along the Northern Rift Zone, NE Iceland

J.F. PERNET-FISHER* AND M.F. THIRLWALL

Department of Earth Sciences, Royal Holloway, University of London, Egham, Surrey, TW20 0EX, UK (*correspondence: j.pernet-fisher@es.rhul.ac.uk)

Previous pressure studies of Icelandic magmas have shown that most basalts crystallise at a wide range of depths within the crust (e.g. [1]). In addition [2] have shown that most central volcanoes have discreet multiple stacked chambers of crystallisation. The majority of these studies, however, either have very small data sets or focus on specific locations.

In this study crystallisation pressures have been calculated using the method of [3] from an extensive collection of 121 post, inter- and intra- glacial basalts from the Krafla, Fremri-Namur, Askja and Kverkfjöll central volcanoes as well as a section of Plio-Tertiary lavas from the surrounding area. This has enabled the location and depth of significant bodies of crystallisation under the length of the Northern Rift Zone (NRZ) to be resolved.

The identification of these bodies as well as comparisons between volcanic centres over time can provide clues into the structure of the Icelandic crust. It is clear that minimal change has occurred within the last 0.7 Ma with lavas crystallising at similar pressures over this time period. Furthermore it is apparent that the shield central volcanoes of Fremri-Namur and Theistareykir have much more complicated plumbing, lacking the presence of stacked bodies that is seen under all other volcanic centres in the NRZ.

The detailed understanding of crustal structure is critical when assessing the role of processes such as magma mixing or assimilation that are occurring within the crust. Many authors have noted that individual lava flows can have complex crystal cargos (e.g. [2]; [4]); in addition to the plumbing dynamics along the NRZ we present olivine data from selected flows that will allow the assessment of the crustal processes that contribute to these complex cargos over time.

Discovery and description with scintillometric and geochemistry of gossans above amethyst deposits in altered volcanic rocks of the Paraná province, South America

JULIANA PERTILLE AND LÉO A. HARTMANN

Instituto de Geociências, Universidade Federal do Rio Grande do Sul, Avenida Bento Gonçalves, 9500, 91501-970 Porto Alegre, Rio Grande do Sul Brazil

We discovered a large number (probably thousands) of gossans in the intraplate volcanic rocks of the Paraná volcanic province, South America, based on observations of satellite images and field work associated with geochemistry and geophysics. We thus define a straitforward propecting guide for agate and amethyst deposits. The study area is located on the border between Brazil and Uruguay, covering the Los Catalanes gemological district and the Quaraí mining district. Anomalies in Google Earth satellite images were identified above six underground mines in the Los Catalanes gemological district, characterized in the pampas of the region as irregular structures of intense green color and sometimes with brownish, rough texture. The vegetation, scintillometric and geochemical anomalies occur at several stratigraphic levels in the volcanic group. Three scintillometric profiles performed on the Maurício Mine in the Los Catalanes gemological disctric indicate low emission rates near 55 cps (sd = 4.7) in the gossan compared with the regional average of colada Cordillera (63 cps). Whole rock geochemical analyses of three samples collected within the underground mine indicate high loss on ignition (4.5, 3.4, 4.5 wt.%). LOI higher than 2% is considered a strong indicator of intense hydrothermal alteration in the gossan. In the Quaraí mining district, gossans were studied in five areas, two in colada Catalán, two in colada Muralha, and one in colada Cordillera. The world-class deposits of amethyst and agate geodes are in coladas Catalán and Cordillera. Negative radiometric anomalies (higher than one standard deviation) occur in these gossans. The detailed study of one gossan included a geophysical grid spacing of 50 x 50 m (K, U, Th and total emission rate) and whole rock geochemical analyses (ACME, Canadá). The whole rock geochemical analyses of 17 samples collected within and outside the gossan classify the rocks as basaltic andesites, low–Ti, Gramado chemical type. The samples inside the gossan display high values of loss on ignition (2.3, 2.8, 2.9, 2.8, 2.9, 2.4, 2.6, 2.6, 2.3 and 2.3 wt.%), while outside the gossan the values are lower (0.8, 2.3, 0.5, 0.5, 1.6, 0.5, 0.6, 0.7, 1.1, 1.3 and 1.9 wt.%). SiO_2, K_2O and Rb show strong negative correlation with loss on ignition, while MgO has a slight enrichment. Were identified by electron microprobe analysis clinoptilolite associated with smectite, as products of hydrothermal alteration in the samples of Gossan.

Magma mixing as a petrological clock to measure the timescale of volcanic eruptions: Experiments and numerical models

D. PERUGINI

University of Perugia, Italy (diegop@unipg.it)

Magma mixing processes generate different fluid dynamic domains in which chemical exchanges between magmas can be strongly modulated, depending on the ability of the two melts to spread across the magmatic system. These structural domains, tightly linked to the chaotic nature of the mixing, are preserved in volcanic glasses as fractal structures.

Detailed petrological studies of lava microstructures generated by magma mixing reveal the presence, in the same system, of highly heterogeneous volumes of melts in which both depletion and enrichment of trace elements occurs, depending on the values of their diffusivity, triggering a 'diffusive fractionation' process.

Numerical simulations in which the mixing process is induced by applying a chaotic advection numerical scheme and a chemical diffusion model, reveal that the 'diffusive fractionation' of trace elements, analogous to that observed in lava flows, can be readily achieved and that the extent of this process depends upon the mixing time.

Chaotic magma mixing experiments were performed by mixing natural magmatic compositions from Phlegrean Fields. Experiments were carried out at different mixing times. Micro-analysis of experimental runs confirms a very variable mobility for the different trace elements, depending on their diffusivity. Equations relating the degree of 'diffusive fractionation' of trace elements to the time-scales of mixing are derived from experimental data.

Application of the 'diffusive fractionation' conceptual model to several pyroclastic sequences from Phlegrean Fields (Italy) allows us to apply the relationships derived from numerical models and experiments to estimate mixing time-scales. Results indicate that mixing processes lasted for a few days prior to eruption. These short time-scales for the mixing process argue in favor of the hypothesis that refilling of magma chambers and magma mixing processes likely was the key processes triggering eruptions.

We show that the combination of chaos theory, classic petrology, microtextural evidence, numerical simulations and experimental petrology is a highly effective and much needed approach to increase our knowledge on the behavior of volcanic systems, especially for the key issue of constraining time-scales of volcanic eruptions and hazard assessment at active volcanic centres.

Competitive ligand exchange between Cu-humate complexes and methanobactin

M.-L. PESCH[1]*, I. CHRISTL[1], S.M. KRAEMER[2] AND R. KRETZSCHMAR[1]

[1]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland (*correspondence: laurie.pesch@env.ethz.ch)

[2]Department of Environmental Geosciences, University of Vienna, Austria

Methane oxidation by methanotrophs depends on the availability of copper and the efficiency of copper acquisition by methanotrophic bacteria. In natural environments such as soils, peat bogs, and surface waters, the presence of natural organic matter, having a high affinity for copper, can potentially control the bioavailability of copper. To mobilize copper, methanotrophs have developed a unique copper uptake system, similar to the siderophore-based iron uptake systems, involving the synthesis of a copper-binding ligand (so-called methanobactin). The aim of the current study is to investigate the competition between methanobactin and natural organic matter for copper binding.

Methanobactin used in the experiments has been isolated and purified from *Methylosinus trichosporium* OB3b cultures [1]. A well characterized humic acid extracted from a humified organic horizon of a Humic Gleysol was used as a model for natural organic matter. Kinetics of ligand exchange between Cu-humate complexes and methanobactin have been studied by means of UV–vis absorption spectroscopy. Concurrent competition of humic substances and methanobactin for copper binding were investigated in batch experiments and analyzed by size exclusion chromatography (SEC) coupled to an ICP-MS. Online monitoring of SEC eluates allowed the direct determination of the amount of copper bound to methanobactin and humic acid, respectively.

UV–vis absorption spectra indicated a fast uptake of Cu from humic acid. A substantial partitioning of methanobactin into humic acid was not observed. The observed equilibrium Cu speciation was quantitatively compared to model calculations using the previously derived conditional stability constants for proton and copper binding by methanobactin and the NICA-Donnan parameters determined for the humic acid used in this study [2].

Sulfate reduction in peatlands – Ecophysiology of a rare microorganism that contributes to a process with increasing importance for the global climate

MICHAEL PESTER, BELA HAUSMANN, PINSURANG DEEVONG, MICHAEL WAGNER AND ALEXANDER LOY

Department of Microbial Ecology, University of Vienna, Austria (loy@microbial-ecology.net)

Methane emission from peatlands contributes substantially to global warming but is significantly reduced by sulfate reduction, which is fuelled by globally increasing aerial sulfur pollution. However, the biology behind sulfate reduction in terrestrial ecosystems is not well understood and the key players for this process as well as their abundance remained unidentified. Linking (phylo)genetic information, obtained through gene-specific or metagenomic/-transcriptomic surveys, to the ecosystem process sulfate reduction is notoriously difficult because (i) known sulfate reducers are phylogenetically intermingled with non sulfate reducers and (ii) marker genes for sulfate reduction [such as *dsrAB*, encoding subunits of dissimilatory (bi)sulfite reductase] are also present and transcribed in some bacteria that lack the capability for sulfate reduction. Here we demonstrate, by comparative 16S rRNA gene stable isotope probing in the presence and absence of sulfate, that a *Desulfosporosinus* species, which constitutes only 0.006% of the total microbial community, is a main sulfate reducer at a long-term study peatland. Parallel stable isotope probing of *dsrAB*, confirmed that no other microorganisms contributed substantially to sulfate reduction in the incubations supplied with *in situ* concentrations of short-chained fatty acids and lactate. Subsequent single substrate incubations revealed that sulfate reduction was stimulated best with lactate, propionate, and butyrate, but not with acetate or formate. For the identified *Desulfosporosinus* species a high cell-specific sulfate reduction rate of 341 fmol SO_4^{2-} $cell^{-1}$ day^{-1} was determined. Thus, the small *Desulfosporosinus* population has the potential to reduce sulfate *in situ* at a rate of 4.0-36.8 nmol (g soil w. wt.)$^{-1}$ day^{-1}, sufficient to account for a considerable part of sulfate reduction in the peat soil. These data show that the identified *Desulfosporosinus* species, despite being a member of the 'rare biosphere', contributes to an important biogeochemical process that diverts the carbon flow in peatlands from methane to CO_2 and, thus, alters their contribution to global warming.

Abiogenic formation of carbon species at hydrothermal conditions using a novel flow apparatus

NICHOLAS J. PESTER* AND WILLIAM E. SEYFRIED, JR

Dept. of Earth Sciences, University of Minnesota, Minneapolis, MN 55455, USA (*correspondence: peste005@umn.edu)

We present an experimental configuration that permits constant high-pressure flow through hydrothermal cells while at the same time maintaining uniform concentrations of multiple dissolved gases. This system provides an additional benefit for kinetic studies as it allows precise redox control without the presence of mineral buffers or the need to rely on the hydothermal breakdown of unstable intermediates in the source fluid. Steady-state equilibrium can be determined when a target species concentration no longer changes with increasing residence time at equivalent temperature, pressure and source fluid composition. For example, we have calibrated the equilibrium constant for the water-gas shift (WGS) reaction ($CO_2 + H_2 = CO + H_2O$) in pure water between 225-374°C and 220-325 bars, including the critical point. In this region the log K_{WGS} is linear with respect to water density. These equilibrium constants, as well as those for formic acid (thought to be the WGS reaction intermediate) are in good agreement with those derived from the HKF equation of state if recent updates for the involved species are incorporated. This is especially noteworthy due to the uncertainty of thermodynamic calculations near the critical point of water with implications for modeling natural hydrothermal systems.

While the low concentrations of CO appear in equilbrium with the WGS reaction, controls on the appreciably higher concentrations of methane in deep-sea hydrothermal fluids are still unclear. However, this methane is often thought abiogenic and CO_2 is the dominant source of carbon. This is an important consideration when studying the kinetically prohibitive synthesis of reduced hydrocarbon species (e.g. $CO_2 + 4H_2 = CH_4 + 2H_2O$). Using a source fluid containing geologically relevant concentrations of H_2 and CO_2, we have observed the formation of C1-C3 hydrocarbons in reaction cells constructed of both titanium and gold, with and without the presence of magnetite, between 200-400°C. Methane generation is linear with respect to residence time in the cells and synthesis is maximized at temperatures near 300°C. Our results demonstrate that hydrocarbon formation is enhanced as much as 200X in the gold cell relative to the titanium cell, while magnetite appears relatively ineffectual as a catalyst for hydrocarbon formation.

Ship emissions and their influence on large scale cloud fields

K. PETERS[1,2]*, J. QUAAS[1], H. GRASSL[1] AND P. STIER[3]

[1]Max-Planck-Institut für Meteorologie, Hamburg, Germany (*correspondence: karsten.peters@zmaw.de)
[2]International Max Planck Research School on Earth System Modelling, Hamburg, Germany
[3]Department of Physics, University of Oxford, UK.

Our study assesses the possibility of detecting an influence of global shipping emissions on the micro- and macrophysical properties of large-scale cloud fields in remote regions of the tropical oceans. We utilise cloud- and aerosol properties as retrieved from satellite measurements as well as results from global aerosol modelling for this purpose.

Our satellite data-based approach differs from many previous studies on ships' influence on clouds because we do not specifically attempt to detect and characterise linear features in stratocumulus cloud-decks known as 'ship tracks'. Ships emit large amounts of aerosols and aerosol precursor gases in remote oceanic areas thereby modifying the composition of marine boundary layer (MBL) aerosol composition and –concentration. It is this modification of MBL characteristics which may alter the properties of liquid water clouds on large scales; a factor which remains to be investigated by use of satellite- and model data.

For the satellite-data based part of our study, we combine cloud- and aerosol properties as derived from satellite measurements (MODIS) and ERA-Interim reanalysis data. We identify regions of large spatial contrast in shipping emissions from an up-to-date shipping emissions inventory. With this data, we separate 'clean' from 'polluted' oceanic regions by using the wind direction as provided by the reanalysis data. The reanalysis data also enable us to characterize the ambient meteorological conditions for the observed scenes.

For the modelling-based part of our study, we use the ECHAM5-HAM aerosol-climate model to assess the climate impact of shipping emissions provided by the shipping emissions inventory. We also sample the model data according to the sampling strategy of the satellite data.

The analysis of the satellite data reveals a potential Twomey-effect on the properties of large-scale cloud fields with regard to shipping emissions. Nevertheless, the results suggest that the observed effects could also be due to a change in dynamical drivers, such as a change in sea surface temperatures. This highlights the difficulty to separate aerosol effects from ambient conditions in satellite based studies. The modelling results generally confirm the findings from the satellite data analysis and enable us to pinpoint the effect of shipping emissions more precisely.

Amphibole antecrysts in deposits of Merapi volcano, Indonesia: A plutonic phase in extrusive magmas

S.T.M. PETERS[1,2]*, J.P. CHADWICK[2] AND V.R. TROLL[3]

[1]Institut für Geologie und Mineralogie, Universität zu Köln, Germany (*correspondence: peterss1@uni-koeln.de)
[2]VU University, Amsterdam, The Netherlands
[3]Dept. of Earth Science, Uppsala University, Uppsala Sweden

Amphibole crystals are present in, but typically in disequilibrium with, the high-K basaltic andesite deposits of Mount Merapi, an active stratovolcano of the Sunda volcanic arc at central Java, Indonesia [1-2]. These *antecrysts* form a potential tool for tracing the physical interaction between the deep and shallow parts of the magmatic system. Moreover, they provide a window into the plutonic REE (rare earth element) evolution of arc magmas, for which amphibole fractionation has been inferred to be a controlling process [3]. We studied amphibole antecrysts from block and ash flow deposits of the 1998 eruption by petrographic and EMP analysis of ten thin sections. Six samples with limited to no visible alteration were selected for REE (Quadrupole ICPMS) and radiogenic Sr and Nd isotope analyses (TIMS).

Major element trends combined with the Al based geobarometer that was developed by [4] indicate that amphibole crystallized from a basic magma at the base of the crust (20-31 km) and re-equilibrated with a more silicic magma at a shallower level (13-18 km). The crystals have similar Nd isotope compositions to the bulk rock whereas their Sr compositions are less radiogenic, most likely reflecting a lesser degree of crustal contamination with respect to later grown phases such as feldspar [5]. Both findings are consistent with a model in which magma ponds at the base of the crust, partially crystallizes and subsequently feeds a shallower, more silicic plumbing system that is increasingly affected by crustal contamination. REE ratios show high Dy/Yb and low La/Yb, but concentrations are typically too low to counterbalance the respectively low and high ratios of the hostrock. Fractionation of an additional phase with similar REE partitioning behaviour but with higher partition coefficients, possibly clinopyroxene, is therefore implied in the deeper parts of the Merapi system.

In spite of its pivotal significance for resource management, the concept of 'groundwater age' remains in many cases elusive. Among various methods proposed for dating groundwater, naturally occurring radioactive isotopes such as ^{36}Cl or ^{81}K and ^{4}He appear as more promising to characterize groundwater transport in the large aquifer bodies where residence times are on the order of 100 kyr to 1 Myr [1-3]. Here, we present new ^{36}Cl analyses obtained on groundwater samples collected in the Tunisian part of the Continental Intercalaire (CI) and Complex Terminal (CT) aquifers that form the North-Western Sahara Aquifer System. These analyses were performed at CEREGE, on the French 5 MV AMS National Facility 'ASTER'. Procedural blanks are routinely measured as less than 1×10^{-16} $^{36}Cl/Cl$ ratio.

In the Tunisian CT, ^{36}Cl contents up to 12×10^{8} at. l^{-1} are observed while $^{36}Cl/Cl$ ratios vary from 13 to 75×10^{-15} at at^{-1}. Lower values are generally obtained in the samples collected in the Tunisian part of the CI ([^{36}Cl]< 2.5×10^{8} at. l^{-1}), as expected from their deeper setting. By comparison, the data obtained by Gendouz and Michelot in the Algerian region of the CI show lower ^{36}Cl contents (<3.7×10^{8} at. l^{-1}) but comparable $^{36}Cl/Cl$ due to lower salinities of the groundwater. The data also show a high heterogeneity in the area of the Tunisian Chotts, probably related to the complex inter-connexions of the aquifer layers in this tectonically fractured basement and/or the complex flowpaths in this area.

The data will be compared to direct predictions obtained from hydrodynamic modelling using MODFLOW implemented with an age-mass calculation subroutine [5], and hydrodynamic parameters and aquifer geometry published previously by Baba Sy [6].

Pb isotopes and the origin of the 'ghost plagioclase' signature in melt inclusions from the Galapagos Archipelago

M. PETERSON[1]*, A. SAAL[1], E. NAKAMURA[2], K. BURGESS[1] AND H. KITAGAWA[2]

[1]Brown University, Providence, RI, 029012, USA (*correspondence: mary_peterson@brown.edu, alberto_saal@brown.edu, katherine_burgess@brown.edu)
[2]ISEI, Okayama University, Misasa, Tottori 682-0193, Japan (eizonak@misasa.okayama-u.ac.jp, kitagawa@pheasant.misasa.okayama-u.ac.jp)

This study looks at olivine-hosted melt inclusions from Santiago and Fernandina islands, Galapagos Archipelago. Although both suites of melt inclusions show plagioclase signature in primitive mantle normalized diagrams, melt inclusions from Santiago show major element composition indicative of plagioclase assimilation. In contrast, the Fernandina inclusions that have the trace-element signature of plagioclase do not show the major element compositions expected during plagioclase assimilation. Thus, the trace-element signature of the original plagioclase is present only as a 'ghost' [1]. Two main hypotheses have been proposed to explain the ghost plagioclase signature, either an ancient recycled plagioclase-rich cumulate intrinsic to the plume [1], or the interaction of melts with plagioclase cumulates within the present day oceanic lithosphere [2, 3]. *In situ* measurement of Pb isotopes in melt inclusions can be used to distinguish between the proposed origins of the ghost plagioclase. We expect that an ancient recycled plagioclase-rich cumulate will have a very different Pb isotopic composition from the present day MORB and FOZO components typical of Santiago and Fernandina lavas [4, 5].

Pb isotopes were measured using the Cameca 1270 SIMS of the Institute for the Study of the Earth's Interior, Okayama University, Misasa, Japan. The 2s errors in our measurements ranged from 0.4 to 2% for $^{207}Pb/^{206}Pb$ and from 0.3 to 1.6% for $^{208}Pb/^{206}Pb$ at a range in ^{208}Pb of 219 to 10 cps. The results show that melt inclusions with plagioclase signature have Pb isotopes that are indistinguishable from the present day MORB and FOZO components typical of Santiago and Fernandina lavas. Therefore, the ghost plagioclase signature in Fernandina melt inclusions is produced by melt-plagioclase cumulate interaction within the crystal mush zone beneath Fernandina Island.

Zircon U-Pb, Hf and O isotope constraints on growth versus recycling of continental crust in the Grenville orogen, Ohio, USA

ANDREAS PETERSSON[1], ANDERS SCHERSTÉN[1], JENNY ANDERSSON[2], MARTIN WHITEHOUSE[3], JOHN M. HANCHAR[4] AND CHRIS FISHER[4]

[1]Department of Earth and Ecosystem Sciences, Lund University, Sölvegatan 12, SE-223 62 Lund, Sweden (andreas.zircon@gmail.com)
[2]Geological Survey of Sweden, Box 670, SE-751 28 Uppsala, Sweden

[4]Department of Earth Sciences, Memorial University of Newfoundland, St. John's, NL A1B 3X5 Canada

The Grenville orogen extends along the present day North American continent, from Labrador in the north to Mexico in the south. It is, however, largely covered by thick piles of Phanerozoic rocks, and the geological evolution of the extensive covered parts of the orogen is poorly known. We present zircon U-Pb, Hf- and O-isotope analyses for six drill-cores in Ohio (USA). U–Pb data dates magmatic and metamorphic zircon crystallization that span from 1643 ±54 Ma to 1025 ±8 Ma. Zircon $\varepsilon Hf_{(t: 1650\text{-}1025\ Ma)}$ values at 1.9 ±1.2 to 9.0 ±0.6 is explained by reworking of a single crustal reservoir derived from the mantle at 1640 ±40 Ma, that evolved with a $^{176}Lu/^{177}Hf$ value of 0.014. One sample, deviates from this trend and its spread in εHf t=1230 Ma indicates a 0-33 wt% contribution of a depleted mantle component to the t_{DM}=1650 Ma reservoir. Zircon (SIMS) $\delta^{18}O$ weighted mean values range from 5.36 ±0.65‰ to 10.88 ±0.21‰, which corresponds to juvenile mantle and recycled crustal oxygen signatures respectively. There is a broad negative correlation between zircon Th/U and $\delta^{18}O$ and age respectively. The general increase in $\delta^{18}O$ with time and progressive metamorphic recrystallization is best explained by the increasing effect of heavy $\delta^{18}O$ metamorphic fluids during Grenvillian continent-continent collision. Together, the new data presented here suggests that the crustal evolution of this part of the North American continent is significantly older, and that the influence of metamorphic fluids on the O-isotope system in zircon is stronger than previously reported.

Glacial interglacial aerosol input over Antarctica and the global hydrological cycle

J.R. PETIT[1]* AND B. DELMONTE[2]

[1]LGGE, CNRS UJF, BP 96 38402 St Martin d'Hères cedex, France (*correspondence: petit@lgge.obs.ujf-grenoble.fr)
[2]DSAT, Università degli Studi di Milano-Bicocca, Piazza della Scienza, 1, 20126 – Milano, Italy (barbara.delmonte@unimib.it)

Questions rise for simulating and interpreting the 5 fold marine and the 50-to-70 fold dust enhancement observed from Antarctic ice core records during the past glacial interglacial cycles. Amongst uncertainties the repective contribution from source, from transport which would be consistent for aerosols of different origin are challenging.

A semi-empirical model has been developed to reproduce the large glacial-interglacial changes of Antarctic dust and sodium concentrations [1]. Tthe model uses a life-time parameter that depends on atmospheric temperature (stable isotope content of ice) which drives the global hydrological cycle and the atmospheric cleansing and which was applied to conceptual pathways for aerosols.

The model reproduces most of the increase in dust concentrations during cold periods with respect to Holocene climate, as observed in Epica Dome C (EDC) and Vostok ice records, on the basis of synergetic changes of three factors associated with temperature (source, transport efficiency, accumulation rate over Antarctica). As supportive results, our model provide source amplitude (up to X 4) and mimics the pattern of a south Atlantic marine record covering the last 300, 000 yr (Martinez Garcia, 2009) along with consistent 3-5°C atmospheric temperature change over the Southern Ocean [2]. The calculated source changes (mostly Patagonia) share the pattern of the sea ice extends over the south Atlantic.

When applied to the sodium, the concentration changes could be reproduced by our model by using two main factors (accumulation rate and transport efficiency) while the source effect is not discernable from an atmopheric temperature effect.

In situ insights to partitioning of highly siderophile elements between silicate and iron rich liquids at extreme conditions

S. PETITGIRARD[1], M. BORCHERT[2], D. ANDRAULT[3], K. APPEL[2] AND H.-P. LIERMANN[2]

[1]European Synchrotron Radiation Facility (ESRF), Grenoble, France
[2]Deutsches Elektronen-Synchrotron (DESY), Hamburg, Germany (manuela.borchert@desy.de)
[3]Universite Blaise Pascal, Laboratoire des Magmas & Volcans, Clermont-Ferrand, France

Experimental data indicate that highly siderophile elements (HSE) sunk down with the iron in the Earth's core at the early stage of the Earth's formation [1]. Consequently, the Earth´s mantle and crust should be depleted in HSE. Thus, the apparent excess of these elements in the Earth´s upper mantle and crust has been a long-lasting enigma in the interpretation of geochemical signatures of the Earth's mantle and the geochemistry of core-mantle differentiation.

So far, all metal-silicate partitioning studies make use of 'classical' HP-HT techniques and therefore are limited to PT conditions of the Earth's upper mantle. There is urgent need for experiments at much higher pressures and temperatures to simulate conditions of core-mantle boundary because it remains unclear if determined metal-silicate partition coefficients of HSE can simply be extrapolated to lower mantle conditions. Here, we present first preliminary data on metal-silicate trace element partitioning from a new experimental approach to obtain *in-situ* information at simultaneous high pressures and high temperatures using synchrotron radiation (SR). First experiments were performed at beamline ID27 (ESRF, France) using laser-heated diamond-anvil cells up to ~50 GPa and 4200 K. Samples are analysed before, during and after laser heating by SR-μXRF/XRD. The sample chamber is loaded with a HSE- doped chondrite glass chip placed next to a HSE-free metal foil ($Fe_{90}Ni_{10}$). MgO is used as pressure media and insulator. Laser heating was performed at the interface between the chondrite glass and metal foil. During stepwise heating, *in-situ* μXRF spectra and μXRD pattern of the metal foil were synchronously collected. Fluorescence analysis is used to quantify trace element concentration whereas diffraction patterns give information on melting stage and appearance of high pressure phases in the laser spot. First qualitative analysis verify existing data and show a strong partitioning of HSE into the metal liquid with increasing temperature. Quantitative data analysis is currently in progress.

Heavy noble gases from the Northern Lau Basin: The Xenon perspective on mantle heterogeneity

MARIA PETŐ[1], SUJOY MUKHOPADHYAY[1] AND KATHERINE A. KELLEY[2]

[1]Deptartment of Earth and Planetary Sciences, Harvard University, Cambridge, MA02138, USA (mpeto@fas.harvard.edu, sujoy@eps.harvard.edu)
[2]Graduate School of Oceanography, University of Rhode Island, RI 02282, USA (kelley@gso.uri.edu)

Constraining the Xenon isotopic composition of the MORB and plume sources is critical to understand Earth structure, mixing between different reservoirs in the mantle, and early degassing. Recent high-precision Xe measurements from Iceland by our group indicate that the $^{129}Xe/^{130}Xe$ ratio in the Iceland plume is low compared to MORBs because of a lower I/Xe ratio. Since ^{129}Xe is produced from now extinct ^{129}I, the Xe data limits the degree of mixing between the Iceland plume source and the MORB source over Earth history.

We will also present CO_2, and noble gas data (He, Ne, Ar and Xe) from gas-rich basalt glasses along the Rochambeau Rift (RR) in the Northern Lau Basin. Our goal is to investigate whether the Xe composition of the Iceland plume is representative of other mantle plumes.

The samples selected for the study have $^3He/^4He$ ratios between 15.8 to 28.2 R_A. Recent work suggests that the high $^3He/^4He$ ratios reflect the presence of a 'Samoan-like' OIB source in the northern Lau Basin [1]. The measured $^{129}Xe/^{130}Xe$ ratios in the 28.2 R_A sample reaches 7.01. Mixing systematics between Xenon and the other noble gases in the samples demonstrate that the maximum $^{129}Xe/^{130}Xe$ ratios in the mantle source is ~7.1**,** much lower than measured values in MORBs. Additionally, the $^4He/^{40}Ar$ ratio of one of the samples is ~3, indicating it to be largely undegassed. Data obtained by multiple step crushes of this sample display a linear trend in $^{129}Xe/^{130}Xe$ vs $^3He/^{130}Xe$ space that overlaps with the Iceland data, but is quite distinct from MORBs. Our new data corroborates observations from Iceland and suggests that OIBs and MORBs evolved with different I/Xe ratios. Further, Xe in the MORB source cannot be derived from the plume source, refuting predictions for the steady-state upper mantle model. Additional work is ongoing to characterize the Pu- to U-derived fission xenon in the RR samples.

Mn(IV) reduction: A driving mechanism for Mg^{2+}-enrichment in shallow marine carbonates?

D.A. PETRASH[1]*, S.V. LALONDE[2], M.K. GINGRAS[1] AND K.O. KONHAUSER[1]

[1]University of Alberta, Edmonton, AB T6G 2E3, Canada (*correspondence: petrash@ualberta.ca)
[2]IUEM Technopôle Brest-Iroise, France

A wide variety of bacterial metabolisms have been suggested to facilitate the precipitation of penecontemporaneous dolomite (e.g. aerobic respiration, sulfide oxidation, sulfate reduction, and methanogenesis), highlighting a strong need for additional insights from modern near-surface dolomite-forming locales. In the transition from intertidal to supratidal settings in a Ca-dolomite-forming lagoon, Archipelago Los Roques, Venezuela, early diagenesis is strongly influenced by a complex microbial mat system. The overlying evaporated seawater is characterized by temperatures in excess of 30°C; elevated alkalinity, ~245 meq/L (as total $CaCO_3$) and pH, ~9.3. Sedimentation in the lagoonal system is dominated by allochemical aragonite, authigenic calcite and gypsum. In the sediment, there is a slightly cemented zone, 8-12 cm below the surface, consisting of aragonite, calcite and Ca-dolomite. EPMA show that within this layer, gypsum is actually being calcified. Such evidence would suggest that the enrichment of Mg in carbonate cements might have been mediated by the terminal stages of degradation of organic matter [1], however, the Mg-enriched zone also corresponds with a local increase in the total organic carbon. Sediment major and trace element data yield a more complex picture of diagenetic processes leading to dolomitization. The trends in sediment trace element concentrations reveal marked changes in redox conditions with increasing depth. Carbonates in the cemented zone have maximum [Mn^{2+}] and minimum [Fe^{2+}], and as compared with underlying sediments, they also record highest Ni and Co concentrations. The incorporation of these elements in authigenic carbonates is though dependent on their solubilisation by Mn (IV) reduction [2], and the trends described here strongly suggest that at this depth, manganese reduction outcompetes sulfate reduction for labile organic carbon. Our results suggest that the trace element composition of carbonate minerals may track the biogeochemical processes that take place during low-temperature diagenesis, and importantly, offers new insight into the formation of penecontemporaneous dolomite.

LP-HT signature from the Adria-Europe plate boundary realm: The role of mantle/crust interaction in granite generation

Z. PETRINEC* AND D. BALEN

University of Zagreb, Faculty of Science, Croatia (*correspondence: zoricap@geol.pmf.hr)

The final geodynamic position of the Moslavačka Gora (MG) on the SW margin of the Pannonian Basin (PB) is related to Mesozoic and Cenozoic evolution of the Dinaric segment of the Alpine-Himalayan orogenic belt formed along the Adria-Europe active continental margin. Overall lithology of the MG crystalline can be broadly divided into three main groups: S-type granites which make the core of the MG complex and high- to medium-grade metamorphic rocks (migmatites, gneisses, amphibolites, metapelites) which are present in form of foreign enclaves i.e. xenoliths inside the MG granite pluton.

Dm- to m-sized xenoliths bear signature of the polyphase metamorphic evolution of the MG complex with at least two phases being identifiable through specific mineral assemblages. First phase (recorded in amphibolites), which preceded granite intrusion, reached maximum conditions of amphibolite facies metamorphism. The second, Late Cretaceous LP-HT phase, can be separated into two closely related metamorphic events (recorded in the metapelite xenoliths) that took place under low-P amphibolite facies conditions. Pseudosection modelling gave temperature range 585-600 °C and pressure range 390-460 MPa for assemblage Bt + Cd + Pl + Grt + Sil + Qtz while younger assemblage Bt + Chl + Pl + And + Qtz gave temperature 540°C and pressure <250 MPa).

Major and trace element chemical data (including REE) favor anatexis of a crustal (meta)pelitic source as a dominant process in the genesis of two dominant types of the Late Cretaceous MG peraluminous granites: two-mica granite (Tmg), and leucogranites (Lg). Occurrence of different types of cognate enclaves, e.g. tourmaline nodules, together with presence of miaroles and magmatic andalusite in the assemblage points to upper crust emplacement level of the intrusion (avg. 5-6 km). Rare MME field occurrences imply genetic link of the MG granite intrusion with Late Cretacoeus LP-HT event and the upper mantle/lower crust mafic intrusion that might be the same that was responsible for Cretaceous gabbro occurences of the MG crystalline complex.

Sorption of Np on magnetite in solutions of different ionic strengths

V.G. PETROV*, A.A. ZADORIN AND S.N. KALMYKOV

119991, Leninskie gory, 1/3, Chemistry Department, MSU, Moscow, Russia
(*correspondence: vladimir.g.petrov@gmail.com)

Neptunium is an element of interest due its high content in spent nuclear fuel and its physico-chemical properties, such as long half-life ($T_{1/2}$ (^{237}Np) = $2.14 \cdot 10^6$ years) and high potential mobility of Np (V) which is the most stable valent state under the environment conditions. Among numerous geochemical reactions controlling the migration behavior of actinides, sorption processes are of main importance. Magnetite is one of the possible iron oxide phases forming as a result of steel containers corrosion. There are number of research works dealing with sorption of neptunium onto different iron oxides in solutions with low ionic strengths in literature. However in near-field conditions due to dissolving of cementitious materials and host rocks formation of brine solutions is possible.

The objective of this work is to investigate sorption of pentavalent neptunium on magnetite in sodium chloride solutions of different concentrations both in aerobic and anaerobic conditions.

Experiments in aerobic conditions were done in contact with atmospheric air in the pHc (pHc = -log [H^+]) range 2.0 – 8.0. Experiments in anaerobic conditions were done in N_2 glove box in the pHc range 2.0 – 10.0. All solutions were prepared using deionized water and NaOH/NaCl, HCl/NaCl for adjusting pHc. The initial neptunium concentration was $1 \cdot 10^{-9}$ M. For activity measurements short-lived gamma-emitting isotope ^{239}Np ($T_{1/2}$ = 2.36 days) was used. Solid/solution ratio was 1 g/L.

The shift of the sorption edge to higher values of pHc (6.5 – 7.5) and decreasing of maximum sorption with increasing ionic strength was observed in both aerobic and anaerobic conditions (from 98% in 0.1 M NaCl solution to 67% in 5 M NaCl solution). In the 0.1 M NaCl solutions typical for cation sorption curve was observed with pHc_{50} (50 % sorption) 6.5. Unusual sorption behavior was observed for 1-5 M NaCl solutions in aerobic conditions with additional maximum in the pHc range 4.5-5.5, that could be explained by reduction of pentavalent neptunium in the presence of iron (II). This maximum has the highest value of 70% for 1 M NaCl and decreases to 20% with increasing of the ionic strength to 5 M NaCl. Further thermodynamic calculations are required for accurate description of obtained results.

Modeling reconciles observations for Traps in East and West Siberia

A.G. PETRUNIN AND S.V. SOBOLEV

GFZ, German Research Centre for Geosciences, 14473 Potsdam, Germany
(*correspondence: stephan@gfz-potsdam.de)

The Permo-Triassic Siberian Traps – the type example and the largest continental Large Igneous Province, is located on both thick cratonic lithosphere of Precambrian Siberian Craton in the East Siberia and on much thinner lithosphere of the Mesozoic West Siberian Basin. Based on largest volumes of the exposed basalts and on highest source temperatures of basalts in the East Siberia, it is believed that the head of a hot mantle plume, which was probably the source of basalts, arrived in the East Siberia. However, there is no evidence of the expected pre-magmatic uplift nor of a large lithospheric stretching of the basaltic sequence in the East Siberia, while these features are reported for the West Siberian Basin [1]. Based on these observations it was suggested [1] that mantle plume head arrived to the base of the lithosphere of the West Siberian Basin and only later leaked below the East Siberian Craton.

Here we test scenarios with different locations of the mantle plume, using thermomechanical modeling technique. The model employs petrological constraints for the source composition and temperature [2, 3], non-linear temperature- and stress-dependent elasto-visco-plastic rheology [4] and pressure- and temperature-dependent melting of a heterogeneous mantle. We show that observations for the West and East Siberian Traps can be reconciled for the large (more than 400 km in radius) and hot (potential temperature up to 1600°C) plume head containing large amount (up to 15 Wt%) of the recycled oceanic crust, that arrived to the thick lithosphere of the East Siberia and was then deflected towards the thin lithosphere of the West Siberia. In this case no uplift and stretching is generated in the East Siberia and major basaltic eruptions may occur first in the West Siberia.

VisualAge: A novel approach to U-Pb LA-ICP-MS geochronology

JOSEPH A. PETRUS* AND BALZ S. KAMBER

Laurentian University, Sudbury, ON, Canada
(*correspondence: japetrus@gmail.com)

This contribution presents VisualAge, a new tool for reducing and visualizing U-Pb geochronology data obtained by LA-ICP-MS. VisualAge was developed as an add-on for Iolite (the freely available ICP-MS data analysis tool [1]) and consists of two main components: an Iolite data reduction scheme (DRS) and Igor Pro visualization routines. The VisualAge DRS improves upon the existing Iolite U-Pb geochronology DRS by calculating the $^{207}Pb/^{206}Pb$ age as well as the common lead corrected ratios and ages (either via the measured ^{204}Pb signal or where ^{204}Pb is unavailable, with Andersen's approach [2]) for each point of the raw ICP-MS data. By far the most important feature of VisualAge is its ability to display a 'live' concordia diagram. This feature allows one to visualize the data of an Iolite integration on a concordia diagram as it is being selected and adjusted, thus providing immediate visual feedback regarding data discordance, uncertainty, and common lead contamination for different regions of the ICP-MS signal. The 'live' concordia diagram is particularly useful for LA-ICP-MS zircon data, where the signal from a single grain can consist of zones of concordance, disturbed or metamict areas, as well as inherited cores or younger overgrowths. Once integrations have been selected in Iolite, VisualAge can also be used to quickly construct age histograms and probability distributions, standard and Tera-Wasserburg style concordia diagrams (including the computation of a concordia age [3]), as well as 3D U-Th-Pb and total U-Pb concordia diagrams.

Secondary organic aerosols (SOA) comprise a significant fraction of the atmospheric aerosol burden and play an important role in direct and indirect aerosol effects on climate. To model SOA-cloud interactions we ultimately seek relationships that can predict a compound's contribution to a particle's ability to serve as a cloud condensation nucleus (CCN) based on its chemical composition. The relative CCN efficiency of a compound is described by the hygroscopicity parameter κ. We find that for sufficiently functionalized molecules, κ can be modeled within a factor two using predictions based on molar volume. Compounds with fewer functional groups strongly deviate from this model, resulting in a continuum of reduced κ values between the molar volume model and zero. We use experimentally determined derivatives of d (κ)/d (number of functional groups of type i) to quantify this effect and to develop a framework that can be used to compute κ based on the molar volume, number of carbon atoms, and the number and type of functional groups present in the molecule.

Ambient organic aerosols consist of a large number of different compounds. We developed a new technique to characterize this distribution by collecting aerosol on filters, extracting the compounds into solvent, separating the extract using high pressure liquid chromatography, and measuring the κ value of each seperated component as a function of column retention time using scanning flow CCN analysis. Kappa generally decreased with retention time, suggesting a relationship between a compound's polarity and its κ value. The frequency distributions of component κ's that make up the mixture provide detailed information linking chemical mechanisms of SOA formation and organic aerosol CCN activity.

LA-ICP-MS Sr isotope ratio analysis of individual fluid inclusions

THOMAS PETTKE[1], FELIX OBERLI[2] AND JACOB J. HANLEY[3]

[1]University of Bern, Institute of Geological Sciences, CH-3012 Bern, Switzerland. (Pettke@geo.unibe.ch)
[2]ETH Zurich, Institute of Geochemistry and Petrology, CH-8092 Zurich, Switzerland

This pilot study addresses the feasibility of precise and accurate Sr isotope ratio analysis by laser-ablation multiple collector ICP-MS of fast transient signals as obtained from the ablation of individual fluid inclusions. We used synthetic (Na±Ca)Cl inclusions containing variable amounts of SRM 987 Sr and Rb.

The principal analytical and data reduction procedures follow those reported in Pettke *et al*. [1] and Burla *et al*. [2]. Masses 83, 84, 85, 86, 87, 88 were recorded on Faraday detectors at 0.2s integration intervals. Raw readings were first corrected for incongruent amplifier response using the quadratic tau correction scheme [1]. Background correction is followed by interference correction, altogether removing overlap by Kr, Ca-argides and Ca-dimers. ^{87}Rb overlap is then corrected by peak stripping using fractionated Rb based on mass bias values obtained for Sr, and the resulting ^{87}Sr/^{86}Sr ratio is then mass bias corrected.

Evaluation of results based on individual readings reveals incongruent signal intensity evolution for ^{85}Rb and ^{86}Sr across the fluid inclusion signal. Tau- and interference-corrected ^{87}Sr/^{86}Sr data are constant (at given analytical precision) across the transient fluid inclusion signal, however.

^{87}Sr/^{86}Sr ratios of synthetic fluid inclusions with variable Rb/Sr abundance ratios were obtained by bulk signal integration. As for synthetic fluid inclusions Sr isotope equilibrium between phases prevails, uncertainties of ^{87}Sr/^{86}Sr ratios could be minimized by cutting off low-intensity and thus imprecise transient signal tails.

Final ^{87}Sr/^{86}Sr ratios correlate with ^{85}Rb/^{86}Sr ratios. The least squares linear fit intercept is at ^{87}Sr/^{86}Sr = 0.71028 ±0.00019, identical to the nominal value of SRM 987 = 0.710245. The correlation could be eliminated by adjustment of ^{85}Rb/^{87}Rb to 2.58676, a value very close to that reported earlier [3], suggesting that an offset in mass bias between Sr and Rb by 5.3% in β values can account for the observed trend.

Association of amino sugars (chitin) with Fe oxyhydroxides in mycorrhizal mat soils – A STXM/NanoSIMS investigation

JENNIFER PETT-RIDGE[1]*, MARCO KEILUWEIT[1,2], JEREMY BOUGOURE[1], PETER S. NICO[3], PETER K. WEBER[1], LYDIA ZEGLIN[2], DAVID D. MYROLD[2] AND MARKUS KLEBER[2]

[1]Lawrence Livermore National Laboratory, Physical and Life Sciences Directorate, Livermore, CA (*correspondence: pettridge2@llnl.gov)
[2]Department of Crop and Soil Science, Soils Division, Oregon State University, Corvallis, OR
[3]Lawrence Berkeley National Laboratory, Earth Sciences Division, Berkeley, CA

Amino sugars and polymers such as chitin represent a major constituent of fungal cell walls and hydrolyzed soil organic matter. Despite their potential importance in soil nitrogen and carbon cycling, comparatively little is known about their dynamics in soils. Here we present the results of an investigation into the mineral interactions and micro-scale behavior of chitin in ectomycorrhizal mats – a system adapted to rapid cycling of amino sugars. The aim of this study was to follow the micro-scale dynamics of ^{13}C- and ^{15}N-labeled chitin during a 3-week incubation in mycorrhizal mat soil collected from a Oregon andic soil under Douglas-fir forest. Based upon previous findings, we hypothesized that the isotopic label would accumulate in bacterial cells associated with fungal hyphae due to their ability to rapidly process amino sugars. In contrast, nano-scale secondary ion mass-spectrometry (NanoSIMS) imaging of hyphae-associated soil organic matter, minerals, and bacteria revealed a preferential association of ^{15}N with Fe-rich particles at the end of the experiment. Synchrotron-based Scanning Transmission X-ray spectromicroscopy (STXM/NEXAFS) at the C, N and Fe K-edge suggests that these hyphae-associated microstructures consist of thin coatings of amine N on Fe (oxyhydr)oxides. Our results are consistent with recent observations of preferential binding of amine N to Fe-rich minerals and suggest a role of Fe (oxyhydr)oxide surfaces in N cycling of organic layers soils. No enrichment of ^{13}C was found at these locations, possibly due to the lower levels of overall ^{13}C abundance. We further discuss advantages and challenges (e.g. data representation, replication, appropriate controls) of the combined application of isotopic and spectroscopic imaging techniques for the investigation of soil C and N cycling.

CO_2 sequestration in olivine rich basaltic aquifers: A reactive percolation experimental study

S. PEUBLE, M. GODARD, P. GOUZE AND L. LUQUOT

Géosciences, CNRS-Université Montpellier 2, France

Injection of CO_2-rich fluids into basaltic aquifers is one of the methods envisaged for mitigation of increasing atmospheric CO_2. Basalts are rich in Mg, Fe and Ca and have a high potential to trap CO_2 as carbonate minerals. However, the role of reaction-transport processes has yet to be investigated in order to predict the capacity and sustainability for CO_2 storage of these highly reactive systems.

We present the results of three percolation experiments performed on the ICARE-2 experimental bench at 180°C and total pressure of 12 MPa. $NaHCO_3$ rich water (0.5 mol/L) mixed with CO_2 (Pco_2 = 10 MPa) was injected through sintered analogues of olivine-accumulation zones in basaltic flows (~95% olivine Fo_{87}, MORB glass, minor chromite). The injection rate was 1 mL/h for exp. 1 and 2, and 0.1 mL/h for exp. 3. The initial porosity and permeability of samples ranges from 4 to 7% and $30x10^{-18}$ to $400x10^{-18}$ m^2 respectively.

All experiments show a strong permeability decrease (down to 10^{-18} m^2) after 90 hours for exp. 1 and 2, earlier for exp 3. Yet dissolution occurs: high concentrations of Zr and Al and of Co in the outlet fluids indicates dissolution of basaltic glass and olivine respectively. Si concentration changes reveal a more complex system with olivine dissolution and the precipitation of Si rich phases. We observed the growth of relatively large (up to 5 microns) Mg-Fe rich phyllosilicates perpendicular to (at the expense of ?) olivine surface. This reaction is typically associated to hydration of (ultra-)mafic rocks and may explain the decrease in permeability during experiments. Finally, the low Ca and Mg fluid concentrations suggests trapping by Ca-Mg rich phases. Ankerite and dolomite were identified by Raman spectrometry in the samples of exp. 1 and 2, while exp. 3 was characterised by precipitation of well developped and abundant magnesite ($Mg_{0.88}Fe_{0.11}Ca_{0.01}CO_3$) replacing dissolved olivine. Carbonation appears to be an efficient process: ~ 0.015g of CO_2 per gram of sample is stored as carbonates during exp. 1, that is, if these results were directly upscaled to the size of an injection site, an average yield of ~45 kg/m^3/day. Our results indicate a strong control of flow rates on carbonation, but also on hydration reactions. This implies not only variations of the CO_2 storage capacity of the basaltic aquifer with distance to the injection well, but also that controlling the injection rate could allow to enhance the efficiency of *in situ* carbonation.

Diffusion of nanoparticles in waters and biofilms-implications for bioavailability

T.-O. PEULEN[1], R.F. DOMINGOS[2], D.F. SIMON[3] AND K.J. WILKINSON[3]

[1]Institute of Molecular Physical Chemistry, Heinrich-Heine-University Düsseldorf, Building 26.32.02, Universitätsstraße 1, 40225 Düsseldorf, Germany

In order to properly assess the environmental risk of engineered nanoparticles (ENP), it is necessary to determine their fate (including dissolution, aggregation and bioaccumulation) and mobility under representative environmental conditions. While the mass transport of nanoparticles in the environment is necessarily lower than that of ions, it is not clear that reduced mobility will result in reduced bioavailability. In this study, two lines of study were examined to determine the effect of increased particle size on the mobility and bioavailability of nanoparticles. The bioaccumulation (and biological effects) of CdTe/CdS quantum dots (QD) was compared with that of free Cd^{2+}. While the bioaccumulation of the QD was largely accounted for by dissolved Cd, whole transcriptome screening using RNA-Seq analysis showed that the free Cd and the QD had distinctly different biological effects. In a second line of experiments, the diffusion of several model nanoparticles (dextrans, fluorescent microspheres, Ag nanoparticles) were studied *in situ* using confocal microscopy and fluorescence correlation spectroscopy in a biofilm. For the most part, relative self-diffusion coefficients decreased exponentially with the square of the radius of the nanoparticle. The nature of the biofilm was also shown to be an important parameter controlling the diffusion of the nanoparticles. Finally, the charge of the nanoparticles also appeared to be important – a greater than predicted decrease in the self-diffusion coefficient was observed for the negatively charged nano Ag, especially in dense biofilms. In order to understand the role of nanoparticles in the environment, it is necessary to understand the important factors affecting their mobility.

Removal Pb^{2+} from water sample, by using Natural Zeolites of Aftar mine (Semnan, Iran)

S. PEYRAVI[1], R. ZAHIRI[2] AND K. MORADI HERSINI[3]

[1]M.Sc in Economic Geology, School of Earth Sciences, Damghan University, Damghan, Iran
[2]Assistant Professor, School of Earth Sciences, Damghan University, Damghan, Iran (zahiri@du.ac.ir)
[3]Assistant Professor, School of Earth Sciences, Damghan University, Damghan, Iran

Zeolites are naturally occurring hydrated Aluminosilicate minerals [1]. The isomorphous replacement of Si^{4+} by Al^{3+} produces a negative charge in the lattice. The net negative charge is balanced by the exchangeable cations (sodium, potassium, or calcium). These cations are exchangeable with certain cations in solutions such as lead [2, 3].

This study represents usage zeolite Aftar mine in ability the zeolites in the removal of lead from water sample. For this purpose, the first crushed zeolites and using the mesh sieve ASTM.E-11 standard classification in size by 1 mm, 0.71 mm and 0.25 mm for use in testing were falling head.

According to falling head test, and calculated parameter such as K (Permeability) water samples (with concentrations of certain lead) the cross of the zeolite and ICP-OES analysis on them. The results show that zeolite of Aftar mine be able removal lead. XRF analysis on the zeolite shows that After passing the water sample in the composition of zeolites lead sensible.

PbO	K_2O	Na_2O	CaO	Fe_2O_3	Al_2O_3	SiO_2	Components

Electric Currents in Marine Sediments

A recent study showed that electric currents can run through marine sediments coupling hydrogen sulphide oxidation at depth and oxygen reduction at the sediment surface [1]. A microbially assisted composition of bacterial nanowires and possibly semiconductive minerals was suggested to play a role in the electron transfer. However, this concept remained hypothetical.

Evaluating the Type of Electron Transmission

We hypothesised that an electric network is entirely composed of solid conduits, performing true electronic conductance (in contrast to electron shuttling).

To test this hypothesis, we first cut horizontally through electrically active sediment systems using a very thin platinum filament. Monitoring proton and oxygen consumptions revealed that the electrochemical reduction of oxygen was instantaneously interrupted by the cut. Moreover, the electric field was equally affected upon cutting.

In a second approach, polycarbonate filters embedded in the sediment were found to obstruct the development of an electric connection, although diffusion of electron shuttles were not impeded by the filters.

Conclusion

The results provide strong evidence that the conductive elements in marine sediments comprise a solid matrix of electronic conduits. Thus, our findings support the proposed involvement of microbial nanowires and semiconductive minerals, i.e. the occurrence of biogeoelectric networks in marine sediments.

Arsenic uptake and speciation in the green marine alga *Ulva lactuca*: Development of a coastal aquatic bioindicator

CATHERINE PHAM[1,2]*, LAURENT CHARLET[2] AND GARRISON SPOSITO[1]

[1]Division of Ecosystem Sciences, University of California, Berkeley, CA 94720-3114, USA (*correspondence: pham@cal.berkeley.edu, gsposito@berkeley.edu)

[2]ISTerre, University of Grenoble, BP 53, 38041, Grenoble, France (charlet38@gmail.com)

Algae are ubiquitous in surface waters and are known to influence the biodynamics of the priority toxic metalloid arsenic (As) in polluted marine environments. In the present study, we investigated the bioavailability and chemical forms of As in algae sampled from contaminated coastal waters in France and California in order to understand As cycling in the marine environment using synchrotron-based spectroscopic techniques.

Given the alga's unique morphology and cell size (15-50 µm cell diameter; 50-100 µm thallus thickness), STXM and µXRF were used for the first time to date to analyze *Ulva lactuca* to distinguish the different target organelles and map As speciation *in situ*. We observed shifts at the carbon 1s edge in response to As and phosphate gradients and are exploring the importance of arsenosugars.

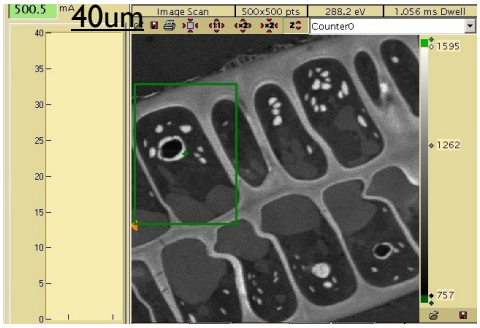

Figure 1: Cross-section of *Ulva lactuca* perpendicular to the axis of the thallus using STXM at 288.2 eV.

We are characterizing the potential risks As may pose to both ecological and human health as it is transformed into various chemical forms and moves from algae up trophic levels, potentially to fish and humans. Our research may serve as a basis for the future use of algae in biomonitoring and phytoremediation scenarios related to metalloid contamination in aquatic ecosystems.

Evidence from zircon ages and Hf isotopic composition for Paleoproterozoic crustal evolution in Northwestern Vietnam

PHAM TRUNG HIEU[1,2]* AND F. CHEN[3]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029, China (*correspondence: fanzhongxiao@126.com)

[2]Hanoi University of Mining and Geology, Vietnam

[3]School of Earth and Space Sciences, University of Science and Technology of China, Hefei, China (fkchen@ustc.edu.cn)

The Phan Si Pan area of NW Vietnam is one of the oldest basements in SE Asia. Paleoproterozoic is worldwide an important era in crustal evolution with occurrence of megascale tectonothermal activities, but the record is not much clear in NW Vietnam. In order to reveal the nature of Paleoproterozoic events in NW Vietnam, a combined study of zircon U-Pb ages and Hf isotopic composition was done on metamorphosed sedimentary rock and migmatite in the Phan Si Pan area, being an Archean basement exposed in NW Vietnam. Zircons yield U-Pb ages of 1.83 ±0.08 Ga. These Paleoproterozoic zircons have Th/U ratios of 0.02-0.25, indicating both magmatic and metamorphic origins. They are characterized by old Hf model ages of ~3.1 Ga and negative ε_{Hf} (t) values of about -10, implying Archean source (s). From these results, it is proposed that the Paleoproterozoic global thermal event (s) must have been taken place in NW Vietnam at least with reworking of Archean continental nucleus.

Based on a survey of the Paleoproterozoic events throughout the Phan Si Pan area, it can be observed that metamorphic and simultaneous magmatic event (s) have occurred in the northern part connected with the South China craton, but only magmatic activity have been distinguished in the southern part (the Bao Ha complex) so far. These metamorphic and magmatic activities were probably associated with the formation of a unified basement in NW Vietnam and likely imply continental accretion during the assembly of the Columbia supercontinent in Paleoproterozoic.

On the potential for CO_2 mineral storage in continental flood basalts

VAN T.H. PHAM *, HELGE HELLEVANG AND PER AAGAARD

Department of Geosciences, Univ. Oslo, Norway (*correspondence: per.aagaard@geo.uio.no)

Continental flood basalts (cfb) are considered as potential objectives for CO_2 storage because they contain abundant divalent cations and therefore have a potential for mineral trapping of CO_2 [1]. Lateral extensive cfb are found in many place in the world within distance from major CO_2 point emission sources.

The potential of cfb to store CO_2 in secondary carbonates was evaluated. Based on mineral assemblage, formation water composition of Colombia River Basalt [2], we estimated the reactive surface of the basalt to be approximately 1/1000 of the total pore space surface. Kinetic dissolution of primary basalt-minerals (pyroxene, feldspar and glass) and local equilibrium assumption for secondary phases (weathering products) were applied for the simulations.

According to the simulations result, formation of carbonates in basalt rock at 40 ºC and CO_2 100 bar is limited, and only small amount of siderite and ankerite formed. Calcium was largely consumed by zeolite instead of forming Ca-carbonates (Figure 1). Potential of carbonate formation is sensitive to reservoir temperature and CO_2 pressure, with intermediate pressures giving more secondary carbonates than the highest pressures. The amount of carbon stored in solid phases after 10.000 years is small relative to solution trapping (approximately 0.23 %).

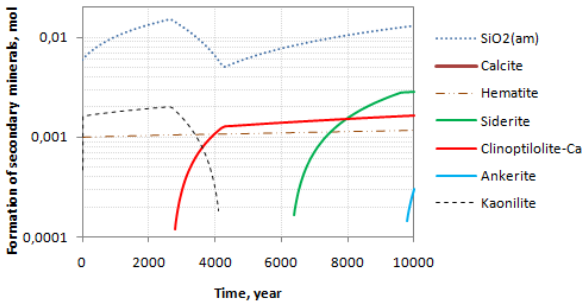

Figure 1: Secondary minerals formed in the batch simulation with the present of injection CO_2 at 40 °C, 100 bar. Only amounts of siderite and ankerite formed in thousand years.

Crustal contribution to the geo-neutrino flux at the Sudbury Neutrino Observatory (SNOLAB)

CATHERINE PHANEUF[1], JEAN-CLAUDE MARESCHAL[1], CLAIRE PERRY[1] AND CLAUDE JAUPART[2]

[1]GEOTOP , Université du Québec à Montréal, PO8888, Station Downtown, Montréal, H3C 3P8, Canada

[2]Institut de Physique du Globe de Paris, 1, rue Jussieu, 75238, Paris Cedex 5, France

Recent improvement in the observation of geo-neutrinos, i.e. low energy anti-neutrinos produced by β decays in the series of radioactive elements U and Th, will permit a direct determination of the abundance of these radio-elements in the mantle and their contribution to the earth's energy budget.

The major fraction, about 80%, of the geo-neutrinos, that will be detected in continental observatories come from the continental crust nearby. In order to estimate the flux from the mantle, we need to precisely account for the crustal contribution.

Crustal radio-activity can be best determined from surface heat flux data which integrate the entire crustal column and are unaffected by small scale heterogeneities.

We analyze heat flux and heat production data to calculate the crustal contribution to the total geo-neutrino flux that will be observed at the Sudbury Neutrino Observatory (SNOLAB).

With all the available data, we show that the heat production is very heterogeneous but that the Sudbury region has significantly higher heat flux than the average Canadian shield (53 mWm^{-2} vs 42 mWm^{-2}). This elevated heat flux is due to the high heat production (>1.5 μWm^{-3}) in the upper part of the crust which is usually enriched in radio-elements.

This high crustal radio-activity leads to as much as 50% increase of the local crustal component of the geo-neutrino flux that will be observed at SNOLAB.

Reconciling the sulfur atmospheric cycle of early Earth with the geological record

PASCAL PHILIPPOT AND MARK VAN ZUILEN

Geobiosphere, Institut de Physique du Globe, Sorbonne Paris Cité, Université Paris Diderot, CNRS, 1 rue Jussieu, 75238 Paris, France

The reports of mass-independent sulfur isotope anomalies (MIF-S) in sediments older than 2.45 Ga have been attributed to photolytic reactions involving volcanic SO_2 in an oxygen-poor atmosphere. Photolysis experiments of SO_2 coupled with various UV shielding scenarios provided additional links to the early atmosphere. However, no simple model can reproduce the mismatch in the $\Delta^{33}S$-$\delta^{34}S$ relationship between the reference Archaean sulfide array (positive $\Delta^{33}S$-$\delta^{34}S$ correlation) and product sulfate (negative $\Delta^{33}S$ but positive $\delta^{34}S$). The discrepancy in the temporal and spatial record of sulfur isotope anomalies, with three main sulfate horizons deposited within less than 300 Ma compare to a global distribution of sulfide over more than 1, 500 Ma, is also unexplained. Here we report a new $\Delta^{33}S$-$\delta^{34}S$ linear trends recovered in two felsic volcanic ash layers of the 3.2 Ga Mapepe Formation in South Africa. This « felsic volcanic array » forms a tight $\Delta^{33}S$-$\delta^{34}S$ linear correlation that is best approximated by SO_2 photolysis experiments at deep UV wavelength. The perfect match to the $\Delta^{33}S$-$\delta^{34}S$ values of associated sulfate and equivalent felsic volcanoclastic and sulfate horizons of the 3.5 Ga old Dresser Formation, Western Australia, indicates that the exogenic sulfur cycle that produced this array was linked to felsic volcanism and sulfate precipitation. An emerging scenario for the early Earth atmosphere is a continuous photochemical haze that is perturbed between 3.5 and 3.2 Gyr by massive and optically thick volcanic plumes. This volcanic activity coincides in time with a period of rapid crust formation (Valbaara supercontinent).

Microbial iron reduction under deep subsurface pressure conditions

AUDE PICARD[1,2,3]*, DENIS TESTEMALE[4], JEAN-LOUIS HAZEMANN[4] AND ISABELLE DANIEL[3]

[1]Max Planck Institute for Marine Microbiology, Biogeochemistry Department, Celsiusstraße 1, 28359 Bremen, Germany (*correspondence: apicard@mpi-bremen.de)

[3]Université de Lyon, F-69622, Lyon, France, Université Lyon 1, ENS Lyon, CNRS, UMR 5570, Laboratoire de Géologie de Lyon, 46 allée d'Italie, 69364 Lyon Cedex 07, France

[4]Institut Néel, CNRS, Université Joseph Fourier, BP166, F-38042 Grenoble Cedex 9, France

Pressure is a key parameter in the deep subsurface which has been estimated to contain a large microbial population [1]. However the effects of pressure on microbial processes involved in important biogeochemical cycles are not constrained yet. At present, iron oxides are recognized as the most abundant terminal acceptors for the oxidation of organic matter in anoxic environments imposing dissimilatory iron reduction (DIR) as a biogeochemically important process in aquatic sediments, soils and aquifers [2]. Many factors are known to influence iron reduction rate and extent, however to our knowledge pressure effects on microbial iron reduction have not been investigated. We investigated the pressure dependence on Fe (III) reduction by the bacterium *Shewanella oneidensis* MR-1 up to 100 MPa using *in situ* X-ray Absorption Spectroscopy (XAS). At pressures up to 70 MPa, MR-1 was able to reduce all 5 mM Fe (III) citrate provided. Above 70 MPa, the final amount of Fe (III) that MR-1 could reduce decreased linearly and DIR was estimated to stop at 109 ±7 MPa. The initial reduction rate was enhanced by pressure up to 40 MPa then decreased to reach 0 at ca 110 MPa. MR-1 is a piezosensitive bacterium with growth rate maximum at atmospheric pressure. However, it can still grow at relatively high rates up to 40 MPa. MR-1 could thus be a potential significant player of the iron cycle in most of the metal-rich freshwater and marine sediments where moderate pressures occur.

Diatom-bound trace metals: A tracer for past changes in micronutrients availability?

LAETITIA E. PICHEVIN*, WALTER GEIBERT AND RAJA S. GANESHRAM

School of Geosciences, Grant Institute, West Mains Road, Edinburgh EH9 3JW, UK
(*correspondence: laetitia.pichevin@ed.ac.uk)

Micronutrient input to the ocean is considered to have played a modulating role on the marine carbon pump and global climate throughout the past. An appropriate proxy for micronutrient bioavailability in the surface ocean and uptake by the phytoplankton was hitherto lacking. Culture experiments have shown that diatoms incorporate elements such as Zn and (potentially) Fe into their frustules in proportion with their availability in the medium [1, 2]. Hence, diatom-bound metals concentrations could be used to track past changes in marine micronutrients availability. However, whether the signal recorded by the living diatoms is fully transferred to the sediment has never been tested. In order to measure the impact of diagenetic processes during settling and burial on the trace metals signal biologically incorporated into the frustules, we compared diatom-bound trace metals content in surface sediments, traps and in suspended particles collected in the overlying surface water. Both ICP-OES and the ion microprobe techniques were used. Our results suggest that for most of the metals considered in this study, diagenetic processes alter the recording of the signal with the notable exception of Zn and, potentially, Mg.

Experimental investigation of garnet-cpx geobarometers in eclogites

J. PICKLES*, J.D. BLUNDY, R. SWEENEY AND C.B. SMITH

University of Bristol, Bristol. UK
(*correspondence: Joe.Pickles@bristol.ac.uk)

The development of accurate geothermometers has greatly helped in the understanding of metamorphic petrology and magmatic processes. The development of geobarometers applicable to eclogitic assemblages has previously not received the same attention. Here we present both empirical and thermodynamic models based on the partitioning of major and minor elements between garnet and cpx as determined experimentally in the P-T range 1-11 GPa and 800-1700 °C.

The cpx-garnet partitioning of Na, Ca and Ti are found to be strongly sensitive to pressure, with Dgt/cpx increasing with increasing pressure. The sensitivity of D_{Ca} to pressure increases with decreasing garnet mg#. An empirical model of D_{Ca} was derived from over 150 mineral pairs from experiments. For garnets with an mg#< 0.7 the following calibration is valid for pressures between 1 and 11 GPa and temperatures between 800 and 1300 °C.

The barometer is:

$$P = (\ln D_{Ca} - 4.48 + 1.26 Si^{gnt} + 0.19 Fe^{gnt} + 1.46 Mn^{gnt} + 0.87 Mg^{gnt}) * 4.17$$

Where D_{Ca} is the concentration of Ca in garnet divided by Ca in cpx and Si^{gnt} is Si in garnet, all in atoms pfu. This model is insensitive to temperature, thus avoiding errors associated with geothermometers. Based on the regression of the data we estimate that the model has a standard error of 0.5 GPa.

We also investigated a number of exchange reactions as potential barometers, including reactions involving silica and rutile. These exchange reactions show considerable compositional sensitivity at fixed P and T, testifying to non-ideality in garnet and cpx. Using a ternary asymmetric model we derive non-ideal interaction parameters for each mineral. We find that barometers based on the exchange of Ca between garnet and cpx provide the most robust barometers.

The structure and lability of Re(VII)-sodalite

ERIC M. PIERCE[1]*, JAMES B. HARSH AND[2] AND JOHNBULL O. DICKSON[2]

[1]Oak Ridge National Laboratory, Oak Ridge, TN 37831 USA (*correspondence: pierceem@ornl.gov)
[2]Washington State University, Pullman, WA 99164 USA (harsh@wsu.edu, j.dickson@ wsu.edu)

^{99}Tc (Tc), a long-lived radionuclide, is one of the most widespread contaminants within the Hanford subsurface with an estimated inventory of 5.31×10^3 curies. For example, Tc contamination has been found in the sediments beneath the C, S, SX, T, and TX Tank Farms as a result of high-level waste (HLW) solutions that have leaked or spilled from Hanford Tanks. The HLW solutions are characterized as highly alkaline (hydroxide ion concentration > 8.5 M) and high ionic strength solutions (up to saturation with respect to $NaNO_3$). Previous research focused on ^{90}Sr and ^{137}Cs has demonstrated that these elements are incorporated into feldspathoid minerals, such as sodalite [Na_8 ($Al_6Si_6O_{24}$)Cl_2], that formed as a result of the contact between Hanford sediments and the HLW solutions [1, 2]. The desire to immobilize Tc in aluminosilicate minerals through the application of subsurface amendments for contaminated sediments as well as the production of mineralized wasteforms further emphasizes the need to understand the long-term stability and release of Tc from aluminosilicate minerals, specifically the feldspathoid mineral sodalite.

In an attempt to determine the structure and reactivity of Re-sodalite (as a chemical analogue for Tc-sodalite), a combination of spectroscopy analyses along with single-pass flow-through experiments were performed under dilute and near saturated conditions at pH (23°C) = 9.0 and 40°C. These initial experimental results suggest the release of elements from Re-sodalite is complex; the saturation state of the solution changes and this behavior may be associated with the formation of other mineral phases.

Long term chemical variations in stream waters draining a granitic catchment (1986-2010). Link between hydrology and weathering (Strengbach catchment, France)

MARIE-CLAIRE PIERRET[1], DANIEL VIVILLE[1], FRANÇOIS CHABAUX[1], PETER STILLE[1] AND ANNE PROBST[2]

[1]LHYGES EOST Université de Strasbourg, 1 rue Blessig 67000 Strasbourg, France (marie-claire.pierret@unistra.fr)
[2]ECOLAB ENSAT, Avenue de l'Agrobiopole 31326 Castanet Tolosan, France (anne.probst@ensat.fr)

The forested Strengbach catchment is an experimental site for which hydrological, geochemical and meteorological data have been collected since 1986. It is located in the Vosges massif on a granitic bedrock with temperate oceanic mountainous climate. The site suffered from acid rains and tree decline was acknowledged in the 1980s.

At the end of the 1980s, in parallel with the decrease of the acid atmospheric depositions, the pH of surface waters increased. At the same time, the chemical composition of the stream water evolved to significant lower cation (Ca, Mg) and anion (SO_4, NO_3) concentrations. Similarly, soil solutions show a decrease in Ca and Mg concentrations since 1986.

The decreasing sulfate concentrations are related to the reduction of anthropogenic acidic rain depositions as well as combination of sorption/desorption in soils**.** The variations of nitrate concentrations, which are not continuous over time, might be related to extremely dry periods causing modification of the N biogeochemical cycle at the catchment scale.

The decreasing cation concentrations cannot be explained by diminishing atmospheric wet and dry depositions. Similarly, hydrological processes do not explain these compositional changes. But the annual chemical fluxes out of the catchment are strongly correlated to the annual water fluxes, which were highly variable during the past 25 years.

Only changes in water-rock interaction and in the nature of the weathered sources might explain the Ca, Mg and K concentration variations at the catchment scale. The mechanisms involved include the formation of secondary soil minerals (mainly clays), cation exchange processes as well as weathering of primary, granite-derived and secondary minerals with resulting cation depletion in soil and saprolite.

Therefore, the long term monitoring of rain, throughfalls, spring and stream waters allows to follow the geochemical evolution of the ecosystem over time in response to changes in atmospheric pollution and forest management.

Chemical and mineralogical profile of the local wind-blown surface soil contribution to respirable airborne PM in Rome (Italy)

A. PIETRODANGELO*, R. SALZANO, S. PARETI, E. RANTICA AND C. PERRINO

Institute for Atmospheric Pollution Research, C.N.R., Italy, 00016 Monterotondo St (Rome)
(*correspondence: Pietrodangelo@iia.cnr.it)

We present the chemical and mineralogical profile of the respirable fraction of resuspended surface soil contributing to airborne particulate matter (PM) in the southern area of Rome. Mineral dust either from rocks and soil or from human activities share an exchangeable fate in the PBL [1] and result often not separable by receptor modelling. Nevertheless, discriminating among dust contributions is critical both for legislative purposes and for modelling improvement. In this work 12 bulk samples of surface rocks were collected at locations where the various geological lithosomes of the southern area of Rome emerge from soil [2]. From these samples the PM10 fraction was extracted. The PM_{10} soil fraction was analysed by ED-XRF and for single–particle microanalysis by SEM–EDX. The mineralogical content of samples was obtained by XRD. Analytical performances of single-particle microanalysis were evaluated against ED-XRF and XRD results. Single particles were classified for mineralogy, by matching the EDS spectra with the database of the RRUFF and/or of the GEOROC projects [3, 4]. Estimated aerodynamic diameter and size-segregation of the mineralogical classes identified in the PM_{10} soil fraction are discussed.

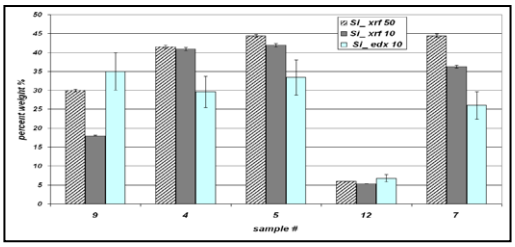

Figure 1: Performance evaluation for the Si determination by field and single-particle SEM-EDX microanalysis.

Slow mantle upwelling on the margin of the Hawaiian plume based on ^{230}Th-^{238}U disequilibria at Lōih‘i Seamount

AARON J. PIETRUSZKA[1], ERIK H. HAURI[2], RICHARD W. CARLSON[2] AND MICHAEL O. GARCIA[3]

[1]Department of Geological Sciences, San Diego State University, San Diego, CA 92182-1020, USA
[2]Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington DC 20015, USA
[3]Department of Geology and Geophysics, University of Hawaii, Honolulu, HI 96822, USA

The shield stage of a Hawaiian volcano is dominated by the eruption of tholeiitic basalts, whereas alkalic lavas are commonly erupted during the submarine pre-shield stage. Geochemical studies (e.g. [1]) relate this difference in lava chemistry to an increase in the degree of partial melting as the volcano drifts onto the Hawaiian mantle plume. We present high-precision U-series isotopic measurements for sixteen volcanic glasses from Lōih‘i Seamount to examine the time scale of the melt generation process during the pre-shield stage of a Hawaiian volcano. All of the samples have small amounts of excess ^{234}U (~0.2-1.0%) due to contamination with seawater-derived U (with ~14.6% excess ^{234}U). These signatures cannot be explained by syn- or post-eruptive interaction between lava and seawater. Instead, mantle-derived magmas at Lōih‘i are probably contaminated by hydrothermally altered rocks within the volcanic edifice. These altered rocks were likely enriched in U that was precipitated from seawater-derived hydrothermal fluids in the region above the volcano’s magmatic plumbing system. The Lōih‘i glasses display a wide measured range in the amount of excess ^{230}Th from ~1-7% (due to the addition of seawater-derived U) that overlaps with lavas from the nearby shield-stage volcano, Kīlauea (~2% excess ^{230}Th [2]). We correct the ^{230}Th-^{238}U disequilibria of the Lōih‘i glasses back to their pre-contamination values using their ^{234}U-^{238}U disequilibria and a simple mass-balance calculation. This correction suggests that mantle-derived magmas at Lōih‘i have a narrow range of ~6-9% excess ^{230}Th, which is significantly larger than observed at Kīlauea. This difference is consistent with the idea that Lōih‘i is tapping mantle that is upwelling slowly (~5-6 cm/yr) on the margin of the Hawaiian plume. This rate is at least an order of magnitude slower than the 50-1000 cm/yr range inferred for the mantle beneath Kīlauea [2].

Melt compositions and processes in the kimberlite provience of southern West Greenland

L. PILBEAM[1,2]*, T.F.D. NIELSEN[1] AND T.WAIGHT[2]

[1]Geological Survey of Denmark and Greenland, Øster Voldgade 10, 1350 KBH K, Denmark (*corresponence: lpi@geus.dk)
[2]Institute of Geography and Geology, Univ. of Copenhagen, Øster Voldgade 10, 1350 KBH K, Denmark

The kimberlite province of southern West Greenland (600-560Ma) comprises kimberlite *sensu stricto* on the Archean craton and aillikites on the paleoproterzoic sheild to the North. Carbonatite melt and xenocrystic olivine dominate the kimberlite *sensu stricto* occurrences of the Manitsoq region [1] whilst the silica content and H_2O/CO_2 ratio of the bulk rocks increases towards Sisimuit [2, 3]. A common carbonatite rich end-member is implicated [2]. This is in contrast to the prevailing dogma of a continuum from carbonatite though aillikite to kimberlite with increasing melting degree [4].

The authors have demonstrated that a process of DFC (digestion fractional crystallisation) whereby the cognate olivine crystallisation is coupled to entrained xenocrystic orthopyroxene assimilation is a key process during the formation of the Majugaa occurrence of the Manitsoq region [5]. Mass balance considerations are here applied to the Majuagaa bulk rock in term of the DFC mechanism obtaining an estimate of parental melt and magma composition for the Majuagaa kimberlite.

We use bulk rock major and trace element geochemistry together with mineral chemistry to investigate the range of melt compositions involved in the region. Melting models involving introduction of a carbonatite melt are applied to inferred lithospheric mantle compositions based upon nodule assemblages. Compositional variations across the southern West Greenland province are explained by interaction of an aesthenospheric carbonatite melt with lithospheric mantle. The major and trace element budgets are understood as a combination of melting regime together with mixing and reaction between the primary melts and the dispersed xenocryst assemblages. Variations of the mineral assemblages of the cognate groundmass are similarly explained.

Evidence for metasomatic enrichment in the oceanic lithosphere and implication for the generation of enriched reservoirs

S. PILET[1]*, D. BUCHS[2], M. COSCA[3], K. FLORES[4], A. BANDINI[5] AND P. BAUMGARTNER[1]

[1]University of Lausanne, Switzerland (*correspondence: Sebastien.Pilet@unil.ch)

[3]US Geological Survey, Denver, USA
[4]American Museum of Natural History
[5]UWA, Perth, Australia

Recycled metasomatized deep portions of oceanic lithosphere are potential candidates for enriched fertile mantle sources accounting for the overall enriched geochemistry of OIBs. However, the mechanisms of metasomatic enrichment in the oceanic lithosphere are poorly constrained. Here we report new petrological data that support the existence of metasomatic veins in the oceanic lithosphere, and explore the isotopic evolution of metasomatized lithosphere after its recycling and storage in the convecting mantle.

Metasomatic veins in the oceanic lithosphere are documented by cpx xenocrysts in accreted basaltic sills from northern Costa Rica. New field observations, ^{40}Ar-^{39}Ar radiometric dating, biostratigraphic ages and geochemical analyses indicate that the sills represent a possible, ancient analogue of petit-spot volcanoes formed by oceanic plate flexure offshore Japan [1]. The cpx xenocrysts are interpreted as relic of metasomatic veins based on their compositions which are similar to cpx from metasomatic veins observed in mantle outcrops and xenoliths. We interpret the formation of these veins as an early stage of the process that led to formation of the basaltic sills; some low degree melts do not reach the surface but differentiate within the lithosphere and form metasomatic cumulates (i.e. veins).

The generation of low degree melts at the base of the lithosphere by plate flexure is likely to represent a common mechanism in the oceanic lithosphere. Our data suggest that oceanic lithosphere is metasomatized before subduction. Monte Carlo simulations of this enrichment process [2] show that such metasomatized oceanic lithosphere is highly enriched in incompatible trace elements and its recycling and storage for 1 to 1.5 Ga could produce an enriched mantle reservoir with trace element and isotope compositions similar to HIMU mantle ‘end-member’.

A close look at the carbon cycle from the Roselend Natural Laboratory using laser-based isotope ratio spectrometry

E. PILI[1,2]*, S. GUILLON[1,2], P. AGRINIER[2] AND M. DELLINGER[2]

[1]CEA,DAM,DIF, F-91297 Arpajon
[2]Institut de Physique du Globe de Paris, 1 rue Jussieu, F 75005 Paris

We study the carbon cycle (fluxes and isotope ratios) in a section of a crystalline mountain belt. At the Roselend Natural Laboratory (French Alps), a tunnel provides access to the heart of the fractured-rock unsaturated zone, at 55m depth below ground surface. From dedicated sampling of matrix flow, fracture flow and runoff, we compute the contributions to Dissolved Inorganic Carbon due to carbonic acid weathering of carbonates and silicates as well as sulfuric acid weathering of carbonates. This reveals that this system is a net source of CO_2.

A recent laser-based CO_2 Carbon Isotope Analyzer (CCIA DLT-100, Los Gatos Research Inc.) allows *in situ* continuous monitoring of CO_2 concentration and carbon isotope composition. We thoroughly assess the performance of this instrument in the view of using it in harsh geological conditions (high water content, large concentration range).

CO_2 degassing can be characterized by flux measurements in closed chambers. In our setting, this requires a preliminary purge with CO_2-free air. Isoflux measurements are performed in small (7 L) horizontal boreholes drilled from the tunnel wall and in an isolated chamber (60 m^3) at the end of the tunnel. We also apply a Keeling plot approach that is well-suited for open systems, such as the entire tunnel ventilated by the atmosphere.

These CCIA measurements confirm that CO_2 is contributed from the rock, and indicate multiple sources (soil respiration, DIC degassing, carbonate precipitation). CO_2 fluxes are highly dynamic in response to meteorological, hydrogeological and mechanical forcing.

The understanding of the natural carbon cycle in the Roselend Natural Laboratory is a preliminary basis for a forthcoming tracing experiment between the isolated chamber of the tunnel and the atmosphere above through 55 m of fractured rocks.

Atomic force microscopy observations of nanostructures and crystal growth in bivalves

C.M. PINA[1], A.G. CHECA[2], C.I. SAINZ-DÍAZ[3] AND J.H.E. CARTWRIGHT[3]

[1]Dept. de Cristalografía y Mineralogía, Universidad Complutense de Madrid, E-28040 Madrid, Spain (cmpina@geo.ucm.es)
[2]Dept. de Estratigrafía y Paleontología, Universidad de Granada, E-18071 Granada, Spain (acheca@ugr.es)
[3]Instituto Andaluz de Ciencias de la Tierra, CSIC-Universidad de Granada, E-18071 Granada, Spain (cisainz@ugr.es, julyan.cartwright@csic.es)

The shells of bivalves are complex nanostructured materials formed by calcium carbonate and organic membranes. Both the variety of hierarchical structures and the selective usage of calcite and aragonite in their shells, reveal the extraordinary ability of bivalves to control crystal growth processes at various length scales. The result of such a multiple scale control is the generation of composite materials with outstanding mechanical properties.

Here we present atomic force microscopy (AFM) observations of calcitic and aragonitic internal structures in shells of a number of bivalves. These structures are constructed by micrometric tablets, whose shape, size and coalescence schemes vary from one species to another. However, in all the species, the surfaces of the tablets are built up by granules and subgranules down to the nanometric scale. These highly hierarchical structures of the tablets provide them with a multiple scale roughness which differs from that commonly observed on inorganic mineral surfaces. To further study the nature of the tablets, we also conducted a series of crystal growth experiments using the inner part of bivalves' shells as a substrate. Crystal growth was promoted by passing supersaturated aqueous solutions with respect to calcite and aragonite over the arrangements of micrometric tablets. The growth on the bivalve's shells was observed in real time by AFM. The analysis of the morphology and orientation of the overgrown crystals provided information about the crystallographic features of the tablets that form the interior of bivalves' shells.

Graphite-bearing norites (Cortegana Igneous Complex, SW Spain): Mantle-derived carbon or crustal contamination?

R. PIÑA[1], E. CRESPO-FEO[1], L. ORTEGA[1], J.F. BARRENECHEA[1,2] AND F.J. LUQUE[1,2]

[1]Faculty of Geology, Univ. Complutense of Madrid, Spain
[2]Institute of Geosciences (UCM-CSIC), Madrid, Spain

The Cortegana Igneous Complex comprises a number of small lens-like intrusive mafic bodies (Tejadillas, Sojalva, El Merendero, La Caballona and Tabarca) located in the southern part of the Aracena Metamorphic Belt (Ossa-Morena Zone of the Iberian Massif). Among these bodies, the Sojalva stock is especially interesting due to the presence of abundant graphite in the igneous rocks (up to 26 wt.% C). Norite is the predominant lithology and consists of plagioclase (An_{80-46}), orthopyroxene (Mg#, 0.53-0.71) and minor biotite, along with cordierite, quartz, hercynite, graphite and Fe-Ni-Cu sulfides, mainly pyrrhotite and minor pentlandite and chalcopyrite. Partially-digested metamorphic xenoliths commonly occur in the igneous rock. The mineral assemblage (qtz+pl+bt+crd+grt+sil+sp) of these metamorphic xenoliths resembles that found in the high-grade gneisses and graphite-rich quartzites from the 'aluminous series' of the Aracena Metamorphic Belt.

Graphite occurs as flakes and aggregates of flakes both in the igneous rock and within the xenoliths. Graphite flakes in the igneous rock may reach up to 200x20 μm and they are usually associated with the sulfides which, in turn, are intersticial with respect to the silicate phases. Locally, small graphite flakes (less than 80 μm) are included within silicates (mostly cordierite, plagioclase and pyroxene).

The study of graphite by XRD reveals that it corresponds to the hexagonal politype and has a high degree of structural order along the stacking direction (c-axis).

The stable carbon isotope ratios of bulk graphite samples are light, with $\delta^{13}C$ values ranging from -19.5 to -23.6 ‰. These values are compatible with biogenic carbon and point to derivation from the assimilation of metasedimentary rocks. This hypothesis is also in agreement with the mineralogical and textural features of the igneous rocks.

The results of this study reveal therefore that mantle-derived rocks may acquire their carbon content also by assimilation during their emplacement rather than from the mantle itself and that petrographic and isotopic studies are crucial to establish the ultimate origin of carbon in these rocks.

$(Ba, Cu)(UO_2)_2(PO_4)_2.nH_2O$ solid solution occurences from an uranyl-phosphate deposit in Portugal

A.J. PINTO[1]*, M. GONÇALVES[1], C. PRAZERES[2] AND M.J. BATISTA[2]

[1]CREMINER, Dep. of Geology, Fac. of Sciences. Univ. of Lisbon, Ed. C6, Campo Grande 1749-016 Portugal (*correspondence: afipinto@fc.ul.pt)
[2]LNEG, Laboratório Nacional de Energia e Geologia, Estrada da Portela, Alfragide, Ap. 7586 2611-901 Amadora

The occurrence of solid solution systems of both anionic and cationic substitution in secondary uranyl phosphate deposits is acknowledged in the scientific literature (e.g. [1] and [2]). Our work focuses on the Ba^{2+}/Cu^{2+} substitution found in uranyl phosphates from Tarabau deposit, Nisa, Portugal, as depicted in the image below.

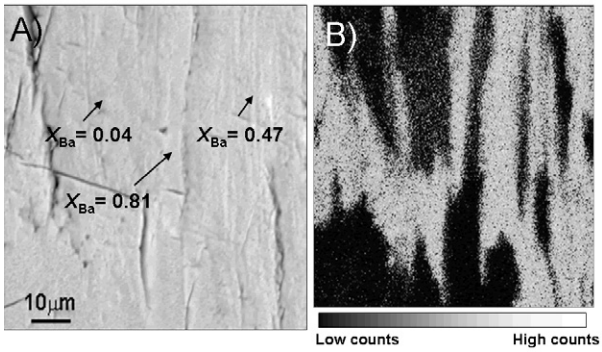

Figure 1: a) Backscattered electron micrograph of a (001) cleavage surface of a Ba-bearing uranyl-phosphate grain. Quantitative point analyses expressed in Ba mole fraction (X_{Ba} = 1-X_{Cu}) are also included, **b)** Electron microprobe X-ray map relative to Ba on the surface shown in a).

A close inspection of the obtained results reveals that the studied materials are not chemically homogeneous, yielding intermediate compositions between pure Cu and Ba-endmember compositions. Moreover, an inverse relationship is found between surface composition in Ba and U, suggesting the occurrence of surface dissolution of a meta-torbernite substrate coupled with co-precipitation of an uranyl defficient (Ba, Cu) solid solution. Powder X-ray diffraction results point towards meta-torbernite-type structures, which implies that such phases are members of the meta-torbernite – meta-uranocircite solid solution system.

Reconstructing Southern and Pacific Ocean deep circulation using Nd isotopes

A.M. PIOTROWSKI*, T.L. NOBLE AND I.N. MCCAVE

Department of Earth Sciences, University of Cambridge, Cambridge, CB2 3EQ, United Kingdom (*correspondence: amp58@cam.ac.uk)

The southwestern Pacific is an important region to reconstruct past ocean circulation since it is the entry point for Southern Ocean waters into the Deep Western Boundary Current of the Pacific. The relationship between deep water neodymium and carbon isotopes in the southwestern Pacific, and their comparison to records from the South Atlantic [1] and Indian Ocean [2], have the potential to provide new information about changes in water mass sourcing and nutrient generation along different deep water flow paths in the Southern Hemisphere [3].

Here we present a new Nd isotope record from ODP Site 1123 on the Chatham Rise (42 S, 172 W, 3.3 km-bsl), and glacial-interglacial Nd isotope changes from Chatham Rise transect of four cores, ranging from 1.4 to 4.8 km-bsl. Nd isotopes were measured by three methods, acid-reductive leaching of bulk detritus, mixed planktonic foraminifera which have authigenic coatings, and those which have been reductively cleaned. The foraminifera with authigenic coatings yeild the expected deep seawater Nd isotopic composition, matching nearby water and Fe-Mn nodules measurements, while bulk detrital leachates do not. Reductively cleaned and uncleaned planktonic foraminifera have Nd isotopic compositions within error of each other, suggesting that the host phase of Nd is difficult to remove.

The Nd isotopic composition of ODP Site 1123 changes on glacial-interglacial timescales, recording a deglacial Nd isotopic shift from -5 ε_{Nd} during the Last Glacial Maximum (LGM) to -7 ε_{Nd} during the Holocene. The 'Pacific-like' Nd isotopic compositions during the LGM suggests reduced Atlantic-sourced water, and is also replicated at the deeper CHAT transect cores. The intermediate depth (1 to 2 km-bsl) cores have a more constant Pacific-like sourcing of waters of -4 ε_{Nd} during the deglaciation. The ODP Site 1123 Nd isotope record appears to track, but is offset from, the South Atlantic [1] and Equatorial Indian Ocean [2] Nd isotope records, suggesting that Atlantic-sector deep water changes are propigated through the Southern Ocean.

Evidence of slab melt transfer in the New Caledonian fore-arc ophiolite

CASSIAN PIRARD[1], JÖRG HERMANN[2] AND HUGH O'NEILL[2]

[1]Department of Petrology, Vrije Universiteit Amsterdam, 1081HV Amsterdam (cassian.pirard@falw.vu.nl)

[2]Research School of Earth Sciences, The Australian National University, 0200 Canberra (joerg.hermann@anu.edu.au, hugh.oneill@anu.edu.au)

The highly depleted harzburgite of the Massif du Sud ophiolite of New Caledonia hosts several late intrusive bodies (hornblendites, granitoids, gabbros) in an area expanding from the crust-mantle transition zone to a couple of kilometers under the palaeo-Moho. The absence of relationship with the basement and lateral variations related to the paleo-depth of the mantle suggest an emplacement in an oceanic environment, several millions years prior to the obductive event. The granitoid intrusions of the Massif du Sud ophiolite are the first known reported case of large amount of felsic magma hosted in a sub-arc mantle.

U-Pb dating of the magmatic bodies provides a similar age than igneous zircon cores occuring in the eclogite terrane in the northern part of the island. This overlap of ages suggests that the magmatic activity witnessed in the felsic intrusions within the ophiolite corresponds to arc volcanic events that produced volcanoclastic sediments representing the protolith of New Caledonia eclogite facies rocks.

Magmatic intrusions are all alkali-rich and cover intermediate to felsic compositions. Mg-numbers range from 0.45 to 0.92 and are positively correlated with sodium and silica contents, ruling out that diorites and trondhjemites are related by differentiation processes. Instead we suggest that the high Mg# trondhjemites represent slab melts that interacted with the mantle wedge.

Pyroxenite reaction zones rimming these intrusions show a direct chemical relationship with pyroxenite dykes occuring deeper in the mantle. These dykes are interpreted as feeder conduits for slab melts which accumulate in large pods at the crust-mantle transition.

A study of amphibole trace element composition in the granitoid intrusions also show a link with amphibole-bearing peridotite and mafic rocks which are located in an area of the ophiolite inferred as a near-trench environment. This lateral variation is interpreted as the result of a thermal gradient in the sub-arc mantle. Slab melt metasomatism affects peridotites at subsolidus conditions in colder part of the fore-arc whereas large pockets of melt accumulate under the oceanic crust in hotter parts of the sub-arc mantle.

U/Pb dating of geodic calcites: A tool for paleohydrological reconstructions

C. PISAPIA[1,2]*, P. DESCHAMPS[1], B. HAMELIN[1], A. BATTANI[2,3], S. BUSCHAERT[2] AND J. DAVID[4]

[1]CEREGE, Univ. Aix-Marseille, France (*correspondence: pisapia@cerege.fr)
[2]ANDRA, Chatenay-Malabry, France
[3]IFP-EN, Paris, France
[4]GEOTOP, Univ. du Québec, Montréal, Canada

This study presents U/Pb dating of secondary geodic calcites carried out to provide chronological constraints on diagenetic processes and past fluid circulations that affected the deep sedimentary formations of the East of the Paris Basin. It is part of projects developed by the French Agency for Nuclear Waste Management (ANDRA) in order to test the feasibility for nuclear waste storage in the Callovo-Oxfordian argillite. This layer is embedded between two carbonated shelf formations, Dogger and Oxfordian in age, characterized by very low porosity due to secondary sparite precipitation. These calcites are thougth to reflect main diagenetic events and phases of fluid circulation within the sedimentary basin since the early Cretaceous period. But the absolute ages of these events are uncertain and still subjet to debate. The aim of this project was thus to date secondary geodic calcites related to these fluid circulations in order to reconstruct the diagenetic and palaeohydrological history of the site.

The U/Pb dating method was optimized to large secondary calcites samples with very low concentrations of lead (from 3 to 26 ppb) and uranium (from 22 ppb to 1ppm). Geodic calcites from Oxfordian and Dogger formations were sampled from drilling cores and were analyzed by TIMS (VG 54 Sector at CEREGE) using a ^{205}Pb-^{236}U-^{233}U-^{229}Th spike.

Results depict clear isochrons and several phases of secondary calcite precipitation were identified. Two ages were obtained on 4 geodes from the Dogger formations at -149.2±5.8Ma and -99.1±1.9Ma. They strongly suggest two phases of sparite precipitation: (1) during early diagenetic processes and (2) during a later recristallization process. On the contrary, 6 geodes from the Oxfordian formations gave a unique age at -33.2±5.5Ma indicating a more recent and unique phase of porosity infilling. This precipitation phase is very likely related to a major fluid circulation event synchronous with the Late Eocene/Oligocene tectonic extension responsible for the formation of major rifts in northern Europe (e.g. Rhine graben). This event affected the whole Oxfordian formations in the eastern part of the basin but did not affect the Dogger formations.

U/Pb dating of geodic calcites thus offers a new powerful way for reconstructing the coupled palaeohydrological and tectonic history of sedimentary basins.

Iron and other metals in the Proterozoic oceans

NOAH PLANAVSKY[1], CLINT SCOTT[1], PETER MCGOLDRICK[2], CHAO LI[1], CHRIS REINHARD[1], ANDREY BEKKER[3], GORDON LOVE[1] AND TIMOTHY LYONS[1]

[3]Department of Geological Sciences, University of Manitoba, Winnipeg, MB, R3T 2N2 Canada

The chemical composition of the ocean changed dramatically with the oxidation of the Earth's surface, and this process has profoundly influenced the evolutionary and ecological history of life. The early Earth was characterized by a reducing ocean-atmosphere system, while the Phanerozoic Eon (<542 million years ago) is known for a stable and oxygenated biosphere conducive to the radiation of animals. The redox characteristics of surface environments during the Earth's middle age (1.8 to 1 billion years ago) are less well known, but over the past decade it has been commonly assumed that the mid-Proterozoic was home to a globally sulfidic (euxinic) deep ocean. Here, we present iron data from a suite of mid-Proterozoic marine shales. Contrary to the popular model, our results indicate that ferruginous (anoxic and Fe^{2+}-rich) conditions were both spatially and temporally extensive across diverse paleogeographic settings in the mid-Proterozoic ocean, inviting new models for the temporal distribution of iron formations and the availability of bioessential trace elements during a critical window for eukaryotic evolution. We suggest that ferruginous shales are not large sinks for bioessential chalcophile elements. In this light, the presence of widespread Fe^{2+}-rich conditions may allow for substantial redox-sensitive trace metal reservoirs in a largely reducing ocean.

Does monsoon rainfall drive arsenic mobilization and organic carbon release in Bangladesh aquifers?

B. PLANER-FRIEDRICH[1]*, C. HÄRTIG[1,4], H. LISSNER[2,4], J. STEINBORN[3,4], E. SÜSS[1,4], M.Q. HASSAN[5], A. ZAHID[5,6], M. ALAM[5] AND B. MERKEL[4]

[4]TU Bergakademie Freiberg, Freiberg, Germany
[5]University of Dhaka, Department of Geology, Bangladesh
[6]Bangladesh Water Development Board, Dhaka, Bangladesh

Organic carbon (DOC) is believed to be the main driver for arsenic (As) release during reductive dissolution of iron hydroxides from sediments in the Bengal Delta. However, the source of the organic carbon remains controversial. Recharge from man-made ponds has recently been claimed as the main source and installation of 'As-safe' wells away from ponds beneath rice fields has been suggested. Our study questions the validity of this approach throughout Bangladesh. Based on a one-year weekly sampling of wells at different depths in the Titas district, 60 km SE' of Dhaka, we propose a model of natural organic carbon and As mobilization from clay and peat layers following monsoonal changes in specific storativity. During the dry season a natural decline in hydraulic heads boosted by intensive pumping for irrigation causes release of porewaters with high DOC concentrations from clay and peat layers. Flushing, diffusion, and water re-storage decrease initially released DOC concentrations in the rainy season. Maximum As concentrations and an increase in the share of arsenite follow DOC peak concentrations with a time lag which we interpret as delayed response in microbially catalyzed arsenate reduction and release of arsenite previously sorbed to sediment. Over time, aqueous As concentrations will decrease in most parts of the Holocene unconfined aquifer as organic matter is consumed. Based on our model, organic carbon and As from clay and peat layers will continue to pose a problem for underlying aquifers as they are seasonally released by changes in specific storativity. Though sorption capacities are higher in the Pleistocene sediments, long-term continuous As input from overlying clay and peat layers as in our study area eventually also leads to increased aqueous As concentrations. Before exploiting deeper aquifers the overlying clay and peat layers should thus be studied for their history of fresh-water flushing, their current pore water biogeochemistry and hydraulic properties.

Why do mafic arc magmas contain 4 wt% water on average?

TERRY PLANK[1]*, KATHERINE A. KELLEY[2], MINDY ZIMMER[3], ERIK HAURI[4] AND PAUL WALLACE[5]

[1]LDEO, Palisades, NY 10960, USA (*correspondence: tplank@ldeo.columbia.edu)
[2]URI/GSO, Narragansett, RI 02882, USA
[3]Los Alamos National Lab, Los Alamos, NM 87544, USA
[4]DTM/CIW, Washington, DC 20015, USA
[5]Univ. of Oregon, Eugene, OR 97403, USA

Over the last fifteen years there has been an explosion in data on the volatile contents of magmas parental to arc volcanoes. This has occurred due to the intense study of melt inclusions, trapped primarily within olivine, as aliquots of magma that have escaped degassing during eruption. The surprising first-order result is the narrow range in H_2O concentrations of the least degassed melt inclusions when averaged by volcano (based on 7 arcs for which such data exist for > 5 volcanoes: Central America, Mexico, Kamchatka, Marianas, Cascades, Tonga and the Aleutians). Nearly all arc volcanoes are sourced with mafic magmas that contain 2-6 wt% H_2O. Moreover, the average for each arc varies even less, from 3.2 (for the Cascades) to 4.5 (for the Marianas), with an average for all seven arcs of 3.8 ± 0.5 wt% H_2O. The narrow range and common average value for H_2O is in stark contrast to that for most other subduction tracers, such as Nb or Ba, which vary by orders of magnitude.

A modulating process, either in the crust or mantle, is likely responsible for the restricted range in the H_2O contents of melt inclusions. One possibility is that melt inclusions reflects vapor saturation at the last storage depth prior to eruption. Magmas rise from the mantle with variable H_2O contents (> 4 wt%), start degassing at the depth of H_2O-saturation, and continue to degas up until the depth at which they stall. If the stalling depths were ~6 km, not atypical for storage depths beneath volcanoes, magmas would be saturated at ~4 wt% H_2O, and melt inclusions, which become sealed during ascent, would thus record ≤ 4 wt% H_2O. Another possibility is that the melting process modulates water content in the melt such that magmas rise out of the mantle with ~4 wt% H_2O. A strong relationship between the water content of the source (H_2O_o) and the degree of melting (F) maintains nearly constant water contents in the melt for a restricted range in mantle temperature. Magmas with 3-4 wt% H_2O can be generated at 1230-1280°C and 1.5 GPa for a wide range in F and H_2O_o. Crust and mantle controls may dominate in different regions and may be distinguished from coupled trace element or CO_2 variations.

[3]Stanford Synchotron Radiation Lightsource, Menlo Park, CA 94025, USA

Uranium is a toxic radionuclide and its contamination of soil and groundwater is a worldwide problem. The oxidized form of U, hexavalent uranium (U (VI)), is the most soluble and mobile form of uranium and therefore, an understanding of its behavior in contaminated environments is of utmost importance. It is known that U (VI) can be biologically reduced to less soluble U (IV) species such as the mineral uraninite (UO_2) or monomeric U (IV) and the stimulation of biological activity to this end is a salient remediation strategy; however, it is as yet unknown if these materials remain stable in their subsurface formation environments. Manganese oxides, also formed biogenically in the subsurface, are capable of rapidly oxidizing U (IV) to U (VI) [1].

Here, we evaluate the effect of Mn redox cycling on the mobility and stability of U in contaminated subsurface environments on various scales. Batch experiments were conducted in which agarose gels, containing Mn-oxidizing spores and biogenic UO_2, were exposed to Mn (II). After optimization of experimental variables using these batch reactors, the redox reactions were analyzed in sediment from a U-contaminated site in Rifle, Colorado USA. Results to date indicate biogenic UO_2 oxidation to U (VI) by nano-scale bio Mn oxides. The U (VI) product is retained within the agarose gel or the sediment matrix suggesting the formation of U (VI) precipitates or strong surface complexes. Various methods, including inductively coupled plasma mass spectroscopy (ICPMS), transmission electron microscopy (TEM) and X-ray absorption spectroscopy (XAS), are used to pinpoint the speciation and spatial distribution of U (VI) relative to Mn. The feasibility of bioreduction as a strategy to immobilize uranium in the contaminated subsurface is contingent on the long-term stability of immobilized U. Hence it is critical that the role of Mn–present at sufficiently high concentrations at Rifle–in this stability be assessed. This study furthers our knowledge of the coupled U/Mn system and therefore is expected to inform future remediation efforts.

Thermal state of subducting plate beneath Kamchatka inferred from H_2O/Ce in melt inclusions

A.A. PLECHOVA[1]* AND M.V. PORTNYAGIN[1,2]

[1]V.I. Vernadsky Institute of Geochemistry and Analytical Chemistry, ul. Kosygina 19, Moscow 119991, Russia (*correspondence: aplech@geokhi.ru)
[2]IFM-GEOMAR, Kiel, Germany

We measured water and trace element contents in a new large set of naturally quenched and reheated melt inclusions in olivine from volcanoes along the Eastern Volcanic Front of Kamchatka (Zhupanosky, Karymsky, Vysokiy, Zavaritsky, Zheltovsky, Ksudach and others), which are located 100-190 km above the subducting plate. H_2O/Ce ratios in the least degassed inclusions correlate inversely with the distance from volcano to slab surface (fig. 1b) and suggest a systematic a change in the composition of slab component with increasing slab depth [1]. This data is used to estimate the temperature of equilibrium of water-bearing components with subducting sediments at the slab top [2].

The data indicate sharp temperature increase (740-800º) at relatively shallow depths (100-110 km) and less efficient slab heating at greater depths (800-950 ºC, 110-190 km). These results are in qualitative agreement with modern numeric SZ models (e.g. [3]) though our petrologic data predict ~50ºC hotter slab for 110-190 km depths beneath Kamchatka.

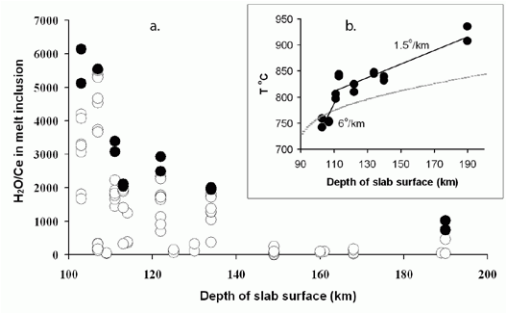

Figure 1: (a) H_2O/Ce ratios in melt inclusions from Kamchatkan volcanoes and (b) calculated temperature of slab fluids [2] versus slab depth beneath volcanoes. Filled circles denote the least degassed inclusions. Gray line in (b) shows a model depth-temperature path of the Pacific plate surface beneath Kamchatka [3].

Geochemical characterization of the hydrocarbons in Domanik Rocks, Tatarstan Republic

IRINA N. PLOTNIKOVA, FIDANIA F. NOSOVA, AND NIKITA V. PRONIN

Kazan Federal University (irena-2005@rambler.ru)

On the basis of combined geological-geochemical analysis of the conditions of hydrocarbon generation and formation of basins, the total petroleum-generating potencial of domanic formation (DF) is estimated at 126 billion tons of liquid hydrocarbons. High-bituminous argillo-siliceous carbonate deposits of DF occurring within pale depressions and down warps in the east of the Russian platform are treated by many investigators as a main source of oil and gas in the Volga-Ural province.

In this study a special attention was turned to organic-rich rocks DF witch outcrop in the central part (Uratminskaya area 792, 806 boreholes) and in the west part (Sviyagskaya, 423) of the Tatarstan Republic.

The aim of the present paper is to characterize the organic matter: origin, depositional environments, thermal maturity and biodegradation-weathering effects.

Nowadays the most informative geochemical parameters are some biomarkers which qualitatively and are quantitatively defined from distributions of n-alkanes and branched alkanes.

Methodology used in this study included sampling, bitumen extraction, liquid-column chromatography and gas chromatography/mass spectrometry analyses. The bitumen was fractionated by column chromatography on silica gel. Non-aromatic or alifatics, aromatics and polar compounds were obtained.

Alifatic were analysed by gas chromatography/mass spectrometry Perkin Elmer. The hydrocarbons present in the sediments of DF and have a carbon numbers ranging from 12 through 38. The samples contain variably inputs from both terrigenous and non-terrigenous (probably marine algal) organic matter as evident in bimodal GC fingerprints of some samples. Pristane and phytane, also, occur in very high concentration in sample extracts. The relatively low Pr/Ph ratios, CPI and OEP<1 imply that the domanik organic matter was deposited in reducing environments.

Mass chromatograms show the distribution of regular steranes, iso-steranes, lower molecular weight C_{21} and C_{22} steranes (pregnanes) (m/z 217) and triterpanes (m/z 191). The biomarkers distribution of the domanic samples generally suggests a major marine phytoplankton contribution relative to terrigenous land plant source input. The marine affinity is evident from the relatively abundant C_{27} steranes, which are biomarkers for marine algal contribution to organic matter and low C_{29} sterane contens.

In this present study, samples are dominated by 5α, 14α, 17α (H)-20R and 5β, 14α, 17α (H)-20R steranes (biological configuration). The ratios of 20S/(20S+20R) for αααC_{29}

The legacy of plastic deformation and pre-existing microstructures during olivine serpentinization

O. PLÜMPER[1], H. AUSTRHEIM[1], S. PIAZOLO[2] AND H. JUNG[3]

[1]Physics of Geological Processes (PGP), University of Oslo, Oslo 0316, Norway (*correspondence: oliver.pluemper@fys.uio.no)

[2]Department of Earth and Planetary Sciences, Macquarie University, NSW 2109, Australia

[3]School of Earth and Environmental Science, Seoul National University, Seoul 151-747, Republic of Korea

High-temperature crystal-plastic deformation of olivine is an inevitable consequence of asthenospheric mantle flow. In this environment olivine commonly yields by dislocation creep to form dislocation walls. Solid-state diffusion along these imperfections is faster than through the bulk crystal. At low temperatures, olivine serpentinization modifies the petrophysical and geochemical properties of the oceanic lithosphere. Under these conditions olivine generally fails to compositionally readjust via diffusion and re-equilibrates via dissolution-reprecipitation. Although plastic deformation and serpentinization are decoupled, we identified compositional readjustments expressed as striped zonings in partially serpentinized and deformed olivine grains from the Leka Ophiolite Complex (LOC), Norway. Combining focused ion beam sample preparation and (scanning) transmission electron microscopy reveals that every zone is immediately related to a subgrain boundary composed of edge dislocations. The zonings are a result of the Fe-Mg exchange potential between olivine and antigorite, where Fe enrichment or depletion is controlled by the silica activity imposed on the system by orthopyroxene and magnetite stability. Nanometer-sized serpentine precipitates along olivine dislocation walls and crystallographic relationships gained by electron backscatter diffraction (EBSD) suggest that hydration was also initiated along these intracrystalline imperfections. The legacy of pre-existing microstructures in the LOC is exhibited by localized occurances of parallel but highly misorientated olivine grains seperated by plastically deformed diopside lamellae. Microtomography combined with EBSD suggest that these areas are a consequence of a hydration-dehydration sequence to result in a complex pseudomorphism of primary mantle orthopyroxene to olivine and the cryptic survival of the primary microstructure.

Our observations provide new insights into the role of primary microstructures and crystal-plastic deformation on subsequent fluid-mediated reactions.

The evolution of a serpentinizing environment inferred from andradite vein networks

O. PLÜMPER[1], A. BEINLICH[1,2], E. JANOTS[3] AND H. AUSTRHEIM[1,2]

[1]Physics of Geological Processes (PGP), University of Oslo, Oslo 0316, Norway (*correspondence: oliver.pluemper@fys.uio.no)
[2]Department of Geosciences, University of Oslo, Norway
[3]ISTerre, F-38000 Grenoble

Serpentinization of the oceanic lithosphere produces a unique geochemical environment. Vein networks from the Feragen Ultramafic Body (Norway) provide new insight into the evolution of a serpentinizing system and the critical role of ortho- and clinopyroxene. The veins are composed of polyhedral serpentine spheres, botryoidal andradite spheres, ferroan brucite, and awaruite. By combining X-ray fluorescence mapping and reactive transport modeling we illustrate how Ca from the dissolving clinopyroxene serves as a proxy for the determination of the system's geochemical evolution. Crystal morphology analysis allows us to infer that stagnant fluid domains were present during vein formation. Microtomography reveals that isolated andradite spheres float in a serpentine matrix within the vein. Calculated particle settling velocity in the vein indicates that rapid crystallization or a gel-type framework prevented the andradite spheres from descending to the vein walls. We infer that the required geochemical conditions, in terms of silica activity and redox conditions were short-lived and vein minerals precipitated rapidly once critical supersaturation was reached. Our observations have implication for the lifetime of the distinct geochemical conditions within a serpentinizing environment.

Se isotope evidence for atmospheric oxidation at ~0.6 Ga

P.A.E. POGGE VON STRANDMANN[1]*, T. ELLIOTT[1], D. CATLING[2] AND S.W. POULTON[3]

[1]BIG, School of Earth Sciences, Bristol University, Bristol, UK (*correspondence: P.PoggevonStrandmann@bristol.ac.uk)
[2]Department of Earth and Space Sciences, Univeristy of Washington, Seattle, USA
[3]School of Civil Engineering and Geosciences, Newcastle University, Newcastle, UK

It is generally thought that atmospheric O_2 levels rose irreversibly twice during Earth history, with the 2nd rise at ~0.8-0.6 Ga [1]. However, the magnitude of the O_2 increase is unclear (estimates range between ~10–100% of the present level), and the specific causes and consequences are uncertain. Knowledge of redox change is fundamental for our understanding of biological evolution and climate systems, because redox constrains the development of a modern biogeochemical cycle. Here we explore the 2nd O_2 rise, using the novel tracer of selenium (Se) isotopes.

Se is a micronutrient. It is strongly redox-dependent and chemically similar to sulphur (S). However, its redox reactions occur at different Eh-pH from S, and therefore Se can provide additional constraints on global redox transitions [2]. Se isotopes are significantly fractionated by microbial reduction, and the degree of fractionation likely depends on atmospheric O_2 in a way similar to S isotopes. This is because when little O_2 is present, microbes will utilise all isotopes, whereas as O_2 increases, more fractionation will occur.

We have analysed Se isotopes in black shales spanning the time of the 2nd O_2 rise, from the Yangtze Platform and the Mackenzie Mountains. Se concentrations in the shales range from the lowest levels so far recorded in shales [3], and show an increase of ~2 orders of magnitude (from 0.02-0.1 to ~10 µg/g), with the highest concentrations in the most recent shales. An overall increase in oceanic Se is consistent with greater supply via oxidative weathering and less hydrothermal scavenging into seafloor selenides once the deep ocean becomes fully oxic. Se isotope ratios in the same samples ($\delta^{82/76}$Se) show a negative excursion of >6‰ across the same period, with a correlated trend of Se and δ^{82}Se. These characteristics suggest that the O_2 content of the atmosphere rapidly increased, providing more selenate and nutrients to the oceans via chemical weathering, allowing microbial reduction to fractionate Se isotopes to a greater degree.

Rare earth elements: Indicators of redox conditions and surface water-groundwater mixing in an estuarine wetland

S.C. POH[1,2,3]* AND M.GASPARON[1,2]

[1]School of Earth Sciences, The University of Queensland, Brisbane, Queensland, Australia (*correspondence: s.poh@uq.edu.au)
[2]National Centre for Groundwater Research and Training, Australia
[3]Department of Chemical Sciences, University Malaysia Terengganu, Kuala Terengganu, Malaysia.

This study was conducted on the Tinchi Tamba Wetlands (TTW) of Moreton Bay, southeast Queensland, as part of a project aimed at characterizing the wetlands' water fluxes. The TTW aquifer is a bowl-shaped aquifer of a semi-confined type, sitting on top of an impermeable clayey layer, with a maximum depth no greater than 20m. The aquifer material comprises high percentage of clay and some medium to coarse sand and gravel. In most cases, coarse grains usually occur as lenses and interbeds. Groundwater flow paths and the extent of mixing of surface and groundwater in the wetlands are difficult to quantify because of the complexity of the geological substrate. In this study we combined field hydrogeological and geochemical data to trace the spatial and temporal evolution of rare earth elements (REEs) distribution in TTW and the adjacent watershed.

Groundwater, ponds, and estuarine waters were sampled monthly over a ten-month period, with additional samples collected during a major storm event that caused significant flooding. Results indicate that a) meteoric water infiltration and evaporation heavily influence the aquifer's geochemistry (electrical conductivity ranging from 3 to 48 ms/cm), b) different sources contribute to the surface water budget, c) REE patterns respond rapidly to changes in redox conditions in the aquifer (redox ranging from -80 to 450mV), d) in areas dominated by low-permeability units, REE patterns are fractionated and exhibited Ce, Pr, Nd, Sm, and Eu depletions, e) the spatio-temporal pattern of REEs indicates mixing of different water sources. In conclusion, the results show that REEs can be used to accurately characterize the surface water and groundwater sources from different reservoirs, as well as the extent of mixing between recharged surface water and groundwater in an estuarine environment.

2-D thermodynamic and trace element models of subduction zones

MICHAEL PÖHLE[1], MATTHIAS KONRAD-SCHMOLKE[1] AND SANDRO JAHN[2]

[1]Institut für Erd- und Umweltwissenschaften, Universität Potsdam, Karl-Liebknecht-Straße 24-25, 14476 Potsdam, Germany
[2]GeoForschungsZentrum Potsdam, Telegrafenberg, 14473 Potsdam, Germany

Fluids derived from dehydration reactions in subducting slabs display major carriers of trace elements tranferred into the mantle wedge. During ascent the fluids interact with the wall rock within the subducted plate, thus it is necessary to quantify element distribution during this fluid-rock interaction in order to get information about the amount and composition of fluids entering the mantle wedge. Complexities in modeling trace element compositions of subduction zone fluids arise from the fact that migrating fluids interact with rocks of different major and trace element compositions undergoing continuous metamorpic transformation within a complex pressure-temperature framework. Based on modeled isotherm patterns of different subduction zone settings we calculate phase relations in the entire subducted slab, considering upward migration of liberated fluids during subduction utilising incremental Gibbs energy minimisation models. The modeled phase relations and fluid amounts are then used to calculate mass balanced trace element distribution among the stable phases at every increment within the slab. Trace element transport occurs within the migrating fluid that equilibrates with the wall rock during ascent, which controls trace element depletion and/or enrichment of fluid and wall rock. With these models we can constrain the absolute amount and the resulting trace element composition of the fluid at the slab surface after fluid-rock interaction within the subducted plate. Preliminary results show that the fluid flux on top of the slab is strongly dicontinuous and shows distinct maxima between 35 and 60 as well as 70 and 80 km slab depth, depending on slab temperature. Potentially fluid-mobile trace elements, such as Li, Be and B show a significant intra-slab fluid rock interaction. Trace element concentration trends of these elements are similar to those observed in arc volcanics, such that Li, Be and B are continuously depleted during subduction and B/Be is significantly decreasing with increasing slab depth. However, in our models the transfer of fluid mobile elements into the mantle wedge already occurs at fore-arc depths, which indicates that mantle dynamics play an important role for element transfer to the sites of melt production beneath the volcanic arc.

Osmium isotopes in manganese nodules from the Labrador Sea

A. POIRIER[1], C. HILLAIRE-MARCEL[1], S. MEREDYK[2] AND E. EDINGER[2]

[1]GEOTOP-UQAM, CP. 8888, Succ. Centre-ville, Montréal, H3C 3P8, Canada (poirier.andre@uqam.ca, chm@uqam.ca)

[2]Memorial University, St. John's, NL, A1B 3X9, Canada (smeredyk@mun.ca , eedinger@mun.ca)

Using a remotely operated vehicle, manganese nodules were retrieved in 2010, at the base (2870 m depth) of a small bedrock-cored mound, south-east of Orphan Knoll (southern Labrador Sea), in a field of rounded polymetallic balls found at the base of a small cliff of weakly consolidated calcareous ooze.

Using a Thermo Triton™ (NTIMS), we measured the osmium $^{187}Os/^{188}Os$ isotopic ratio in the outer <1mm-thick layer of three nodules. These outer layers were expected to yield the Os isotopic composition of modern seawater (ca. 1.06), in relation with recent co-precipitation of hydrogenous osmium and Fe/Mn oxyhydroxides.

We obtained Os-isotopic values (<0.92) much lower than expected, both for the bulk analysis of the Fe/Mn material, and for mild cold HBr-leachates. We are currently investigating possible reasons for such low values, notably a lower than average growth rate (less than few mm/Ma), or a recent gap in precipitation, or some on-site contamination by the calcareous ooze found within the nodules field area. These contain nanofossils of Eocene age and yielded a low Os-composition (0.59) reflecting typical marine-Os values of this interval.

Isotope composition of iron delivered to the oceans by intertropical rivers: The Amazon River case

F. POITRASSON[1,2]*, L.C. VIEIRA[1], P. SEYLER[2], G.M. DOS SANTOS PINHEIRO[1,2], D. MULHOLLAND[1,2], B.A. FERREIRA LIMA[1], M.P. BONNET[1,2], J.M. MARTINEZ[1,2] AND J. PRUNIER[2]

Riverborne iron is a notable source for this biogeochemically key element to the oceans. A proper understanding of the Fe cycle at the surface of the Earth require a good characterization of the isotopic composition of the various reservoirs of this element.

However, as the database growths, it appears that the isotope composition of the riverborne Fe delivered to the oceans may be more varied than initially thought, in agreement with inferences from soil studies from different climatic contexts. It is therefore important to compare major rivers from different latitudes. We focused our attention on the Amazon River and its tributaries that represent ca. 20% of the freshwater delivered to the oceans by world rivers.

Preliminary experiment suggests that water filtration may induce biases in stable Fe isotope composition. Therefore, we worked first on bulk waters, sampled through multidisciplinary field campaigns on the Amazon River and its tributaries, including the Solimoes, Negro, Madeira and Tapajos Rivers. Besides a complete sample physical-chemical characterization, Fe isotope determinations were conduced after water sample mineralization, iron purification and MC-ICP-MS analysis.

Our first results reveal that most bulk water samples cluster close to the continental crust value (0.1‰ $\delta^{57}Fe_{IRMM-14}$) with an overall range of 0.2‰. This is consistent with the restricted range found in lateritic soils elsewhere that represent 80% of the Amazon basin surface. This result holds whatever the relative proportion of dissolved Fe in the bulk waters budget, that ranges from 5 to 50% in these waters, whatever the sample depth and whenever the samples were taken in the river cycle. Hence, the bulk waters from the Amazon River delivered to the ocean have an isotopic composition that is close to that of the continental crust.

A new view on sulfur speciation in geological fluids at elevated temperatures and pressures

G.S. POKROVSKI[1]*, L.S. DUBROVINSKY[2] AND J. DUBESSY[3]

[1]GET, Géosciences Environnement Toulouse, 31400, Toulouse, France (*correspondence: gleb.pokrovski@get.obs-mip.fr)
[2]Bayerisches Geoinstitut, Bayreuth, Germany (leonid.dubrovinsky@uni-bayreuth.de)
[3]G2R, Géologie et Gestion des Ressources Minérales et Energétiques, Vandoeuvre-lès-Nancy, 54506, France (jean.dubessy@g2r.uhp-nancy.fr)

The amount and chemical speciation of sulfur in geological fluids are controlling factors in the formation of magmatic-hydrothermal deposits of many economically critical metals [1]. The two major forms of sulfur in crustal fluids over a wide range of temperature and pressure are believed to be sulfate (HSO_4^- and SO_4^{2-}) and sulfide (H_2S, HS^- and S^{2-}). They are regarded as the key agents controlling the transport and precipitation of metals by deep and hot fluids. However, this belief is based almost exclusively on observations of sulfate and sulfide in minerals, silicate glasses, and fluid inclusions brought to the Earth's surface and/or extrapolations of thermodynamic data for most aqueous sulfur species obtained at near-ambient conditions. It thus suffers from the lack of *in situ* approaches for analyzing sulfur in geological fluids and melts at elevated temperatures and pressures.

In this keynote contribution, we present *in situ* measurements using Raman spectroscopy [2] in model sulfur and thiosulfate aqueous solutions and vapors across a wide range of acidity (pH~2–8), sulfur concentration (0.3–6 wt%), temperature (150–500°C), and pressure (5–50000 bars). Results show that sulfur in the low-density vapor phase is represented by $H_2S \pm SO_2$. In contrast, the dominant stable sulfur species is the dense liquid and supercritical fluid phase is the trisulfur ion S_3^- that forms rapidly and reversibly at the expense of sulfide and sulfate above ~250°C in a wide pressure and acidity range. The large stability of S_3^- may favor the mobility of sulfur and chalcophile metals such as Au, Cu and Pt in hydrothermal fluids over a range of depth, and thus provide the source of these elements for the important types of gold deposits in Achaean greenstone belts and porphyry-epithermal systems.

While the major macroscopic parameters of metals interactions with inorganic constituents of continental aquatic systems are well known, the role of biota remains poorly understood. Here we studied the interaction of one of the most phyto-toxic metals, copper, with different phototrophic microorganisms as a function of exposure time via physico-chemical characterization of metal adsorption on and incorporation into cells under controlled laboratory conditions. For this purpose, we have combined two different approaches, the 'macroscopic' stable-isotope techniques with the 'microscopic' molecular-level observations using XAS spectroscopy of the complexes formed.

Results show that drastic changes in local chemical environment of copper occur upon its adsorption onto or incorporation in the cells, similarly to Zn and Cd [1-3]. To investigate the local atomic environment of Cu in peryphytic biofilms, freeze-dried samples with 1 to 5000 ppm Cu were examined by XAS at ID26 beamline (ESRF). The high-resolution mode, for the first time used for copper in biological matrices, allowed establishing specific features of the Cu pre-edge and quantifying the oxidation state and nature and number of neighbours around Cu. Low-concentrated samples (1-20 ppm), demonstrate the presence of sulfur in the nearest atomic shell of Cu, whereas in concentrated samples, carboxylic complexes of Cu predominate. These findings help establish the interaction mechanism of autotrophic photosynthetic microorganims with copper at trace and toxic level. The results of this integrated study can be useful for tracing the environmental effects of metal-biota interactions, and may provide new insights on the mechanisms of Cu stable isotope fractionation in biological systems.

Influence of conditions past and present on bacterial mineral precipitation

T.K. POLACSEK *, C.S. COCKELL AND T.L. GLADDING

The Open University, Walton Hall, Milton Keynes, Buckinghamshire, MK7 6AA, United Kingdom (*correspondence: t.k.polacsek@open.ac.uk) (c.s.cockell@open.ac.uk, t.l.gladding@open.ac.uk)

Bacterial mineral precipitation is thought to be a complex process, being influenced by biological, chemical and geological factors throughout time [1, 2]. This study focused on calcium mineral precipitation in the Cretaceous (~120Ma ago) and the present day, using marine bacteria. We investigated parameters such as (i) the Magnesium: Calcium ratio of seawater [3] and (ii) the atmospheric partial pressure of carbon dioxide [4], both of which showed great variations over time. We further investigated (iii) possible inhibitors of precipitation, (iv) availability of nutrients and (v) the necessity of metabolic active cells.

Electron-microscopy (EM) techniques, powder X-Ray diffraction and elemental spectra were used to screen the cultures for precipitates and to analyse polymorph mineralogy. For some bacterial strains, calcium mineral spheres were observed in the Cretaceous-like medium only, with a nutrient concentration of > 0.25% yeast promoting their formation. EM analysis not only revealed micropores and bacterial matter on the surface of the spheres but also demonstrated such pores in the interior of the spheres, containing cells being entombed in precipitate. For the first time these data elucidate the interplay of different parameters and their influence on the formation of bacterially induced calcium minerals in the Cretaceous.

The Jurassic (Lias) black shale-hosted Mn-carbonate ore deposit was studied by XRD mineralogy (260) and rock microscopy (80) to determine mineral components and microstructure to better understand the sequence of microbial communities that existed during ore accumulation. Formation of the main Mn ore bed in the Úrkút deposit occurred via a two-cycle bacterial sequence: (1) an aerobic, chemolithoautotrophic microbial cycle, followed by (2) an anaerobic bacterial cycle. During cycle 1, microbial Mn (II) enzymatic oxidation resulted in the fine-grained accumulation of biooxides (with reactive organic matter), which later transformed during diagenesis into Ca-rhodochrosite via bacterially mediated processes during early suboxic diagenesis [1, 2]. These redox conditions supported celadonite formation from the mixing of warm geofluids with seawater. This clay formation occurred at the sediment/seawater interface or near it during synsedimentation or very early diagenesis under neutrophylic pH. The near seabed environment was continuously dysoxic-suboxic and was colonized by Fe (II) oxidizing microbes. Those microbs were interlaced with the host sediment and probably initially concentrated ferrihydrite, which was later transformed to goethite. Conditions became more reducing with a higher rock/water ratio during burial. This resulted in smectite formation and pyritization of goethite in the zone of bacterially mediated sulphate reduction.

The study was supported by Hungarian Science Foundation (OTKA-NKTH No. K 68992).

In situ O & Si isotopic microanalysis of diagenetic cements: Basin brines vs. weathering, low vs. high T

ANTHONY D. POLLINGTON*, REINHARD KOZDON, KOUKI KITAJIMA, ARIEL STRICKLAND AND J.W. VALLEY

WiscSIMS, Dept. Geoscience, Univ. Wisconsin, Madison, WI 53706, USA
(*correspondence: apolling@geology.wisc.edu)

Secondary minerals, such as diagenetic overgrowths, are potential recorders of processes in surface and shallow sub-surface environments. Quartz overgrowths incorporate chemical and isotopic signatures of the fluids from which they grow; the composition of these fluids in turn being influenced by factors such as chemical weathering of the source region and interactions with rocks along a flow path.

In situ microanalyses of $\delta^{18}O$ in isotopically-zoned quartz overgrowths from the Cambrian Mt. Simon Sandstone in central North America reveal growth from a compositionally ($\delta^{18}O$) constant fluid during an evolving temperature history of burial and heating [1]. The temperatures calculated from $\delta^{18}O$ values indicate that drill core samples from the Illinois Basin grew in response to burial/heating and are consistent with geotherm temperature-depth estimates (50 to 110°C). However, overgrowths from most outcrop samples on the Wisconsin Dome, which have never been deeply buried, indicate growth at low temperatures (~35°C).

We have also measured Si isotope ratios and trace element concentrations in the same overgrowths. The $\delta^{30}Si$ values for most samples indicate growth from a source dominated by primary igneous Si (such as detrital sand grains). However, samples from one outcrop, ~5m above the Precambrian unconformity, have $\delta^{30}Si$ values that are among the lowest terrestrial values reported (-5.44‰ to -0.40‰) as well as unusually low $\delta^{18}O$ values suggesting hydrothermal precipitation. Chemical weathering has been proposed as a mechanism to explain low $\delta^{30}Si$ values in overgrowths [2].

Trace element concentrations are relatively low in detrital quartz, and overgrowths from the basin samples. In quartz overgrowths from outcrop samples though, concentrations of some elements (in particular Li and Al) are at least 1-2 orders of magnitude higher than the detrital material. Trace element concentrations, $\delta^{18}O$ and $\delta^{30}Si$ values are distinctly different for outcrop samples versus basin samples. This possibly reflects interaction of fluids with a weathered protolith, such as the nearby paleosol that underlies the formation on the Cambrian-Precambrian unconformity.

Reaction paths and volume changes of solid solutions in coupled dissolution-precipitation reactions: The role of endmember solubility

K. POLLOK[1]*, C.V. PUTNIS[2] AND A. PUTNIS[2]

[1]Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany
(*correspondence: kilian.pollok@uni-bayreuth.de)
[2]Institut für Mineralogie, Universität Münster, Corrensstr. 24, D-48149 Münster, Germany

Mineral-fluid reactions towards equilibration involve readjustment of the phase assemblage and its composition. Such reequilibration is commonly accomplished by dissolution and precipitation reactions at Earth's surface and at crustal conditions when fluid flow is pervasive. As most rock-forming mineral systems are, to various extents, solid solutions, they respond to the fluid chemistry by readjusting their composition. This can be often observed as a pseudomorphic replacement. In this context, the concept of solubility becomes complicated once solid solution-aqueous solution (SS-AS) relationships are taken into account [1].

Based on the internally consistent description of solubility and SS-AS equilibrium states in the model KBr-KCl-H_2O system [2] a quantitative treatment of various reaction paths and their associated volume changes is presented. It allows to derive various scenarios for dissolution-precipitation reactions based on solid-fluid ratio, local equilibrium or limited transport at the reacting interface which in turn can provide qualitative predictions on the kinetics of the replacement reaction.

In many cases, volume changes are preserved in replaced minerals as intracrystalline porosity which can facilitate transport from and to the reaction front [3]. Data on the solubility of solid solutions in complex aqueous fluids at higher temperature and pressure is still limited. However, the determined porosity in partly replaced minerals (either natural or experimental) can be used to roughly estimate the solubility difference of the parent and product phases. This concept as well as its limitations will be demonstrated for various rock-forming minerals and is intended to facilitate more experimental work to ascertain the role of porosity generation in interface-coupled dissolution-precipitation reactions.

Adsorption and oxidative transformation of aromatic acids by Fe(III)-montmorillonite

T. POLUBESOVA*, S. ELDAD AND B. CHEFETZ

Department of Soil and Water Sciences, the Robert H. Smith Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, P. O. Box 12, Rehovot 76100, Israel
(*correspondence: polubeso@agri.huji.ac.il)

Aromatic acids are involved in important soil processes, such as mobilization of microelements by plants and formation of humic components. The interactions of aromatic acids (ferulic, p-coumaric, syringic, vanillic and benzoic) with montmorillonite enriched with Fe (III) was investigated. Adsorption of the phenolic acids on Fe (III)-montmorillonite was accompanied by their oxidative transformation and formation of Fe (II). Oxidative transformation of phenolic acids was affected by their molecular structure. The order of maximal transformation at the initial acid concentration of 20 mg/L on the surface of Fe (III)-montmorillonite was: ferulic (94%), syringic (60%), p-coumaric (35%) and vanillic (25%). Benzoic acid which was used as a reference aromatic compound exhibited only 5% transformation [1]. Adsorption of benzoic acid by Fe (III)-montmorillonite increased in the presence of 5 mM $CaCl_2$. Desorption of benzoic acid from Fe (III)-Ca^{2+}-montmorillonite was greater than that from Fe (III)-montmorillonite [2]. Removal of aromatic acids from solution by Fe (III)-montmorillnite increased with decreasing pH. LC-MS analysis demonstrated the presence of dimers, trimers, and tetramers of ferulic acid on the surface of Fe (III)-montmorillonite [1]. Oxidation and transformation of ferulic acid were more intense on the surface of Fe (III)-montmorillonite as compared to Fe (III) in solution due to stronger complexation on the clay surface: 90% of the ferulic acid was transformed following by interaction with Fe (III)-montmorillonite at an initial concentration of 0.1 mM, whereas only 20% was transformed in $FeCl_3$ solution. The concentrations of Fe (II) formed in Fe (III)-montmorillonite-ferulic acid suspensions at equilibrium was 0.46 mM. In the corresponding $FeCl_3$-ferulic acid system, the concentrations of Fe (II) was 0.06 mM [1]. The results of the current study demonstrate the importance of Fe (III)-clay surfaces for the abiotic formation of humic materials and for the transformation of aromatic (phenolic) pollutants.

Isotope fractionation between metallic Fe and Fe^{3+}- and Fe^{4+}-bearing compounds

V.B.POLYAKOV* AND D.M.SOULTANOV

Institute of experimental mineralogy, RAS, Chernogolovka, Moscow region, 142432, Russia
(*correspondence: polyakov@iem.ac.ru, dll@iem.ac.ru)

We determined β-factors for Fe^{3+} and Fe^{4+} ($CaFeO_3$ and $SrFeO_3$) compounds at ambient pressure from Mössbauer and inelastic nuclear resonant x-ray scattering (INRXS) spectra [1-6] using techniques developed previously [7-10]. The pressure effect on Fe β-factors were estimated from a relation between pressure and temperature derivatives of β-factors [11]. For metallic Fe, we used the pressure dependence of β-factors [12] calculated from INRXS spectra [13].

Compound	Equilibrium fractionation factor (‰)			
	2000 K		3000 K	
	ambient	24 GPa	ambient	32 GPa
Fe_2O_3	0.05 - 0.07	0.07 - 0.09	0.03 - 0.04	0.05 - 0.06
$ReFeO_3$-Pv*	0.03 - 0.09	0.05 - 0.12	0.02 - 0.06	0.03 - 0.10
$CaFeO_3$-Pv	0.12 - 0.17	0.15 - 0.21	0.06 - 0.09	0.07 - 0.12
$SrFeO_3$-Pv	0.15 - 0.25	0.19 - 0.30	0.08 - 0.13	0.10 - 0.17
(Mg, Fe)SiO_3-Pv ferric	0.04 - 0.09	0.06 - 0.11	0.02 - 0.04	0.03 - 0.05

Table 1: Equilibrium isotope fractionation factor between Fe^{3+}- and Fe^{4+}-bearing compounds and metallic Fe.
* Re is the rare earth element, except Yb.

The isotope fractionation between Fe^{3+} compounds and Fe-metal is smaller than observed isotopic shifts (~0.1‰ [14]) between Earth's basalts and those from Mars and Vesta. The putative disproportionation via Fe^{4+} species might allow one to agree estimations and observations. Addition of S, H, and C to the Fe metallic phase is also a favorable factor for the enrichment of Earth's core in light Fe isotope [15].

Arsenic concentration influences secondary mineral formation during simultaneous As(V) and Fe(III) reduction by *Shewanella* sp.

S.A. POMBO[1]*, J.-H. HUANG[1], C. MIKUTTA[1], U. DIPPON[2], A. KAPPLER[2] AND R. KRETZSCHMAR[1]

[1]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland (*correspondence: silvina.pombo@env.ethz.ch)

[2]Geomicrobiology, Center for Applied Geosciences, University of Tuebingen, 72076 Tuebingen, Germany

Microbial reduction of As (V) and Fe (III)-oxyhydroxides largely controls the solubility and mobility of As in soils and natural waters. Under most conditions, As (III) is sorbed less strongly to oxide mineral surfaces than is As (V), and changes in specific surface area and reactivity resulting from reductive Fe-mineral transformations also influence the sorption of As.

The extent of simultaneous microbial reduction of Fe (III) in ferrihydrite and sorbed As (V), as well as secondary Fe-mineral formation, were studied in batch cultures (serum bottles). Ferrihydrite suspensions (2 g L^{-1}) containing 20, 200 or 2000 μM As (V) and 20 mM lactate in mineral medium were incubated for 38 days in the presence of *Shewanella* sp. ANA-3 under anoxic conditions at 25°C. Iron mineral transformations were monitored by Fe K-edge EXAFS (extended X-ray absorption fine structure) and ^{57}Fe Mössbauer spectroscopies.

Increasing As concentrations resulted in an increase in the percentage of As (V) reduced during 38 days (from 40 to 90%). The average As (V) reduction rate increased from 0.24 to 86 μmol As L^{-1} d^{-1}. The concentrations of dissolved As, mainly As (III), also increased with time up to 80 μM at the higher As concentration, whereas no dissolved As was detected in suspensions containing 20 μM As. The average Fe reduction rate decreased from 32 to 26 mmol Fe L^{-1} d^{-1} with increasing total As concentration, while the dissolved Fe (II) concentration decreased by 50%. EXAFS and Mössbauer spectra revealed that mainly magnetite was formed in the presence of 20 μM As, while chloride green rust was identified as the dominating secondary mineral in the presence of 2000 μM As.

In conclusion, the presence of a high As concentration (molar ratio As/Fe~0.1) resulted in an increased As (V) reduction rate, a decreased Fe reduction rate, and inhibited magnetite formation in favor of formation of chloride green rust.

Reactivity of chemically modified nanodisperse anatase

A.V. PONARYADOV AND O.B. KOTOVA

Institute of Geology of Komi SC UB RAS, Russia, 167982, Syktyvkar (alex401@rambler.ru)

Titanium minerals are the most important source of titanium, a strategic metal of modern industry. They act in natural and technological processes as interacting substances, homogeneous and heterogeneous catalysts coated on surface of support and consisting of relatively small particles of metal or metal oxides (1–2 nm). Mechanism of nucleation and growth of minerals on nanoscale as well as nonautonomous phases on mineral surfaces could be studied using synthetic analogues of titanium minerals as research model.

Three different TiO_2 have been used as support of Au-systems: commercial Aldrich Titanium (IV) oxide, nanopowder, 99.7 %, anatase and two nanotube-structured TiO_2 with different pH and geometrical parameters. Nonautonomous phases were deposited on the surface of supports by means of a liquid dispensing robot. Chemical reactivity of prepared samples were tested in reaction of preferential oxidation of carbon monoxide. In temperature programmed reactions (TPR) conversion of CO and O_2 as well as selectivity of O_2 towards CO has been determined as a function of temperature.

As CO conversion over the Au-only sample is very low, the selectivity of this system is much smaller, than that obtained over the modified multicomponent systems. Hence, the main role of the modifiers in case of catalysts supported on commercial TiO_2 and titaniun dioxide nanotubes is the enhancement of the selectivity. On the bases of previous studies it is very probable that Pb is alloyed with Au, which is main reason for the selectivity enhancement [1]. The bimetallic Au-Pb particle suppresses adsorption of hydrogen; therefore oxidation of CO obtains higher probability.

Addition of Sm can change the nanoenvironment of Au in such a way that it stabilizes dispersion of gold during the reaction, as well as the interfaces between the Au nanoparticles and Sm_2O_3 can facilitate oxygen adsorption. Moreover, due to the atomic contact between oxide modifiers and gold the formation of metal ion – gold nanocluster ensemble sites can activate CO oxidation over the multicomponent catalysts. All these effects contribute to the enhancement of CO oxidation rate.

Numerous studies of the synthesis of carbon nanostructuring materials were conducted after publication [1] (1952 year), and [2] (1991 year), and it was thought after that the nanotubes can be obtained only by artificial means in the laboratory. However, studies of graphite-like globules (size - 2 ÷ 10 mm) from leykogabbro with age of 250 million years have shown the possibility of formation of carbon nanotubes in magmatic processes.

Analytical procedures include following steps: 1) acid decomposition of silicate rocks, 2) selection of graphite particles under a microscope, 3) study of morphology and composition using a scanning microscope, and 4) identification of the C-C bond (Raman microscopy) and carbon isotopic composition.

'Anatomy' of globule (from the edge to the center) is as follows: 1) the thin layer of carbon film (graphene?), 2) outer shell, made of a porous carbon material with thickness of ~ 20μm (turbostatic graphite), 3) the inside of the shell is covered by 'forest' of carbon microtubes; 4) the length of the microtubes – 0.2-0.3 mm, diameter - 1-5μm (Fig. 1, left part); 5) multi-walled carbon nanotubes 'growing' from the microtubes (Fig.1, right part). Temperature of the carbon nanostructuring material formation (Raman spectroscopy) ranges from 650 to 470°C. $\delta^{13}C$ values of different forms vary from -16 to -12‰. In general, the data, obtained in this study, have shown that nano- and microtubes were formed in gaseous environment (from CO^2) through the molecular dynamic mechanism.

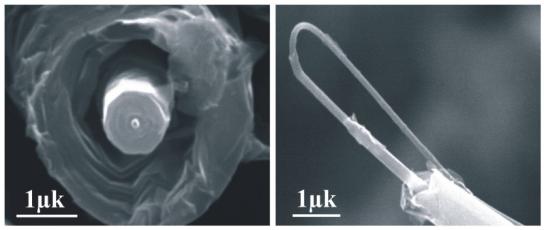

Figure 1: left - section of the carbon microtube, right – nanotube growing from microtube.

Stable isotope composition and volume of Early Archaean oceans

E.C. POPE[1]*, M.T. ROSING[2] AND D.K. BIRD[3]

[1]Geological Museum, University of Copenhagen, 1350 Copenhagen K., Denmark (*correspondence: ecpope@stanford.edu)

Oxygen and hydrogen isotope compositions of seawater are controlled by volatile fluxes between mantle, lithospheric (oceanic and continental crust) and atmospheric reservoirs. Throughout geologic time oxygen was likely conserved within these Earth system reservoirs, but hydrogen was not, as it can escape to space [1]. Hydrogen isotope ratios of serpentinites from the ~3.8Ga Isua Supracrustal Belt in West Greenland are between -53 and -99‰; the highest values are in antigorite ± lizardite serpentinites from a low-strain lithologic domain where hydrothermal reaction of Archaean seawater with oceanic crust at elevated temperatures was geochemically preserved, indicating that the $\delta D_{SEAWATER}$ was at most 25 ± 5‰ lower than modern VSMOW. We propose that the progressive increase in $\delta D_{SEAWATER}$ since this time is due to preferential uptake of hydrogen in continent-forming minerals and to hydrogen escape via biogenic methanogenesis [2]. Mass balance considerations within the Earth system places a cumulative upper limit on elemental hydrogen loss to space of ~$1.8x10^{22}$mol elemental hydrogen H, constraining maximum Archaean atmospheric methane levels at ~3.8Ga to <500ppmv (depending on the volume of continents present at that time), and the mass of Early Archaean oceans to ~109 to 126% of present day oceans. Oxygen isotope analyses from these Isua serpentinites ($\delta^{18}O$ = +0.1 to 5.6‰ relative to VSMOW) indicate that early Archaean $\delta^{18}O_{SEAWATER}$ similar to modern oceans. Our observations suggest that the low-$\delta^{18}O$ values of Precambrian sedimentary cherts and carbonates are not a consequence of isotope variability of seawater or extreme ocean temperatures [3, 4], but rather are due to isotopic exchange with shallow hydrothermal fluids on the ocean floor or during diagenesis [5].

REE behavior during the formation of Sn-W deposits

J.A. POPOVA[1]*, A.YU. BYCHKOV[1], S.YU. NEKRASOV[1] AND T. SUSCHEVSKAJA[2]

[1]Moscow State Universiy, Moscow,Russia (*correspondence: julka_p@rambler.ru)
[2]GEOKHI RAS, Moscow, Russia

REE behaviour was considered for two Sn-W deposits, Svetloe and Iul'tin (Chukotka, Russia). Both deposits take place within the Iul'tin ore district. The isotopic composition of oxygen and hydrogen allowed to conclude that meteoric waters were probable source of hydrothermal fluids in these deposits [1]. REE content in fluorites may be used as an indicator to determine the nature and the evolution of fluids [2]. Regularities of REE spectra changes indicate the presence of two generations of fluorite. REE concentations in thehydrothermal solutions in equilibrium with fluorites were obtained by conversion of two generations of fluorite into fluids using the distribution coefficients of mineral / fluid [2]. For the first fluorite generation the fluid is magmatic one, for the second fluorite generation the fluid is exogenous. Mixing these two fluids leads to the deposition of ore. The deposition of cassiterite and arsenopyrite occurs when acidic magmatic fluid carrying the ore elements mixed with alkaline meteoric water. As a result pH increases and the following association is formed:

$3Sn^{II}Cl_2^{\circ}+2As^{III}(OH)_3^{\circ}+2FeCl_2^{\circ}+2H_2S^{\circ}=$
$=3Sn^{IV}O_2+2FeAs^{\circ}S+10HCl^{\circ}.$

The wolframite deposition occurs under the following reaction:

$NaHWO_4^{\circ}+FeCl_2^{\circ}=FeWO_4+Na^{+}+2Cl^{-}+H^{+}.$

The compositon of wolframite changes in the vertical section of Iul'tin deposite from 47% to 64% mol% FeWO4. For Svetloe deposite it is shown that wolframite is depleted of iron (from 39 to 5 mol% FeWO4) under the joint deposition of wolframite and arsenopyrite.

Methylotrophy in Yellowstone National Park hot springs

A.T. PORET-PETERSON[1]*, S.J. ROMANIELLO[1], N. ZOLOTOVA[1], Z. MARTINEZ[1], J.J. ELSER[2] AND A.D. ANBAR[1,3]

[1]School of Earth and Space Exploration, Arizona State University, PO Box 871404, Tempe, AZ 85287, USA (*correspondence: aporetpe@asu.edu)

[3]Department of Chemistry and Biochemistry, Arizona State University, PO Box 871604, Tempe, AZ 85287, USA

Autotrophic microorganisms in hot springs, like their mesophilic counterparts in other aquatic ecosystesm, likely play a major role in supplying reduced organic C to these systems [1]. However, hot springs are surface expressions of geologic activity that releases compounds that may serve equally well as sources of C, such methane (CH_4). Indeed, CH_4 assimilation pathways may be less energetically expensive in terms of ATP and reductant than the Calvin Cycle or alternative pathways for CO_2 fixation [2]. Thermodynamic calculations also show that microbes capable of aerobic CH_4 oxidation can thrive in hydrothermal ecosystems due to the amount of energy released from its catabolism [3]. Several recent studies have isolated CH_4-oxidizers from geothermal environemnts [4].

The goal of this study was to investigate whether methylotrophs (utilizers of reduced C_1 compounds) were present and active in various thermal features in Yellowstone National Park. To accomplish this objective, we incubated hot spring sediments and microbial mats in microcosms amended with stable-isotope labeled and unlabeled methanol (CH_3OH) overnight at *in situ* temperatures. We found evidence for methylotrophy in the sediments of slightly acidic hot springs (pH 6.0) based on ^{13}C enrichment of CO_2 and bulk sediment. To complement our isotopic data, we extracted DNA from hot spring sediments and retrieved functional genes encoding key enzymes in aerobic CH_4 and CH_3OH oxidation. Sequencing of these genes suggests that a complex methylotrophic community may be present in the hot spring, as clones grouped with gammaproteobacterial obli-gate methanotrophs and betaproteobacterial obligate methylo-trophs.

Understanding Early Jurassic ocean connectivity using Os isotopes

SARAH J. PORTER[1], DAVID SELBY[1], KATSUHIKO SUZUKI[2] AND DARREN R. GRÖCKE[1]

[1]Department of Earth Sciences, Durham University, Durham, DH1 3LE, UK
[2]Japan Agency for Marine-Earth Science and Technology, Yokosuka, 237-006, Japan

Marine organic-rich sedimentary rocks (ORS) hold the key to understanding past chemical changes to the oceans. The osmium isotope system ($^{187}Os/^{188}Os$) is a particularly powerful tool for tracing these changes, and as such makes it possible to determine the effects of continental weathering, meteorite impact and mantle-derived fluxes [1].

Although the present-day seawater Os isotope composition is relatively uniform ($^{187}Os/^{188}Os$ ratio of ~ 1.06), it has varied significantly throughout geological time [2, 3]. The Jurassic was a particularly dynamic period that witnessed full-scale plate reorganisation associated with the supercontinental break-up of Pangea. The Triassic-Jurassic boundary saw the onset of Central Atlantic Magmatic Province (CAMP) volcanism as the Central Atlantic lineament began to rift. Ocean chemistry at this time was therefore subject to significant fluctuations.

The marine ORS sequence of the Sinemurian-Pliensbachian GSSP, Robin Hood's Bay, UK, was located on the margins of the shallow European epicontinental sea in relative proximity to the rifting Central Atlantic, making it an ideal candidate for studying the affect of the CAMP on seawater chemistry.

Our results indicate that there was a significant contribution of unradiogenic Os to the oceans across the Sinemurian-Pliensbachian boundary, that can only be resolved by a mantle-derived, hydrothermal Os input. Evidence for sudden increased faunal exchange between the western Tethyan and eastern Pacific Oceans at this time, suggests that initiation of flooding of the Hispanic Corridor occurred close to this boundary. Our Os data provides evidence for opening of this seaway and better constrains the timing of flooding, therefore improving our understanding of palaeogeography and ocean connectivity during the Early Jurassic.

Arc magmas are generated by a number of mantle and crustal processes. Our multidisciplinary, long-term research is aimed at deciphering these processes for a single arc volcano, Kliuchevskoy volcano in Kamchatka. Some key results of the study follow:

1) Modeling of trace element and H_2O contents in melt inclusions suggests that the primary magmas originate via hydrous flux-melting of the mantle wedge at temperatures close to the dry peridotite solidus. The role of decompression melting is minor or absent at Kliuchevskoy and other arc volcanoes built on relatively thick crust.

2) Geochemistry of high-Mg olivine suggests that primary Kliuchevskoy magmas have substantial contribution from olivine-free pyroxenite (up to 30 %), which could be formed by reaction of slab melts (or supercritical fluids) with mantle wedge peridotite.

3) Parental Kliuchevskoy melts start to crystallize as deep as the Moho boundary, and the erupted magmas reflect multi-stage and complex processes of crystallization, magma mixing and crustal assimilation. None of the Kliuchevskoy rocks analyzed thus far represent true primary melt compositions.

4) The Kliuchevskoy Holocene eruptive history is not steady-state in terms of eruption rate and geochemistry. There are two millenial cycles with major and trace element and O-Sr-Nd-Pb and U-series isotope compositions of the magmas changing gradually from more to less affected by crustal (?) assimilation. The onset of the cycles correlates with periods of enhanced volcanic activity in Kamchatka, suggesting that the extent of magma-crust interaction is inversely related to magma production rate and thus magma flux from the mantle.

[5]ANKA/Inst.Synchotron Radiation, Forschungszentrum Karlsruhe GmbH, Hermann-von-Helmholtz-Platz 1, Eggenstein-Leopoldshafen, D-76344 Germany

There is new evidence that micro-diamonds not only formed at high pressure and high temperature conditions in the diamond window. We found that, under favorable thermodynamic, stoichiometric and kinetic circumstances, micro diamonds can be synthesized by polycondensation of light carbon bearing molecules at medium to low pressure conditions, even close to the Earth's surface in the studied eclogites from the Victor Diamond Mine, South Africa. The studied eclogites contain OH, CO_2, CO, CH_4, CH_2O and CH_3OH around totally embedded micro-cracks in nominally anhydrous minerals (NAMS). Micro cracks act like monomineralic and interphase grain boundaries, and can also interpreted as two dimensional defect structures. We used high-resolution synchrotron based FT-IR to detect C-O-H bearing volatiles around two-dimensional defect structures in NAMS as garnet. At micro diamond bearing defect structures, a correlation between the different C-O-H bearing volatiles is visible, whereas in inclusion free defect structures no correlation of the different C:O:H containing volatiles can be recognized. The findings from our study show that the C:O:H bearing volatiles, and their distribution pattern around the studied micro cracks, are indicative for the formation of micro diamonds in natural eclogites. Our outcomes confirm the results from experimental studies on the growth and synthesis of diamond crystals as a consequence of polycondensation of light carbon molecules.

Iron mineralization in anoxic, non-sulphidic systems

SIMON W. POULTON

School of Civil Engineering and Geosciences, Newcastle University, Newcastle upon Tyne, NE1 7RU, UK (s.w.poulton@ncl.ac.uk)

It has long been considered that Earth's early oceans were anoxic and rich in dissolved Fe (ferruginous). The evidence for this comes from the widespread preservation of banded iron formations (BIF) in the geologic record. Although BIF deposition occurred in pulses, recent reconstructions of oceanic redox conditions during deposition of marine shales have increasingly provided evidence for persistent deep water ferruginous conditions throughout the Archean. It has been proposed that following the termination of global BIF deposition ~1.8 billion years ago, the oceans underwent a fundamental change in response to rising Earth surface oxygenation. The most recent reconstructions suggest that this may have led to widespread euxinia along continental margins and in epicontinental seas, with the deep ocean remaining ferruginous. Deep ocean ferruginous conditions have also been advocated for much of the Neoproterozoic, while recent high resolution reconstructions of ocean redox conditions during Phanerozoic oceanic anoxic events have also shown distinct orbital timescale cycling between deep water euxinic and ferruginous conditions.

Yet, despite the significance of ferruginous conditions during past periods of ocean anoxia, very little is known about biogeochemical cycling of elements and nutrients under such conditions. To address this we have recently focussed on assessing Fe mineralization in anoxic, non-sulphidic settings, in particular Lake Matano, Indonesia, and Golfo Dulce, Costa Rica. At Lake Matano, we find clear evidence for water column precipitation of the mixed ferrous-ferric mineral, green rust, at the oxycline. This is the first identification of green rust in a natural water body and we propose that this mineral would have played a major role in elemental cycling during precipitation (through adsorption/co-precipitation) and during subsequent transformation processes. At both Lake Matano and Golfo Dulce, we also find evidence for authigenic magnetite formation on an unprecedented scale, both in the water column and during diagenesis. This new insight ultimately provides process understanding of mineralization pathways and associated elemental cycling under anoxic, ferruginous conditions, and provides insight into the genesis of BIFs, while also aiding the reconstruction of environment conditions based on BIF geochemistry.

The anatomy of the Great Oxidation Event

SIMON W. POULTON[1], ANDREY BEKKER[2], JAMES FARQUHAR[3], AUBREY L. ZERKLE[1], DAVID T. JOHNSTON[4] AND DONALD E. CANFIELD[5]

[1]School of Civil Engineering and Geosciences, Newcastle University, UK (s.w.poulton@ncl.ac.uk)
[2]Department of Geological Sciences, University of Manitoba, Canada
[3]Department of Geology, University of Maryland, USA
[4]Department of Earth and Planetary Sciences, Harvard University, USA
[5]Nordic Center for Earth Evolution, University of Southern Denmark

The Palaeoproterozoic was characterised by three major glaciations that coincided with the transition from a dominantly anoxic to a well-oxygenated atmosphere (the Great Oxidation Event; GOE). This transition has been dated at 2.32 Gyr ago, based on a loss of S isotope mass-independent fractionations (MIF) in sediments from the Transvaal Supergroup, South Africa [1]. These South African sediments are considered to correlate with the second of three widescale glaciations recorded in the Huronian Supergroup, Canada [2].

To provide more insight into links between the detailed dynamics of the GOE and Paleoproterozoic glaciations and ocean chemistry, we have performed a multi-proxy reconstruction of Earth surface oxygenation across the second Huronian glaciation. We combine a variety of sensitive indicators of oxygenation, including the role that sulphate exerts on ocean redox state, Mo concentrations, and multiple S isotopes. We find clear evidence for euxinic depositional conditions during deposition of the Bruce glacial diamictite. Coupled with enrichments in Mo, this implies significant pervasive atmospheric oxygenation that was glacially-driven. However, persistence of mass-independent S isotope fractionations suggests that this was at a low level. The MIF signal is possibly transiently lost in the lower part of the overlying Espanola Formation, implying that oxygenation may have been close to the upper threshold for MIF generation. However, a clear S isotope MIF signal is present throughout the upper succession, despite enrichments in Mo, suggesting that atmospheric oxygen levels fluctuated around a low level between the second and third glaciations.

High precision analysis of all REEs in chondrites and Earth

A. POURMAND[1,2]*, N. DAUPHAS[1] AND T.J. IRELAND[1]

[1]Origins Lab., Dept. of Geophys. Sci., Univ. of Chicago, Chicago, IL 60637, USA
[2]RSMAS - Division of Marine Geology and Geophys., Univ. of Miami, Miami, FL 33149, USA (*correspondence: apourmand@rsmas.miami.edu)

Advances in rare earth element (REE) analyses have succeeded in increasing the precision of measurements, while concurrently decreasing preparation time (e.g. [1, 2]). Here, we present high precision data for the REEs, Sc and Y that were collected following an innovative technique that we developed for the separation and purification of these elements. This technique applies a low-blank flux fusion procedure to ensure the complete digestion of a sample, followed by column chromatography to separate the REEs, Sc and Y from matrix elements, prior to analysis on a Neptune multi-collector ICP-MS [1, 3]. The REE patterns in all geostandards are in excellent agreement with compilations of literature values, albeit at a higher precision.

Rare-earth element, Sc and Y data were obtained for 10 carbonaceous chondrites, 16 enstatite chondrites and 15 ordinary chondrites. Previously, U, Th and Hf concentration, as well as Hf isotopic data were gathered for these meteorites [4]. In general, REE patterns for carbonaceous chondrites are relatively flat, although some CV3 samples (e.g. Allende) show a group-2 CAI pattern. Other chondrite groups show evidence for REE re-distribution during metamorphism, consistent with Dauphas and Pourmand [4].

A critical goal of this study was to re-evaluate CI-chondrite abundances, and if necessary, suggest a revised composition for normalizing purposes. We analyzed three CI-chondrites (Orguiel, n=5; Ivuna, n=2; Alais, n=1) and based on these 8 measurements, we propose a revised CI-composition for the REEs [3].

In addition to chondrites, we analyzed several terrestrial samples. When normalized to our revised CI composition, terrestrial rocks show smooth REE patterns except possibly for a small anomaly at Tm (also reported by [5]). This REE is seldom reported in literature, as it is mono-isotopic and often used as an internal standard. Further work is currently in progress to assess whether this effect is real.

The importance of magnetic and correlation effects in high-pressure research is often overlooked. The usual motivation here is that under compression the overlap between localized states increases and so does the bandwidth W, while the local Coulomb repulsion U between those states is screened more efficiently. The reduction of U/W ratio is used to rationalize the neglect of electronic correlations beyond state-of-the art local density approximation (LDA) or semi-local generalized gradient approximation (GGA) at high-pressure conditions. Concerning magnetism, the Stoner theory becomes more realistic at very high temperature $T >> T_c$ (T_c is the Curie temperature) where the disappearance of local magnetic moments can be expected.

In particular, based on these arguments iron at the inner Earth's core conditions is modeled as non-magnetic within LDA-based approaches. To challenge this point of view, we have performed calculations with a new implementation of the dynamical mean-field theory (DMFT). It is based on a highly precise full-potential linear augmented plane wave (FLAPW) method for the band structure calculation combined with DMFT in conjunction with a continuous-time quantum Monte Carlo (CTQMC) impurity solver for treating the strong correlations [1]. The application of the methodology has shown anumbigously that inclusion of correlation effects beyond LDA/GGA has led to qualitatively new physical effects predicted in Fe at moderate, as well as at ultra-high pressure and temperature.

Cadmium isotopes in the western North Atlantic — GEOTRACES cruise PE319

C. POWELL[1]*, W. ABOUCHAMI[1], S.J.G GALER[1], M.O. ANDREAE[1], J. DE JONG[2], L. GERRINGA[2] AND H. DE BAAR[2]

[1]Max Planck Institute for Chemistry, PO Box 3060, 55020 Mainz, Germany (*correspondence: Claire.Powell@mpic.de)

[2]Royal Netherlands Institute for Sea Research, PO Box 59, 1790 AB Den Burg, The Netherlands

We present cadmium concentration and isotopic composition data for four depth profiles from GEOTRACES cruise PE319, which sailed from Scrabster, UK to Bermuda during April and May 2010, following the eruption of the Eyjafjallajoekull volcano in Iceland.

Recent Cd isotope data have shown that the cadmium biogeochemical cycle in the high nutrient, low chlorophyll (HNLC) regions of the Southern Ocean is controlled by both ocean circulation and primary production [1]. In contrast, the surface waters of North Atlantic subtropical gyre are considered oligotrophic for much of the year, and the high latitude (>55°N) North West Atlantic is seasonally HNLC [2].

Seawater samples, collected using a titanium frame and ultra clean sampling techniques [3], were analysed for cadmium isotopic composition and concentration using a double-spike technique using Thermal Ionization Mass Spectrometry (DS-TIMS) at MPI. One litre seawater samples were processed as described by Abouchami *et al.*[1]. Data are reported relative to our NIST SRM 3108 standard ($^{110}Cd/^{112}Cd$=0.520121±4 (2SD, n=14)).

Preliminary results from the Irminger Basin (at 64.0°N, 34.25°W) show relatively constant cadmium concentrations, with a mean concentration of 0.25 ± 0.02 nmol kg^{-1} in the upper water column. The $\varepsilon^{112/110}Cd$ show little variation, with a mean value of +2.9 ± 0.26, and are similar to those reported in surface waters from the Arctic and North Atlantic [4]. Additionally, the ratio of phosphate to cadmium concentration appears to be coherent with models and observations of this ratio at low phosphate concentrations [5]. These results are consistent with seasonal observations of hydrographic mixing and stratification in the region [6].

Biogeochemical prospecting and the environmental control in highly polluted areas presume the correct selection of the biogeochemical material for sampling and the interpretation of the analytical results that takes into account the physiological mechanisms of plant adaptation and, in particular, the pedogeochemical phenomena.

In this work, have been characterised the species present in the old mining area of Cavalo (Oleiros, Castelo Branco, Central Portugal); environment with important W, As and some Cu contamination.

The species were selected envisaging their use as bioindicators, meaning that they are able to detect the pollution present in soils for use in mineral exploration; and seeking their potential use in the restoration with metalotolerant species able to tolerate the geochemical stress imposed by these conditions. The analyzed species included: *Erica australis, Erica umbellata, Pterospartum tridentatum, Halimium ocymoides, Arbutus unedo, Cistus salvifolius, Hypochaeris radicata, Pinus pinaster, Anarrhinum bellidifolium, Conyza canadensis, Andryala integrifolia, Agrostis delicatula* and *Agrostis curtisii*.

The results of analysis show that the species best suited for biogeochemical indicating are by order of importance: *Erica australis, Arbutus unedo* (leaves), *Halimium ocymoides, Erica umbellata, Cistus salvifolius* and *Pterospartum tridentatum* for As; *Halimium ocymoides* for Cu; *Erica umbellata, Arbutus unedo* (leaves and stems), *Erica australis, Pterospartum tridentatum, Halimium ocymoides* e *Cistus salvifolius* for W.

On the possibility of using these species in revegetation of areas with this type of contamination, it appears that all species accumulate in their tissues the main elements causing contamination (As and W). On the other hand, these species only have medium physiological barriers, not implying a high intake of these elements in the ecosystem.

Uranium in aquatic plants from uranium contaminated water in Central Portugal

JOÃO PRATAS[1,4], PAULO FAVAS[2,4] AND M.N.V. PRASAD[3]

[1]Dep. of Earth Sciences, University of Coimbra, Largo Marquês de Pombal, 3001-401 Coimbra, Portugal (jpratas@dct.uc.pt)
[2]Dep. of Geology, UTAD, Ap.1013, 5000-801 Vila Real, Portugal (pjcf@utad.pt)

[4]Geosciences Center, University of Coimbra

The work presented here is a part of an on-going study on the uraniferous geochemical province of Central Portugal in which, the use of aquatic plants as indicators of uranium (U) contamination is being probed using aquatic plants emphasizing their potential use in the emerging phytotechnologies.

Several of the uraniferous deposits were exploited either by underground or surface mining methods. Many of the places were left in different stages of degradation.

The samples were collected in running and in standing waters (lentic and lotic) in the places where it was possible to observe aquatic species. In these sites, samples of the waters and of the vegetable species were taken. The plants collected represented the free floating and the rooted emergent plants. In the ponds, only free floating plants were found growing. The methodology adopted for the determination of the U content in the water and plants was fluorometry.

Even though we have observed very low concentration of U in the fresh waters of the studied sites we found a set of vegetable species with the ability to accumulate U in concentrations which are orders of magnitude higher than the surrounding environment. We have observed that *Callitriche stagnalis* (1948.41 mg/kg DW), *Lemna minor* (52.98 mg/kg DW) and *Fontinalis antipyretica* (234.79 mg/kg DW) accumulated significant amounts of uranium, whereas *Oenanthe crocata* excluded U. These results indicate substantial scope for proper radiophytoremediation and phytosociological investigation exploiting the native flora. These species show great potential for phytoremediation because they are endemic and easy to grow in their native conditions. *C. stagnalis* have high bioproductivity and yield good biomass.

[4]Department of Chemical Engineering, Vanderbilt University, Nashville, Tennessee 37235, USA

In the last 10 years we have been studying by molecular dynamics (MD) the structural and dynamic properties of aqueous solutions in contact with metal-oxide surfaces, mainly rutile [1-3]. We will present the results of our non-equilibrium MD simulations focusing on the molecular level origin of electrokinetic phenomena - electroosmosis and electrophoresis. We will comment on the asymmetry of the density profiles of cations and anions at positive and negative surfaces, discuss the properties of the diffuse and shear layers, if definable at all on the molecular scale, and present our zeta potential predictions from molecular simulations. Our results of zeta potential are in qualitative agreement with experimental data [5]. However, our molecular explanation is rather contradictory to at least some of the commonly used theories of the solid-liquid interface including the common double- or triple- layer models. We observe that the composition and structure at the interface, influenced by the surface charge, are the key factors, while the electrostatics of the aqueous solution is rather independent of the surface charge.

Recycling plus: A new recipe for making orogenic mantle

D. PRELEVIC

University of Mainz, Germany, (prelevic@uni-mainz.de)

Fluids and melts liberated from the subducting oceanic crust ± sediments recycle a number of chemical elements back into the mantle wedge. The recycling rate of key chemical elements is controled by the dichotomy of subsolidus dehydration vs. melting. Thermal models based on active subduction zones suggest that the majority of arcs are able to activate fluid-related transport dominantly, while the melt-related material recycling is only possible in unusually hot arcs. Paleo-subduction zones within orogenic belts, such as these within the Cenozoic Alpine-Himalayan belt, may serve as an advanced source of information regarding recycling styles during subduction. The composition of their mantle section is poorly constrained, but may be studied using postcollisional mantle-derived ultrapotassic lavas as a proxy.

The whole rock and mineral chemistry of postcollisional lavas suggests that the orogenic mantle underwent much more intense and complex material recycling than anticipated only by fluid- or melt-dominated transport. This is based on several fundamental constraints: i) Extremely enriched Sr, Nd, Hf, Pb and Os isotopic signature, which complement exceptionally low Ce/Pb and Nb/U ratios, are recognized in all mantle-derived postcollisional lavas along the Alpine-Himalayan belt; ii) Mixed ultra-depleted+ultra-enriched character of olivine phenocrysts and xenocrysts, with high Mg and Ni contents coupled with extremely high Li concentrations. Phenocrystal olivines have more than 40 ppm Li, and xenocrystal ones up to 10 ppm Li. iii) Extremely high Th/La coupled with high Sm/La of ultrapotassic mantle-derived lavas.

The above observations suggest that neither fluids nor melts alone are able to precondition orogenic mantle using known mechanisms, thus a new model is required. In my contribution, I will use the peculiar compositions of ultrapotassic mantle-derived lavas from across the Mediterranean for fingerprinting processes within the continental lithosphere. I will present a hypothesis that orogenic mantle is produced by accretion of suprasubduction fore-arc oceanic lithosphere plus trench sediments beneath older lithosphere during collisional tectonic events. The model demands conversion of principally oceanic lithosphere into the phlogopite-bearing continental lithospheric mantle and production of ultrapotassic lavas, which is a multi-episodic process.

Marine and terrestrial palaeoclimate proxies from the stable isotope analysis of North African molluscs

AMY L. PRENDERGAST[1], RHIANNON E. STEVENS[2], TAMSIN C. O'CONNELL[2], CHRISTOPHER HUNT[3] AND GRAEME BARKER[2]

[1]Department of Archaeology, University of Cambridge, Downing Street, Cambridge
[2]McDonald Institute for Archaeological Research, University of Cambridge, Downing Street, CB2 3ER
[3]Queens University Belfast, School of Geography, Archaeology and Palaeoecology, 42 Fitzwilliam Street, Belfast

Stable isotope analyses from the topshell *Osilinus turbinatus* and the pulmonate snail *Helix melanostoma* from the Haua Fteah, an archaeological site in North Africa have allowed the construction of paired marine and terrestrial climate curves that extend from c.20, 000 years ago to c. 7000 years ago. These analyses have been interpreted with reference to analogue studies on modern marine and terrestrial molluscs from Libya. In marine molluscs, $\delta^{18}O$ records fluctuations in sea surface temperature. In terrestrial molluscs, $\delta^{18}O$ varies according to the water ingested by the animal as the shell grows, which in turn is linked to water and air temperature at the moment of precipitation whilst $\delta^{13}C$ provides a proxy for palaeovegetation patterns and water stress. Intrashell stable isotope series from the Haua Fteah record snapshots of sub-seasonal climatic variations covering rapid and profound climatic fluctuations from MIS 2 to MIS 1. This high-resolution climatic framework coupled with the well-dated record of cultural change in the archaeological record, allows an examination of human-environment interactions during critical periods of late Pleistocene to early Holocene climate change.

Effects of ocean acidification in a supersaturated ocean (Carnian, Late Triassic)

N. PRETO[1], J. DAL CORSO[1] AND G. ROGHI[2]

[1]Dipartimento di Geoscienze, Iniversità degli Studi di Padova, via Gradenigo 6, 35131, Padova, Italy (*correspondence: nereo.preto@unipd.it)
[2]Istituto di Geoscienze e Georisorse, CNR, via Gradenigo 6, 35131, Padova, Italy

Ocean acidification triggered by recent anthropogenic emission of CO_2 is predicted to impact negatively on calcifying organisms. Here we present the response of lower Carnian shallow-water microbial carbonate platforms to an early-Late Triassic (~230 Myrs) episode of increased pCO_2. A negative carbon isotope excursion (CIE) of 2-4‰ was discovered in the lower Carnian (Upper Triassic) of the Dolomites (Southern Alps, Italy) which testifies for a rapid injection of light carbon in the atmosphere-ocean system linked to the eruption of Wrangellia large igneous province. The observed rise of the Carbonate Compensation Depth (CCD) in the deep-water succession and the crisis of shallow water carbonate systems [1] is best explained by an episode of ocean acidification triggered by increasing pCO_2.

Point-counting of calciturbidites and carbonate storm layers interbedded with the shales of the Carnian San Cassiano and Heiligkreuz formations show that carbonate grains with microbial origin are dominant below the CIE, but fall to less than 10% above, where skeletal grains and ooids become dominant. The turnover point coincides exactly with the CIE. It seems that ocean acidification favored metazoans and higher carbonate-secreting organisms over calcifying microbes. Thus, the Carnian case study seems a counter-example of today ocean acidification. However, Carnian seawater where microbes flourished was extremely supersaturated ('Neritan ocean' state [2]), and the effect of CO_2 injection in the system was probably just to drive supersaturation closer to present-day values. The Carnian case study demonstrates, at least at the short time-scale of the Carnian CIE, that the effects of ocean acidification can be strongly non-linear, and dependent on boundary conditions as the local saturation state of seawater with respect to carbonate.

Several studies have underlined the importance of sulfide phases as trace element carrier in anoxic river and estuarine bottom sediments. Moreover, thermodynamic and kinetic studies in oxic waters have shown that the oxidation process of this reduced phase process may be relatively slow [1].

In the present study, Zn speciation was investigated in suspended particulate matter (SPM) in an oxic water column of the Seine River downstream of Paris, an urbanized watershed significantly impacted by Zn contamination [2].

First coordination shell around Zn was determined using Synchrotron-based Extended X-ray Absorption Fine Structure (EXAFS) spectroscopy at the Zn K-edge. Analysis of samples dried under pure nitrogen atmosphere indicated a dominant sulfur first coordination environment around Zn in the form of amorphous/poorly crystalline. In contrast, an oxygen first coordination environment around Zn was observed in the samples dried under ambient oxygenated atmosphere. The presence of ZnS solid phases in nitrogen-dried samples was confirmed by scanning electron microscopic observations coupled with energy dispersive x-ray spectroscopy analyses.

This study highlights the importance of preserving oxidation state for metal speciation studies, even in an oxic water column.

The Longwood Igneous Complex of southern New Zealand: An intra-oceanic, subduction-related batholith

R.C. PRICE[1]*, C. SPANDLER[2] AND R.J. ARCULUS[3]

[1]Science and Engineering, University of Waikato, Hamilton, New Zealand (*correspondence: r.price@waikato.ac.nz)
[2]Earth and Environmental Sciences, James Cook University, Townsville, Queensland 4811, Australia (carl.spandler@jcu.edu.au)
[3]Research School of Earth Sciences, Australian National University, Canberra, ACT 0200, Australia (Richard.arculus@anu.edu.au)

The Longwood Igneous Complex (LIC), which is located in Southland, New Zealand, is a batholith-scale plutonic complex made up of troctolite, gabbro, gabbroic diorite, granite and basaltic dyke rocks ranging in age from Permian to Jurassic. Whole rock samples of the LIC have the trace element patterns of intra-ocaeanic, subduction-related magmas. Mineral chemistry and mineral phase relationships indicate emplacement depths of 15 to 25 km.

Ultramafic rocks and most of the gabbros of the LIC have petrographic and geochemical features indicating that they formed as cumulates. Few have direct compositional analogues among modern intra-oceanic volcanic rocks (e.g. [1, 2]). LIC intrusions represent crystal cumulates and mushes left over from the processes that generated the magmas that would have been erupted at the contemporaneous volcanic arc (c.f. [3]).

Across the LIC, there is a systematic change in the age of the intrusives from 254 Ma in the east to 142 Ma in the west. There is also a correlation between age of emplacement and Sr and Nd isotopic compositions, which together with inheritance in zircons dated by ion probe, suggests that crustal recycling became significant as the LIC subduction system evolved and matured. The LIC can therefore be used to estimate the composition of lower – middle crust assembled beneath an intra-oceanic arc over a 100 Ma time scale. LIC crust is on average andesitic and compositionally similar to bulk continental crust.

Subcritical phase separation, extreme arsenic enrichment, and the search for arsenotrophs in the marine shallow-water hydrothermal vents off Milos Island, Greece

ROY E. PRICE[1]*, KATJA NITZSCHE[2], ANKE MEYERDIERKS[2] AND JAN P. AMEND[1]

[1]Earth and Planetary Sciences, Washington University, St. Louis (*correspondence: royprice@wustl.edu)
[2]Max Planck Institute for Marine Microbiology, Bremen, Germany

Recent investigations [1] revealed the highest arsenic concentrations measured to date for any submarine hydrothermal vent fluid, occurring in the shallow waters (<20 m) of Paleochori and Spathi Bay, off the southeast coast of Milos Island, Greece. Concentrations reached as high as 79 μM, which equals nearly 3000 times the concentration of seawater As and far exceeds the concentrations typically found in mid-ocean ridge (MOR) and back-arc basin (BAB) fluids (typically >10 μM). Orange hydrotheral precipitates at the site were characterized as non-crystalline orpiment. Both a high Cl (enriched in Cl by up to 47% compared to seawater) and a low Cl fluid (depleted by up to 66%) were encountered, and geochemical data indicate that the hydrothermal fluids underwent subcritical phase separation (boiling) and vapor/brine segregation prior to discharge.

We utilized both culture-dependent and molecular microbiological approaches to search for arsenotrophs in white and orange mats found on the seafloor in the area of venting. Field inoculations were performed using hydrothermal fluids and sediment slurries on designer growth media, including autotrophic and heterotrophic arsenate (AsV) reduction, as well as aerobic and anarobic arsenite (AsIII) oxidation, and incubated at 50 and 80 °C. Thusfar, enrichments in autotrophic AsV reduction with H_2S as the electron donor were successful, and efforts to characterize this community continue.

16S rRNA analysis showed a high diversity in the bacterial community, while archaea constituted only a minor fraction of the microbial community, with low diversity. The presence of diverse genes for the large subunit of arsenic oxidase (*aro*A) in the white and orange mats at Milos indicates the capability of the microbial community to metabolise arsenic.

[1] Price, R.E. Pichler, T. Planer-Friedrich, B. Bühring, S.I. Savov, I. (2011) The behavior of arsenic in subcritically phase-separated hydrothermal fluids from the marine shallow-water hydrothermal vents off Milos Island, Aegean arc, Greece. Submitted.

Interfacial tension, metastability, and solubility of solid solutions

M. PRIETO*, D. KATSIKOPOULOS AND A. FERNÁNDEZ GONZÁLEZ

Dept. Geology, University of Oviedo, Oviedo, Spain (*correspondence: mprieto@geol.uniovi.es)

The existence of a relationship between metastability and solubility is widely recognized in the crystal growth literature [1]. In general, the lower the solubility of a substance the higher is its 'ability' to form supersaturated solutions. The metastability limit of a supersaturated solution can be defined by the threshold below which the solution can remain supersaturated longer than an arbitrarily chosen waiting time. This definition is in the framework of the classical nucleation theory (CNT), which connects metastability, interfacial tension (σ) and solubility. The nucleation rate depends strongly on σ, which is in turn related to the solubility by the rule that the higher the solubility, the lower σ. In CNT, the interfacial tension is actually an 'artificial' parameter, but empirical estimations [2] of σ are typically used to account for precipitation in natural systems [3] and to model the precipitation in sequential order of lesser and lesser soluble minerals constituted of the same elements, according the Ostwald step rule. In a similar way, when solid-solutions crystallize from supersaturated solutions, the partitioning of the substituting ions usually differs from the equilibrium values [4]. 'More soluble' solid solution compositions are kinetically favored and tend to nucleate even though the aqueous solution is less supersaturated for these compositions than for less soluble members. This effect has been modeled by considering the differences between the interfacial tensions of the end-members [5], but empirical estimations of σ for intermediate members of solid solutions are rare.

The aim of this work was to determine interfacial tensions of intermediate members of a number of binary (ideal and non-ideal) solid solutions and to correlate them with the corresponding solubilities (Lippmann's solidus relationships). The interfacial tensions were determined from nucleation experiments carried out at 25 °C in a solution calorimeter. As a final outcome, for each solid solution system an empirical $\sigma(x)$ function of composition is proposed.

Tracing anthropogenic nitrogen in the vicinity of industrial emitters in the Athabasca oilsands region, Alberta, Canada

B. PROEMSE[1]*, B. MAYER[1] AND M. FENN[2]

[1]Department of Geoscience, University of Calgary, 2500 University Drive NW, Calgary, Alberta, T2N 1N4 (*correspondence: bcpromse@ucalgary.ca)
[2]USDA, Forest Fire Laboratory, 4955 Canyon Crest Dr., Riverside, CA 92507, USA

The Athabasca oilsands deposit in northeastern Alberta, Canada, constitutes an unconventional energy source that is becoming increasingly important as the supply of conventional oil decreases. However, the rapid expansion in the exploitation of this oil resource over the last few years has caused increasing concerns regarding potential effects of elevated nitrogen (N) deposition. Hence, monitoring of N deposition and a better understanding of the N cycle in the Athabasca oilsands region are crucial for a thorough assessment of the impacts of elevated N emissions and depositions on surrounding terrestrial and aquatic ecosystems. Stable isotope techniques were used to trace the sources and fate of anthropogenic N emitted from the oilsands development. We determined $\delta^{18}O$ and $\Delta^{17}O$ values of atmospheric nitrate and $\delta^{15}N$ values of nitrate and ammonium collected in bulk deposition at various distances from the industrial emission sources to gain a better understanding of atmospheric N cycling in the vicinity of the industrial emitters. $\delta^{15}N$ values of total N in bitumen and oil sand samples were ~2‰. $\delta^{15}N$ values of atmospheric nitrate and ammonium varied with season and distance from the industrial emission source. Biogenic nitrogen emissions appeared to affect the isotopic composition of atmospheric nitrate in the summer ($\delta^{15}N$ -4.9 to +1.9‰), while vehicle exhaust appeared to be a major NO_x contributor influencing $\delta^{15}N$ values of atmospheric nitrate in the winter (-2.0 to +6.3‰). $\delta^{15}N$ values of ammonium as high as +10‰ close to the emission stack are believed to be associated with NH_3 released by the bitumen desulfurization process. $\Delta^{17}O$ analyses on atmospheric nitrate (n=22) showed non-zero values (+15.3 to +32.0‰) and hence mass-independent isotope fractionation. There was a trend towards higher $\Delta^{17}O$ values of atmospheric nitrate with increasing distance from the emission source, confirming the anthropogenic origin of nitrate in the vicinity of Athabasca oilsands development. We conclude that isotope analyses on atmospheric N compounds can reveal important information about sources and fate of natural and anthropogenic N compounds.

High-temperature gold deposits of Transbaykalia (Russia): Ore fluids compositions and its connection with magmatic process

V.Y. PROKOFIEV[1], N.N. AKINFIEV[1] AND L.D. ZORINA[2]

[1]IGEM RAS, Russia, Moscow, Staromonetny st., 35 (vpr@igem.ru)
[2]Vinogradov Imstitute of geochemistry, 664033, Russia, Irkutsk, Favorsky st., 1a (irazor@rambler.ru)

There are some atypical gold deposits with high-temperature veinlets-dissiminated ore at the territory of East Zabaykaliya (Talatuy, Kariyskoe, Pilinenskoe and others). Except Au, from the ore of these deposits can be extracted Ag, Cu, W, Mo, Bi. The Main mineral ore assotiation – tourmaline-pyrite-magnetite. The early native gold has high fineness (up to 996‰), silver deposits in late associations under low temperatures. Alteration of host rocks are presented by prophilites and orthoklasites. Three types of fluid inclusions are recognized: (1) inclusions of chloride brine that contain a gas bubble, water solution, one or several isotropic crystals, and occasionally an opaque ore mineral; (2) substantially gas inclusions that contain gas with a thin rim of aqueous solution and an occasional cubic isotropic crystal; and (3) two-phase gas–liquid inclusions of diluted solutions. The results of thermo- and cryometric studies, which involved 440 individual fluid inclusions in quartz and calcite, indicate that Mg, Na, and occasionally Ca chlorides participated in the ore formation. The complete homogenization of brine inclusions is achieved at a temperature of 610–270°C, and the salt concentration amounts to 56.3–29.9 wt % NaCl equiv. The gas fluid inclusions are homogenized into gas at 590–290°C and contain a fluid with salt concentrations ranging from 33.8 to 0.9 wt % NaCl equiv. Some inclusions contain carbon dioxide. The pressure estimates based on the inclusions of this type are 1170–110 bar. The two-phase gas–liquid inclusions of diluted solutions are homogenized into liquid at 495–145°C. The salt concentration in solutions that fill inclusions varies from 23.2 to 0.4 wt % NaCl equiv. The chemical composition of fluid inclusion was studied. Fe, Cu, Mo, Zn, Pb, Au, Ag, Bi and the other elements were determined into fluid composition. The ore formation at the deposits of this type took place against the background of boil-off (heterogenization) of chloride fluid near the cooling magma pocket. The particularities of the chemical fluid composition witness about the occurrence of magmatic fluid. The thermodynamic model of gold and silver separation in such fluid-magmatic system was built.

Organic matter alteration due to high heat flow in the northern Gulf of California

ROSA M. PROL-LEDESMA[1], CATALINA ANGELES[2], RUTH VILLANUEVA-ESTRADA[1] AND CARLES CANET[1]

[1]Departamento de Recursos Naturales, Instituto de Geofísica, Universidad Nacional Autónoma de México, Ciudad Universitaria, Delegación Coyoacán, 04510 México D.F., México

[2]Posgrado en Ciencias del Mar, Instituto de Ciencias del Mar y Limnología, Universidad Nacional Autónoma de México, Ciudad Universitaria, Delegación Coyoacán, 04510 México D.F., México

Studies in the northern Gulf of California have discovered high heat flow anomalies related to intensive gas discharge in the Wagner and Consag basins. The basins present a thick sediment cover of at least 5 km and bathymetry data show a maximum depth of 200m. Both basins have intense seismic activity and they are similar to other tectonically active basins in the Gulf of California plate border system. Intense gas discharge has been reported along the Wagner Fault, which is a continuation of the San Andreas transform fault. Chemical studies of the sediments from the Wagner Basin show that they have been subject to alteration of the sediment organic matter due to hydrothermal activity, similarly to what has been reported in the Central Gulf of California (Guaymas Basin), where high heat flow has been related to hydrocarbon generation and thermogenic methane abundance. Identification of the isoprenoid (PM1) related to the phylum Crenarchaeota is evidence of high temperature (75 to 105 °C) as this is the optimal temperatura for those organisms. High variability was observed in the maturity of organic matter in the sediments of the basins in correlation with the presence of hydrothermal activity.

Microbial community development and mineral-organic matter interactions in an artificial soil incubation experiment

GEERTJE J. PRONK[1], KATJA HEISTER[1], GUO-CHUN DING[2], KORNELIA SMALLA[2] AND INGRID KÖGEL-KNABNER[1]

[1]Lehrstuhl für Bodenkunde, Technische Universität München, Freising-Weihenstephan, Germany

[2]Julius Kühn-Institut (JKI), Institute for Epidemiology and Pathogen Diagnostics, Braunschweig, Germany

Artificial soils with 8 different mixtures of illite, montmorillonite, ferrihydrite, boehmite, charcoal and quartz sand, and manure as organic matter (OM) source were inoculated with the same microbial extract and incubated up to 18 months. The artificial soils were incubated under constant environmental conditions so that the effect of microbial activity on OM-mineral interactions alone could be studied.

The amount of organic carbon (OC) associated with minerals and microaggregates was determined by density fractionation. Solid state ^{13}C nuclear magnetic resonance (NMR) spectroscopy was used to characterize OC composition. Development of the microbial community in the first 90 days was followed by denaturing gradient gel electrophoresis (DGGE) analysis of 16S rRNA gene fragments amplified from total community DNA.

Density fractionation showed that significant microaggregation took place within 3 months of incubation and up to 24% of the OC present was associated with microaggregates and minerals in all mixtures at the end of incubation. This indicates that a fast development of OM-mineral interactions took place, providing microbial habitats. This is supported by the development of the bacterial community structure in the artificial soils, which depended on the mineral composition. Charcoal was shown to strongly influence the reassembly of bacterial communities. Effects of montmorillonite, illite and iron oxide on microbial communities were observed at day 90.

The results clearly show that mineral composition shaped the microbial community structure. This experiment therefore allows for the study of the development of organic matter-mineral associations, facilitated by micro-organisms, from clean model materials to soil-like systems.

Funginite and secretinite in coals Southern Pechora basin

O.S. PROTSKO

Institute of Geology of Komi Science Center Ural Branch of Russian Academy of Sciences, Syktyvkar (procko@geo.komisc.ru)

Funginite and Secretinite are one of not enough studied components inertinite maceral group. Earlier these components were called Sclerotinite. These components are rare in the Permian coals and sedimentary rocks (1-3 %). Content funginite and secretinite a increased to 10 % in Permian coals of their Nechensky layer. Nechensky low-rank coal deposits located in southern Pechora basin. The well section consists from is thin-is rhythmical alternating layers of different types coals, coals argillites and clays.

Secretinite occur in 15 samples, contents <1 - 9.5 %, on the average 3-5 %. The maximum content is revealed in the high part of a layer coals argillite, in other samples don't observed defined dependence to concrete types of rocks, it meets both in argillite, and in semibrilliant coals. The small part of inclusions secretinite it is concentrated in gelification layers and it is possibly characterized by the transferred forms. Funginite is found out in 29 samples, its content changes <1 – 10 %, on the average 5 %. Variation of funginite also non-uniformly on a section also meets in all rocks types. Its maximum content of 10 % mets in a layer coals argillite, height 100 mm. Often secretinite occurs together with funginite, e.g. in a layer of semimatte coal (обр 408-42) occur inclusions funginite (to 8 %) and secretinite (to 2 %). High contents the inertinite maceral group and minerals matter occurs together with for samples with inclusions funginite. Probably, these components indicate to oxidizing conditions sedimentation and swamp conditions with active hydrodynamics.

Classical geothermobarometry versus pseudosections: Practical experiences and strange encounters

A. PROYER[1]* AND E. BRUAND[2]

[1]Institute of Earth Sciences, University of Graz, 8010 Graz, Austria (*correspondence: alexander.proyer@uni-graz.at) p.a.: Inst. of Geological Sciences, FU Berlin, 12249, Berlin

[2]SEES, University of Portsmouth, Portsmouth PO1 3QL, UK

Practical experiences with geothermobarometry of the classical type and with pseudosections have revealed a number of particularities that might be of interest to both petrologists and geodynamicists trying to transform *P-T* data into geodynamic models. As an example, Fe-Mg geothermometry with grt-cpx in an eclogite can err considerably when ferric iron is not measured but calculated from stoichiometry. Such a deviation by >200°C could only be detected after Moessbauer microspectroscopy on garnet and clinopyroxene. The average*PT*-method (av*PT*) of THERMOCALC however, as a multi-equilibrium technique, is not as sensitive to these Fe-Mg exchange reactions and produced the correct result in the first place. Av*PT* has the potential to highlight a wrong choice of 'phases in equilibrium' but can also give (apparently correct) results on disequilibrium assemblages if its statistical elimination procedure is not used with proper diligence. Pseudosection modelling of eclogites with PERPLEX revealed two weaknesses. One is intrinsic to PERPLEX: significant changes in the shape and topology of some assemblage fields when the grid refinement parameters are changed. The second is due to the activity-composition models, mainly of amphibole, which results in more or less unrealistic assemblages and or mineral compositions, no matter what amphibole model is used. Two examples of THERMOCALC pseudosection modelling also produced significant inconsistencies with observation, i.e. 'unpublishable' diagrams. In a metapelite, the rather open secret of poor thermodynamic data for Mn-phases resulted in the fact that the calculated garnet composition isopleth just would not match those observed in the rock. In a metabasite, quartz predicted as stable in a large *P-T* range around peak conditions is not found in the rock – reason hitherto unknown. As 'failed results' usually (not always) escape publication, such weak points of methods are probably discussed less than they ought to be. The main problem is still the lack or scarcity of good thermodynamic data for many substances. Whereas pseudosection and geothermobarometry calculations are popular tools, we find that segment of experimental petrology which generates the fundamental data largely abandoned today.

The stable vanadium isotope composition of the bulk silicate Earth

J. PRYTULAK[1]*, S.G. NIELSEN[1,2] AND A.N. HALLIDAY[1]

[1]University of Oxford, Dept. of Earth Sciences, South Parks Road, Oxford, OX1 3AN, UK (*correspondence: Julie.Prytulak@earth.ox.ac.uk, alex.halliday@earth.ox.ac.uk)

[2]WHOI, Department of Geology and Geophysics, 266 Woods Hole Road, 02543, Woods Hole, MA, USA (snielsen@whoi.edu)

We have developed the first analytical method capable of producing accurate stable vanadium isotope ($^{51}V/^{50}V$) compositions to a precision useful for geologic problems [1, 2]. Vanadium exists in multiple valence states (V^{2+}, V^{3+}, V^{4+}, V^{5+}) and its partitioning is directly related to changing oxidation states. Stable vanadium isotopes are expected to respond to oxidation-reduction processes, although this has yet to be demonstrated. USGS reference materials display significant, resolvable isotope variation [2] and the system appears to have great potential for a variety of geologic applications including studies of oceanography, igneous petrology, oxygen fugacity, cosmochemistry, and hydrocarbon genesis. The first step to enable the application of new 'non-traditional' stable isotope systems is to estimate and define the bulk silicate earth (BSE). Here we present measurements of peridotites, suites of Mid-Ocean ridge basalts, picrites and other primitive mantle-derived magmas to permit an initial estimate of BSE. Our results support an analytically significant difference between terrestrial and extraterrestrial material [2, 3].

Mechanisms controlling the release, transport and attenuation of mercury in riverine sediments

C.J. PTACEK*, K.A.N. DESROCHERS, B.D. GIBSON, P. LIU, O. WANG, J.A. TORDIFF, S.D. DAUGHERTY, K.E. BLOWES, J. VAN DE VALK, M.B.J. LINDSAY, AND D.W. BLOWES

Department of Earth and Environmental Sciences, University of Waterloo, Waterloo, ON, Canada (*correspondence: ptacek@uwaterloo.ca)

The release and transport of Hg at industrial sites are controlled by a complex series of interrelated physical and biogeochemical processes. This study evaluated mechanisms controlling the release and transport of soluble and particulate forms of Hg from contaminated river sediments and the effectiveness of amending the sediments with reactive media to stabilize Hg. The sediment was characterized using sequential extractions and synchrotron radiation based techniques. Long-term column experiments, 6-8 months in duration, were conducted under variable flow conditions. During the early stages of the experiments, concentrations of Hg in the column effluent increased sharply after periods of flow stagnation, whereas, during later stages, the releases were lower and spikes were not observed after stagnations. The observed releases were not correlated to the masses of Hg released in the sequential extraction analyses. Reactive media, including clay, C, S and Fe bearing media, were added in batch style experiments as single-media additions or in combinations. Amendment of the sediments reduced the aqueous Hg concentrations by 50 to >99%. Under continuous saturated flow conditions, concentrations of Hg in the column effluent were maintained in the low ng L^{-1} range for the amended sediment. Following periods of stagnation, concentrations of Hg increased in the column containing the unamended sediment and the sediment amended with clay, whereas sediment amended with C, S, and Fe bearing media showed no increases. These results indicate that large decreases in Hg concentrations can be achieved under varying flow conditions through the addition of reactive media.

Evolution of deep mantle sources as inferred from Os-Nd isotope systematics of Archean komatiites

IGOR S. PUCHTEL AND RICHARD J. WALKER

Dept. of Geology, University of MD, College Park, MD 20742, USA (ipuchtel@umd.edu, rjwalker@umd.edu)

We present ^{190}Pt-^{186}Os and ^{187}Re-^{187}Os isotopic and highly siderophile element (HSE) abundance data for eight well preserved komatiite systems from around the globe, including 3.6 Ga Schapenburg, 3.5 Ga Komati, 3.3 Ga Weltevreden, 2.9 Ga Kamennoozero, 2.8 Ga Kostomuksha, 2.7 Ga Belingwe, 2.7 Ga Abitibi, and 2.5 Ga Vetreny. These data provide important insights to the evolution of absolute and relative HSE abundances in the deep mantle throughout the Archean. Based on precise initial $^{186}Os/^{188}Os$ and $^{187}Os/^{188}Os$, models for the komatiite sources suggest long-term evolution to the times of melting with $^{190}Pt/^{188}Os$ and $^{187}Re/^{188}Os$ of 0.00183±15 and 0.412±8, respectively ($2\sigma_{mean}$). These source parameters are remarkably uniform and fall well within the range of those measured in chondritic meteorites. The evolution of the komatiite sources over >1 Ga generally shows no shifts in trajectory that would reflect major changes in Pt/Os or Re/Os, as might occur due to progressive melt extraction or crustal recycling. Over the same time interval, absolute HSE abundances in the komatiite sources increase. The trend, however, is far from linear; e.g. Pt abundances in the sources increase from 2 ppb to 6 ppb between 3.6 and 3.3 Ga and then level at 6 ppb through the rest of the Archean. In contrast, the komatiite sources were characterized by strong depletions in highly incompatible lithophile trace elements, as compared with chondrites. Sm-Nd isotopic data indicate evolution with time-integrated $^{147}Sm/^{144}Nd$ averaged at 0.214±3 and 0.209±1 for the early and late Archean systems, respectively. The collective Os-Nd results indicate that during the period of time examined, processes acting on the mantle sources affected Sm/Nd, yet did not substantially modify Re/Os or Pt/Os. These characteristics are consistent with mixing between two mantle reservoirs. The Sm-Nd constraints on the earliest reservoir are similar to the hypothesized Early Depleted Reservoir of Boyet and Carlson (2006). This could represent either a primitive early crust, or a reservoir created during magma ocean crystallization. The lower HSE, yet chondritic Re/Os and Pt/Os, would be consistent with the establishment of this reservoir by late accretion, but prior to accumulating a full complement of HSE. The second reservoir would potentially be representative of the upper mantle.

Chondritic-like xenon in the Archean atmosphere

MAGALI PUJOL[1] AND BERNARD MARTY[2]

[1]ETH - Zürich, Switzerland (magali.pujol@erdw.ethz.ch)
[2]CRPG-CNRS, Nancy Université, Vandoeuvre les Nancy France (bmarty@crpg.cnrs-nancy.fr)

Xenon in the present-day atmospheric is depleted compared to lighter atmospheric noble gases and isotopically fractionated (i.e. enriched in heavy isotopes) by 3-4 % par amu related to condritic or solar Xe. Because it is the heaviest noble gas, any mass dependent process such as atmospheric escape would have resulted in the reverse situation, that is, bettter retention of Xe and lower isotopic fractionation of Xe compared to e.g. Kr. This observation, known as the xenon paradox is one of the most intersting problems in geochemistry. It has resisted decades of modeling efforts.

We have reported in [1] the analyses of xenon and other noble gases in meso-Archean sedimentary rocks (baryte and fluid inclusions in hydrothermal quartz) from North Pole (Pilbara, Australia), which show that Xe alone is isotopically fractionated and intermediate between chondritic and modern atmospheric compositions. This observation suggests that Xe isotopic fractionation, and, by inference, Xe depletion in the atmosphere was still ongoing 1 Ga after Earth's formation and was not limited to the Earth's building period as previously thought. In laboratory experiments, the only processes able to fractionate Xe isotopes at the percent level require ionization (e.g. [2]), suggesting that the fractionation of atmospheric Xe was related to the solar UV light during the first half of Earth's history. Independent evidence for deep UV penetration in the atmosphere stems from mass independent fractionation of sulfur isotopes trapped in Archean sedimentary rocks [3]. A delayed loss of atmospheric xenon has implications for the early evolution of Earth. The age of the Earth computed from retention of ^{129}Xe produced by the decay of ^{129}I ($T_{1/2}$ = 16 Ma) becomes ~50 Ma instead of ~110 Ma computed previously with the present-day inventory of atmospheric Xe. The depletion in the mantle and atmosphere of Xe isotopes produced by extinct ^{244}Pu ($T_{1/2}$ = 82 Ma) is more understandable if Xe loss continued well after the decay of plutonium-244.

Noble Gas in Basin Centred Gas: Sampling techniques and preliminary results

MAGALI PUJOL[1]*, SANDER VAN DEN BOORN[2], BERNARD BOURDON[3], ROLF KIPFER[4], RAINER WIELER[1] AND MATTHIAS BRENNWALD[4]

[4]EAWAG, 8600 Dübendorf, Switzerland

Noble gas have become a powerful tool to constrain the origin of fluids as well as the rates of fluid migration in sedimentary basins and have found applications in environmental and petroleum research [1]. The aim of this study is to apply some of these concepts to understand the genesis and evolution of Basin Centred (Hydrocarbon, HC) Gas (BCG) systems, which are abnormally pressured pervasive accumulations of gas in tight reservoirs. Poor understanding of HC gas-water interaction in the subsurface and the mechanism of gas transport make the inert noble gasses ideally suited for the geochemical investigation of these systems' dynamics. Natural lab for this study is the Deep Basin of the Western Canadian Sedimentary Basin (WCSB) in Alberta (Canada) where HC gas is being produced from tight Cretaceous sandstones [2].

Twenty wells were selected in the Deep Basin including a transect from the deep southwestern part of the basin to shallower regions in the northeast. Samples were collected in 500cc stainless steel cylinders using two different sampling techniques: (1) collection in pre-evacuated cylinders without purging ('vacuum technique'), and (2) collection in cylinders that were purged for 15 seconds ('purged technique'). All samples were analyzed for He, Ne, Ar, Kr and Xe concentrations and selected isotopes.

Noble gas concentrations in HC gas from the Deep Basin are extremely low and large differences were observed between 'purged' and 'vacuum' samples from individual wells. These inconsistencies are believed to be largely the result of contamination of the vacuum samples by dead volumes in the sampling line. Lab experiments demonstrate that purging cylinders for 15 seconds is sufficient to eliminate potential mass fractionation artefacts. Despite some remaining uncertainties related to the sampling protocol, the preliminary noble gas data of Deep Basin natural gas show some interesting trends which may provide new insights into gas-water interactions in the subsurface.

The transfer of aqueous fluid and melt at high pressures is an essential mechanism in the creation, evolution and dynamics of terrestrial planets like Earth's. Volatiles control the density and viscosity of magmas generated in the Earth's interior and have an important effect of melt segregation processes. The densification of melt under high pressure conditions and the general density between the melt and solid components are very important to understand the heterogeneities of the Earth's mantle. Experimental studies show coexisting aqueous fluid and melt phases at high pressure and temperature conditions. Therefore, the current paradigm in geosciences is if aqueous fluid and melt can be coexist in natural peridotites formed at P-T conditions of 5GPa and 1300°C. Aqueous fluid and initially formed melt moves preferably along grain boundaries. The problem to detect aqueous fluid along grain boundaries is that H_2O has a higher solubility in the melt as in anhydrous nominally minerals. Thus, the aqueous fluid will partitioning in the melt during the uplift of the peridotite xenoliths to the Earth's surface. We have overcome this problem by using high-resolution synchrotron based FTIR images of higher dimensional defect structures within garnet revealing a strong variation of aqueous fluid and melt concentration at all length scales. Our analysis has three major ramifications: *i)* it shows aqueous fluid around monomineralic grain boundaries in the lithospheric mantle; *ii)* it shows coexisting aqueous fluid and melt under P-T conditions of 5GPa and 1300°C; *iii)* it shows fundamental reassessment of the dynamics of aqueous fluid transfer within the lithospheric mantle. This research was supported by the Mid-career Researcher Program through an NRF grant funded by the MEST (No. 3345-20100013) and is a contribution to UNESCO IGCP 557.

Mantle-protocore system evolution in the case of heterogenic accretion: Paleomagnetic and isotopic evidences

Y.D. PUSHKAREV[1]* AND S.V. STARCHENKO[2]

[1]Institute of Precambrian Geology and Geochronology, St.-Petersburg, Russia
(*correspondence: ydcanon@rambler.ru)
[2]Institute of Terrestrial Magnetism, Troitsk, Moscow, Russia

The Earth evolution model for the case of heterogeneous accretion is developed as alternative to traditional hypotheses. According to this model the considerable part of the Fe and Ni should initially concentrate in the protocore in which content of the metal component was decreasing to the periphery, but content of chondrite silicates was increasing. The evolution of such 'mantle-protocore' system begins with fast formation of the liquid core geosphere in outer part of the planet. This geosphere expands while moving down, but due to growth of pressure the melting of metal is replaced by its slow erosion on the protocore surfaces. It occurs owing to interaction of metal and such component of the liquid core as S or FeO which lowers temperature of melting. During the protocore erosion its silicate component is liberated and than floats-up through liquid core, producing composite convection which is the main drive of geodynamo. The model calculations show that this process could culminate in early Precambrian, and so the evolution of paleomagnetc records should be observed. At the same time the emerging of the protocore silicate component to the lower mantle should be accompanied by appearance of elements having isotope characteristics of the chondritic material (the high contents of ^{3}He, ^{20}Ne, ^{129}Xe, ^{204}Pb). All these effects most likely confirm the reality of the described scenario of the 'mantle-protocore' system evolution. It is noteworthy that the energy released due to the protocore density differentiation (up to 20 TWT during 4 Ga) could be enough for a long overheat of the core-mantle boundary and for the plum-formation. The analysis of evolution of the geodynamic activity demonstrates that maximum of such endogenous energy generation also corresponds to the early Precambrian.

The interplay between chemical and textural evolution across a shear zone

ANDREW PUTNIS[1]*, HÅKON AUSTRHEIM[2] AND CHRISTINE V. PUTNIS[1]

[1]Institut für Mineralogie, University of Münster, Germany
(*correspondence: putnis@uni-muenster.de)
[2]Physics of Geological Processes, University of Oslo, Norway

The extent to which chemical reactions and mineral replacement reactions due to fluid infiltration influence textural evolution during the formation of shear zones is described from anorthositic granulites in the Lindås Nappe, Bergen Arcs, Norway, where the Grenvillian age granulites (~930 My) are transected by Caledonian age (~420My) eclogite and amphibolite facies shear zones [1, 2]. We focus on the evidence for fluid-induced reactions in the plagioclases which form coarse, clear crystals with composition ~An_{50} in the most pristine anorthositic granulites and become milky as the shear zone is approached, reacting with fluid to form more albitic plagioclase (~An_{25}) with numerous inclusions of clinozoisite, and finally developing an intracrystalline domain structure defined by planar zones of composition ~An_{64} within the plagioclase (~An_{25}) crystals. This apparent 'chemical fragmentation' of the plagioclase single crystals is a precursor to the formation of the much smaller grain size plagioclase crystals within the shear zone. A combination of electron microscopic and analytical techniques is used to describe the interplay between the chemical reactions, the recrystallisation of the plagioclase and the physical deformation forming the shear zone.

The importance of the fluid-mineral interface in the control of crystal growth

CHRISTINE V. PUTNIS[1]*, ENCARNACIÓN RUIZ-AGUDO[2], LIJUN WANG[3], JOLANTA KLASA[1,4] AND ANDREW PUTNIS[1]

[1]Institut für Mineralogie, University of Münster, D-48149 Germany (*correspondence: putnisc@uni-muenster.de)
[2]Department of Mineralogy and Petrology, University of Granada, 18071 Granada, Spain (encaruiz@egr.es)
[3]Huazhong Agricultural University, Hubei 430070, Wuhan, China (ljwang@mail.hzau.edu.cn)
[4]Mineralogy Department, Natural History Museum, SW7 5BD London, UK (j_klas03@uni-muenster.de)

Atomic force microscopy (AFM) experiments have shown that growth on mineral surfaces can occur from solutions when the bulk fluid composition is undersaturated with respect to the precipitating phase. The implication is that the composition of the solution in the fluid boundary layer in contact with the mineral surface must become supersaturated with respect to the new phase growing at the mineral surface. This has been reported in a number of systems, including the growth of new phases on calcite cleavage surfaces, such as Ca phosphonates [1], and on gypsum surfaces, such as Ca phosphates [2], where the dissolution of the substrate provides ions included in the new phase. The thickness of the boundary layer can be estimated by considering the following: the solubility of the solid in the fluid phase; the diffusion rate of the dissolved ions in the fluid phase; the composition of the fluid; the saturation state of the fluid with respect to all possible phases; possible epitaxial relationships between the mineral surface and the new phase.

The concept of a boundary layer becoming supersaturated with respect to another phase, which then precipitates, is essential for the understanding of coupled dissolution-precipitation as a mechanism of mineral replacement [3]. Real-time phase-shift interferometry has been used to show the steep compositional gradient at the surface of a crystal of KBr being pseudomorphically replaced by KCl [4] and this has been used as a model system for more complex Earth systems involving mineral-fluid reactions during such processes as metasomatism, metamorphism and weathering. This concept is also relevant to many industrial processes and nuclear waste management.

Mantle metasomatic events related to alkaline volcanism during incipient rifting: NE Eger Rift (Central Europe) example

J. PUZIEWICZ[1]*, M. MATUSIAK-MAŁEK[1], T. NTAFLOS[2] AND M. GREGOIRE[3]

[1]Univ. Wroclaw, Poland (*correspondence: jacek.puziewicz@ing.uni.wroc.pl)
[2]Univ. Wien, Austria (theodoros.ntaflos@univie.ac.at)
[3]CNRS-UMR 5562, Univ. Toulouse, France (michel.gregoire@get.obs-mip.fr)

Mantle metasomatism is preceding alkaline volcanism at initial stages of continental rifting. The complete example of its various effects is offered by xenolith suite occurring in the Miocene Księginki nephelinite (SW Poland). The latter occurs at the NE termination of the Eger Rift, the easternmost of the rifts forming the European Cenozoic Rift System.

The lithospheric mantle was infiltrated by alkaline silica-undersaturated magma resembling the Księginki nephelinite. Olivine clinopyroxenites originated by crystal accumulation in channelized magma flow. The 'Fe-metasomatism' operated in mantle harzburgites subjected to pervasive magma flow. It lowered olivine Fo (down to 86 %) and resulted in REE patterns of clinopyroxene identical to those ocurring in olivine clinopyroxenites. The clinopyroxene megacrysts occurring in the Księginki nephelinite are the remnants of very coarse-grained clinopyroxene cumulates, uncompletely solidified and disaggregated during eruption. The fine-grained glass-bearing aggregates of olivine + clinopyroxene ± plagioclase or titanian phlogopite offer the snap-shot picture of the various stages of metasomatism and show that part of the xenoliths resided shortly in transient magma chambers located near the Moho, under pressures enabling plagioclase crystallization. Alternatively plagioclase crystallization in melt pockets could take place en route to the surface at low pressures. All the lithospheric mantle section sampled by the Księginki nephelinite was thermally rejuvenated during volcanism and shows the temperatures of 1060 - 1120 °C.

The Lower Pre-Cambrian, the Urals

A.M. PYSTIN AND YU.I. PYSTINA

Institute of Geology, Komi Science Centre, Uralian Branch of RAS, Syktyvkar

The presence of Early Pre-Cambrian complexes is mostly proved in the western paleocontinental part of the Urals (to the west from the Main Uralian Deep Fault). Polymetamorphic complexes, different in material composition, structure, and metamorphic peculiarities of rocks, are related to them. The main types can be established among them: gneiss-granulite, gneiss-migmatite, crystallo-schist, granulite-metabasite, eclogite-gneiss, and eclogite-schist one [1].

The metamorphic evolution of rocks constituting the polymetamorphic complexes in the western part of the Urals (the western slope of the Urals) falls down within the interval 2.7–0.35 Ga.

Distinctions in material composition, as well as facial conditions, and especially the type of rock metamorphism allow for distinguishing two groups of the polymetamorphic complexes. One of them is characterized by moderate-pressure metamorphism and prevalence of acidic rocks in a section, mainly of initially-sedimentary origin. In the other group, the essential role belongs to initially-magmatic formations, mainly of the basic series, which underwent high-pressure metamorphism. It is possible to allocate vertical (age) series of the polymetamorphic complexes in each of the named two groups. The first vertical (age) series is composed of (from below-upwards): gneiss-granulite →gneiss-migmatite →crystallo-schist complexes. The second vertical series is made of (from below-upwards): granulite-metabasite → eclogite-gneiss→ eglogite-schist complexes.

Along with the vertical series, certain lateral relations between the various complexes, indicating their formation in different geodynamic settings, are outlined.

Available geochronological data allow one to conclude that distinctions in geodynamic settings during formation of the considered structural-material complexes existed, beginning at least with the Late Archaean and then lasting throughout the Early Proterozoic. The established regularities in composition and structure of the polymetamorphic complexes of the Western Uralian slope, as well as ages of initial high-temperature metamorphic manifestations (the granulitic and eclogitic facies) give reason to think that they are fragments of the crystalline basement of Volgo-Uralian part of Baltica.

Modern sedimentation rate and heavy metal accumulation in Jiaozhou Bay sediments

J. QI

Guangdong Food and Drug Vocational College, Guangzhou 510520, PR China (jungzh@163.com)

Introduction

The sediments that accumulate in Jiaozhou Bay of the Shandong Peninsula recorded the information about the history of changes in the source of the material, the rate of deposition and the influence of human activies [1, 2]. Six cores were collected from the Jiaozhou Bay by the Cruise work on Gold Star boat on Sep. 6th, 2003. The ^{210}Pb radioactivities of the sediments were determined by ^{210}Pb geochronology method and ICP-MS was employed for the determination of Zn, Cu, Cr, Ni, Pb, Cd and Co concentrations.

Discussion of Results

The sedimentation rates were found to be higher in margin areas of the bay, especially in the dumping areas, where the rates were about 0.77cm/a ~ 3.96cm/a. While in the central region of the bay, there was a patch of fine-grained mud, with the sedimentation rates being lower. The profiles ^{210}Pb radioactivity at sample cores mostly appeared in two-segment model, which indicate that the modern sedimentary environment of this region was very stable. Differences in the profiles reflect spatial and temporal variations in hydrodynamic conditions and the grain size of sediments in the Jiaozhou Bay.

The main heavy metals in the sediments of Jiaozhou Bay were Zn, Cu, Cr, Ni and Pb, while the concentrations of the elements Cd and Co were much lower. The concentrations of the main heavy metals of the sediments in Jiaozhou Bay were higher than that in the China Shelf Sea, which showed that the area had been contaminated to a certain extent. But these concentrations were low in comparison with the highest background level in former global modern industrialization times and that in other industrialized areas. The heavy metal profiles Zn, Cr, Ni, Co and Pb from the six cores showed a high variability, but also a decreasing trend since 1980s, while the element Cu presented an increasing trend and the element Cd presented a more chaotic profile than the other elements.

The bioavailability of selenium and risk assessment for human selenium poisoning in Se-high areas, China

H-B. QIN[1,2], J-M. ZHU[1]* AND H. SU[3]

[1]State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (*correspondence: zhujianming@vip.gyig.ac.cn)

[2]Graduate University of Chinese Academy of Sciences, Beijing 100049, China

[3]Center for Disease Control and Prevention of Enshi Prefecture, Enshi 445000, China

Enshi, China, is one of the selenosis areas in the world, where sporadic cases of selenium (Se) poisoning in livestock and human were still being found at present. However, selenium bioavailibility in soils and current situation on intake of Se by human have not been reported in detail. In this study, selenium levels and its speciation in water and cropland soils, Se content in crops from Enshi were investigated, as well as estimating the daily intake of Se by local residents. Results showed that the geometric mean of Se concentration was 54.2 μg/L (2.0-519.3 μg/L, *n*=62) and 6.2 mg/kg (2.67-87.3 mg/kg, *n*=37) in water and soils, respectively. Selenium content ranged from 0.18 mg/kg to 37.1 mg/kg in crops, which was dependent on crop species and Se bioavailability in soils. On the basis of consumption and Se contents of foods, cereal consumption is the major pathway of Se intake by local residents, followed by vegetables, meats, and drinking water. The total daily intake of Se was approximately 3000 μg/day for human in Se-high areas in Enshi, which was considerably higher than the upper tolerable nutrient levels (UL, 400 μg/day) referred by WHO and US EPA, suggesting that a high risk for human chronic Se poisoning still exists in this areas. Furthermore, the daily Se intake through drinking water (108.4 μg/day) was up to 27.1% of referred Se UL. Thus, unlike previous studies, it is should not ignore the contribution of Se in drinking water when assessing the health risk for human daily intake of Se in Se-high areas. Local residents should be advised to avoid planting crops in areas with Se-high soils or irrigated by Se-high water, and to consume foods mixed with the exotic.

The study was supported by the Knowledge Innovation Program of the Chinese Academy of Sciences (KZCX2-YW-JC101), and the National Natural Science Foundation of China (40973085, 40721002, 40573050).

Cr isotope fractionation during biogeochemical reduction of Cr(VI) by Hanford native aquifer microbial communities

L. QIN*, J.N. CHRISTENSEN, S.T. BROWN, L. YANG, M.E. CONRAD, E. SONNENTHAL AND H.R. BELLER

Lawrence Berkeley National Laboratory, 1 Cyclotron Rd., Berkeley, CA 94720 (*correspondence: lqin@lbl.gov)

Hexavalent Cr contamination in groundwater within the DOE complex has been a long-standing issue. Injection of electron donors, such as lactate, to Cr contaminated aquifers to stimulate the growth of native microbial communities, and thus promote reduction of Cr (VI) to Cr (III), has become a widely utilized remediation practice. However, whether these conditions are optimal for Cr reduction is to a large extent unknown. It has been demontrated that reduction of Cr (VI) can cause Cr isotope fractionation [1, 2]. The Cr fractionation factor changes under varying experimental conditions even with the same bacterial strain [2]. Cr isotopic measurements are more direct and effective than concentration analyses to distinguish between different reduction pathways, and also between reduction and simple dilution.

To evaluate the effects of differing electron acceptors on Cr (VI) reduction by native microbes, small-scale column experiments with homogenized material from the Hanford 100H aquifer were conducted. All columns had a continuous inflow of solutions with constant concentrations of Cr (VI), lactate, and the targeted electron acceptor (nitrate, sulfate, no electron acceptor added). Different Cr fractionation behaviors were observed under different conditions. The least extensive Cr reduction occurred in no-electron-acceptor-added columns and had the largest Cr isotope fractionation (α~0.997). The greatest Cr reduction occurred in two sulfate-containing columns that were fermenting the lactate. Samples from one such column had the smallest Cr fractionation (α~0.999). Denitrifying columns had intermediate α values. One sulfate-added (not fermentative) column showed two distinctive stages of fractionation, suggesting a change in reduction processes. Our α values mostly fall in the range 0.997-0.999, which are smaller than those observed in cell suspension experiments with *Shewanella oneidensis* and much lower lactate concentrations [2]. Reactive tranport modeling will be conducted to further evaluate the effects of various experimental parameters on Cr isotope fractionation.

Precise $^{40}Ar/^{39}Ar$ geochronology of gas migration and accumulation

H.N. QIU[1], J.B. YUN[1,2], H.Y. WU[2] AND Z.H. FENG[2]

[1]State Key Laboratory of Isotope Geochemistry, Guangzhou Institute of Geochemistry, CAS, Guangzhou 510640
[2]Exploration and Development Research Institute, Daqing Oilfield Company Ltd., Daqing 163712, China

It is very difficult to determine the exact age of natural gas emplacement because no suitable mineral for dating with common isotope geochronometers was formed during gas migration and accumulation, although illite K-Ar dating has been widely used to constrain the maximum ages of petroleum accumulation since Lee *et al*.'s [1] report. Selby *et al*. [4] demonstrated a possibility to date hydrocarbon deposits by Re-Os isotopes. Mark *et al*. [2] obtained oil migration age by UV laser microprobe $^{40}Ar/^{39}Ar$ dating of authigenic K-feldspar bearing oil fluid inclusions.

In this study, we show a novel promising approach to obtain high precision ages of gas emplacement into the Songliao Basin, NE China, by $^{40}Ar/^{39}Ar$ progressive crushing technique. The igneous quartz from the Cretaceous volcanic rocks in Yingcheng Formation (117–111 Ma) hosting the gas reservoir contains abundant K-rich secondary fluid inclusions (8.3–0.4 wt% in salinity) with high partial pressures of methane (66–9 MPa) trapped during gas emplacement. Based on our previous studies, quartz with abundant K-rich fluid inclusions provides an excellent closed system well suited for $^{40}Ar/^{39}Ar$ progressive crushing technique. Three irradiated igneous quartz samples were measured by stepwise crushing to release these secondary fluid inclusions. All three samples yielded well-defined $^{40}Ar/^{39}Ar$ isochrons with ages in close agreement, precisely constraining that the gas emplacement occurred at 42.4 ± 0.5 Ma (2SD) below the famous Daqing Oil Field in the Songliao Basin, extending possible gas reservoirs from the upper Cretaceous to the middle Eocene.

This study provides a new effective solution to gain the ages of gas emplacement. See [3] for detail.

The relationship between gabbros and I-type granites in the southeast coast of Fujian, South China: Evidence from *in situ* zircon U-Pb dating, Hf isotopes and whole-rock geochemistry

JIAN-SHENG QIU* AND ZHEN LI

State Key Lab for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China (*correspondence: jsqiu@nju.edu.cn)

Two representative gabbro–granite complexes from Quanzhou (QZ) and Huacuo (HC) in the southeast coast of Fujian, South China have been selected for a detailed geochronological and geochemical study, aiming to probe the genetic relations between the acid and basic magmas.

These complexes are composed predominantly of I-type granitoids, with lesser amounts of hornblende gabbro (<5% of the total igneous rocks). Zircon U-Pb dating yields consistent crystallisation ages of 109 ± 1 and 108 ± 1 Ma for the QZ gabbros and granites, and an age of 111 ± 1 Ma for the HC gabbros, which is contemporaneous with the spatially coexisted HC granites. Both the gabbros and granitoids are enriched in light rare earth elements and large ion lithophile elements (e.g. Rb, Ba, Th and U), and depleted in high field strength elements (e.g. Nb and Ta). Moreover, they show similarly homogeneous Sr–Nd isotopic compositions. All these factors indicate that they are genetically related.

Although the Sr–Nd isotopic signatures of the QZ and HC gabbros seemingly point to an enriched mantle source (EM-1), they have highly variable zircon Hf isotopic compositions, with ε_{Hf} (t) values ranging from negative to positive (specifically –4.6 to +6.1 for the QZ gabbros and –4.8 to +11.6 for the HC gabbros). On the other hand, their associated granitoids show relatively high whole-rock $\varepsilon_{Nd}(t)$ values (–2.5 and –4.1 for the QZ and HC granites, respectively), and homogeneous and neutral zircon $\varepsilon_{Hf}(t)$ values (–1.9 to +1.8 for the QZ granite). Based on an integration of petrography, geochronology and geochemistry, we interpret the parental basic magmas of these gabbros have originated from a depleted mantle source, but experienced a significant crustal contamination by the felsic melts that gave rise to the associated granitoids. Contributions from such a depleted mantle source resulted in the growth of juvenile basaltic lower crust, the partial melting of which generated the parental felsic magmas of the QZ and HC complexes.

A new recognition of Grenvillian volcanic suite in the South China Block and its connection with Rodinia assembly

X.F. QIU[1], W.L. LING[1]* AND X.M. LIU[2]

[1]State Key Laboratory of Geological Processes and Mineral Resources, China Univ. of Geosciences, Wuhan 430074, China (qxf_424@yahoo.com.cn,) (*correspondence: wlling@cug.edu.cn)

[2]State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi'an 710069, China (xiaomingliu@263.com)

Contrasting proposals have been suggested for the position of the South China Block (SCB) in the Rodinia reconstruction, which is partly due to a poor understanding of the SCB history during the late Mesoproterozoic to early Neoproterozoic. Here we report a newly recognized Grenvillian arc-volcanic sequence in the Shennongjia area, western SCB. It comprises alkali-, calc-alkaline basalts and tholeiitic andesitic rocks, and is dated at 1152±24 Ma. The alkali basalts have high TiO2, low Mg# (42-55) and positive εNd, and display OIB-like elemental patterns. By contrast, the calc-alkaline basalts have higher Mg# (57-68), Cr and Ni contents and large negative εNd, and exhibit pronounced depletion in HFSE. The andesites show Eu deficiency, HFSE depletion and small negative εNd.

The alkali-, calc-alkaline basalts are suggested to have been derived from depleted asthenospheric- and metasomatised lithospheric mantle sources, respectively, whereas the andesites from mafic lower crustal anatexis; the volcanic sequence was developed within an island-arc setting. Integrating with previously documented works, the western Yangtze craton is suggested to have comprised a collage of microcontinents during the Grenvillian period and underwent a westward lateral continental growth by subduction accretion and subduction-related collision. Increasing lines of evidence infer a western Yangtze-South Australia connection during Rodinia assembly, which provides a new insight into the SCB position in the supercontinent.

Raman spectroscopic analysis of heterogeneous carbonaceous matter in the 2.0 Ga Zaonega Fm, Karelia, Russia

Y. QU[1]*, M.A. VAN ZUILEN[1,2] AND A. LEPLAND[3]

[1]Centre for Geobiology, University of Bergen, Allegaten 41, 5007, Bergen, Norway (*correspondence: Yuangao.Qu@geo.uib.no)

[2]Equipe Geobiosphere, Institut de Physique du Globe - Sorbonne Paris Cité, Université Paris Diderot, CNRS, 1 rue Jussieu, 75238 Paris cedex 5, France (vanzuilen@ipgp.fr)

[3]Geological Survey of Norway, Leiv Eirikssons vei 39, 7491 Trondheim, Norway (Aivo.Lepland@NGU.NO)

Carbonaceous matter in sediments is gradually matured during metamorphism, as increased temperature causes structurally disordered organic molecules to rearrange themselves progressively into crystalline graphite. Raman spectroscopy is commonly used to describe the degree of this transformation, since the relative band intensities at 1350 cm-1 (D1) and at 1580 cm-1 (G) can be directly related to the defect-bound crystal domain size of graphitic crystallites. Intensity-based (R1) and especially area-based (R2) band ratios of carbonaceous matter have therefore been used as reliable indicators for the metamorphic grade that a rock has experienced.

The 2.0 Ga old Zaonega Formation in Karelia, Russia, contains sediments that are highly enriched in organic carbon. They represent the first known record of oil generation and migration on Earth, and form a key target for drill-core-based studies on the evolution of life during the Archean-Paleoproterozoic transition period. Carbonaceous matter consisting of residual kerogen and pyrobitumen throughout the succession has experienced local contact-metamorphism caused by gabbroic sills and lava flows, regional greenschist-facies metamorphism, and migration in silicate saturated fluid systems. This complex geologic history prevents simple straightforward interpretation of original isotopic ($\delta^{13}C$) and chemical characteristics of carbonaceous matter, and requires an *in situ* tool such as Raman spectroscopy to distinguish between variously altered carbonaceous fractions and small scale heterogeneities.

Here we report the variation in Raman spectral indicators R1 and R2 of carbonaceous matter throughout a 7 m long drill-core section that represents the upper contact zone of a gabbroic sill. Considerable heterogeneity in both R1 and R2 on a small spatial scale, indicates that factors other than temperature - such as organic precursor material, mineral matrix, and local variation in stress and strain - have influenced the overall process of graphitization. The implications for Raman-based geothermometry on complex metamorphic terrains will be discussed.

Estimating aerosol forcings using the MACC aerosol reanalysis

JOHANNES QUAAS[1]* AND NICOLAS BELLOUIN[2]

[1]Institute for Meteorology, University of Leipzig, Stephanstr. 3, D-04103 Leipzig, Germany (*correspondence: johannes.quaas@uni-leipzig.de)

[2]Hadley Centre, Met Office, FitzRoy Road, Exeter EX1 3PB, United Kingdom (nicolas.bellouin@metoffice.gov.uk)

In the EU-funded project 'Monitoring Atmospheric Composition and Climate' (MACC), MODIS satellite retrievals of aerosol optical depth (AOD) are assimilated into the IFS global atmospheric model enhanced by an aerosol module, and used for quasi-operational numerical weather forecasts. This MACC aerosol reanalysis yields a 3D field of concentrations of different aerosol components consistent with the MODIS AOD retrievals, along with the reanalysis of meteorological fields, and cloud and radiation distributions as computed by the model. This new dataset provides a unique opportunity to estimate aerosol climate forcings. On the basis of the method by Bellouin *et al*. [1] and Quaas *et al*. [2], where the aerosol radiative forcings have been derived from satellite data, we develop an improved method using this new dataset. Preliminary results show a global annual (year 2003) mean radiative forcing by the aerosol direct effect of -0.5 Wm^{-2}, and an indirect effect (first indirect effect or Twomey effect) of -0.3 Wm^{-2}. The product now also allows for a detailed analysis of the spatial and temporal variability of aerosol forcings.

Diamond-facies fluid flow during subduction: Evidence & consequence

ALEX QUAS-COHEN[1]*, SIMON CUTHBERT[2], GILES DROOP[1], CHRIS J. BALLENTINE[1] AND RAY BURGESS[1]

[1]School of Earth, Atmospheric and Environmental Sciences, University of Manchester, Manchester, UK (*correspondence: alexandra.quas-cohen@postgrad.manchester.ac.uk)
[2]School of Sciences, University of the West of Scotland, Paisley, UK (Simon.Cuthbert@uws.ac.uk)

Exhumed, subducted crustal terranes record the most extreme metamorphic conditions that continental rocks are known to experience and enable us to gain insight into the more elusive systems and processes of the Earth. Abundant fluid flow and fluid-rock interaction is evident during subduction even at the highest-grade conditions: numerous veins within a Fe-Ti, crustal garnet peridotite body in the Western Gneiss Region (WGR) of Norway contain microdiamonds [1]. Many questions remain unanswered regarding fluids and interactions at these depths. Our study focuses on the metasomatism of ultra-high pressure (UHP) rocks in the WGR; in particular, on determining the signature, source and recycling of noble gases and halogens. I present field maps and sketches of various UHP WGR localities to demonstrate the petrophysical relationships between various rock-types and features which demonstrate the nature and composition of intruding fluids; particularly, the associations of pegmatitic garnet websterites, carbonaceous and hydrous phases and different vein-types with Fe-Ti garnet peridotite and bimineralic eclogite bodies. I also present preliminary geochemical data demonstrating phase compositions, P-T conditions, chemical change due to fluid-rock interaction and noble gas compositions. Data gathered so far indicates that garnet websterites represent metasomatised domains of the peridotite and eclogite bodies within the WGR.

Arctic temperatures have increased at almost twice the global average rate over the past 100 years [1]. Warming in the Arctic has been accompanied by an earlier onset of spring melt, a lengthening of the melt season, changes in the mass balance of the Greenland ice sheet, and a decrease in sea ice extent. Short-lived, climate warming pollutants such as black carbon (BC) have recently gained attention as a target for immediate mitigation of Arctic warming in addition to reductions in long lived greenhouse gases. Model calculations indicate that BC increases surface temperatures within the Arctic primarily through deposition on snow and ice surfaces with a resulting decrease in surface albedo and increase in absorbed solar radiation. In 2009, the Arctic Monitoring and Assessment Program (AMAP) established an Expert Group on BC with the goal of identifying source regions and energy sectors that have the largest impact on Arctic climate. Here we present the results of this work and investigate links between mid-latitude pollutants and Arctic climate.

Pressure induced phase transitions in $MnTiO_3$: Insights from first principles

CARMEN QUIROGA* AND ROSSITZA PENTCHEVA

Section Crystallography, Department of Earth and Environmental Sciences, Ludwig-Maximilians Universität München
(*correspondence:
Carmen.Quiroga@lrz.uni-muenchen.de,
Pentcheva@lrz.uni-muenchen.de)

$MnTiO_3$ is an example of an ABO_3 compound which at ambient conditions crystallizes in the ilmenite structure and remains stable at least up to 26 GPa [1]. A denser $LiNbO_3$ phase can be quenched from high pressure and high temperature experiments to ambient conditions [2].

Using density functional theory calculations we determine the ground state properties and magnetic coupling of $MnTiO_3$ in the ilmenite, perovskite, $LiNbO_3$ and postperovskite phases. As $MnTiO_3$ is a strongly correlated material, we explore the influence of the exchange correlation functional beyond the local density and the generalized gradient approximations within LDA/GGA+*U* method and hybrid functionals. Our calculations show that ilmenite is the most stable phase at ambient conditions. The $LiNbO_3$ transforms into the perovskite phase at ~2.5 GPa in agreement with experiments [3]. A transition from perovskite to the post-perovskite phase ($CaIrO_3$-type) is predicted at pressures above 50 GPa.

Funding by DFG SPP1236 (PE883/8-1) and computational time at the Leibniz Rechenzentrum is acknowledged.

Tourmaline from porphyry copper belts as a proxy to assess boron budget in arc magmas

O.M. RABBIA AND L.B. HERNÁNDEZ

Instituto de Geología Económica Aplicada, Universidad de Concepción, Casilla 160c, Concepción, Chile (rabbia@udec.cl, lahernan@udec.cl)

In the Andes, world-class porphyry Cu deposits are intimately associated to major changes in the subduction geometry (progressive flattening) resulting in episodes of intense deformation, crustal thickening, rapid uplift and erosion (major orogenic phases), accompanied by migration of the volcanic front and changes in the geochemistry of magmas (appearance of the adakitic signature). As consequence of these highly compressive events, volcanism tends to vanish leaving mostly plutonic rocks in the geologic record. Whole-rock analysis of these intrusive rocks offers no quantitative appraisal of the B content in their magmas if volatile exsolution has taken place. On the other hand, during these particular periods of the Andean orogen evolution, volatiles exsolved from magmas are the main source of B-bearing hydrothermal fluids from which tourmaline may precipitate in porphyry Cu deposits. Therefore, the assessment of the relative abundance of this borosilicate in copper deposit belts could cast some light on B abundance in the associated arc magmas during metallogenic periods.

Tourmaline breccia complexes, with up to ~20 vol% of tourmaline, are a characteristic feature of world-class porphyry Cu deposits from the ~370 km long, Late Miocene-Early Pliocene Cu belt from Central Chile, as well as, of prospects and deposits from the ~1500 km long, Paleocene-Early Eocene Cu belt from Northern Chile and Southern Peru. In contrast, tourmaline is rarely developed or relatively uncommon in most porphyry Cu deposits from the ~2000 km long, Late Eocene-Early Oligocene belt from Southern Peru and Northern Chile.

Considering that the amount of fluid involved in giant porphyry Cu deposits formation requires huge volumes of magma (up to ~2000 km^3), the tourmaline-poor nature of the Late Eocene-Early Oligocene Cu belt, hosting giant Cu deposits (e.g.: Chuquicamata, La Escondida), suggests that the associated magmatism, and by extension its source, was fluid-bearing but B-poor. A possible explanation for the low B budget in these arc magmas could be related to a particular thermal configuration of the downgoing oceanic plate.

A high-resolution paleohydrological record of the Younger Dryas episode from Western Europe – Using lipid biomarker D/H ratios

OLIVER RACH[1]*, ACHIM BRAUER[2], HEINZ WILKES[2] AND DIRK SACHSE[1]

[1]University of Potsdam, Institute of Earth andEnvironmental Science, Karl-Liebknecht-Str. 24-25 14476 Potsdam-Golm (Germany) (*correspondence: rach@geo.uni-potsdam.de)
[2]GeoForschungsZentrum Potsdam, 14473 Potdsdam

Despite the recognized importance of the hydrological cycle within the climate system it is difficult to predict hydrological consequences of current and future climatic changes on regional scales. However, regional climatic variations on the continents are often most dramatically expressed through hydrological changes. A key tool to better understand the underlying mechanisms is the reconstruction of the past climate changes from high-resolution lacustrine proxy data. We investigated how fast hydrological changes have taken place during abrupt climatic shifts, such as the Younger Dryas cold episode (YD) ca. 12 ky BP. We assessed this question with a novel proxy, the stable hydrogen isotope composition of higher-plant derived lipid biomarkers.

We analyzed sediments from Lake Meerfelder Maar (Germany), with a continuous annual varving during the YD, which provide an excellent archive to resolve this issue. We measured the hydrogen isotope ratios of higher plant lipid biomarkers (long-chain *n*-alkanes) and conducted X-Ray fluorescence analyses (XRF), with focus on catchment-typical allochthonous elements (K, Al, Ti) in high-resolution (8-33 years per sample). The average chain length of the *n*-alkanes shows short-term variabilities, suggesting changes in lake catchment ecology. While *n*-alkanes with the highest concentration are long-chain homologues (nC_{25}, nC_{27}, nC_{29}, nC_{31}) of terrestrial origin, an increase in nC_{23} produced mainly by aquatic macrophytes suggests changes in the aquatic ecology during the early YD. XRF data show pronounced changes in sedimentary conditions with more allochthonous sediments in the later YD, probably related to hydrological variations. Indeed, the results from hydrogen isotope analysis, with a significant isotopic depletion in leaf-wax *n*-alkanes of about 20 ‰ during the initial part of the YD relative to Allerød, suggest colder conditions and/or enhanced precipitation. Furthermore, our data provide additional evidence for two hydrologically distinct periods within the YD interval. Through a combination of biomarker D/H ratios with XRF data our results deliver new insights into the timing and magnitude of regional hydrological changes as a consequence of abrupt global climatic variations.

Chemical weathering and erosion rates in Lesser Antilles: An overview in Guadeloupe, Martinique and Dominica

SÉTAREH RAD[1], KARINE RIVE[2], OLIVIER CERDAN[1], VITTECOQ BENOIT[1] AND CLAUDE ALLÈGRE[3]

[1]BRGM, 3, avenue Claude-Guillemin, Orléans, France
[2]CEGEO, 159 allee chardin, Villeneuve d'ascq, France
[3]IPGP, PRES Paris Cite´ , 75238 Paris Cedex 05, France

Guadeloupe, Martinique and Dominica Islands alike numerous tropical environment present extreme weathering regimes.

Physical denudation is mainly controlled by landside, This reflects the torrential dynamics of the rivers. For Guadeloupe, the mechanical weathering rates are 800-4000 t/km^2/yr.

The lithology is very porous with high infiltration rates, which induces that most of the elements fluxes are produced on subsurface as the chemical erosion rates are 2 to 5 time higher than the rates from surface water. We show how kinetic of chemical weathering rates depends on the age of the lava and subsurface circulation.

In addition, timescale of erosion have been calculated from U-series analyses sediments from rivers. Our results show a large range: from 0 to 150 ka in Martinique and from 0 to 60 ka Guadeloupe. From analyses from the dissolved loads, we propose to evaluate residence times in the river water. It would appear that waters circulation is globally 3 times longer for subsurface water than for surficial water (Rad *et al*. 2011).

Moreover these islands are highly impacted by agriculture. It is therefore interesting to assess the impact of such influence on the weathering rates. Our result show that human activity brings no disturbance on Critical zone processes contrary to what one might think. Indeed, we show that among the combined impact of all parameters (climate, runoff, slopes, vegetation…), the basins age seems to be the control parameter on chemical weathering and land use: the younger the basin, the higher the weathering rate.

We could observe a combined effect between the higher erodibility and a higher climate erosivity of the younger reliefs.

Impact of a small downstream reservoir on metal cycling in acid mine drainage impacted waters

L.K. RADEMACHER[1]*, K.L. FAUL[2] AND G. MCDANIEL[1]

[1]University of the Pacific, Stockton, CA 95211, USA (*correspondence: lrademacher@pacific.edu)
[2]Mills College, Oakland, CA 94613, USA (kfaul@mills.edu)

The results of ongoing work in an acid mine drainage impacted watershed suggests downstream reservoirs play an important role in the cycling of metals and trace elements under variable flow conditions. The former Leona Heights Sulfur mine in Oakland, California produces acid mine drainage (AMD) that enters the Lion Creek watershed. These waters flow into the Lake Aliso reservoir, which is kept full during the dry summer months, thus contributing to the development of chemical gradients. Lake Aliso is drained during the wet winter months, allowing Lion Creek to flow freely across the lake bottom. The different flow regimes in Lake Aliso provide a wide range of geochemical conditions under which to study metal cycling in a single system.

Beginning in July 2009, monthly water samples were collected from Lion Creek and its two tributaries, Leona and Horseshoe Creeks, as well as from the inlet and outlet of Lake Aliso. Leona Creek is the source of AMD impacts within the watershed and Horseshoe Creek represents background watershed conditions. Lion Creek intergrates these two tributaries and discharges into Lake Aliso. Sediment cores collected from Lake Aliso provide a history of lake conditions and metals cycling.

Metals concentrations, including Pb, Cd, Fe, Ni, Cu, and Zn, in the AMD impacted Leona Creek tributary are significantly elevated above levels in the Horseshoe Creek tributary. After these tributaries mix in Lion Creek, measured concentrations of metals at the Lake Aliso inlet are lower than those measured in Leona Creek, due part to dilution by Horseshoe Creek waters. However, dilution alone cannot explain the reduction in metals concentration. Although all metal conentrations are lowered, only Cu (on most sampling dates), Fe, and Pb approach background levels. In addition, whether concentrations of metals at the Lake Aliso outlet are greater than or less than the lake inlet depends on whether the lake is full or empty, as well as the recent precipitation history. Depth profiles of lake temperature, pH, and dissolved oxygen suggest the chemical gradients that develop when the lake is full likely control the mobility of metals. Additionally, sediment cores from the lake exhibit fine scale (sub cm) oscillations in redox conditions.

Polar twins? Deglacial carbon and circulation records from the deep North Pacific and Southern oceans

J.W.B. RAE[1]*, G.L. FOSTER[2], M. GUTJAHR[1], M. SARNTHEIN[3], L.C. SKINNER[4], D.N. SCHMIDT[1] AND T. ELLIOTT[1]

The cause of glacial – interglacial CO_2 transfer between the deep ocean and the atmosphere is one of the oldest puzzles in palaeoclimatology. The regularity of these cycles, and their strong coupling to a range of climate proxies, suggests a well-ordered set of controlling mechanisms [1]. The Southern Ocean is thought to play a key role by providing a (stemable) link for carbon and nutrients between the deep ocean and the atmosphere [2]. The North Pacific shares some of these nutrient and mixing characteristics; records from both locations may thus help us understand the fundamental processes driving glacial deep ocean CO_2 storage and release [3].

We present novel proxy data from the deep North Pacific and Southern oceans that provide new constraints on deep ocean chemistry and circulation changes during deglacial pCO_2 rise. Boron isotopes ($\delta^{11}B$) from benthic foraminifera are used to record the state of the deep ocean carbonate system, and are coupled with neodymium isotopes (ε_{Nd}) and benthic-planktic radiocarbon ($\Delta^{14}C$; [4]) to explore the influences of water mass mixing and ventilation age changes. Our $\delta^{11}B$ data show a pronounced pattern of millennial carbonate system variations that is consistent between two cores in the Southern Ocean and one in the North Pacific. In contrast, Southern Ocean ε_{Nd} shows a relatively smooth deglacial transition, suggesting that mixing of differently sourced water masses has minimal control on our millennial carbonate system variations. Rather, the $\delta^{11}B$ and $\Delta^{14}C$ data are best explained by increases in vertical mixing, consistent with the breakdown of glacial stratification in these high latitude oceans during the Heinrich Stadial 1 and Younger Dryas intervals of atmospheric CO_2 rise.

Since the industrial revolution, the partial pressure of carbon dioxide in the atmosphere has been rising. The increase of carbon dioxide in the atmosphere and the related uptake by the oceans [1] will result in a decrease in ocean pH by 0.2-0.4 units over the next century [2] and in a decline of calcium carbonate saturation states in the seawater surface. The potential for marine life to adapt to increasing CO_2 concentration are not well known, especially for the organisms living at high latitudes in waters which have naturally low saturation levels.

The effects of elevated pCO_2 were investigated in the high latitude coralline alga *L. glaciale*, an high Mg-Calcite calcifier. The algae were kept in the aquaria for 3 months at 8 ± 0.5 °C with 20 µmol photons m^{-2} sec^{-1} in 12 hours light/ dark cycle at four different CO_2 concentrations: 410 ppm (control), 563 ppm, 838 ppm and 1120 ppm according to the IPCC prediction.

During this incubation period, *L. glaciale* showed a significant linear trend towards lower 'apical tip' growth rates (from 1.0 mm $year^{-1}$ to 0.8 mm $year^{-1}$) with increasing pCO_2 in the water. In water undersaturated with respect to aragonite (pCO_2 1120 ppm- ΩAr = 0.9), the cell density of the newly grown thallus was 68 % less compared to the control together with a 56 % decrease in the cell walls thickness. Reduced growth rates and the weakening of the coralline thallus could have severe consequences for the biodiversity, growth and stabilization of carbonate reefs.

Ba, Sr and $^{87}Sr/^{86}Sr$ in Indian estuaries: Impact of submarine groundwater discharge

WALIUR RAHAMAN AND SUNIL K. SINGH

Physical Research Laboratory, Ahmedabad-380009, India (waliur@prl.res.in, sunil@prl.res.in)

Dissolved Sr, Ba and $^{87}Sr/^{86}Sr$ were studied in three Indian estuaries linked to the Arabian Sea i.e. the Narmada, Tapi and the Mandovi. The concentration of dissolved Sr and Ba in the rivers show significant variations; ranges from 0.7-2.5 μmol/kg, 27-207 nmol/kg respectively whereas $^{87}Sr/^{86}Sr$ vary between 0.70875 and 0.71062 reflecting the lithologies they drain. The Sr/salinity profile in all these estuaries shows conservative mixing between river water and seawater end members whereas Ba shows nonconservative mixing with its gain in mid salinity region (10-15‰). The $^{87}Sr/^{86}Sr$ shows non-conservative behaviour; its distribution exhibits significant departures from the expected conservative mixing lines in all these estuaries. This difference in the behaviour between dissolved Sr and its $^{87}Sr/^{86}Sr$ is intriguing and suggests that there is supply of Sr from additional sources to these estuaries. Similarly, Ba gain could not be explained by Ba release from particles in the estuaries and river-seawater mixing and requires its additional source. The additional source seems to be submarine groundwater discharge (SGD). The non-conservative behaviour of $^{87}Sr/^{86}Sr$ provides a handle to estimate the quantum of SGD to these estuaries. Inverse model calculations have been used to characterize the Sr concentration, $^{87}Sr/^{86}Sr$ and salinity of the SGD and estimate its water fluxes to the Narmada estuary. The model derived SGD flow rates to the Narmada estuary are ~7 and 275 cm/day during nonmonsoon and monsoon respectively indicating large seasonal variability of SGD. This estimate is consistent with those reported from the south-west coast of India using dissolved ^{222}Rn [1] and other coastal regions of the world [2].

Constraints on the formation of a lunar core from metal-silicate partitioning of siderophile elements

NACHIKETA RAI AND WIM VAN WESTRENEN

Faculty of Earth and Life Sciences, VU University Amsterdam, The Netherlands (nachiketa.rai@falw.vu.nl)

Most models for the interior of the Moon include a small iron–rich core with a maximum diameter of several 100 km [1], but the composition and formation conditions of the lunar core are poorly constrained. One major consequence of core-mantle differentiation in planetary bodies is that the majority of the siderophile elements are strongly partitioned into the iron-rich core. Since the degree of extraction of these elements into the metallic phases is governed according to their metal/silicate partition coefficients (D) and the pressure-temperature-composition conditions during core formation, abundances of these elements in the silicate Moon can in principle be used to constrain lunar core formation and chemistry.

Estimates of siderophile element abundances in the lunar mantle have previously been used to argue for the presence of a small metallic core (0.1-5.5 wt%) [2-4], but recent improved approaches to terrestrial core formation models (including better thermodynamic models and the ability to model changing conditions through time) have not yet been applied to the Moon.

Here we re-examine whether a consistent set of conditions can be obtained to match observed siderophile element depletions in the silicate Moon. We combine new metal-silicate partitioning data for Ni, Co, Cr, Mn, Ga, P, Pb, W and V with literature data and characterize the dependence of the partition coefficients on temperature, pressure, oxygen fugacity and silicate melt structure and composition to derive equations of the following form: $\log D = \alpha + \beta (\Delta IW) + \delta (1/T) + \varepsilon (P/T) + \chi (nbo/t)$.

Initial results suggest that when using the proposed bulk Moon composition of [5] and siderophile element abundances from [6], data are consistent with the Moon possessing a small metallic core, with metal-silicate equilibration pressures close to the current core-mantle boundary, consistent with whole-Moon melting at the time of core formation.

Geochemical and isotopic composition of quartzites near the MCT zone (Garhwal Himalaya, India): Implications to their provenance & deposition

SANTOSH K. RAI[1], SUNIL K. SINGH[2] AND H .K. SACHAN[1]

[1]Wadia Institute of Himalayan Geology, Dehradun (India) (rksant@wihg.res.in, hksachan@wihg.res.in)
[2]Physical Research Laboratory, Navrangpura, Ahmedabad (sunil@prl.res.in)

Quartzites are one of the major clastic sedimentary rocks in the Himalaya that had deposited in the Tethys Ocean basin and exhibit varying chemical composition, protoliths, age (pre-Himalaya) and depositional settings [1, 2, 3]. In this study, geochemical and isotopic composition were determined in the quartzite samples collected form the either side of MCT zone of the Garhwal Himalaya to determine their provenances and nature of the protoliths.

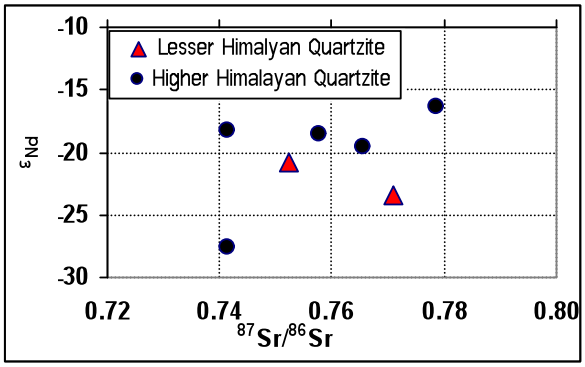

Figure 1: $^{87}Sr/^{86}Sr$ & ε_{Nd} of the Himalayan Quartzites near the MCT zone of the Garhwal Himalaya (India).

Major elements data of the Lesser Himalayan quartzites (Kaliasaud-Alaknanda region) demonstrate significant difference from those of the Higher Himalaya. For example, TiO_2/SiO_2, Al_2O_3/SiO_2, Fe_2O_3/SiO_2 are one to two order of magnitude higher for Higher Himalayan quartzites compared to those from the Lesser Himalaya. These differences could be related either to source variability or to mineralogical sorting during their weathering, transport and deposition. The limited samples measured in this study indicate overlapping Sr and Nd isotope composition between Higher (ε_{Nd} -16.5 to -27.7; $^{87}Sr/^{86}Sr$ 0.7414-0.7788) and the Lesser (ε_{Nd} -20.8 to -23.5; $^{87}Sr/^{86}Sr$ 0.7524-0.7714) Himalayan quartzites making it difficult to differentiate their sources. More work is underway to generate larger data set to study their protoliths.

Heat flow in the laser-heated diamond anvil cell and the thermal conductivity of the lower mantle

E.S. G. RAINEY[1]*, A. KAVNER[1] AND J. HERNLUND[2]

[1]Department of Earth and Space Sciences, University of California Los Angeles, Los Angeles, CA 90095 (*correspondence: erainey@ucla.edu)
[2]Department of Earth and Planetary Science, University of California Berkeley, Berkeley, CA 94720

The thermal conductivity of the lower mantle is a critical parameter for understanding the current heat budget and thermal evolution of the Earth. However, thermal conductivity measurements at high pressure and temperature are difficult due to the small sample volumes and large temperature gradients characteristic of the laser-heated diamond anvil cell (LHDAC) [1]. Temperature distributions in the LHDAC are determined by laser and sample geometry as well as physical properties such as sample absorbance and thermal conductivity [2]. During heating experiments, precise measurements of peak sample temperatures and 2-D hotspot intensity gradients can be made [3]. In order to infer physical properties of a sample using measured temperature distributions in the LHDAC, a quantitative understanding of heat flow in the LHDAC is needed.

We have developed a 3-D numerical model of steady-state heat conduction for continuous heating experiments in the LHDAC. The numerical model has been benchmarked against an existing 2-D analytic solution [2], yielding agreement in predictions of temperature distributions as a function of input laser power, sample geometry, and sample thermal conductivity. Model calculations show that peak temperature and hotspot width are strongly correlated and dependent on laser power, laser and sample geometry, and sample thermal conductivity. The rate of change of the peak temperature and hotspot width as a function of input laser power is especially dependent on sample thermal conductivity, all other variables being equal.

In situ U-Pb dating of scheelite: Constraints on the age and genesis of the Felbertal tungsten deposit

J.G. RAITH[1]*, A. GERDES[2] AND D.H. CORNELL[3]

[1]Chair of Resource Mineralogy, Montanuniversitaet Leoben, 8700 Leoben, Austria (*correspondence: johann.raith@unileoben.ac.at)
[2]Institut für Geowissenschaften, Goethe Universität Frankfurt (gerdes@em.uni-frankfurt.de)
[3]Geovetarcentrum, Gothenburg Sweden (cornell@gvc.gu.se)

The Felbertal scheelite deposit, Salzburg province, Austria, is one of the biggest tungsten producers in the world. It has long been regarded as the type locality of stratiform-stratabound scheelite deposits. The deposit is situated in the Habach Complex, an Early Cambrian to Ordovician metavolcano-sedimentary ophiolitic to arc sequence. A chemically unusual W-bearing granite, the K1 orthogneiss, was emplaced in the Early Carboniferous into the western ore zone of the deposit. Several economic scheelite ore bodies are spatially associated with this orthogneiss. The ore deposit was overprinted during the Variscan (~330 Ma) and Alpine (~30 Ma) orogenies. Economic scheelite mineralisation is associated with SiO_2-rich lithologies including foliated fine-grained scheelite-quartz ores ('Scheelite-rich quartzite'), deformed quartz veins and stockwork like mineralisation. Trace element analyses using LA-ICP-MS techniques, controlled by cathodoluminescence (CL) images, confirmed the previously established classification of scheelite stages. Scheelite 1 is preserved as relict cores in fine-grained scheelite in the mylonitic scheelite-quartz ores. It preserves delicate oscillatory growth zoning, is characterised by flat wing-shaped REE patterns, and contains between 50 to 1120 ppm U. *In situ* U-Pb dating by LA-SF-ICP-MS of Scheelite 1 yielded a concordia age of 335.5 ± 4.6 (2 sigma). This new age constrains the timing of scheelite formation of this ore type for which a Cambrian age was previously assumed [1]. Within the uncertainty this new age is indistinguishable from the published 336 ± 19 Ma emplacement age of the K1 orthogneiss. The new scheelite age is inconsistent with previous genetic models, which proposed either syngenetic ore formation in the Cambrian or two stages of epigenetic ore formation, the first in the Cambrian and the second in the Early Carboniferous [1]. The Felbertal scheelite deposit is best interpreted as a metamorphosed granite-related magmatic-hydrothermal ore deposit of exclusively Early Carboniferous age.

Geochemical and mineralogical features of coal combustion wastes (CCW) of Angren Thermal Power Station (TPS) and possible ways of their recycling, Uzbekistan

SH.SH. RAKHMONKULOV A.* AND N.E. SHUKUROV

Institute of Geology and Geophysics Academy of Science of Uzbekistan, 49, Khodjibaeva Str. Tashkent, 100041, Republic of Uzbekistan (*correspondence: rshakhnoza@yahoo.com)

The Angren TPS working on the basis of Angren lignite was found in 1958, during this 53 years functioning were generated 13 million tons of CCW and disposed in 3 coal ash dumps (203 acre). The physical and chemical characteristics of CCW have bearing on both its potential for use and its potential to present some level of risk to human health and the environment. Elemental and mineralogical content of samples from Angren CCW were checked by XRF and JEOL Superprobe microzond. The results of chemical and mineralogical analyses showed high content of metals and minerals with magnetic features (magnetite, haematite, titan-magnetite etc.), concentration of trace elements, as well as rare- earth elements etc. were elevated also. Subsamples were subjected to magnetic separation, results show that content of minerals with ferromagnetic feature is 65% of total mass. Investigations under the JEOL microanalizer show that in spherical magnetic aggregates are containing Fe, Ti, Mn and W in high value.

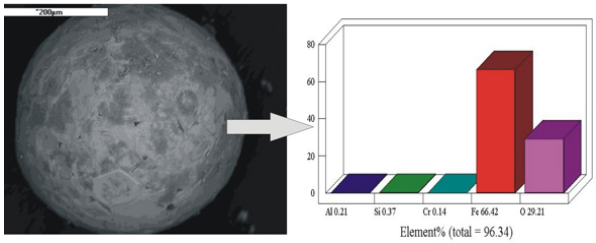

Figure 1: SEM image of magnetic particle and distribution ratio some magnetic elements.

High concentration of Fe and Mn in studied CCW samples showing their effective utilization and bright perspective for using as a raw material for producing several kinds of Ferroalloy for metallurgical industry.

Magnetic resonance imaging of pollutant mass transport in biofilms

B. RAMANAN[1,2,3], W.M. HOLMES[2], W.T. SLOAN[3] AND V.R. PHOENIX[1]*

[1]School of Geographical and Earth Sciences, University of Glasgow, G12 8QQ, UK (*correspondence: vernon.phoenix@glasgow.ac.uk)
[2]GEMRIC, Wellcome Surgical Institute, University of Glasgow (william.holmes@glasgow.ac.uk)
[3]School of Engineering, University of Glasgow (william.sloan@glasgow.ac.uk)

Introduction

Biofilms play a key role in immobilizing and degrading pollutants in both natural and engineered systems. Quantifying the mass transport of these pollutants in biofilms is critical for effective modelling of biofilm performance. Thus methods are needed which spatially image pollutant transport in a non-invasive manner. However, imaging inside biofilms thicker than several hundreds of microns becomes challenging for photon based methods such as CLSM due to attenuation of photon penetration and the fluorescent signal. These thicker biofilms, however, are by no means rare. For these, such as phototrophic biofilms in natural systems and those in granular waste-water treatment systems, alternative imaging methods must be sought.

Results and Discussion.

Here we report the use of Magnetic Resonance Imaging (MRI) for structural and mass transport imaging in a 2.5 mm thick phototrophic biofilm using a small (5 mm diameter), simple-to-construct RF coil. Notably, the RF coil is also far less expensive than similar commercially available coils.
