Gd [DTPA] (molecular mass 547 g/mol) was chosen as a surrogate for an organic contaminant; the parmagnetic Gd making the molecule visible to MRI. The transport of Gd [DTPA] through the biofilm was imaged by aquiring a series of T_2 weighted images (T_2 being the spin-spin relaxation rate of ^{1}H nuclei in the water surrounding the Gd [DTPA]). Because T_2 is inversely proportional to the concentration of Gd [DTPA], fully quantitative maps of Gd [DTPA] transport inside the biofilm were constructed. MRI was also used to image structural heterogeneity and water diffusion within the biofilm. Biofilm structure, water diffusivity and Gd [DTPA] transport were clearly correlated. MRI is a valuable tool for imaging pollutant transport and fate in biofilms too thick for photon based imaging methods.

$Au_3(Pb,Sb)_4$ mineral phase from Tetrem gold deposits, Ghana, West Africa

R.P. RAMDOHR[1] AND T.L. EVSTIGNEEVA[2]

[1]High River Gold Exploration Burkina SARL 01 BP 4418 Ouagadougou Burkina Faso (reinramdohr@yahoo.com)
[2]IGEM RAS, 35, Satromonetny, 119017, Moscou, RF (evst@igem.ru)

The new Au-mineral phase with the composition ~$Au_6Pb_5Sb_3$ [Au_3 (Pb, Sb)$_4$] and parameters (Å) of tetragonal cell a=8.401 (2), c=8.239 (1) is found in the gold deposit Tetrem, SW Ghana, Tarkwa area. The orebodies consist of a series of sedimentary Banket quartz reef conglomerates similar to those in the Witwatersrand Basin. Gold mineralization in Tetrem deposits is located in quartz veins, and appears to have formed during Eburnean II (2, 116-2, 080 Ma) within shear and fault networks developed during contraction deformation.

Gold minerals occur as free particles with an average size of 50-150 μm. The main gold mineral is native gold. There are only minor electrum and Au with 3-7% Ag. Gold is associated with sulphides: pyrite, sphalerite, galena, chalcopyrite, arsenopyrite, pyrrhotite, and molybdenite. Accessory oxides in the ore are magnetite, goethite, ilmenite, and rutile. The mineral proportions vary in gold occurrences of the area. Ore minerals occur in silicified and albitized (?) granite cut by numerous quartz veins and stringers.

The mineral $Au_6Pb_5Sb_3$ was found in quartz veins in association with: free gold containing up to 7.2 Wt% Ag, and up to 5.7 Wt% Hg, and hunchunite, Au_2Pb. Native Au in the sample contain also tiny, <5-10 μm grains of aurostibite, and altaite.

Data of study obtained using MRSA, SEM+EDD, and XRDA. show that by composition, physical properties, and crystallochemical characteristics $Au_6Pb_5Sb_3$ differs from other natural compounds of gold with metals and 'semi-metals': Au and Au-Ag tellurides; aurostibite, $AuSb_2$; maldonite, Au_2Bi; hunchunite, Au_2Pb; anyuiite, $AuPb_2$; and yuanjiangite, AuSn.

$Au_6Pb_5Sb_3$ analogue has been synthesized from the melt in multi-component Ag-Pb-Bi-Sb system for detail study of mineral properties and associations.

Petrography and chemistry of zircons from the Chaltén Plutonic Complex and implication on the interpretation of U-Pb zircon ages

CRISTÓBAL RAMÍREZ DE ARELLANO[1], BENITA PUTLITZ[1], OTHMAR MÜNTENER[1] AND MARÍA OVTCHAROVA[2]

[1]Institute of Mineralogy and Geochemistry, University of Lausanne, Switzerland. (ramirez.andes@gmail.com)
[2]Department of Mineralogy, University of Geneva, Switzerland

The absolute geochronology of the Chaltén Plutonic Complex (CHPC), located in the Southernmost Andes, has a strong influence on the geodynamic interpretation of Patagonia. In addition, the textural and chemical features of zircons from the different plutonic units of this composite intrusion provide important constraints for understanding the growth of zircons in magmas with variable degree of differentiation. These features should be taken into account for the interpretation of zircon ages, since increasing precision of ages is obtained thanks to the development of the U-Pb CA-TIMS dating techniques during the last decades.

The CHPC is a calc-alkaline (arc related) intrusion, which was emplaced at upper crustal levels (3.5 to 2 kbar). The zircon ages (16.90 ± 0.05 to 16.37 ± 0.02 Ma) are consistent with the relative geochronology inferred from field relationships. Where undulated ductile contacts are observed, the age difference cannot be resolved. In the case of brecciated contacts a minimum age difference of 80ky was obtained, which is at the limit of the obtained precission (±40ky).

The petrographic textures of zircons from mafic rocks indicate crystallization in isolated pockets, i.e. interstitial. The application of the Ti-in-zircon thermometer yield constistently low temperatures (~760°C). This indicates that most zircons from these samples might have crystallize near solidus temperatures and consequently post-date the emplacement. In contrast, the textures of zircons from granitic rocks indicate a more protracted crystallization. The chemistry (LA-ICP-MS analysis) of zircons from granitic rocks displays systematic variation of U/Th and U/Ta ratios between core and rim. This pattern can be correlated with the observed variations of calculated temperatures and Ce^{III}/Ce^{IV} ratios. These features suggest that in granitic melts there could be several episodes of zircon crystallization at different temperatures. These temperatures are 100° to 200° higher than the solidus, which implies that many zircons might have crystallize prior to the emplacement (antecryst).

Predicting the character of future eruptions: Insights from single crystal analyses

F.C. RAMOS[1]*, J.B. GILL[2], J.A. WOLFF[3], C.A. DIMOND[1] AND D.L. TOLLSTRUP[4]

[1]Dept. of Geological Sciences, New Mexico State University, Las Cruces, NM, 88003, USA (*correspondence: framos@nmsu.edu)
[2]Dept. of Earth and Marines Sciences, UC Santa Cruz, Santa Cruz, CA, 95064, USA
[3]School of Earth and Environmental Sciences, Washington State University, Pullman, WA, 99164, USA
[4]Thermo Fisher Scientific, 1400 N. Pointe PWKY, West Palm Beach, FL, 33407, USA

While the science of predicting volcanic eruptions is becoming a viable practice, few constraints exist as to the chemical nature of future eruptions, especially regarding the composition and character of the magma or magmas to be erupted. Usually compositional assessments can only be undertaken post-eruption. However, volcanoes characterized by a variety of volcanic products (i.e. a variety of erupted rock compositions) that erupt in short geological time periods (e.g. <10ky), may allow for assessing magma composition/ character prior to when an eruption actually occurs. Baitoushan volcano, located along the China/North Korean border, is known for the largest rhyolitic, caldera forming eruption in the last 2000 years and has shown signs of recent seismic activity. Baitoushan is characterized by at least three recent eruptions (<5000 ka) involving at least four distinctive highly evolved magma compositions. Following a detailed approach involving Sr and Pb isotopes of single mineral crystals, we have identified specific mineral populations that cannot have originated from host magmas, but rather, must have originated from magmas seen only in later eruptions. These populations become more common in subsequent eruptions until they become the dominant mineral population in the latest-erupted magmas. Results suggest the presence of crystals in older erupted materials up to 5000 years prior to eruptions where these crystals are the dominant population. Results are consistent with a magma residence age of ~10 ky and document the first time in which crystals associated with future magmatic activity are observed in materials from earlier eruptions. In addition, isotope variations in selected crystals suggest open system processes occurring ~3000 years prior to eruption in highly viscous, high-silica rhyolites. Ultimately, detailed crystal evaluations offer compositional constraints of magmas resident under volcanoes 1000s of years prior to their eventual eruption.

Li-O-Pb-Nd-Hf isotope and trace element systematics and S in residual peridotites: Evidences for ancient hydrothermal fluid-rock interactions at mid-ocean ridges

L.V. RANAWEERA, T. MORIGUTI, R. TANAKA, A. MAKISHIMA AND E. NAKAMURA*

The Pheasant Memorial Laboratory (PML), Institute for Study of the Earth's Interior, Okayama University at Misasa, Tottori-Ken, 682-0193, Japan
(*correspondence: eizonak@misasa.okayama-u.ac.jp)

Massive plagioclase lherzolite (MSPL) from the Horoman orogenic massif, Japan, which formed at ~ 1 Ga at a mid-ocean ridge (MOR), represents the most unradiogenic Pb reservoir ever found in the mantle [1]. New data for O and Li isotopes of these MSPL combined with previously published trace element, S contents, and Pb, Nd and Hf isotope data reveal evidences for ancient hydrothermal fluid-rock interaction (HFRI) at mid-ocean ridges.

The trace element patterns of MSPL show element enrichment and depletion in variably melt extracted residues. They show 2-43 times lower U/Pb and 3-11 times lower Ce/Pb than those of the depleted MORB mantle or DMM indicating Pb enrichment. Several MSPLs show bulk rock S elemental abundance (146-273 ppm) higher than those of the DMM (116 ppm) and primitive mantle (250 ppm) also suggesting S enrichment. In addition, S positively correlates with Pb. $\delta^{18}O$ (5.11-5.49 ‰) and $\delta^{7}Li$ (-0.83-3.96 ‰) compositions of MSPL suggest a mixing between DMM and a light Li and O isotope source. These oxygen isotope values negatively and positively correlate with age corrected Pb and Nd and Hf, respectively at ~ 1 Ga.

The correlation in O-Li isotope system indicates hydrothermal fluid and MSPL interaction. Hydrothermal fluids can react with residual peridotites at MORs giving rise to sulfide which can sequester Pb and increase S. The correlation of O with Pb, Nd and Hf indicates that HFRI of MSPLs occurring around 1 Ga. Thus, our data reveal evidences for hydrothermal fluid alteration of peridotites occurred at ancient time at MORs and account for origin of highly unradiogenic Pb reservoirs in the mantle.

Stable isotope (SI) ratio of calcites in stalagmite samples collected from 3 different caves in the Jaintia (Krem Syndai and Rupasor; N25°09′ and E92°00′) and Khasi Hills (Krem Mawmluh; N25°20′ and E42°45′) of Meghalaya in northeast Himalayas reveals change in rainfall intensity during the last 21 ka BP. Analysis of stalagmite collected from Mawmluh Cave (6.95 – 21.6 ± 0.5 ka) revealed signature of the glacial maxima registered as an abrupt drop in $\delta^{18}O$ values by ~7‰. This is the first observation documenting large variability in isotopic ratio. The Syndai stalagmite (1.8 ± 0.05 ka – 4.69 ± 0.15 ka) captures climatic amelioration across 2.5 to 5 ka. The actively growing Rupasor stalagmite covers the period 0.42 ± 0.14 ka – 2.5 ± 0.03 ka. The late Holocene events, like the Medieval Warm Period (MWP) and Little Ice Age (LIA) have also been captured. Comparing the seasonal variability of present day average rainwater SI record from the Shillong region and wind speed observation from the nearest meteorological observatory allows defining an empirical relationship for predicting the contribution of BoB moisture. The estimates suggests more than 60% drop in the Wind speed (WS) vector corresponding to the ~7‰ difference observed between glacial and non-glacial times.

Geospeedometry applied to El'gygytgyn impact glass

U. RANTZSCH[1]*, T. HABER[1], D. KLIMM[2] AND G. KLOESS[1]

[1]Institute for Mineralogy, Crystallography and Materials Science, University of Leipzig, Germany (*correspondence: rantzsch@uni-leipzig.de)
[2]Leibniz Institute for Crystal Growth, Berlin, Germany

The El'gygytgyn impact glass has been investigated with the method of relaxation geospeedometry. The sibirian impactite was found in the 3.6 Myr old El'gygytgyn impact structure in lacustrine terraces.

The aim of this research was to determine the natural cooling rate of the El'gygytgyn rhyolitic glass (71.3 % SiO_2, 14.9 % Al_2O_3, 4.1 % K_2O, 2.8 % CaO, 2.8 % Na_2O_3, 2.7 % FeO, 1.1 % MgO, 0.3 % TiO_2, in wt-% by 20 EMPA analysis).

The method of geospeedometry based on the structural relaxation in silicate melts was first applied to natural glasses by [1]. The procedure is referred to the Tool-Narayanaswamy approach [2]. The cooling history of the impactite is frozen in its structure. The temperature-dependent reheating across the glass transformation was used to obtain the original cooling history. The relaxation of the enthalpy was achieved by measurements of the heat capacity.

Therefore, differential scanning calorimetry (DSC) measurements with certain heating and cooling rates were performed. The impact glass was heated above the glass transition (T_g) to ensure the complete relaxation of the glass structure. Thereupon, the kinetic parameters were adjusted for each thermal cycle.

We can deduce that the cooling rate for the impact glass is between 0.15-0.85 K/min. The cooling rate is comparable to the data determined for phonolite obsidian flows on Tenerife [3] but significantly slower than for tektites reported in literature. Hence, we present that the final cooling of the El'gygytgyn impact glass originated witin the hot impact structure.

The influence of physically-induced porewater advection, benthic photosynthesis and respiration on $CaCO_3$ dynamics in reef sands

Reduced net calcification owing to increasing pCO_2 from the burning of fossil fuels suggests a potential reduction in carbonate accumulation in continental margins, where a large fraction of global carbonate accumulation occurs. This feedback in the ocean carbonate cycle lends particular importance to understanding the factors controlling carbonate accumulation and dissolution in coastal and shelf deposits. Permeable biogenic carbonate sediments in reef environments are poised to play a crucial role in the response of ocean margin environments to ocean acidification, because of the interplay between porewater exchange, benthic community metabolism and $CaCO_3$ dynamics in these deposits.

Sediment oxygen consumption rates, porewater profiles and benthic fluxes of oxygen, pH, calcium, alkalinity, and dissolved inorganic carbon were determined in reef sands (Heron Island, Australia) of different permeability across a range of hydrodynamic conditions. In these biogenic deposits, porewater advection and light stimulate rates of benthic photosynthesis, which, in turn, fuels calcification in surface sediments. Furthermore, our results indicate an important damping effect of porewater advection on the efficiency of respiration-driven carbonate dissolution in sediments. Therefore, we argue that the synergistic effects of porewater advection, benthic respiration, photosynthesis, calcification and carbonate dissolution promote carbonate preservation in permeable ocean margin deposits, and have a direct bearing on past, present and future changes in the ocean carbonate cycle.

The impact of sea level rise on salt water intrusion into coastal aquifers

JOHN RAPAGLIA[1], HENRY BOKUNIEWICZ[2], ATHANASIOS VAFEIDIS[3] AND TSVI PICK[4]

According to the IPCC (2007) sea level rise is one of the more certain consequences of climate change. Salt water intrusion into coastal aquifers is an important impact of sea level rise, which has received some attention among the coastal scientific community in recent years (e.g. [1]).

Several studies have produced global scale salt water intrusion maps, buth these maps are at a coarse spatial resolution, which limits their use. We contend that there remains a need to investigate how future changes in climate will affect freshwater-seawater interactions in coastal aquifers both in terms of seawater intrusion as well as groundwater discharge.

We present a first order, global model intended to predict change in the salt water intrusion length into coastal aquifers under different sea level rise scenarios. Forecasts are made up to a pixel resolution of 30 arc-seconds. This model is based on existing sea level rise scenarios, the Bruun Rule and assumptions concerning the relation between surface topology and the hydraulic head which is expected to be a function of aquifer recharge and public consumption. Saltwater intrusion lengths in water stressed areas are likely to increase with sea level rise but that the effect of changing consumption rates due to population change is often greater than the effect of sea level rise alone.

Several limitations remain regarding the utility of the analysis based on data quality; however the model remains a useful first step towards understading future salt water intrusion at a global level.

Exploring geoengineering using climate and detailed modelling strategies

PHILIP J. RASCH*, HAILONG WANG, JIN-HO YOON, DILIP GANGULY, PO-LUN MA AND VINOJ VELU

Pacific Northwest National Laboratory (PNNL) (*correspondence: philip.rasch@pnl.gov)

Geoengineering (the deliberate perturbation of the planet to counteract some of the effects of increasing CO_2 concentrations) has received increasing attention in scientific and policy communities due to concern about the difficulty of transforming the planet's energy infrastructure and the scientific consensus that reductions in emissions must take place soon to avoid the risk of undesirable impacts and dangerous climate change. Due to the difficulty of energy transformation, societies have been slow to respond, in spite of the risks.

As a stopgap measure, a number of geoengineering strategies have been suggested that introduce aerosols into the atmosphere to increase the planetary albedo, or to reduce the opacity of the atmosphere to longwave energy to cool the planet. The conflation of aerosols, energy, and climate make these strategies a natural topic for this Goldschmidt session. I will describe some modeling studies that explore three geoengineering strategies: 1) introducing sources of stratospheric aerosols; 2) introducing sea salt aerosols to brighten marine stratocumulus clouds; 3) introducing aerosols that act as ice nuclei to reduce the opacity of cirrus clouds.

Geoengineering is complex, and it is important to consider a variety of issues in considering this topic:

1. What are the consequences of particular geoengineering strategies to climate, ecosystems, and society?
2. How do these geoengineering strategies compare to each other?
3. How well do we understand the fundamental physics and chemistry of the processes employed by each strategy? Are climate models providing an adequate representation of these processes so that they may be used for studying geoengineering consequences?

Climate models can be used to explore the planetary response to geoengineering. Process models can be used to better understand the fundamental physics and chemistry that the strategies depend upon. I will describe a number of studies performed by our group using both types of models and identify some of the remaining challenges.

Secondary origin for 'primary' mineral inclusions in detrital zircons from Jack Hills, Western Australia

B. RASMUSSEN[1]*, I.R. FLETCHER[1], J.R. MUHLING[2], C.J. GREGORY[1] AND S.A.W. WILDE[1]

[1]Dept Applied Geology, Curtin Univ., Bentley, 6102, Australia (*correspondence: B.Rasmussen@curtin.edu.au, I.Fletcher@curtin.edu.au, C.Gregory@curtin.edu.au, S.Wilde@curtin.edu.au)

[2]CMCA, Univ. Western Australia, Crawley, 6009, Australia (janet.muhling@uwa.edu.au)

The Hadean crust has long been regarded to comprise mainly primitive mafic and ultramafic rocks. However, detrital zircons up to 4.4 Ga from Jack Hills, Australia, have been used to infer the existence of extensive granitic crust during the Hadean. Mineral inclusions in these zircons have been interpreted to be primary and magmatic, and therefore to provide important clues about the chemistry of the early crust.

In situ U-Pb dating of monazite and xenotime inclusions in detrital zircon grains from Jack Hills, shows that the inclusions are much younger than their zircon host, and formed during episodes of regional metamorphism at 2.68 Ga or 0.8 Ga. Monazite-xenotime thermometry of intergrowths in the inclusions and the quartz-muscovite rock matrix constrain temperatures to ~450°C, corresponding with conditions during peak metamorphism. Evidence from inclusions in zircon from other localities indicates that the replacement of primary inclusions may commence in the granite host-rock and continue after deposition through to high-grade metamorphism. In metasedimentary rocks, the inclusion assemblage in detrital zircon may increasingly resemble the composition of the rock matrix. In Jack Hills, the most abundant minerals filling inclusions are also the main matrix minerals (quartz and muscovite), consistent with their formation during metamorphism.

Our results show that detrital zircon is not impermeable to post-depositional fluids. We suggest that many of the primary inclusions were replaced by secondary minerals during metamorphism, raising doubts about the use of mineral inclusions in zircon to infer magma chemistry.

Integrating climate and landscape controls on regolith depth, chemistry and mineral assemblage

CRAIG RASMUSSEN[1]*, REBECCA LYBRAND[1], ANGIE JARDINE[2], JON PELLETIER[3], PETER TROCH[2] AND JON CHOROVER[1]

[1]Dept. of Soil, Water, and Environmental Science, Univ. of Arizona, AZ-85721, USA (*correspondence: crasmuss@cals.arizona.edu)

[2]Dept. of Hydrology and Water Resources, Univ. of Arizona, AZ-85721, USA

[3]Dept. of Geosciences, Univ. of Arizona, AZ-85721, USA.

Linkages among climate, erosion and mineral weathering are central to pedogenesis and critical zone evolution. We approach these linkages through synthesis of climate, erosion and regolith geochemical data for upland terrain, coupled with detailed studies on climate and landscape position controls on pedon-scale regolith weathering patterns across the steep semiarid climate gradient encompassed by the Santa Catalina Mountain (SCM) Critical Zone Observatory in southern Arizona, USA. Climate forcing was quantified in terms of effective energy and mass transfer (*EEMT*), that includes energy flux to the subsurface critical zone in the form of primary production and effective precipitation, whereas chemical depeletion and mineral transformation were quantifed using a combination of geochemical, isotopic and mineralgocial analyses. The regional synthesis indicated regolith chemical depletion increased exponentially with water availability and *EEMT* for sites with annual temperature greater than 5°C and erosion rates greater than 10 $g/m^2/yr$, suggesting first order control of climate on chemical depletion, and second order control of temperature and erosion. SCM geochemical and mineralogical data indicated strong linkages among *EEMT*, phyiscal erosion, regolith depth, chemical depletion and mineral assemblage. Specifically, divergent landscape positions demonstrated a pattern similar to that in the regional synthesis of increasing chemical depletion with increasing *EEMT*. In contrast, convergent landscape positions demonstrated minimal mineral mass loss and relatively greater content of neogenic secondary mineral phases. Solution chemistry data suggest the convergent positions concentrate soluble weathering products from adjacent divergent positions, thus resulting in locally reduced mineral-solution weathering gradients and promotion of neogenic mineral precipitation. The coupled datasets indicate that timing and amount of available water is a central control on regolith weathering with strong local-scale modification related to landscape position.

Behaviour of Zr/Hf and Y/Ho ratios during transition between seawater column and deep-sea brines

M. RASO[1], F. SAIANO[2], E. OLIVERI[3], M. YAKIMOV[4] AND P. CENSI[1,3]

[1]Dipartimento DiSTeM, Università di Palermo, Via Archirafi, 36 90123 - Palermo (Italy)
[2]Dipartimento S.A.G.A., Università di Palermo, Viale delle Scienze, ed.4, 90128 Palermo, Italy
[3]I.A.M.C.-CNR –UOS di Capo Granitola, Via del mare, 3 - 91026 Torretta Granitola, C.bello di Mazara (Italy)
[4]I.A.M.C.-CNR –UOS di Messina, Spianata S. Raineri, 86 - 98122 Messina (Italy)

During the oceanic cruise Mamba 2011 in the Eastern Mediterranean Sea seawater, biogeochemistry of the oxic layers and of the underlying anoxic deep-sea brines was studied. In order to extend the knowledge of processes occurring at oxic-anoxic interface in seawater, Zr/Hf ratio, coupled for the first time with Y/Ho and lanthanide behaviour, was investigated. Lanthanides and especially Y/Ho ratio are considered powerful probes of geochemical processes and a coherent behaviour with respect to Y/Ho was shown by the Zr/Hf ratio in several geochemical systems [1]. Observed covariance of Zr/Hf ratio with respect to dissolved Mn and Fe in anoxic brine, suggest that Zr was preferentially scavenged on MnO_2 surfaces under oxic conditions and the same process occurred for Hf onto FeOOH. These data confirm the observed behaviour in pore water studies [2] and extend the knowledge of Zr and Hf reactivity also onto Mn-oxides.

Different is the Y/Ho behaviour that correlates with dissolved Fe content, especially in brine from Tyro basin but not with Mn content, neither in brines, nor in oxic seawater. The observed lack of correlation observed among Y/Ho and Zr/Hf with respect Fe and Mn contents in seawater is probably due to the delivery of detrital materials in shallowest water layers.

The role of multicomponent diffusion and electromigration for reactive transport in porous media

PEJMAN RASOULI[1]*, K. ULRICH MAYER[1] AND SERGIO A. BEA[1,2]

[1]Department of Earth and Ocean Scinces, University of British Columbia, Vancouver, BC, Canada (umayer@eos.ubc.ca) (*correspondence: prasouli@eos.ubc.ca)
[2]now at: Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, USA (sabea@lbl.gov)

Aqueous diffusion is the dominant mass transport process in low permeability formations or in the absence of significant advection. There are systems in which electrostatic interactions between diffusing molecules strongly affect the apparent diffusion coefficients. Neglecting electromigration may lead to the inability of reactive transport models to adequately simulate diffusion dominated transport and to properly reproduce key phenomena such as mineral dissolution and precipitation [1]. An application for which electrochemical migration plays a significant role is the electrokinetic remediation of contaminated groundwater. Electrokinetic remediation is based on controlled application of low intensity direct current through the soil between electrodes. The change of redox condition induced near the electrodes shifts the thermodynamic conditions and ionic mobility with the goal to decontaminate the soil.

The formulation for numerical modeling of reactive transport including multicomponent diffusion and electromigration will be presented and preliminary results from simulations of electrokinetic remediation of metal contaminated soils will be discussed.

This modelling effort evaluates the importance of feedback mechanisms between electromigration, applied electric current, and homogenous and heterogeneous reactions in the aqueous phase and attempts to integrate the simulated response with observed geochemical data.

Mineral compositions indicate magma recharge processes in the Ilímaussaq Complex, Greenland

B. RATSCHBACHER*, M. MARKS, K. PFAFF AND G. MARKL

Eberhard Karls Universität Tübingen, 72072 Tübingen, Germany
(*correspondence: barbara.ratschbacher@yahoo.de)

The peralkaline Ilímaussaq intrusion, South Greenland, exhibits various types of syenites and nepheline syenites. The latest magma pulse represents the most evolved rocks (lujavrites), which mainly consist of eudialyte group minerals (EGM), feldspar, Na-pyroxene (aegirine) and sodic amphibole (arfvedsonite). Based on varying proportions of aegirine or arfvedsonite the lujavrites are subdivided into several units (Fig. 1). Our investigated samples cover the whole sequence of these rocks, including the upper part of the underlying cumulates (kakortokites). We analyzed early magmatic EGM to track the geochemical evolution of their parental melt. Textures (change from poikilitic to dispersed amphibole) and compositional variations (Fe/Mn and Ca/REE ratio systematics) imply that aegirine lujavrites I & IIA continuously evolved from the underlying kakortokites (Fig. 1). Data for arfvedsonite lujavrite A shift back to similar element ratios as aegirine lujavrite I and evolve further on a comparable trend. In contrast, aegirine lujavrite IIB and arfvedsonite lujavrite B data seem to evolve differently. We take these data as indication for the presence of three melts batches responsible for the formation of the lujavrite sequence, which is in contrast to earlier interpretations, who suggested that the kakortokite-lujavrite sequence formed from one single magma batch [1].

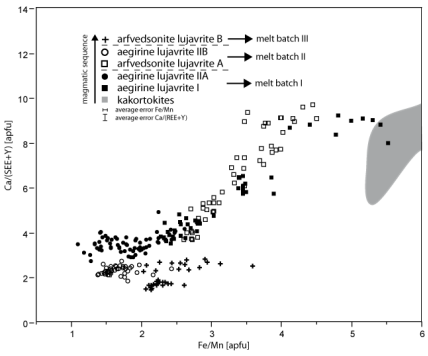

Figure 1: Element ratios in eudialyte; combined with data from [2].

Electrochemical enhancement of carbonate and silicate weathering for CO_2 mitigation

GREG H. RAU[1,2]* AND SUSAN A. CARROLL[2]

[1]Inst. Marine Sciences, Univ. Calif., Santa Cruz, CA 95064
[2]Carbon Management Program, Lawrence Livermore Nat. Lab., Livermore, CA 94550, USA
(*correspondence: rau4@llnl.gov)

Given the urgent need to stabilize if not reduce atmospheric CO_2 levels, might it be possible to safely and cost-effectively accelerate the consumption and storage of CO_2 via mineral weathering? Exposure of silicate and especially carbonate minerals to elevated CO_2 (e.g. flue gas) can effectively increase the reaction rates leading to CO_2 capture and storage via bicarbonate and/or carbonate formation (1). However, the slow kinetics of the silicate/CO_2 reactions appear to require additional chemical and/or physical treatment, especially in consuming more dilute CO_2 such as found in air. Because of the sensitivity of carbonate and silicate mineral dissolution to acids, and given the ability of saline water electrolysis to generate strong acids, it has been previously shown that electrochemistry can be used to accelerate mineral weathering for purposes of air CO_2 mitigation (2, 3). To explore this further, powdered wollastonite or ultramafic rock standard (UM-4) was encased around the acidic anode of a saline water electrolysis cell composed of graphite electrodes and a 0.25M Na_2SO_4 electrolyte solution. After 0.5 to 1.5 hrs of electricity application (3.5V_{dc}, 5-10mA), the electrolyte pH rose to as much as 11.1 (initial and blank pH's <6.6). Subequent bubbling of these basic solutions with air lowered pH by at least 2 units and increased dissolve carbon content (primarily bicarbonate) by as much as 50X that of the blanks. While Ca^{2+} and Mg^{2+} concentrations were elevated, these were insufficient to balance the majority of the bicarbonate anions in solution. We suggest that in these experiments the silicate minerals acted as acid absorbers, forming mostly insoluble $CaSO_4$ and $MgSO_4$ at the anode, thus allowing NaOH formation at the cathode to accumulate in solution, in turn reacting with air CO_2 to form $NaHCO_3$. Longer electrolysis times and/or alternative electrolyte solutions might allow formation and precipitation of Ca or Mg carbonates. Such electrochemistry might ultimately provide a safe, efficient way to harness the planet's: i) large, off-peak or off-grid renewable electricity potential, ii) abundant basic minerals, and iii) vast natural brine electrolytes for air CO_2 mitigation and carbon-negative H_2 production.

Calcium carbonate veins in ocean crust record a threefold increase of seawater Mg/Ca and Sr/Ca in the past 30 Million years

SVENJA RAUSCH[1], FLORIAN BÖHM[2], ANTON EISENHAUER[2], ANDREAS KLÜGEL[1] AND WOLFGANG BACH[1]

[1]Geoscience Department, University of Bremen, Germany (srausch@uni-bremen.de)
[2]IfM-GEOMAR, 24148 Kiel, Germany

Carbonates in the basaltic ocean crust form during low-temperature alteration and provide a significant sink of CO_2 in the global carbon cycle. Coggon *et al*. [1] calculated ancient seawater Mg/Ca and Sr/Ca ratios based on the record of calcium carbonate veins in the ocean crust and proposed that these ratios were quite uniform throughout the period between 170 and 24 Ma, but then suddenly increased by a factor of 4 to present-day seawater composition. This increase, although delayed by tens of millions of years, is interpreted as an effect of decreasing ridge flank hydrothermal activity, which may be related to a decrease in ocean crust production rate in the late Cretaceous. The goal of this study was to use calcium carbonate veins in reconstructing seawater Mg/Ca and Sr/Ca ratios with a specific emphasis on young sites (≤ 57 Ma) in cold ridge flanks. While our data fill gaps in the critical interval of compositional change in the past 30 Ma, they strongly corroborate the results of Coggon *et al*. [1] in showing simultaneous increases in Mg/Ca and Sr/Ca. Our data also indicate that the Mg/Sr ratio of seawater did not change in the Neogene. We find this to be at odds with a hydrothermal driver of seawater compositional change which should not leave Mg/Sr unchanged. We suggest that a scenario first proposed by Wallmann [2], can explain both the observed trends and the time lag between the late-Cretaceous and the Neogene compositional canges of seawater. The late Cenozoic decrease in ocean crust production rate led to an increase in the average age of the crust und thus to a sea level drop. Lower sea level caused a shift of carbonate deposition from the shelves to the pelagic ocean. Finally, subduction-recycle delayed transfer of CO_2 from deep-sea carbonates to volcanic arcs in combination with accelerated erosion increased the carbonate alkalinity input to the oceans and boosted the Ca sink flux by carbonate formation.

How Jupiter's two-phase gas-driven migration shaped the inner Solar System

SEAN N. RAYMOND[1], KEVIN J. WALSH[2], ALESSANDRO MORBIDELLI[2], DAVID P. O'BRIEN[3] AND AVI M. MANDELL[4]

Accretion simulations cannot adequately reproduce the terrestrial planets, in particular Mars' small mass [1]. Currently, the best solution to this problem assumes that the terrestrial building blocks were initially concentrated in a narrow annulus from 0.7-1 AU [2]. These initial conditions could have been sculpted by Jupiter's two-phase migration in the gaseous Solar Nebula: Jupiter first migrated inward due to standard type 2 torques, then back outward once Saturn grew and was trapped in 2:3 resonance [3]. If the turnaround point or "tack" occurred when Jupiter was at 1.5 AU then the inner disk of material would be truncated at 1 AU, forming a small Mars (Figure 1). In this scenario, the asteroid belt was first emptied and then re-filled by Jupiter: S-type asteroids (red in Figure 1) originated between 1-3 AU and C-types (blue) originated between the giant planets and beyond Neptune [4].

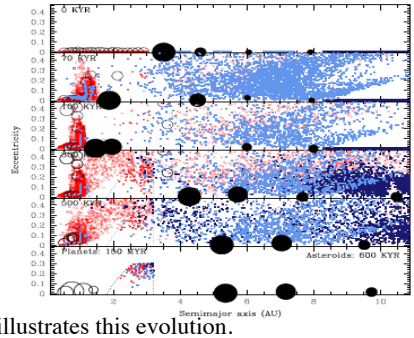

Figure 1: illustrates this evolution.

In the absence of migration, primitive C-type asteroids represent a plausible source for Earth's water [5]. In the context of the 'grand tack' model [4], this same population may still deliver water to the growing Earth: for every C-type planetesimal injected into the asteroid belt, ~10 were scattered onto eccentric orbits that intersect the terrestrial planet-forming region. These scattered C-types can deliver several oceans of water to the growing Earth.

Juvenile glass fragments in phreatic explosion debris from Turrialba Volcano, Costa Rica

MARK K. REAGAN[1], MICHAEL C. ROWE[2], ELIECER DUARTE[3] AND ERICK FERNANDEZ[3]

[1]U. Iowa, Iowa City IA, 52242 USA, (mark-reagan@uiowa.edu)
[2]Washington State U., Pullman WA, 99164 USA
[3]OVSICORI, UNA, Costa Rica

After several years of increasing fumarolic activity, Turrialba volcano experienced small phreatic explosions on January 5-6, 2010, leaving a 55x20 m crater with an incandescent floor. Ash and lapilli from the explosions consists mostly of crystal-rich and altered material originally erupted in 1864-1866 and earlier. Nevertheless, careful examination of the tephra revealed that ~1% of the medium to coarse ash-sized particles consists of fresh glass. The freshness of the glass and its unusual chemical traits suggest that this glass is juvenile. EMP analysis of the glass fragments showed them to be calcalkaline andesites, whose major element compositions were largely consistent with derevation by low-P crystal fractionation of basaltic parental magmas. Na_2O, however, is depleted in most glass fragments (1.1-2.8 wt. %) compared to Turrialba's basaltic lavas (2.8-3.8). Incompatible trace element compositions determined by LA-ICPMS are broadly similar to those of the 1864-1866 basalts. REE element patterns are strongly light enriched and most fragments have the elevated Ba/Ce and La/Nb ratios (8-16 and 1.8-2.2 respectively, which is commonplace for calcalkaline lavas. However, one fragment had Ba/Ce and La/Nb ratios (5 and 1.1) more typical of an ocean island basalt, but was otherwise similar in composition to the other fragments.

The concentrations of S in all fragments were near the EMP detection limit, and Cl in most samples were also unusually low for a Turrialba basalt. The concentrations of F, however, were highly variable, ranging from 0.03 to 0.6 wt. %. High F was associated lower concentrations of Na, REE and HFS elements. We speculate the F was enriched by interaction with high-T fumarolic gasses which also leached highly-charged cations and Na.

Important findings are: (1) phreatic explosion debris can contain juvenile glass fragments that provide compositional information about the magma triggering the unrest; (2) magmas intruding into Turrialba's upper edifice at present are basalts or basaltic andesites with varying La/Nb; and (3) gas streaming can affect compositions of apparently fresh glass, particularly Na concentrations.

Glass composition impact on water reactivity at the glass surface

D. REBISCOUL[1]*, F. BRUGUIER[1], V. MAGNIN[2] AND S. GIN[1]

[1]CEA Marcoule,CEA/LCLT, BP 17171, 30207 Bagnols-sur-Ceze BP 17171, 30207 Bagnols sur FRANCE (*correspondence: diane.rebiscoul@cea.fr, florence.bruguier@cea.fr, stephane.gin@cea.fr)
[2]ICSM,/LDD, BP 17171, 30207 Bagnols-sur-Ceze, FRANCE (valerie.magnin@cea.fr)

Understanding the interactions of water with glass surface is of great interest to improve glass alteration models. In this study, the impacts of soda-lime borosilicate glass composition [1] and particularly the effect of network formers such Si and Zr, and of charge compensators such Ca and Na, on water penetration and water structure at the first time of alteration were investigated. Two surface characterizations were used: X-ray reflectometry to determine the thickness and density of the modified glass zone and attenuated total reflection infrared spectroscopy to precise the predominant alteration mechanisms (water diffusion through glass network or hydrolisis) resolving the O-H streching band into four components corresponding to different types of water in glass (hydroxilic group, free, newtwork and ion bounded water). The results of glass alteration at pH=3 and 30°C have shown that hydrolisis was the predominant mechanism after few seconds for glass having a low ZrO_2/SiO_2 ratio. This phenomenon can be explained by the high amount of NBO content. For the other glasses, the diffusion was the limiting reaction characterized by a modified zone having a density close to the hydrated glass and a high amount of free water. The calculated water diffusion coefficients hilighted a decrease of the water diffusion with an increase of Ca content in glass probably due to the compaction of the network by incorporation of divalent cations [2].

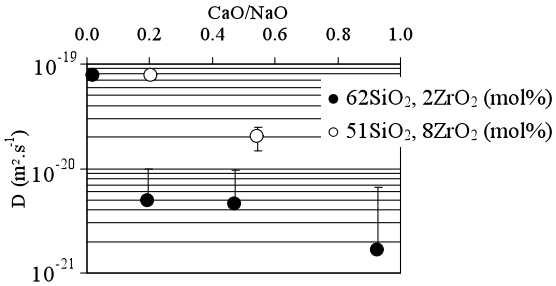

Figure 1: Diffusion coefficients of water through the glasses at pH=3 and 30°C calculated from the first Fick law.

The combined use of CALIOP, MODIS and OMI aerosol and cloud products for calculating direct aerosol radiative effects

JENS REDEMANN[1], M. VAUGHAN[2], Y. SHINOZUKA[1], P. RUSSELL[3], J. LIVINGSTON[4] AND L. REMER[5]

[1]BAER Institute/NASA Ames, 290 Maple Ct. Ste. 268, Ventura, CA 93003, USA (*correspondence: Jens.Redemann-1@nasa.gov)
[2]NASA Langley Research Center, Hampton, VA 23681, USA
[3]NASA Ames Research Center, MS 245-5, Bldg. 245, P.O. Box 1, Moffett Field, CA 94035, USA
[4]SRI, International, G-179, 333 Ravenswood Ave., Menlo Park, CA 94025, USA
[5]NASA Goddard Space Flight Center, code 613.2, Bldg. 33, Greenbelt, MD 20771, USA

We describe a technique for combining CALIOP aerosol backscatter, MODIS spectral AOD (aerosol optical depth), and OMI AAOD (absorption aerosol optical depth) measurements for the purpose of estimating full spectral sets of aerosol radiative properties, and ultimately for calculating direct aerosol radiative effects. We will present first results using 1-month of collocated CALIOP V3, MODIS and OMI data collected in October 2007, as well as a test of our methodology using airborne observations in the ARCTAS field experiment. As a prerequisite for the application of our methodology to the actual satellite observations, we assessed the consistency between comparable measurement quantities from the different A-Train sensors. For eight months in 2007 and 2009, comparisons of the standard MODIS-Aqua AOD data to AOD calculated from CALIOP aerosol extinction profile data show differences in global, monthly mean, over-ocean AOD (532nm) between CALIOP and MODIS ranging between between 0.025 and 0.04 for CALIOP V3, with CALIOP generally biased low. Differences for CALIOP V2 are often smaller, but correlation with MODIS AOD is significantly lower.

Anelastic processes in minerals at high temperature: Examples of quartz and spinel

S. REDFERN*, Z. PENG, J. WALSH AND M. DARAKTCHIEV

Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge, CB4 2BD, UK (*correspondence: satr@cam.ac.uk)

Features of recent mechanical spectroscopic studies in Cambridge will be reviewed. The first measurements of higher-order harmonic responses of coelastic materials at displacive phase transitions are reported: Second and third harmonics of strain have been measured by forced torsion pendulum for quartz at the high-low transition. The incommensurate phase and the highly non-linear thermal expansion of quartz at this transition may play a role in controlling higher order elastic moduli. Jerky elastic and strain responses to applied stress also reveal themselves in such experimental arrangements, and we have seen the development of power law distributions of such elastic noise in a number of systems. Self-induced defects appear to lead to such crackling microstructures.

As a contrasting example, the high temperature behaviour of $MgAl_2O_4$ spinel is known to be dominated by kinetic rearrangements of Mg and Al cations as the system undergoes non-convergent order-disorder. We have measured the anelastic loss associated with such order-disorder processes in crystals and ceramics of spinel at ambient and high pressure. The loss is revealed as a strong anelastic relaxation, with well-defined activation energy and relaxation time, in the seismic frequency range. Finally, the implications for seismic damping in ringwoodite spinel are considered.

Methane geochemistry's 'stealth' process: Microbial oxidation

WILLIAM S. REEBURGH

Earth System Science, University of California Irvine, Irvine, CA, 92697, USA (reeburgh@uci.edu)

For the purposes of this presentation, I consider a 'stealth' process as one that cannot be directly measured. Microbial methane oxidation, aerobic and anaerobic, are examples. Most of the fluxes used to assemble the global methane budget are net fluxes, the difference between production and consumption, so direct measurements of production and consumption require tracer measurements. Several recent high-profile climate modeling papers have fallen into the 'stealth process' trap by failing to explicitly consider microbial oxidation.

This talk reviews recent developments in quantifying methane oxidation in the oxic ocean and estimates the global importance of both aerobic and anaerobic oxidation in a range of environments as controls on global change induced production. New methods sre discussed and remaining challenges are enumerated.

Phase separation, degassing and anomalous methane at the Menez Gwen hydrothermal field

EOGHAN P. REEVES[1], X. PRIETO[1], M. HENTSCHER[1], M. ROSNER[2], J. SEEWALD[3], K.-U. HINRICHS[1] AND W. BACH[1]

[1]MARUM Center for Marine Environmental Sciences, Universität Bremen, Bremen 28359, Germany (*correspondence: reeves@uni-bremen.de)

[2]Fachbereich Geowissenschaften, Freie Universität Berlin, Berlin 12249, Germany

[3]Woods Hole Oceanographic Institution, Woods Hole MA 02543, USA

The Menez Gwen neovolcanic dome, lying at ~800m depth, hosts one of the shallowest basalt-hosted hydrothermal systems on the Mid-Atlantic Ridge and vent fluids there have unusually high CH_4/H_2 ratios relative to ultramafic- and other basalt-hosted systems [1]. To further constrain the origin of this CH_4, fluids were sampled in 2010 from vents on the dome's eastern flank, and from a newly discovered vent field, Bubbylon, 5km to the south of the Menez Gwen dome.

Maximum vent temperatures (270–298°C) in the eastern Hot Sands and AzorAna areas are near the 2-phase boundary and near-seafloor subcritical phase seperation (boiling) is pervasive. Endmember CH_4 (0.37–3.6mmol/kg) and CO_2 (11–78mmol/kg) concentrations are high, but H_2 (0.06–0.57mmol/kg) is low, and only a narrow Cl range (202–368mmol/kg) is evident. Two volatile-rich diffuse fluids (91–117°C) sampled appear to have formed by subsurface mixing of near zero salinity vapor phases with entrained seawater, with apparent CH_4 and CO_2 end-member concentrations of ~30 and ~600mmol/kg, respectively. Such extreme volatile enrichments due to boiling are likely responsible for the ubiquitous gas bubble exsolution evident at the seafloor, releasing substantial CO_2 and CH_4 to the water column. Despite boiling-related variability, endmember CH_4/H_2 ratios (2.5–18) remain anomalously high in 2010. Trace NH_4^+ concentrations (<5µmol/kg) and $\delta^{13}C_{CH4}$ values (-16.6‰ to -19.9‰) within the typical range of unsedimented systems preclude any subsurface sedimentary source of thermogenic CH_4 [2]. Thermodynamic considerations also exclude abiotic CO_2 reduction to CH_4 at the conditions encountered by fluids. This suggests a deeper source of CH_4, such as the volatile-rich fluid inclusions found in oceanic crust Layer 3 [3]. CH_4 radiocarbon and C_{2+} hydrocarbon analyses are ongoing.

Oceanic basalts provide a biased view of mantle composition

MARCEL REGELOUS, KARSTEN M. HAASE AND PHILIPP A. BRANDL

GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Erlangen, Germany (regelous@geol.uni-erlangen.de)

Chemical and isotopic variations in oceanic basalts are commonly used to infer the chemical structure and evolution of the Earth's mantle. The mantle source of intraplate oceanic basalts is thought to be more 'enriched' than that which melts beneath spreading ridges, due to a greater contribution from recycled oceanic crust or sediment, which can be identified using incompatible trace element and isotope ratios. This approach assumes that mantle melts inherit the incompatible trace element and isotope ratios of their mantle source, an assumption which is also inherent in many geochemical models for melting at spreading ridges and ocean islands.

We will present geochemical data for lavas erupted during slowdown and after the end of active spreading on the fossil Galapagos Rise spreading centre, which show that many oceanic basalts probably do not faithfully record the average composition of the volume of mantle that is melted. Galapagos Rise lavas were generated by variable degrees of melting from 'normal' depleted upper mantle, yet display an enormous range of compositions. At 9.2 Ma, before spreading ceased, incompatible element depleted NMORB (0.75 ppm Nb, Nb/Zr 0.011, $^{87}Sr/^{86}Sr$ 0.70251) were erupted. Younger post spreading lavas, dated at between 7.5 and 5.7 Ma, were produced by smaller degrees of melting and are increasingly enriched. The youngest basalts are trace element enriched EMORB with 77.9 ppm Nb, Nb/Zr 0.256, $^{87}Sr/^{86}Sr$ 0.70311.

The correlated trace element and isotope variations in Galapagos Rise lavas are inconsistent with simple mixing of endmember melt compositions, and also cannot be explained by melting of variably heterogeneous mantle in which enriched and depleted materials contribute equally to melting. Instead, our data can be explained by variable degrees of melting of heterogeneous mantle, within which incompatible element enriched lithologies melt to a greater extent than the more depleted 'matrix'. Our results have implications for the way in which oceanic basalts can be used to infer mantle melting processes and source compositions. For example, the 'garnet signatures' inferred from rare earth element and Nd isotope compositions in MORB may be more sensitive to variations in mantle composition, than to the average depth of melting. Melts of heterogeneous mantle will be biased towards the compositions of more fertile, enriched lithologies, so that the mantle may be significantly more depleted than is often assumed.

Monitoring fluid properties in a geothermal plant

SIMONA REGENSPURG*, HARALD MILSCH, RONNY GIESE AND MATHIAS POSER

Helmholtz-Centre Potsdam, German Research Centre for Geosciences (GFZ) Potsdam, Germany (*correspondence: regens@gfz-potsdam.de)

Measuring chemical properties of geothermal fluids, processed in a geothermal plant is challenging due to high temperatures, salinities and change of conditions resulting in chemical reactions such as corrosion or scaling (=mineral precipitation). At the geothermal *in situ* research laboratory Groß Schönebeck (Germany) chemical reactions of a fluid produced from a Permian sandstone at ~ 4300 m depth, are investigated by a newly developed, fluid-chemical monitoring unit. The apparatus can be connected to different locations at the above ground installations. At these adapters, part of the fluid from the main pipe, would flow through a bypass containing a small heat exchanger. On both sites of the heat exchanger a sampling unit as well as probes to measure pH value and redox potential are installed which can be operated at 150 and 70°C, respectively. Besides high temperatures, the sensors need to be corrosion resistent due to the high chloride concentration typically found in geothermal brines (up to 5 M).

The device simulates processes occuring at heat exchangers which are typically installed in geothermal plants to transfer the heat of the fluid for electric energy production. The chemical informations obtained from this monitoring unit describe not only the compositional variability of the produced fluid over time, but also chemical processes and their kinetics potentially occurring within the plant due to temperature decrease, which could result in corrosion or clogging of the pipes and components. In Groß Schönebeck, chemical equilibrium caculations indicated oversaturation of sulfate-, silicate-, iron- and lead minerals due to temperature drop. The monitoring validates modeled reactions and thus gives evidence on these reactions and might finally predict plant failures.

The ^{129}I isotopic composition of supergene iodine minerals in Chile and Australia

MARTIN REICH[1,2], FERNANDA ALVAREZ[1], ALIDA PÉREZ[1], GLEN T. SNYDER[3], C. PALACIOS[1], G. VARGAS[1], Y. MURAMATSU[4], EION M. CAMERON[5] AND UDO FEHN[6]

[4]Department of Chemistry, Gakushuin University, Tokyo, Japan
[5]Eion Cameron Geochemical Inc., Carp, ON, Canada
[6]Department of Earth and Environmental Sciences, University of Rochester, Rochester, NY

Because of its large ionic radius, iodine (I) is rarely incorporated into minerals and remains in the aqueous phase much longer than other halogens. Naturally-formed I minerals are very rare, but are found in the nitrate ore fields of the Atacama Desert in Chile and the supergene zones of base and precious ore deposits in extremely arid environments (Chile, Australia). The presence of I in Cu deposits in northern Chile has not been investigated previously, but provides the opportunity to apply the ^{129}I system for the study of the tectonic history of the area and of climatic changes, particularly the desiccation of the Atacama region.

Here, we report the first ^{129}I data of iodide minerals from supergene zones of Cu and Ag deposits from the hyperarid Atacama Desert. Two marshite (CuI) samples from the supergene zone of the Chuquicamata Cu deposit show ^{129}I/I ratios of 218 ± 72 and 562 ± 77 ($\times 10^{-15}$ at·at^{-1}), similar to the ^{129}I isotopic signature of a geochemically anomalous, iodine-rich soil sampled above the Spence porphyry Cu deposit (473 ± 75). Therefore, mineral and soil samples range between typical volcanic arc fluids (^{129}I/I~700-1000) and forearc fluids (^{129}I/I~100-250). In contrast, marshites and iodargyrites (AgI) from the Broken Hill Pb-Zn-Ag deposit in Australia and the Chañarcillo Ag deposit in Chile show a wider dispersion of ^{129}I/I ratios, ranging from ~100 to 2000, indicating a significant meteoric influence.

We suggest that I-rich fluids were involved in supergene enrichment and recycling of Cu in the Atacama region, revealing a complex link between mutliple sources of fluids, active tectonics and climate change.

Melting conditions associated with the Colorado Plateau, USA

M.R. REID[1]*, ROMAIN A. BOUCHET[2] AND J. BLICHERT-TOFT[2]

[1]School of Earth Sciences and Environmental Sustainabiliy, Northern Arizona University, Flagstaff, AZ 86011-4099 USA (mary.reid@nau.edu)
[2]Ecole Normale Supérieure de Lyon, 69007 Lyon, France

Continental foundering occurs by lithospheric detachments associated with gravitational instabilities as well as by shear-related thinning. Volcanic activity is progressively encroaching on the otherwise tectonically stable Colorado Plateau in the southwestern U.S. We show that decompression melting of local ambient enriched mantle lithosphere - rather than compression melting of lithospheric mantle drips or delaminations, or decompression melting of the asthenospheric mantle return flow - is likely responsible for this volcanism. New Hf and Nd isotope data (>120 analyses) significantly expand evidence for heterogeneous enriched mantle sources beneath the Colorado Plateau. ^{206}Pb/^{204}Pb values <18.5 and as low as 17, characterize those samples with Hf-Nd isotope signatures that are evocative of mantle enrichment by mixing with pelagic ± terrigenous sediments: values >18.5 would be expected if Cordilleran and other sediments had been incorporated into their sources during Laramide-aged (80–40 Ma) shallow subduction. Relative abundances of minor and trace elements further show that the more volumetrically significant melts are sourced dominantly in peridotite rather than in pyroxenite or eclogite. Silica- and MgO-based thermobarometry supports evidence from trace element fractionation that melting locally transcends the garnet-spinel transition (~75 km), with shallower melts characterized by higher degrees of partial melting. Low P- and S-wave velocity domains, pronounced thinning of the lithosphere beneath the margins of the Colorado Plateau, and possible evidence for lithospheric delamination [1] may be further evidence that localized mantle upwelling is responsible for Colorado Plateau volcanism.

Biogeochemistry as a regional mineral exploration tool: Northeast Yilgarn Craton, Western Australia

N. REID[1]*, M.J. LINTERN[1], R.R.P. NOBLE[1], R.R. ANAND[1], D.J. GRAY[1], G. SUTTON[2] AND R. JARRETT[2]

[1]CSIRO Earth Science and Resource Engineering, Kensington WA 6151, Australia (*correspondence: nathan.reid@csiro.au)

[2]CSIRO Mathematics, Informatics and Statistics, Urrbrae SA 5064, Australia

Regional biogeochemical surveys can potentially be of great use for mineral exploration where access problems and the hindrance of transported overburden make other techniques problematic. A large area of the north Yilgarn Craton hosting numerous Ni, Au, U and VMS deposits was selected for this proof of concept study. *Acacia aneura* (mulga) was sampled approximately every 8 km in this region as it is one of the most widespread plant species across Australia. Mulga samples were collected at water wells and bores corresponding to a regional hydrogeochemistry sampling program. Vegetation samples were dried, split, milled, digested in aqua regia then analysed using ICP-MS/OES. A large, robust, statistically verified geochemical data set was generated which provides the ability to detect lithological signatures using geochemical indices and multivariate statistics (with around 20% error of prediction). Uranium in mulga was the only distinct target element for secondary U deposits, and was successful for most known prospects. Gold exploration potential was improved by the use of multi-element indices. Nickel prospects were identified where the samples were close to the prospects (<2 km) or where supergene mineralisation was dispersed. The Leinster and Murrin Murrin areas were highlighted by elevated Ni, Co, Cr and Fe concentrations compared to background with haloes up to 20 km wide. Detection of VMS style deposits is hampered by Zn and Cu being essential plant nutrients however, high Zn values seen on the regional scale may warrant further investigation. Little correlation exists between hydrogeochemistry and biogeochemistry, meaning one cannot be used as a surrogate for the other; however, both are useful tools in detecting mineralisation and lithological signatures using different chemical properties for a regional setting. Also, mulga can be sampled without the need for drilling to access groundwater.

Sensitivity and feedback in the oceanic molybdenum cycle

C.T. REINHARD[1]*, C.T. SCOTT[2] AND T.W. LYONS[1]

[1]Dept. of Earth Sciences, Univ. of California, Riverside, Riverside, CA 92521 (timothyl@ucr.edu) (*correspondence: christopher.reinhard@ucr.edu)

[2]Dept. of Earth and Planetary Sciences, McGill Univ., Montreal, QC H3A 2A7 (clinton.scott@mcgill.ca)

The oceanic inventories of trace elements have fluctuated markedly during Earth's history as a function of prevailing Earth surface redox conditions. Given the importance of many trace elements in a wide variety of enzymatic processes, such changes may have had significant downstream effects on the global biogeochemical cycling of carbon, nitrogen, and oxygen [1]. Molybdenum (Mo) is particularly important in this regard, being a crucial catalytic component of enzymes involved in biological N_2 fixation, assimilation of NO_3^-, and oxygen atom transfer reactions.

Here, we explore the response of the oceanic Mo reservoir to perturbations in marine redox in a one-box ocean model in which Mo enrichment and burial are first-order with respect to the ambient Mo reservoir. Despite imposing this negative feedback, we find that relatively small changes in ocean redox can have significant effects on the concentration of Mo in seawater ($[Mo]_{sw}$) at steady state, and that relaxation to steady state following perturbation occurs relatively quickly. In addition, although it is possible to draw down $[Mo]_{sw}$ to levels that would have been likely to exert negative effects on some biological processes, the muted enrichments seen in many Proterozoic black shales [2] are likely not compatible with global-scale sulfidic conditions.

In order to further explore the feasibility of attaining varying degress of expanded anoxia we employ a simple oxygen budget for the modern North Atlantic. This exercise corroborates that of [3], and suggests that the redox state of the deep ocean could have been severely impacted purely by air-sea gas exchange limitations at presumed Proterozoic atmospheric oxygen levels. Further, a simple regional budget of sulfide and highly reactive iron (Fe_{HR}) fluxes to marine sediments suggests that were the ocean to become anoxic due to limited O_2 supply (as in the Proterozoic) the deep ocean would most likely have become ferruginous (anoxic and Fe-rich) [4] while marginal environments would likely have been prone to sulfidic conditions.

Transformations of silver nanoparticles in environmental systems

B.C. REINSCH[1,2], R MA[1,2], C. LEVARD[2,3], N. KABENGI[2,4], G.E. BROWN JR.[2,3], C.S. KIM[5] AND G.V. LOWRY[1,2]*

[1]Carnegie Mellon University, Pittsburgh, PA 15213, USA (*correspondence: glowry@cmu.edu)
[2]Center for the Environmental Implications of Nanotechnology (CEINT)
[3]Stanford University, Stanford, CA 94305, USA
[4]University of Kentucky, KY 40546, USA
[5]Chapman University, Orange, CA 92866, USA

The persistence, toxicity, and effects of silver nanoparticles (AgNPs) released to the environment depends on their eventual speciation. Reduced sulfur-silver species are predicted to dominate the eventual species that form. However, in the environment, especially in aerobic conditions, other ligands are more abundant, such as Cl^-, organic thiols, SO_4^{2-}, Br, and I^-. To idenity important transformations from 'weathering' and predict the speciation of silver naoparticles weathered in environmental samples, engineered AgNPs were weathered in various environmental conditions including: wastewater treatment byproducts, aerobic and anaerobic soils, and in simulated wetland mesocosms. Synchrotron-based X-ray absorption spectroscopy was used to speciate AgNPs aged under simulated weathering conditions in the laboratory. Comparisons between the speciation of AgNPs that had been weathered for up to 18 months in a simulated wetland and laboratory weathering can be used to create particles that mimic the observed changes in environmental samples. Protocols to rapidly weather engineered nanomaterails will allow researchers to use NPs with properties representative of the materials that will be in the environment rather than those of the pristine materials. This will enable better predictions of the environmental fate, transport, and effects of engineered nanoparticles.

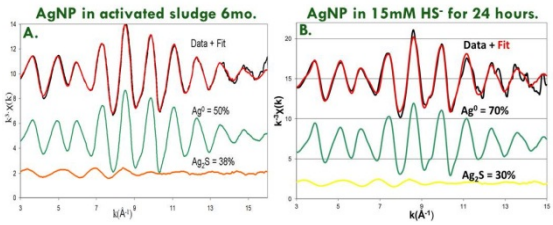

Figure 1: The original AgNPs containing ~90% Ag^0 have been transformed to approximately 50% Ag^0 and 30%Ag_2S after 6 months of ageing in activated sludge, shown in A. B shows the resulting particles from a laboratory ageing process that has produced a particle of somewhat similar composition after only 24 hours of ageing in Na_2S.

The Os isotopic record of organic rich sediments from the Benguela Upwelling System, Namibia

L. REISBERG[1]*, D. BLAMART[2] AND C. ZIMMERMANN[1]

[1]CRPG (CNRS UPR2300), Université de Lorraine, BP 20, 54501 Vandoeuvre-les-Nancy, France (*correspondence: reisberg@crpg.cnrs-nancy.fr)
[2]LSCE (CEA-CNRS-UVSQ), Avenue de la Terrasse, 91198 Gif-sur-Yvette Cedex, France

Several recent studies [1-5] have shown a correlation between osmium isotopic variations in marine sediments and glacial-interglacial cycling. These correlated variations have been used to argue for direct climatic control on weathering intensity and/or on the composition of erosional products. However these rapid fluctuations in the marine Os isotopic records suggest a residence time for Os in seawater (3 to 10 ka) that is much shorter than that inferred from mass balance (~ 25 to 40 ka, [6-8]). Furthermore, potential problems linked to sampling site or sediment type, such as basin isolation, detrital contributions, and low sedimentation rate, could bias many of the existing Os records.

To obtain a reliable, high resolution record of marine Os isotopic variations in Quaternary times, we are analyzing sediments from ODP Leg 175, Site 1084, drilled off the coast of Namibia beneath the Benguela Upwelling System. This is an open ocean site containing rapidly deposited (~ 18 cm/kyr) organic rich sediments, which should be unaffected by the possible problems that may have plagued earlier studies. We currently have results for 9 samples spanning the most recent 35 ka of this record. These samples have extremely high Re and Os concentrations (58-157 ppb and 0.19-0.34 ppb, respectively). Their $^{187}Os/^{188}Os$ ratios are quite constant (1.044 ±0.013, 2σ), and show only a tiny hint of the nearly 7% decrease in $^{187}Os/^{188}Os$ during the last glacial maximum observed in several previous studies. Instead, the uniformity of the Benguela Os record is similar to that reported for an early Pleistocene record from the equatorial Pacific Ocean [9]. The discrepancies between the Os records from different sediment types and localities must be better understood before these records can be used to constrain relationships between climate and weathering.

The geomicrobiology of gold: Fundamental processes to industrial applications

FRANK REITH[1], GREGOR GRASS[2], CARLA ZAMMIT[1], GORDON SOUTHAM[3] AND JOËL BRUGGER[1]

[1]The University of Adelaide, Geol. & Geophys., Adelaide SA5005, Australia (Frank.Reith@csiro.au)
[2]University of Nebraska-Lincoln, Lincoln NE 68588-0666, USA
[3]University of Western Ontario, London, ON, Canada N6A 5B7

The biosphere catalyzes a variety of biogeochemical reactions that transform gold (Au) [1, 2]. Microbial weathering contributes to the mobilization of Au by releasing Au trapped in minerals and by solubilizing it via complexation. Subsequent microbial destabilization of Au (I/III)-complexes coupled to bio-precipitation and biomineralization leads to secondary Au formation, completing the cycle. Secondary Au occurs as nano-particles as well as micro-crystalline and 'bacteriomorphic' Au, the latter being a controversial form of 'biogenic' Au. Recent research provides an understanding of genetic and biochemical mechanisms that microorganisms utilize to drive this biogeochemical cycle. These studies show that: (1) microorganisms mediate Au solubilization via excretion of metabolites, e.g. cyanide, amino acids and thiosulfate; (2) precipitate Au intra- and extracellularly, and in products of their metabolism leading to the formation of Au biominerals; and to achieve this (3) have developed biochemical responses to deal with toxic Au (I/III)-complexes.

Using genomic, proteomic and synchrotron spectroscopic techniques genes and proteins involved in Au detoxification have been characterized. For example, a transcriptional regulator (GolS) in the bacterium *Salmonella enterica* is activated specifically by Au-complexes. Activated GolS then activates the expression of a metallochaperone gene (*golB*) and of a transmembrane efflux ATPase (*golT*), which promote Au resistance [3]. Using these results a biosensor for Au is in development allowing the quantification of Au from environmental samples. This will provide a cost-efficient and environmentally sustainable technique for the improvement of Au exploration and ore processing.

Mobility of platinum and gold in the Australian regolith – Spectroscopic and electron microscopic analyses

FRANK REITH[1], CHRISTINE TA[2], BARBARA ETSCHMANN[1], CLAIRE LENEHAN[2] AND JOËL BRUGGER[1]

[1]The University of Adelaide, Geol. & Geophys., Adelaide SA5005, Australia (Frank.Reith@csiro.au)
[2]Flinders University, Adelaide SA5001, Australia

Biogeochemical cycling of gold (Au) and platinum (Pt) appears to play a fundamental role in the formation of secondary Pt and Au in placer deposits, and secondary 'biogenic' Pt and Au has been reported from Brazil and Australia [1, 2]. To compare Pt and Au mobility, Pt/Au nuggets, soils and groundwaters were collected from a platinoferous and auriferous site near Fifield, New South Wales, Australia. Collected materials were analyzed using (FIB)-SEM-(EDXA/EBSD), ICP-MS, EPMA, ICP-MS/OES, X-ray tomography, synchrotron-μXRF, and thermodynamic modeling.

Secondary morphologies, presence of nano-particle and formation of micro-crystalline enrichment zones of Pt/Au on surfaces of Pt/Au grains suggest (bio)geochemical dissolution and re-precipitation that promote the mobility of Pt and Au in surface environment. This is supported by X-ray tomography of a rare specimen of deep lead material (Fe-oxides, silicates and clays) with embedded Pt- and Au grains. Grain surfaces display filigree and perforated structures, strong rounding of grains and the formation of nano- and micro-particles. Synchrotron μXRF-mapping and FIB-SEM of polished sections uncovers differences in Au and Pt mobility. This is supported by groundwater data and geochemical modeling, suggesting lower Pt compared Au reactivity, and hence mobility, in surface environments.

Distinguishing periods of crustal growth and recycling by U-Pb dating, Sr, Pb and Hf isotopes among the Eastern Cordilleran granitoids of South Peru

MARIËL REITSMA[1]*, U. SCHALTEGGER[1], R. SPIKINGS[1], M. CHIARADIA[1], A. ULIANOV[2] AND A. GERDES[3]

[1]Université de Genève, Rue des Maraîchers 13, 1205 Geneva, Switzerland (*correspondence: martje.reitsma@unige.ch)
[2]Université de Lausanne, Switzerland
[3]Goethe University, Frankfurt am Main, Germany

The backbone of the Eastern Cordillera of south Peru is built of plutons that have previously been mapped as Permo-Triassic. They were related to an extensional event that generated continental basins at the surface, filled with the sediments of the Mitu Group.

The aim of this study is to decipher age trends among the granitoids and asses their contribution to crustal growth. U-Pb laser ablation ICPMS dating of zircons shows that the plutons of the north-west trending Cordillera de Carabaya are middle to upper Triassic in age, while the plutons in the Abancay deflection are older: Ordovician, Carboniferous and Permian. Triassic plutons continue in north-western direction to the south of the Abancay deflection.

Hf-isotope data show positive εHf (~+2 to +4) for the Paleozoic plutons indicating a mantle dominated source while the Triassic plutons have εHf around 0 to -4 indicating mixing of mantle and crustal sources.

The Triassic plutons match exactly the age of the sediments of the Mitu group. Therefore, we conclude that these granitoids formed via partial crustal anatexis associated with extension. The offset of the plutons around the Abancay deflection could be interpreted as a step over in the Mitu rift. The Ordovician, Carboniferous and Permian plutons coincide with times of known continental arc magmatism along the western Gondwana margin and were emplaced in a back-arc setting.

Hf-isotope results for both tectonic settings indicate variable amounts of juvenile input from the mantle and/or from a lower crustal source, reflecting an increasing importance of a crustal component in the Triassic. However, with the present data we cannot quantify crustal growth versus crustal recycling yet.

Historical perspective of passive aerosol remote sensing: Bridging the years

LORRAINE A. REMER AND OMAR TORRES

NASA Goddard Space Flight Center, Greenbelt MD 20771 USA (Lorraine.A.Remer@nasa.gov, Omar.O.Torres@nasa.gov)

For nearly three decades space sensors designed for other purposes were used to observe, quantify and characterize atmospheric aerosols. During this ‘heritage period’, algorithm development focused on three primary methods. (1) Occultation methods that measure the extinction of solar radiation and provide vertical profiles of aerosol extinction through the stratosphere. (2) Dark target methods that use the brightening of the scene to infer aerosol loading. (3) UV methods that use the deviation of the observed signal from expected Rayleigh scattering values. Besides these three main methods applied to the SAM/SAGE, AVHRR and TOMS measurements, respectively, to produce long aerosol time series, other methods have been developed to make use of multiangle, polarization and geosynchronous capabilities. These satellite aerosol products applied to data collected in the 1980s and 1990s made way for the era of the modern sensors that began with the launch of Terra in late 1999. The modern sensors: MODIS, MISR, OMI etc., were designed with aerosol in mind, but specifically with the goal of providing information that would help reduce uncertainties in estimates of climate forcing. The quantitative information they provided was unexpectedly also used in other applications including air quality forecasting, public health studies, and long-range transport of dust and pollutants. Thus, the modern satellite data helps to bridge the scales, as well as the years.

An experimental study of brine-CO_2 metal fractionation: Applications to the geological storage of CO_2

KIRSTEN U. REMPEL*, AXEL LIEBSCHER, WILHELM HEINRICH AND GEORG SCHETTLER

GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany (*correspondence: rempel@gfz-potsdam.de)

In this study, we have measured the fractionation of Fe, Cu, Zn and Na between brine and carbon dioxide at pressure-temperature conditions applicable to the saline aquifers used for the geological storage of CO_2, in order to evaluate the potential for trace element remobilization within the injected CO_2 plume. The experiments were carried out at 6.5-16 MPa and 60°C in a Ti autoclave loaded with a 20 wt% NaCl solution containing a known concentration of Fe, Cu or Zn, in addition to pressurized CO_2. Paired samples of brine and CO_2 were extracted from separate capillary lines and analyzed for metal concentrations.

The vapour-brine partition coefficients $(D_i^{V/L} = C_i^V/C_i^L)$ ranged from $4x10^{-4}$ - $2x10^{-3}$ for Fe, $8x10^{-5}$ - $4x10^{-4}$ for Cu, $4x10^{-6}$ - $2x10^{-4}$ for Zn, and $1x10^{-6}$ - $1x10^{-3}$ for Na. The fractionation of these elements into the CO_2 did not cause a measureable decrease of their concentrations in the brine. The total element concentrations in the CO_2 samples ranged from 0.2 to 1.4 mg/kg (ppm) Fe, 0.1 to 0.6 mg/kg Cu, 0.004 to 0.4 mg/kg Zn and 0.6 to 92 mg/kg Na, and generally displayed a small positive correlation with CO_2 density. The values of $D_i^{V/L}$ in a CO_2 storage reservoir at 7-28.5 MPa and 35-98°C, in which the density of CO_2 is ~0.3-0.7 g/cm^3 (as compared to 0.1-0.6 g/cm^3 in this study), could be expected to be approximately equivalent to those determined from these experiments.

Considering the metal concentrations typical of brines in CO_2 storage aquifers that have reacted with CO_2 and sandstone (20-200 mg/kg Fe, 0.3-1 mg/kg of Cu, 3-5 mg/kg Zn), and neglecting the increased solvent capability of higher-density CO_2, these results suggest that a plume of injected CO_2 could contain up to 0.1 mg/kg Fe, 0.3 µg/kg Cu and 1 µg/kg (ppb) Zn, in addition to 16 mg/kg Na. At a Sleipner (North Sea)-sized reservoir used to store 14 Mt of CO_2, this would lead to the mobilization of about 1 t Fe, 5-10 kg Cu and Zn, and 200 t Na. In terms of long-term CO_2 storage, the potential consequences of these results include the precipitation of carbonate minerals in shallower, more distal regions of the aquifer and the transferral of metals to adjacent aquifer systems.

Combining NanoSIMS with STXM/TEM imaging to shed new light on organic matter contained in micron-sized particles

L. REMUSAT[1]*, D. DERRIEN[2], P.J. HATTON[2], P. NICO[3] AND J.-N. ROUZAUD[4]

[1]CNRS/Muséum National d'Histoire Naturelle, Paris, France (*correspondence : remusat@mnhn.fr)
[2]INRA Nancy, Champenoux, France
[3]Earth Science Division, LBNL, Berkeley, USA
[4]CNRS / ENS Paris, Paris, France

During the past 10 years, NanoSIMS has opened a new window on the study of the spatial distribution of light elements and their isotopic composition in natural samples. This instrument, with its high sensitivity, high precision and high spatial resolution, is suitable to study organic matter (OM) in meteorites and soil aggregates. Nevertheless, this technique suffers from the influence of the nature and the topography of the sample surface on the ion yield (the so called matrix effect) making the unambiguous characterization of the carbonaceous phases sometimes problematic. Moreover, the intrument cannot deliver molecular information, often required for the study of OM.

We illustrate here, through several examples, the benefits to combine NanoSIMS imaging with TEM and STXM, in order to improve the characterization of the carbonaceous materials and to strengthen the conclusions arisen from NanoSIMS images. This is a challenging task because these cutting edge techniques, while sharing high spatial resolution capabilities, have very different intrumental constrains.

The combination TEM+NanoSIMS was used to characterize the carbonaceous phases isolated from an Enstatite chondrite by HF/HCl dissolution. Graphite and poorly organised OM were identified by TEM (and Raman spectroscopy). With NanoSIMS, we measured the D/H and $^{13}C/^{12}C$ isotopic ratios along with the H/C and N/C elemental ratios of each phase, without ambiguity. Hence, we entirely characterized the carbonaceous phases separately to understand their relationship and origin.

We could also assess the fate of labelled OM after a 10 years *in situ* incubation experiment in a natural forest by combining NanoSIMS and STXM. While NanoSIMS was able to map ^{15}N-labelled OM in soil microaggregates recovered from this forest, it has to be combined with STXM imaging (of the same aggregates) to reveal the molecular structure of the organic constituents. The combination of these instruments allows us to follow, at the submicron scale, the processes leading to the soil OM recycling.

Trace and rare earth elements characteristics of scheelite from the Sanjiazi tungsten deposit in Siping area, Northeastern China

Y.S. REN[1]*, H. WANG[1], N. JU[1] AND C.Z. WU[2]

[1]College of Earth Sciences, Jilin University, Changchun 130061, China (*correspondence: renys@jlu.edu.cn)
[2]State Key Laboratory for Mineral Deposits Research (Nanjing University), Nanjing 210093, China

The Sanjiazi skarn scheelite deposit is lately discovered in northeast China and there are many key questions on its genesis still unresolved. Scheelite is a widespread mineral in many hydrothermal deposits, its trace and rare earth elements can be used to constrain the derivation of the metal and mineralising fluids [1, 2]. Trace elements and rare earth elements (REE) compositions of the scheelite from Sanjiazi deposit were analyzed by ICP-AES.

Scheelite in Sanjiazi deposit is depleted in Sr, Be, Co, Ni, Ta and with enrichment of such metallogenic elements as Pb, Zn, Mo, Bi and Ag. Generally, these enriched trace elements, together with W, are prone to accumulate in magmatic hydrothermal fluids and precipitate in mesothermal condition. Moreover, scheelite shows accordant primitive mantle-normalized trace element spidergram with the Mesozoic granite and pre-mineralizing diorite porphyry dikes, indicating that they have the common material source.

The total content of REE in scheelite is 134.59ppm. The content of the LREE is nearly equal to that of the HREE. Chondrite-normalized REE patterns of the scheelite are overall flat curves with obvious Eu peak, which indicates a strong LREE/HREE fractionation. Scheelite has strong positive Eu anomalies (δEu=2.05), weak negative Ce anomalies (δCe=0.77), low LREE/HREE (1.09) and $(La/Yb)_N$ (0.54). The REE characteristics of scheelite in Sanjiazi deposit is similar to those in some skarn tungstern deposits in south China associated with magmatic hydrothermal fluid [4].

A conclusion can be safely drawn that the Sanjiazi tungsten deposit belongs to skarn ones, its ore source was derived from the granitic magmatic fluid instead of ore-hosting skarn. The Mesozoic granitic magmatism played an important role in scheelite mineralization in this area.

This research was supported by basic research grants from Jilin University (Grants 200903025 and 201004001).

REE fractionation during crustal anatexis: Constraints from the South Bohemian batholith (Bohemian Massif)

M. RENÉ

Institute of Rock Structure and Mechanics, Academy of Sciences, Prague 8, Czech Republic (rene@irsm.cas.cz)

The processes controlling rare earth element (REE) behaviour during origin of S-type granite melts have profound implications for REE abundances in these granites. For typical protoliths of S-type two-mica granites, such as are metapelites of the Moldanubian Zone from the Bohemian Massif (Central European Variscides), a high amount of bulk rock LREE are sited in monazite and of HREE in garnet, apatite and zircon. The LREE and Th concentrations of a metapelite-derived melt are buffered by monazite stability. During anatexis, dissolution of monazite, apatite and zircon in the melt results in increasing bulk REE abundances and LREE/HREE ratios with increasing temperature of melting and a negative Eu anomaly in the melt. Both these features are displayed in the REE geochemistry of two-mica granites from the South Bohemian batholith (SBB) in the Bohemian Massif.

Three main geochemical two-mica granite types can be distinguished in the SBB: the low-Th Deštná granite, the intermediate-Th Eisgarn granite and the high-Th Lipnice and Steinberg granites. Th concentrations and REE element patterns are quite distinct class marks for the above mentioned three geochemical types of two-mica granites. The highest bulk content of REE is significant for the Lipnice and Steinberg granites (207–242 ppm), whereas the lowest bulk of REE was observed in the Deštná granites (33–69 ppm). The content of REE is controlled by variable amount of apatite, monazite and zircon enclosed usually in biotite and/or in apatite. The accessory minerals assemblage in the Deštná granite consists of monazite, zircon, apatite and xenotime usually enclosed in K-feldspar. The Eisgarn granitic melt was generated from dehydration melting of biotite at temperatures in the range 830–850 °C, whereas the Deštná granitic melt was generated by dehydration melting of muscovite at temperatures in range 670–750 °C, in agreement with REE concentrations. The highest Th contents in monazite and high Th/U ratios are significant for monazites from the Lipnice and Steinberg granites. On the other hand, monazites from the Deštná granites show higher values of U and Y.

This study was supported by the Ministry of Education, Youth and Sports of the Czech Republic (project No. ME10083).

Quantification of waste silicates for mineral carbonation

P. RENFORTH[1]*,
C-L. WASHBOURNE[2] AND D.A.C MANNING[2]

[1]Department of Earth Sciences, University of Oxford, Oxford, OX1 3AN, United Kingdom (*correspondence: Phil.Renforth@earth.ox.ac.uk)
[2]School of Civil Engineering and Geosciences, Newcastle University, NE1 7RU, United Kingdom

Historic Production

Silicate minerals are an ubiquitous component of some anthropogenic material streams (cement, construction waste, slag, fuel ash etc.). Generally, they are produced by calcining carbonate minerals in the presence of silica (mine/aggregate waste is composed of naturally occuring silicates). We estimate that humans have produced approximately 89-103 billion tonnes (Gt) of silicate material since the early 1800's (Table 1; [1]). The fate of this material is likely one of several namely, disposal in the ocean or in lanfill, spread onto land, or material in engineering. While some of this material has carbonated in the environment [e.g. 2], it is possible that a substantial quantity remains available for carbon capture (with a total potential in the order of 10^3 MtC).

Material	Current (Mt a^{-1})	Historic (Mt)
Aggregate fines	3, 300	unknown
Mine waste	2, 000-6, 500	unknown
Cement kiln dust	420-568	9, 000-12, 000
C & D waste	1, 400-5, 900	*
Slag	380-500	12, 100-15, 900
Fuel Ash	198-383	76, 000-14, 600

Table 1: Global production estimates for anthropogenic silicates since the early 19th century. *historic production of C&D waste is unknown, but the upper limit is based on the historic production of cement (60 Gt). See [1] for more details.

Current production

Current annual production of silicate material is estimated to be approximately 7.6-17.2 Gt. With an estimated carbon capture potential of around 190-332 Mt of carbon. Production of silicates is increasing by approximately 2 % a^{-1}, largely in China, carbonation of which is likely to an increasly important role for mitigating some of the associated carbon emissions.

Further progress towards synchronizing geochronometers

PAUL R. RENNE[1,2]

[1]Berkeley Geochronology Center, 2455 Ridge Rd., Berkeley, CA, USA 94709 (prenne@bgc.org)
[2]Dept. of Earth and Planetary Science, Univ. California, Berkeley, CA, USA 94709

A recent calibration of the $^{40}Ar/^{39}Ar$ system [1] has largely reconciled the $^{40}Ar/^{39}Ar$ and $^{238}U/^{206}Pb$ geochron-ometers, but reveals several apparent inconsistencies with previous results. For example, recalculating a previous result [2] for the Cretaceous/Paleogene boundary (KPB) produces an age of 66.236 ±0.060 Ma (1σ here and throughout), slightly older beyond stated errors than an astronomically tuned age of 65.957 ±0.040 Ma [3] for the KPB at Zumaia (Spain). To investigate this disparity, renewed analysis of circum-KPB events has been initiated. Arguably the most definitive age for the KPB would be that for the Beloc (Haiti) tektites. Previous results for these tektites are consistent with a KPB age though not with sufficient precision to advance the present discussion. With rigorous attention to neutron fluence monitoring via the Fish Canyon sanidine (FCs) standard, a suite of Beloc tektites was irradiated along with sanidine from a Z-coal tonstein (stratigraphically ~60 cm above the KPB) from the Hell Creek area of Montana (USA). Three positions of the standard closely bracketing the samples yielded an average *J*-value with 0.02% precision. Seven tektites with Ca/K between 2.8 and 4.8 heated incrementally in 14-18 steps with a CO_2 laser and analyzed with a single collector MAP 215 mass spectrometer all yielded 100% concordant age spectra. The weighted mean of the seven plateau ages, calibrated per [1], is 65.946 ±0.067 Ma, indistinguishable from the astronomical age [3]. Combined with previous results [4, 5] a weighted mean age of 66.043 ±0.049 Ma is obtained for the Beloc tektites. Additional work in progress will further refine the age of the tektites and enhance their importance to a precise age for the KPB. Calibrated per [1], 71 single crystals of sanidine from the Z-coal yielded an age of 65.926 ±0.066 Ma. No xenocrysts are evident in the data, justifying step-heating analysis of multigrained aliquots currently in progress. These results disfavor the possibility raised by [1] that the astronomical age [3] of the KPB is miscalibrated by a 405 ka eccentricity cycle and serve to validate intercalibration between the Ar/Ar, U/Pb and robust astronomical chronometers.

Continental flood basalts and biotic crises: Does the Paraná-Etendeka exception prove the rule?

PAUL R. RENNE[1,2]

[1]Berkeley Geochronology Center, 2455 Ridge Rd., Berkeley, CA, 94709, USA (prenne@bgc.org)
[2]Dept. Earth & Planetary Science, Univ. California, Berkeley, CA, 94720

The temporal correlation between continental flood volcanism and severe paleoenvironmental effects including mass extinctions are well known although the causal mechanism (s) remain unclear. Various metrics of the magnitude of either phenomenon (e.g. % taxa extinct or volume of magma erupted) define positive correlations but the extent of scatter in such relationships implies that other variables are important. Some of the larger CFB's that fail to coincide with profound extinction events (e.g. Ferrar-Karoo) turn out to be temporally distributed over several million years and their anomalously feeble impact may be due to lower effusion rates reducing atmosheric loading rates for volcanogenic volatiles. Among the largest CFB's clearly erupted mainly over a short time interval (< 3 Ma; e.g. Siberian, CAMP and Deccan), the Paraná-Etendeka province (PEP) stands out distinctly as an outlier in the correlation with biotic crises. Extensive incremental-heating Ar/Ar data demonstrate unequivocally that the PEP was brief (>90% erupted 135-132 Ma; calibration per [1]), and previous studies suggesting a protracted event spanning ~10 Ma were flawed. The resolution of this apparent conundrum may lie in the importance of thermogenic volatiles (mainly CO_2, methane and sulfates) released from country rocks during CFB events, as has been proposed in many recent studies. Virtually throughout the PEP, volcanic effusions were emplaced atop up to 450 m of eolian sands of the Botucatu and Etjo Fms., and the nearest-surface carbonaceous strata (< 80 m thick Iratí Fm.) at the time of the PEP event were >2 km beneath the surface. We suggest that thermogenic CO_2 was minimal in the PEP event due to a combination of (1) relatively sparse carbonaceous sediments in the thermal aurole; (2) depth (lithstatic pressure) of these sediments being sufficiently high to retain CO_2 in metamorphic assemblages and inhibit brittle fracturing, limiting transmissivity for thermogenic volatiles. Moreover, PEP magmas are exceptional among the largest brief CFB's in the dominance of lithospheric melt sources, suggesting minimal magmatic contributions to volatile loading of sulfates and CO_2.

Iron species in soils on a mofette site studied by Fe *K*-edge XANES

T. RENNERT[1]*, K. EUSTERHUES[1], V. DE ANDRADE[2], J. PRIETZEL[3] AND K.U. TOTSCHE[1]

[1]Institut für Geowissenschaften, FSU Jena, Germany (*correspondence: thilo.rennert@uni-jena.de)
[2]NSLS-II, Brookhaven, USA
[3]Lehrstuhl für Bodenkunde, TU München, Germany

Ascending geogenic CO_2 is a soil-forming factor on mofette sites: With increasing soil CO_2, the amounts of pedogenic Fe decrease, and Fe oxides are poorly crystalline according to extraction with oxalate and dithionite [1]. To further study the Fe speciation (especially that of Fe (II)), we applied spatially resolved X-ray absorption near-edge spectroscopy (XANES) to soil samples from a mofette site in the NW Czech Republic. The samples originated from spots with 4 and 100% CO_2 in the soil atmosphere. Point XANES spectra (1 μm^2) at the Fe *K*-edge (7112 eV) were collected at beamline ID 21 of the ESRF, Grenoble, in fluorescence mode. Altogether, we recorded 73 spectra on regions of interest identified from 5 fluorescence maps of 3 thin sections prepared from undisturbed soil samples. Linear combination fitting of reference spectra from a whole of 51 references including various Fe (II)- and Fe (III)-bearing minerals and organic species was used for Fe-species identification. In almost all cases, two references were sufficient as checked by the sum of squared differences.

The Fe-fluorescence maps explicitely showed a heterogeneous spatial distribution of Fe with accumulation in larger pores (e.g. former root channels) and depletion in the soil matrix. We conclude small particles (< 1 μm), because point spectra could not be explained by a single reference spectrum. We identified smectites, illite and ferrihydrite in the Fe-accumulation zones. Iron in the Fe-depletion zones was mostly present in clay minerals such as different smectites, illites and chlorites in 68 spectra. Especially at 100% CO_2, we identified Fe (II)-containing minerals such as green rust, vivianite, siderite and magnetite in the soil matrix. According to XANES, Fe sulphates and Fe sulphides were not present. We detected only slightly more Fe (II) complexed by organic species at 4% CO_2 than at 100% CO_2 indicating that CO_2 impedes the association of organic matter with Fe-containing minerals. This is in line with the observation of mainly non-decomposed, probably particulate organic matter in soils on mofette sites and only a small fraction of organo–mineral associations [1].

Constraining the fidelity of sulfate-oxygen in the geological record

VICTORIA RENNIE* AND ALEXANDRA V. TURCHYN

Dept. Earth Sciences, University of Cambridge (*correspondence: vcr22@cam.ac.uk)

The oxygen isotope composition of aqueous sulfate ($\delta^{18}O_{SO4}$) in natural environments reflects microbially-mediated oxygen isotope exchange with water during bacterial sulfate reduction, as well as oxygen isotope fractionation during sulfide oxidation. When the $\delta^{18}O_{SO4}$ is preserved in the geological record, it is a potentially powerful tool for reconstructing these key microbial metabolisms (sulfate reduction and sulfide reoxidation) over time. This may be of critical importance in the NeoProterozoic, when the existence and evolution of these metabolisms is intimately related to the redox evolution of the Earth's surface environment.

The viability of using the $\delta^{18}O_{SO4}$ to elucidate these processes in both modern and ancient environments rests on the assumption that there is minimal abiotic exchange between sulfate-oxygen and water-oxygen during the variety of conditions imposed by sample storage, mineral extraction, and laboratory processing. Previous work has shown that oxygen isotope exchange between sulfate and water occurs readily at very low pH (<1) and/or at high temperatures (>100°C). Aqueous samples are routinely acidifed prior to analysis, but current estimates for timescales of exchange under these conditions rely on extrapolation from highly dissimilar solutions.

We present results from exchange experiments mimicking pore fluids under a variety of conditions. These rule out short and medium-term exchange of sulfate-oxygen with water during sample treatment over a range of acidic conditions. Additionally, the presence of aqueous sulfide in sedimentary pore fluids may facilitate sulfate-oxygen exchange with water-oxygen via the transient formation of thiosulfite complexes. Our experiments constrain the range of pore fluid (and natural) conditions over which $\delta^{18}O_{SO4}$ will remain stable. Finally, in contrast with aqueous sulfate, results from extracted carbonate-associated-sulfate (CAS) show that mineral bound $\delta^{18}O_{SO4}$ is not solely a function of the oxygen isotope composition of the aqueous sulfate during carbonate crystallization. This points towards further controls on $\delta^{18}O_{SO4}$ in CAS possibly imposed by the presence of the carbonate lattice.

Investigating the transport of strontium through biogenic hydroxyapatite Barriers

J.C. RENSHAW*, S. HANDLEY-SIDHU, F. SINCLAIR SMITH, Q. GRAIL, M. CUTHBERT, M RILEY AND L.E. MACASKIE

University of Birmingham, Edgbaston, Birmingham B15 2TT, UK (*correspondence: j.c.renshaw@bham.ac.uk)

Hydroxyapatite (HAp) has potential as a material for the remediation of metal contaminated waters [1] and in reactive barriers [2]. *Serratia* sp. cells bio-manufacture nanophase hydroxyapatite (Bio-HAp) from the substrates glycerol 2-phosphate and Ca^{2+} [3]. This Bio-HAp has properties that increase metal uptake (e.g. decreasing crystallite size, increasing specific surface area and organic content).

Column experiments were conducted to investigate the transport of Sr^{2+} (0.5 mg) through Drigg sand (sampled near low level waste repository) and Drigg sand containing either 0.25% commercial (Com-HAp) or Bio-HAp. Figure 1 shows the elution of Sr^{2+} through columns containing groundwaters (GW) with high levels of competing ions (100 and 50 mg L^{-1} of Ca^{2+} and Mg^{2+}, respectively). The Com-HAp and Bio-HAp retained 2.5 and 3.7 mg of Sr^{2+} per 1 g of HAp, respectively. Work is now been undertaken with GW containing lower cation concentrations. Numerical modelling is also being carried out to test various hypotheses regarding Sr^{2+} transport processes.

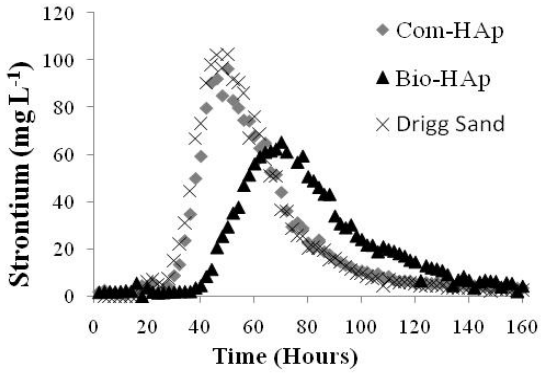

Figure 1: The Transport of Sr^{2+} through Drigg Sand (x), with Com-HAP (♦) and Bio-HAp (▲)

Time scales of metasomatism, differentiation and degassing at Volcán de Colima

O. REUBI[1], K.W.W. SIMS[2], J. EIKENBERG[3], M.K. REAGAN[4], N.R. VARLEY[5] AND B. BOURDON[1,6]

[1]ETH Zurich, Switzerland (olivier.reubi@erdw.ethz.ch)
[2]University of Wyoming, USA
[3]Paul Scherrer Institute, Switzerland
[4]University of Iowa, USA
[5]Universidad de Colima, Mexico,
[6]Ecole Normale Supérieure de Lyon and CNRS, France

Volcán de Colima, Mexico (VDC) nearly continuous activity since 1998 provides a unique opportunity to asses the times scales characteristic of intermediate arc volcanoes. VDC andesites have ($^{238}U/^{230}Th$) = 1, but have significant excesses of ^{231}Pa and ^{226}Ra. These excesses, and relatively low Th contents, indicate that addition of Th-rich sediments in secular equilibrium to the mantle source cannot account for ^{238}U-^{230}Th equilibrium, as generally advocated. In the VDC case, the U-series suggest that slab fluids carrying U were not added to the mantle wedge in the last 350 kyr and ^{226}Ra excesses are most likely mantle melting signals. ^{226}Ra and ^{231}Pa excesses indicate that the time scales of differentiation from primary mafic to dacitic melt (composition of the crystallizing melt) are short and < 1.6 kyr.

Most 1998-2010 magmas have ($^{210}Pb/^{226}Ra$) = 1, however small ^{210}Pb deficits are measured in few samples. This indicates that the magmas erupted at the onset of the eruptive phase (1998) degassed either more than 100 yr ago or within few months of eruption. Observed changes in petrology and the SO_2 flux measured prior to 1998 concur to suggest that significant degassing occurred within few months of eruption. Increasing maximum ^{210}Pb deficits with time are consistent with progressive degassing of a magma batch since 1998, but require several influxes of undegassed magmas and incomplete mixing between the magma batches. Influxes of undegassed magmas may cause the observed shifts in activity from Vulcanian to effusive.

Long residence (> 6 Ma) time of Paleoproterozoic seawater sulfate revealed by *in situ* and *ex situ* sulfur isotope measurements

MARLENE REUSCHEL[1]*, M. WHITEHOUSE[2],, V.A. MELEZHIK[3], A. LEPLAND[3], A.E. FALLICK[4] AND H. STRAUSS[1]

[1]Corrensstrasse 24, D-48149 Münster, Germany (*correspondence: marlene.reuschel@uni-muenster.de)
[2]Swedish Museum of National History, Box 50007, SE-10405 Stockholm, Sweden
[3]Geological Survey of Norway, Leiv Erikssons vei 39, N-7491 Trondheim, Norway
[4]Scottish Universities Environmental Research Centre, Rankine Avenue, East Kilbride, G75 0QF, Scotland, UK

The 2.0 Ga Tulomozero Formation, Fennoscandian Shield, NW Russia, consists of shallow marine carbonates and silicilastics, dissolution breccias and widespread syndepositional marine evaporites, now mostly present as pseudomorphs after Ca-sulfates.

Ex situ measured carbonate-associated sulfate (CAS) and breccia-associated sulfate (BAS) throughout the entire formation ($\delta^{34}S_{CAS}$= 10.9±2.7 ‰, $\delta^{34}S_{BAS}$=9.0± 1.1 ‰) resemble the *in situ* SIMS sulfur isotope data from relics of sulfate evaporites in ubiquitous pseudomorphs after Ca-sulfates ($\delta^{34}S_{anhydrite}$= 9.6 ±1.0 ‰; $\delta^{34}S_{barite}$= 11.0±3.1 ‰).

The $\delta^{34}S$ record of the Tulomozero sulfates matches the sulfur isotopic composition of other broadly time equivalent evaporite successions [1, 2]. Furthermore, the homogeneity of the sulfate sulfur isotope record within the Tulomozero Formation together with an estimated minimum depositional time of the formation (based on average carbonate precipitation rates) suggests a residence time of seawater sulfate in the Mid-Proterozoic of at least 6.5 Ma.

Consequently, the apparent presence of Ca-sulfate evaporites and the homogeneity of sulfate sulfur isotope data from various lithologies support the existence of a sizeable seawater sulfate reservoir already in the Mid-Paleoproterozoic ocean.

Electrical conductivity of the serpentinised mantle and fluid flow in subduction zones

BRUNO REYNARD[1,2], KENJI MIBE[2] AND BERTRAND VAN DE MOORTELE[1]

[1]Université de Lyon, CNRS, ENS de Lyon, Parvis Descartes, 69007, Lyon, France (bruno.reynard@ens-lyon.fr)

[2]Earthquake Research Institute, University of Tokyo, 1-1-1 Yayoi, Bunkyo-ku, Tokyo 113-0032 Japan (mibe@eri.u-tokyo.ac.jp)

In the mantle wedge of subduction zones, electromagnetic profiles reveal high electrical-conductivity bodies. In hot areas (> 700°C), water released by dehydration of the slab induces melting of the mantle under volcanic arcs that can explain the observed high conductivities. In the cold (<700°C) melt-free fore-arc mantle wedge, fluid water migrates and causes serpentinisation detected as low seismic wave velocities in the mantle wedge. High conductivities in the serpentinized wedge may picture serpentinisation or instantaneous fluid flow depending on serpentine electrical conductivity. We measured the electrical conductivities of three natural serpentine samples from subduction zone context using complex impedance measurements, and find they have low electrical conductivities ($< 10^{-4}$ S. m^{-1}) similar to those of dry mantle minerals below 700°C. Because of the negligible conductivity of serpentine, electrical conductivity in the hydrated mantle wedge is only sensitive to the fluid content and salinity, not to serpentinisation. A small fraction (*ca*. 1% in volume) of connective high-salinity fluids accounts for the highest observed conductivities. The low-salinity fluids (≤ 0.1 *m*) released by slab dehydration evolve towards high-salinity (≥ 1 *m*) fluids during progressive serpentinisation of the mantle wedge. These fluids can mix with arc magmas at depths and account for high chlorine/water ratios in arc lavas.

Modelling vertical stable isotope and elemental distributions in the upper ocean

BEN C. REYNOLDS AND GREGORY F. DE SOUZA

ETH Zurich, Institute of Geochemistry and Petrology, Zurich, Switzerland (*correspondence: reynolds@erdw.ethz.ch)

The stable isotope compositions of elements dissolved in seawater are a valuable source of information on ocean biogeochemistry. Depth profiles of elemental ratios and isotope compositions often show large vertical gradients near the surface due to the uptake and fractionation by biota in the surface ocean. However, interpretations of observed distributions are often based on overly simplistic models of the fractionation behaviour, such as the Rayleigh equation [1], which ignore dynamic mixing in the oceans. The processes governing the spatial and chemical gradients do not fit the fundamental assumptions underlying Rayleigh-type behaviour. In order to more effectively describe the processes governing the depth profiles we argue that simple one-dimensional advection-diffusion-reaction (1-D ADR) models should be applied. These models incorporate the interaction between biogeochemical cycling and physical redistribution, and thus help to realise the true potential of stable isotopic tracers to quantify biogeochemical cycling.

Applications of our models to stable isotope variations in the upper ocean demonstrate that, within the thermocline, elemental concentration gradients and isotope distributions are strongly affected by physical mixing processes. The biological cycling, however, controls the composition of the surface mixed layer. Our models provide a combined physical-biological framework for the interpretation of novel metal stable isotope variations currently being determined. It is apparent from the models that estimations of the fractionation factors derived using the Rayleigh equation will systematically underestimate the true values; the degree of underestimation depending upon the relative importance of mixing. We show how our models can be applied to published datasets.

Assessment of water/rock interaction to safeguarding drinking water quality

M. REZVANIKHALILABAD

Mahabghodss, Integrated studies on water,soil and environment Division, Affilated to Ministry of Power, Tehran, IRAN, P.O. Box: 19395-6875 (mahnazrezvany@yahoo.com)

Water storage, transfer and deliver to end users for drinking and sanitary purposes have been a challenge over the years in IRAN. IWRM strategies were focused to ease the Scio-economical aspects of the water shortage that vulnerability of the resources and the Environmental flow simply was ignored. Geological characteristics of artificial lakes and their natural or manmade transfer routs, exclusively studied from geotechnical prospects. Water/Rock interaction of bed rocks or reservoir body was neglected.

Chamgardalan dam located in IYLAM province, which water/rock interaction made an odor and taste problem in reservoir water is the best example [1]. Reservoir rocks consist of interbeded coal layers highly rich in sulfur and iron changed the quality of the dam lake water over years. The costly remediation study is ongoing (2009 till now). Contamination changes the quality of the water as effective as intensive interaction of water with bed rocks. In small projects in local or regional scale considering such studies will be costly and developers may not include it in their action plans. National or international fundamental research should provide such information.

In the new approach a methodology established to consider the effect of geological formation on the quality of surface water in the basin scale. Faults, intrusives, salt domes & massive evaporation sediments, closed & operating mines, progressive alteration, and etc. were assessed. Defined guideline played a major role in IWRM study of Caspian and Uromieh lake basins in north of Iran which has been carried out in 2010 [2]. The result concluded in generating a 1:250000 scale geological map on potential effect of geological formations on surface water quality regarding the heavy metals & trace elements, salinity and sediment production. The integrated map will give a glimpse of possible potential which has to be assessed meticultly.

The variation of magnetic susceptibility with grain size: Its implication on forensic studies

C. RIBEIRO, A. GUEDES*, B. VALENTIM, H. SANT'OVAIA, H. RIBEIRO AND F. NORONHA

Centro de Geologia da Universidade do Porto e Departamento de Geociências, Ambiente e Ordenamento do Território, Faculdade de Ciências, Universidade do Porto, Rua do Campo Alegre 687, Porto, Portugal (*correspondence: aguedes@fc.up.pt)

Detectable quantities of magnetic and paramagnetic minerals are almost always found in soils, being the magnetic susceptibility the sum of all contributions from the forming minerals, and varying due to concentration and composition those minerals. The magnetic susceptibility (MS) measurements of soils at room temperature are non-destructive. Additionally, does not require sample preparation, and can be used as a simple and fast method which may be operable in small samples. So, MS is an excellent tool for studies of soils being used as trace evidence in forensic investigations.

During this study, twenty four soil samples were collected on two different coastal sites from North Portugal, Mindelo and Cabedelo. At each site twelve samples were collected with a plastic spade from the surface soil. The samples were subjected to dry sieving using a column of sieves, resulting in different size classes: >2mm; [2mm-1mm]; [1mm-0.5mm]; [0.5mm-0.25mm]; [0.25mm-0.125mm]; [0.125mm-0.063mm] and <0.063mm. The MS analyses were performed directly on 1g of each size fraction after homogenisation, applying an external magnetic field of 300 A/m to the sample, and a Kappabridge, model KLY-4S of Agico balance equipped with the Sumean software used. The MS was calculated in m^3/kg. It was observed that in all samples the MS increases from coarse to fine grain size. The coarser fractions >2mm and [2mm-1mm] generally show negative values of MS and this is generally followed by low positive values of MS that increase ten times on the next fine fraction. These data show that fine fractions are the mostly enhanced in terms of MS. Finally, higher reproducibility was observed on the lower size fractions.

We conclude that although the magnetic susceptibility analysis is suitable to be used in a forensic soil investigation, it is important to adopt the same protocol during the analysis.

This research was supported by Project PTDC/CTE-GEX/67442/2006 of FCT (Portugal).

Phosphorus mobility in lake sediments

D.C. RIBEIRO, G. MARTINS, A.G. BRITO, AND R. NOGUEIRA

University of Minho, Campus de Gualtar, 4710-057 Braga, Portugal (dcribeiro@deb.uminho.pt)

For several decades, the paradigm that phosphorus release in sediments is the consequence of the absence of oxygen in the hypolimnium is recurrent among limnologists. At that time, the relation between the reduction of Fe (III) complexes and phosphorus (P) release in anoxic sediments was stated as hypothesis and later demonstrated. Although the theoretical statements matched the practical findings, these could not be generalized since several field observations and laboratory experiments lead to other conclusions. This has lead to a need of deeper understanding of factors that influence the phosphorus mobility besides oxygen concentration.

P mobility in lake sediments was assess through a microcosm experiment. Sediments from Lake Furnas (Portugal) were examined through a P sequential extraction procedure before and after a shift in redox potential achieved by means of O_2 concentration variation. Microsensors were used to measure pH and O_2 concentration in the sediments, during oxic and anoxic periods. The sediments that were under anoxic conditions released P from Fe minerals (BD fraction) compared with the initial conditions. The P bounded to Al minerals remained approximately the same comparing with the initial conditions (NaOH fraction), indicating the this fraction remains stable with redox potential changes. When the reactor was exposed to O_2, Fe minerals re-adsorbed P which is consistent with the classical paradigm. However, we found that Al minerals released P in the oxic phase of the experiment leading to a P concentration raise in water column. The reason was not due directly to O_2 concentration but to a raise in pH. A possible explanation is related with the recent findings that oxygen in the oxic layers could oxidize H_2S in deeper sediment layers trough a microbial network connected with nano-wires from H_2S in the deep anoxic sediment layer to oxygen in the upper layers, with concomitant pH raise.

Calcium minerals bounded to P remained stable between anoxic and oxic conditions (HCl fraction), as well as the refractory pool (NaOH 85 °C). P bounded to Al and Fe represent the most mobile fraction and is an indicator of exhaustion of sediments' retention capacity.

Zoned calc-silicated boudins in quartz-pelitic metatexitic rocks, NW Portugal

M.A. RIBEIRO*, M. AREIAS, A. DÓRIA AND P. FERREIRA

Centro Geologia, Faculdade de Ciências, Univ. Porto R. Campo Alegre, 4169-007 Porto, Portugal (*correspondence: maribeir@fc.up.pt)

In the coastal zone of NW Portugal, at north of Porto, a banded and sheared migmatitic structure outcrops, with a general NNW-SSE to NW-SE trend. This structure shows strong asymmetric interlayer folds with generally subvertical axes, plunging to SE. Metatexites are widely prevalent, over diatexite lithologies. These are leucocratic to mesocratic with no foliation or locally with an incipient one, with a very irregular orientation. The metatexite lithologies present a well defined foliation in the metapelitic or quartz-pelitic melanosome, trending N160°-N175°, 75°-90° NE, or N15°, 90°, but with considerable dispersion. The neosome occurs as irregular lenticules, elongated parallel to this foliation.

Calc-silicated rocks occur in small ovoid or ellipsoid bodies, always with internal zoning, more or less concentric: in the core, a zone of granoblastic texture with quartz +clinopyroxene+wollastonite+garnet+sphene+ plagioclase +/- biotite, surrounded by a zone of granoblastic texture of lower granularity with quartz+biotite+plagioclase+sphene+ garnet+/- clinopyroxene+amphibole. The outer zone (metatexites) is more irregular and presents heterogranular texture with variation in the % of biotite associated with quartz, muscovite and feldspar +/-sillimanite. The core zone of the ellipsoid bodies is relatively richer in CaO and Al_2O_3 while the intermediate zone is enriched in SiO_2 and Na_2O. The surrounding metatexites present higher content of K_2O and similar content of Na_2O, regarding the buffer zone.

The foliation of the metataxites is deflected around the calc-silicated ellipsoidal bodies of variable size (5 cm to 1 m), and its major axis elongation has general direction NNW-SSE, parallel to the foliation of the surrounding migmatites. These bodies represent 'resister' of palaeosome in the migmatites that have undergone metasomatism during the migmatisation and boudinage during the coeval shear deformation of the surrounding metaxites, trending NNW-SSE. The protolith of these calc-silicated rocks may be a Ca-rich quartz-pelitic metasedimentary rock. It is thought to correspond to a Ca-plagioclase-rich greywacke.

This work has been financially supported by POCI 2010 (FCT-Portugal, COMPETE/FEDER).

Conditions for uranium transport in unconformity-related U deposits

A. RICHARD[1]*, C. ROZSYPAL[1], J. MERCADIER[1], D.A. BANKS[2], M. CUNEY[1], M.C. BOIRON[1] AND M. CATHELINEAU[1]

[1]G2R, Nancy-Université, CNRS, BP 239, 54506 Vandoeuvre-lès-Nancy Cedex, France (*correspondence: antonin.richard@g2r.uhp-nancy.fr)
[2]School of Earth and Environment, University of Leeds, Woodhouse Lane, Leeds LS2 9JT, UK

Our knowledge of massive metal transfer within the Earth's crust is limited by the lack of direct analysis of deep fluids and experimental work. During the Mesoproterozoic Era (1.6-1.0 Gyr ago), giant uranium deposits were formed from large-scale circulation of uranium-bearing brines at the interface between sedimentary basins and their crystalline basements (unconformity-related uranium deposits) [1, 2].

However, the key processes leading the exceptionally high ore grades and tonnages of these deposits, especially the transport of uranium in the brines, remained poorly understood.

Here, we show that the uranium was transported under unexpectedly low pH conditions and at the highest concentrations recorded for crustal fluids so far.

By using laser ablation inductively coupled plasma mass spectrometry analysis of natural fluid inclusions we found that the uranium concentration varies over four orders of magnitudes in the ore-forming brines (from 10^{-6} up to 2.8×10^{-3} mol. l^{-1} U).

We combined these results with the first experimental determination of the solubility of U (VI) in H_2O-NaCl mixtures analogous to the ore-forming brines (up to 6 mol. l^{-1} NaCl) and we found that the pH (between 3 and 4 at 155°C) is the major control on U (VI) solubility in these conditions.

More generally, models for the formation of 'world-class' hydrothermal ore deposits imply either protracted fluid flow with relatively low metal concentration, or more discrete events characterised by exceptionally metal-rich fluids. Our results strongly suggest that the second hypothesis can be applied to the world's richest uranium deposits.

[4]Geography and Earth Sciences, McMaster Univ. Canada

The success of speleothems as accurate chronological markers of landscape evolution and climate change is well acknowledged, but accuracy and precision become particularly limiting beyond 350 ka for a number of reasons beyond the theoretical, including interlaboratory comparison and common standard/half-life usage. We illustrate here plans to take advantage of high-precision U-Th methods in concert with U-Pb techniques [1-3], which have the added advantage of community-supported accuracy (via EARTHTIME), to date important material in the range 0.35 to 1 Ma.

We are currently optimising a combination of U-Th-Pb techniques that utilise solution and *in situ* methods with MC-ICP-MS at the BIG and NIGL to analyse a variety of secondary calcite deposits previously demonstrated to be beyond the age range of traditional methods. We focus on an unusually U-rich flowstone sample (>60 μg g^{-1} ^{238}U) from the Grotte Valerie system in the Mackenzie Mountains, NWT, Canada [4]. Ten high-resolution sub-samples were cut as wafers from the growth layers identified in original publication. Several sub-samples have a extremely high ^{230}Th/^{232}Th atomic ratio (> 3), which demonstrates that the Th isotope signal is dominated by the radiogenic component. We obtained an age and 2σ uncertainty of 120 ± 1.2 ka from the youngest phase of growth. U-Th ages for older sub-samples, between 8.5 and 30 mm above base are not finite, and are therefore > 500 ka. We present preliminary U-Pb ages and *in situ* LA U-Th-Pb and gamma mapping for this older material. The latter are also used to screen future sub-samples useful for a host of applications.

From the Lower Amazon to the Mekong: How floodplains modulate fluxes of carbon from land to the sea

JEFFREY E. RICHEY*, JOHN M. MELACK AND KIMBERLEY N. IRVINE

(*correspondence: jrichey@uw.edu)

The large rivers of the tropics account for a significant fraction of the flux of carbon to the oceans and of fluvial and lacustrine CO2 and CH4 to the atmosphere. Through dynamic hydrologic, geomorphological, and biogeochemical processes, their floodplains and deltas provide a significant modulation to the materials transported by the river. In the process, the template set by these surface processes produces strong chemical disequilibria at the interface between water and sediments, impacting reactions down through the sediment column. But the magnitude, and even the specific dynamics, of these processes is poorly known. The last sampling stations on major rivers are typically above the delta and channel regions of tidally-impacted lower rivers, precisely to avoid dealing with the complexities. Which means that not only are time-series of the fluxes and controls from upriver not well-known, what happens in the lower river is even more poorly characterized. Here we examine recent results from the lower Amazon River and its floodplain, in comparison to the lower Mekong and the Tonle Sap Great Lake. About 20% of the Amazon basin is seasonally inundated, with extensive floodplains along several thousand kilometers of the main channel. These aquatic environments are sites of high evasion rates of methane and carbon dioxide, up to ten times the riverine flux to the ocean, and equivalent to sequestration by the forest. Considerable spatial and seasonal differences in carbon dioxide concentrations and evasion occur in the large shallow lakes common in the lower floodplains, with floodplain and geomorphological processes attenuating the chemical signal at the 'traditional' measuring station of Obidos. In contrast, floodplains of the Mekong are constrained to the lower reaches, with fluxes impacted by the Tonle Sap great lake. Higher pH than the Amazon results in greater export of respired carbon as bicarbonate relative to pCO_2. Implications for boundary conditions for deltaic sediment chemistry will be discussed.

High-temperature kinetic isotope fractionation in silicate systems: Laboratory and natural examples

F.M. RICHTER

Geophysical Sciences, The University of Chicago, Chicago, IL 60637, USA (richter@geosci.uchicago.edu)

The talk will focus on kinetic processes (see Table below) in silicate systems that result in easily measured stable isotope fractionations. The table below provides selected references that will provide the interested reader with a good introduction to the present state of affairs.

Process	Isotopic systems	laboratory examples	natural examples
Evaporation	Mg,Fe,Si, O	[1], [2], [3], [4]	CAIs [5] spherules [6]
Chemical diffusion	Li,Ca,Mg, K	[7],[8], [9]	Vinal Cove, Maine [10]
Grain-boundary diffusion	Li		Tin Mtn.[11] Pegmatite
Thermal diffusion	Mg,Ca, Fe, Si, O	[12],[13]	

In those cases where there is both laboratory and natural examples, I will focus on the commonality of what has been found. Recent developments in better understanding kinetic isotope fractionations by molecular dynamics simulations [8] and transition state theory [14] will also be discussed.

Cytochromes and iron reduction

K. RICHTER AND J. GESCHER*

Department for Microbiology, University of Freiburg, Germany (*correspondence: johannes.gescher@biologie.uni-freiburg.de)

The key innovation that enables cells to respire on metals like ferric iron or manganese is the development of a respiratory chain to the cell surface. Most of the known bacterial ferric iron reducers are proteobacteria. These cells all have in common the canonical blueprint of a Gram-negative cell with cytoplasm, cytoplasmic membrane, periplasm and outer membrane as separated reaction compartments. We study the electron transport chain to the cell surface using *Shewanella oneidensis* MR-1 as a model organism. *C*-type cytochromes are the dominant electron transferring proteins in *Shewanella*. They establish a conductive connection to the cell surface and catalyze the final reduction step onto a metallic electron acceptor. Interestingly, *S. oneidensis* as well as other dissimilatory iron reducers produces a multitude of different cytochromes while growing under dissimilatory ferric iron reducing conditions. Our work aims at elucidating as to why expression of this high number of cytochromes might result in a selective advantage. We can show that periplasmic cytochromes build a dynamic electron-transferring network. We can furthermore show that these cytochromes can catalyze ferric iron reduction. Hence, so called outer membrane cytochromes that are localized to the cell surface simply allow for contact between respiratory electrons and the electron acceptor. Although these surface localized cytochromes are crucial for wild type cells to respire on ferric iron or manganese, we could surprisingly establish that they are not necessary. Two simple point mutations can enable a *Shewanella* mutant to find a way around this necessity for outer membrane cytochromes. We currently complete our studies concerning these point mutations but will already provide evidence for the possible functions of the genetic exchanges.

The relase of Hf isotopes during weathering

J. RICKLI, A.R. KEECH, C. ARCHER AND D. VANCE

Bristol Isotope Group, School of Earth Sciences, University of Bristol, Wills Memorial Building, Queen′s Road, Bristol, BS8 1RJ, UK (*correspondence: J.Rickli@bristol.ac.uk)

Studies of river and ocean waters suggest that Hf isotopes are released incongruently during weathering of the continental crust. The governing processes in soils are poorly understood because the release of Hf isotopes from soils during weathering has thus far hardly been explored. Such an understanding is crucial to the eventual use of Hf isotopes for the reconstruction of past weathering conditions. Here we explore Hf isotope behaviour in a soil chronosequence from Scotland, spanning an age-range of 0.1-13ka.

Bulk soil Hf isotopes digested in a pressure bomb span a relativley small range between εHf = -22.1 and -19.7. Hot plate digests, which exclude most Hf from zircons, are more radiogenic and also show a larger isotopic range (εHf = -20.1 to -16.0). The isotopic compositions of both digestion procedures are well correlated, which indicates that zircons attenuate the variabilty that is imparted by weathering of the zircon-free portion and seem largely inert on the time scales of the chronosequence. Although all soil profiles consistently show a depletion of radiogenic Hf in their upper horizons, documenting the removal of radiogenic Hf, the evolution of the soils with time is not very systematic. In particular the 10 ka profile is less radiogenic throughout, which is likely to indicate heterogenity in the parent material of the chronosequence.

Currently, it is diffult to asses the proportion of removed Hf from the soils and derive an estimate of the corresponding Hf isotopic composition released to the hydrosphere. Hf/Zr ratios in the bulk soils (bomb digestions) are relatively homogenous and a calculation of the depletion of Hf from these geochemical twins seems inappropriate. A correlation of Hf/Zr with Hf isotopes which would support such an approach is not observed.

In summary the data shows that Hf isotopes removed from soils is more radiogenic than the bulk. This preferential removal of radiogenic Hf mainly relates to the zircon free portion of the soil, in which weathering imparts a variablity of 4 εHf. These findings will be consolidated by establishing the Hf budget of the rocks (zircon free crustal Hf vs bulk Hf) and the measurement of Hf isotopes in the draining rivers.

Oxygen and silicon partitioning between molten iron and silicate melts up to 70 GPa and 4000 K

A. RICOLLEAU[1]*, J. BADRO[1], J. SIEBERT[1,2], D. ANTONANGELI[1,2], M. CANTONI[3], C. HEBERT[3], D.T.L. ALEXANDER[3] AND P. GILLET[3]

[2]Institut de Minéralogie et de Physique des Milieux Condensés, Paris, France
[3]École Polytechnique Fédérale de Lausanne, Switzerland

The Earth's core is mainly composed of a Fe-Ni alloy. The core density compared to that of pure iron highlights a deficit that calls for the presence of light elements in addition to Fe and Ni to be explained. Si and O are among the likely candidates. Core formation is speculated to occur in a deep magma ocean in which the molten metal equilibrates with the silicate melt. The depth of this magma ocean, constrained by siderophile element partitioning, appears larger than previously thought. Thus, the experimental studies carried so far that have focused on Si and O partitioning between molten metal and silicates only up to 25 GPa, or at higher pressure, between metal and (Mg, Fe)O to interpret the behavior of oxygen in iron melts, have to be extrapolate to be relevant for the conditions of Earth's core formation.

In this study, we investigated directly the partitioning of oxygen and silicon between molten iron and silicate melts from 40 to 70 GPa using the laser-heated diamond anvil cell. We loaded the DAC with samples of olivine surrounding pure iron metal. Three olivine compositions, from 0 to 8 wt% FeO, were loaded with iron at 50 GPa to study the effect of oxygen fugacity on partitioning. Recovered samples were milled with the Focused Ion Beam technique and analyzed with electron microprobe and Transmission Electron Microscopes to obtain compositions of quench metal and silicate. The partition coefficients of oxygen and silicon between metal and silicate were determined as a function of pressure and oxygen fugacity. Quenched analyzed samples clearly show an oxidation of the silicate during the experiments. We report large amounts of oxygen (6-12 wt%) and silicon (2-10 wt%) in the metal at fO_2 around IW-1. The obtained results are used with literature lower-pressure data to thermodynamically parameterize the partitioning of oxygen and silicon. Oxygen and silicon solubility trends at high pressure are different than what expected on the basis of the extrapolation of lower pressure data.

A comparison of the reactivity at the solid-solution interface of nano- and micro-crystalline TiO_2 phases

MOIRA K. RIDLEY[1]*, MICHAEL L. MACHESKY[2] AND JAMES D. KUBICKI[3]

[1]Texas Tech University, Lubbock, TX 79409, USA (*correspondence: moira.ridley@ttu.edu)
[2]Illinois State Water Survey, Champaign, IL 61821, USA (machesky@illinois.edu)
[3]The Pennsylvania State University, University Park, PA 16802, USA (jdk7@psu.edu)

The acid–base surface reactivity of rutile (α-TiO_2), with the (110) crystal face predominant, has been studied extensively. Specifically, theoretical simulations, X-ray techniques and potentiometric titration studies have provided molecular-scale and macroscopic details on the ion adsorption behaviour of rutile. Results of the collective studies have been integrated into the multisite complexation (MUSIC) model. Similar detailed studies examining the surface charging properties of nano-crystalline anatase samples are now being conducted.

Primary surface charging curves of rutile in LiCl, NaCl, KCl, and RbCl electrolyte media are compared with similar titration data for nanoparticle anatase samples. The effect of electrolyte media and ionic strength on the primary charging behaviour of anatase was studied as a function of nanoparticle size (3–40 nm diameter). The primary charging curves of rutile and all nano-anatase samples are generally analogous, when normalized to their respective pH_{znpc} values. At low ionic strength (0.03 m) the development of negative surface charge was similar for all electrolyte cations. However, with increasing ionic strength negative surface charge development was enhanced as the bare crystallographic radii of the cations decreased. Subtle differences in the macroscopic charging behaviour of the 3 nm diameter anatase sample were noted, particularly below the pH_{znpc} value were Cl^- counterions screen the surface from bulk solution.

For rutile, X-ray data and MD simulations show that electrolyte cations are adsorbed as inner-sphere complexes, principally in tetradentate geometry. Similarly, DFT-MD simulations show inner-sphere sorption of monovalent cations onto anatase; however, bidentate sorption predominates. For both anatase and rutile, a CD-MUSIC model, coupled with a Basic Stern layer description of the electric double (EDL), successfully integrates all microscopic information with the macroscopic experimental results. Though for the smallest anatase particles, it is necessary to account for some curvature of the EDL.

Supply-limited and kinetic-limited chemical erosion

CLIFFORD S. RIEBE[1]*, KEN L. FERRIER[2], W. JESSE HAHM[1] AND JAMES W. KIRCHNER[3,4]

[1]Dept. Geology & Geophysics, U. Wyoming, WY, USA (*correspondence: criebe@uwyo.edu)
[2]Dept. Earth Atmospheric & Planetary Sciences, MIT, USA
[3]Dept. Earth & Planetary Science, U. Calif., Berkeley, USA
[4]Swiss Federal Institute for Forest, Snow, & Landscape Research (WSL), CH

Downslope transport of hillslope sediment is often usefully cast in terms of two end-members of a spectrum of erosional regimes. At one end of the spectrum, 'transport-limited' physical erosion develops when downward propagation of weathering outpaces erosional losses from a slope, such that the removal of material is limited only by the sediment transport rate [1]. At the other end of the spectrum, 'weathering-limited' erosion develops when sediment transport matches the rate at which physically competent material loses its structural integrity, such that erosional removal of material is limited by how fast it breaks down by weathering [1]. As originally defined, the concepts of transport-limited and weathering-limited erosion only strictly apply to physical fluxes, yet they are commonly misappropriated in discussions of chemical fluxes. We suggest the interpretive framework for hillslope processes needs to be clarified and expanded for studies of chemical fluxes. Here we define and discuss two end-members in a spectrum of possible chemical erosion regimes. On one end, 'supply-limited' chemical erosion develops when physical erosion rates are slow enough (or regolith residence times are long enough) that further chemical erosion of regolith is not possible due to exhaustive depletion of reactive phases [2, 3]. On the other end, 'kinetic-limited' chemical erosion develops when physical erosion is so fast that chemical erosion can only partially deplete regolith of its weatherable phases before they are removed from slopes [3]. Using published data from field and modeling studies, we show how supply-limited and kinetic-limited chemical erosion can be distinguished from one another based on differences in relationships between chemical erosion rates and mineral supply rates—two variables that can be measured in mountainous landscapes using cosmogenic nuclides.

Inferring process from provenance using apatite (U-Th)/He ages of coarse sediment in mountain streams

CLIFFORD S. RIEBE[1]*, CLAIRE E. LUKENS[1], LEONARD S. SKLAR[2], JONATHAN D. BEYELER[2] AND DAVID L. SHUSTER[3]

[1]Dept. Geology & Geophysics, U. Wyoming, WY, USA (*correspondence: criebe@uwyo.edu)
[2]Dept. Geosciences, San Francisco State Univ., CA, USA
[3]Berkeley Geochronology Center, CA, USA

The lithology and size distribution of sediment in a streambed reflects a jumble of integrated processes, from the breakdown of bedrock on slopes to selective transport and comminution as particles bash together in transit downstream. If this jumble could somehow be disentangled, it would reveal much about how physical and chemical processes shape landscapes. Here we show how processes of sediment production, transport, and breakdown can be resolved in new quantitiative light using a novel methodological adaptation of existing sediment tracing techniques. If apatite-helium (AHe) cooling ages in bedrock increase with elevation, the distribution of AHe ages in stream sediment reveals the distribution of elevations of sediment source areas [e.g. 1]. To the extent that differences in source elevations reflect differences in geomorphic processes [1, 2], AHe ages in sediment can provide a powerful indicator of the dominant modes of landscape change in a watershed [1, 3]. However, previous AHe tracer studies have focused solely on sand, which represents a small fraction of bed sediment in steep mountain streams where the technique has been applied. Hence, insight on the production and delivery of sediment from hillslopes remains incomplete. Moreover, source elevations of sand reveal little about the movement and downstream fining of coarse sediment in channel networks. Here we show how a much fuller understanding of weathering, erosion, and sediment transport can be obtained by quantifying AHe ages in all grain size classes, including sand, gravel, cobbles, and boulders. What controls the grain size distribution of sediment supplied to channels? Where do boulders come from? How long do they persist in mountain streams? How important is particle comminution in the downstream evolution of grain size distributions? We show that answers to such fundamental questions about surface processes are within closer reach through AHe tracing of coarse sediment.

A HPSEC-ICP-MS study on the affinity of trace elements (Fe, Cu, I) to dissolved organic matter in natural water samples

T. RIEDEL AND H. BIESTER

Institut für Umweltgeologie, Technische Universität Braunschweig, Germany (thomas.riedel@tu-bs.de)

The speciation of trace elements in natural waters strongly influences their mobility and geochemical behavior in the environment. Especially, the presence of dissolved organic matter (DOM) in soil and peat runoff may favor complexation of certain metals, thereby increasing the solubility. Earlier studies were focused on the concept of metal binding to organic molecules which were thought to be of considerable size (some ten to hundred thousand Da in molecular weight). The existence of large organic substances, however, has recently been challenged. It was proposed, on the basis of several different studies, that DOM may consist of much smaller molecules, probably in the size fraction of only a few hundred to thousand Da. This raises the question if these smaller fractions can be separated by analytical techniques thereby enabling a study of the metal-binding capacity of 'small' DOM.

To resolve this question we used inductively coupled plasma mass spectrometry hyphenated with gel filtration liquid chromatography. The size exclusion column used was selected to efficiently separate substances with relatively low ionic radii thus resolving predominantly smaller fractions of DOM. Samples were river waters taken from remotes sites in Patagonia, Chile as well as from the Harz mountain region, Northern Germany. All samples were filtered with 0.45 μm. Samples were initially measured in their original composition. The influence of pH was studied via the addition of nitric acid.

We found remarkable differences between the investigated metals with up to four different peaks in the chromatograms suggesting that a number of colloids/complexes of different size exist which can be separated. While some elements occurred exclusively in one or two fractions (Fe) others occur in all fractions (I, Cu) suggesting a rather non-specific binding. The addition of protons yielded the expected shift from larger to smaller fractions, possibly because metals desorb from the binding sites on the DOM or colloids/particles dissolve.

Further investigations aim to exploit the characteristic size distributions observed to create fingerprints of natural waters that help to understand the environmental distribution and cycling of these trace metals.

Microbially mediated iron reduction in the methanic zone of sediments from the Western Argentine Basin

Variable depositional conditions in marine sediments can have a strong impact on the associated biogeochemical cycles. In areas with high sedimentation rates, including mass transport-related deposition, (highly-) reactive mineral phases can be buried rapidly. This situation leads to the availability of reactive compounds for microorganisms in deep-subsurface anoxic environments. To unravel the influence of dynamic depositional conditions on biogeochemical processes in rapidly deposited sediments we applied inorganic and organic geochemical analyses and microbiological methods on marine sediments from the western Argentine Basin collected during the RV Meteor Expedition M78/3 (May-July) 2009. Our results show that the sediments are characterized by high concentrations of highly reactive iron phases accompanied by low amounts of organic carbon throughout the sediment column. Pore water accumulations of hydrogen sulfide are restricted to a small interval at the sulfate-methane transition zone. Below this zone, methane concentrations increase strongly with depth in association with appreciable availability of highly reactive Fe (III) phases. Elevated iron concentrations in the pore water in the same depth interval indicate ongoing iron reduction. Based on preliminary results we suggest that contributions from organo-clastic Fe reduction in these sulfide-depleted sediments can be neglected. Instead, because of the abundance of methane and reactive ferric Fe in the absence of sulfide, we propose that reduction of biologically available Fe phases in the methanic zone is coupled to methanogens via hydrogen or to anaerobic oxidation of methane.

Short-lived nuclides of the U and Th-series probing recent pedogenic processes in soils

S. RIHS[1]*, J. PRUNIER[1,2], B. THIEN[1,3], D. LEMARCHAND[1], M.C. PIERRET[1] AND F. CHABAUX[1]

[1]LHyGeS/UdS, 1 rue Blessig, 67084 Strasbourg cedex, France (*correspondence: rihs@unistra.fr)

[2]Present address: LMTG/ Université Paul Sabatier, 14 avenue Edouard Belin 31400 Toulouse, France

[3]Present address: Paul Scherrer Institut, CH-5232 Villigen PSI, Switzerland

The recent chemical dynamic occurring in a podzolic forest soil section (from the Strengbach watershed, France) was investigated using U and Th-series nuclides, including short-lived nuclides. Analyses of (^{230}Th), (^{226}Ra), (^{232}Th), (^{228}Ra) and (^{228}Th) activities in the soil particles, the seepage waters, the roots and the mature leaves of the beeches growing on this soil were performed by mass spectrometry (TIMS) or gamma spectrometry. Moreover, the exchangeable fraction was extracted from the soil particle and analysed. The simultaneous analysis of the different soil (*sl*) compartments allows to demonstrate that the overall Ra and Th transfer scheme is fully consistent with the acido-complexolysis weathering mechanism prevailing in podzols. Using a continuous open-system leaching model, the coupled (^{226}Ra/^{230}Th) and (^{228}Ra/^{232}Th) disequilibria measured in the different soil layers permit to date the contemporary processes such as recent (< 18 years) change in organic-colloids migration occurring in the shallow soil horizons. The Monte Carlo simulation approach used to resolve this system shows that a semi-infinite range of Th-isotopes leaching rates can explain the observed data, but minimum values can be inferred, leading to an upper limit age for the beginning of the perturbation. The model predicts distinct leaching rates of Th isotopes, in excellent agreement with the apparent preferential ^{230}Th over ^{232}Th leaching recorded in seepage water. The lower soil horizons are also affected by such Th mobilization, though lasting over several centuries at least, with a much smaller leaching rate.

Ra and Th isotopic ratios also appear to be valuable tracers of some mineral-water-plant interactions occurring in a soil. The (^{228}Ra/^{226}Ra) ratio discriminate the Ra flux originating from leaves degradation and from mineral weathering in the shallow -10cm seepage soil waters. This ratio, combined to the ^{232}Th-^{228}Ra-^{228}Th radioactive disequilibria measured in the different soil compartments allows to constaint the shallow bio-geochemical cycle of Ra, including residence time in vegetation cycling and scavenging in the soil exchangeable fraction.

Intrabasaltic paleosols from the North Atlantic Igneous Province record late Paleocene global climate trends and hyperthermals

M.S. RIISHUUS[1]* AND D.K. BIRD[2]

[1]Nordic Volcanological Center, Institute of Earth Sciences, University of Iceland, IS-101 Reykjavik, Iceland (*correspondence: riishuus@hi.is)

[2]Department of Geological and Environmental Sciences, Stanford University, Stanford, California 94305, USA (dbird@stanford.edu)

Weathering of basaltic tephra and lava produces clays preserved in intrabasaltic paleosols. We propose that hydrogen isotopes of smectite clays formed by weathering of intraflow tephras (redbeds) of the North Atlantic Igneous Province preserve isotopic records of past global climate. In support we present smectite δD compositions of 70 tephras from West (~61.5-60.0 Ma) and East (~56.5-55.0 Ma) Greenland (64-66°N paleolatitude) for comparative analysis with global paleoclimate trends and aberrations recorded in higher-resolution marine records.

The observed smectite δD compositions range from -145 to -104 ‰. In the East Greenland section smectite δD varies around -130 to -120 ‰ at ~56 Ma prior to an abrupt increase to a maximum of -104 ‰ before returning gradually to -117 ‰ at ~55 Ma. This trend corresponds inversely to the δ^{18}O deep-sea foraminifera record depicting a warming trend from mid-Paleocene (~59 Ma) towards the Early Eocene Climatic Optimum (~52 Ma) superimposed with the Paleocene-Eocene Thermal Maximum (~55.5 Ma). The ~5 m. y. older West Greenland tephras display an initial abrupt increase in smectite δD from around -135 to -130 ‰ up to ~-120 ‰, followed by a more gradual decrease to ~-140 ‰. The more depleted δD compositions reported from West Greenland relative to East Greenland are in agreement with the cooler global conditions that prevailed in the earliest Paleocene (65-58 Ma). While the general decrease to ~-140 ‰ correlates with global cooling towards 59 Ma, we suggest that the initial increase in smectite δD from West Greenland could be recording a similar, but weaker, hyperthermal as the PETM.

We speculate that both the East and West Greenland continental flood basalt volcanism had an indirect short-lived warming effect through release of methane from organic-rich sediments by contact metamorphism from overflowing lavas and sill intrusions, as well as a direct longer-lasting cooling effect through degassing of SO_2.

Dissolved Fe in the Western Atlantic Ocean: Distribution, sources, sinks and cycling

M.J.A. RIJKENBERG [1]*, L.J.A. GERRINGA, [1], P. LAAN [1], V. SCHOEMANN [1], R. MIDDAG [1], S.M.A.C. VAN HEUVEN [2], L. SALT [1], H.M. VAN AKEN [1], J.T.M. DE JONG [1] AND H.J.W. DE BAAR [1,2]

[1]Royal Netherlands Institute for Sea Research, PO Box 59, 1790 AB Den Burg, The Netherlands (*correspondence: Micha.Rijkenberg@nioz.nl)
[2]University of Groningen, PO Box 11103, 9700 CC Groningen, The Netherlands

Iron (Fe) plays a key role in the regulation of primary production and dinitrogen fixation in large parts of the world oceans. Because there is an increasing urgency to understand the role of the oceans in global climate, it is paramount that we understand the biogeochemical cycle of bio-essential elements such as Fe. Despite this recognized importance there is still limited knowledge of the sources, sinks, chemistry and internal cycling of Fe. To fill this gap in our knowledge, the distribution and organic speciation of dissolved Fe (DFe) have been measured during three Dutch GEOTRACES cruises. Together, these cruises form a comprehensive, high resolution, full-depth section through the western Atlantic Ocean from Iceland to 58°S. In this presentation we will evaluate the distribution of DFe and its speciation using many other parameters such as dissolved inorganic carbon, total alkalinity, pH, dissolved oxygen, fluorescence, the macronutrients phosphate, nitrate and silicate and trace elements like dissolved aluminum (DAl) and dissolved manganese (DMn), to understand the processes that determine the distribution of DFe.

The influence of CO_2 on phase relations at Mount St. Helens

J.M. RIKER[1], J. BLUNDY[1], C.J.G. VAN HOEK[2] AND S.R. VAN DER LAAN[2]

[1]School of Earth Sciences, University of Bristol, Bristol, BS8 1RJ, UK (*correspondence: jenny.riker@bristol.ac.uk)
[2]Ceramics Research Centre, TATA Steel RD&T, P.O. Box 10000, 1970 CA, Ijmuiden, The Netherlands

Volatile components play a fundamental role in the ascent and eruption of silicic arc magmas. Although the effect of water on phase relations in these systems is well-studied, CO_2 is also present and may at times be abundant, for example, during instances of gas fluxing. Recent work on melt inclusions from Mount St. Helens suggests CO_2 may exert a strong influence on both depths of vapor saturation and shallow crystallization [1].

To this end, we have performed a series of experiments at shallow crustal pressures in rapid-quench cold seal pressure vessels. Experiments were designed to simulate equilibrium crystallization at depths between the magma chamber and the surface. Run temperatures (880 °C), pressures (<3 kbars), and fugacties (NNO+1) are constrained by natural erupted products, while fluid compositions vary from pure H_2O to XCO_2 = 0.5. This work builds on previous experimental studies of phase equilibria at Mount St. Helens [e.g. 2, 3].

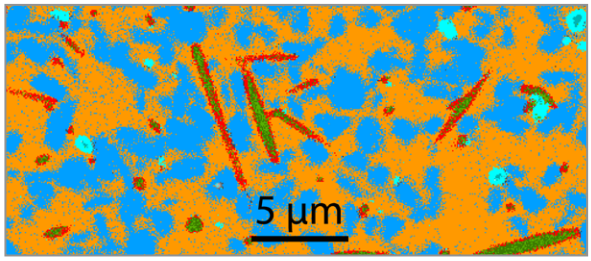

Figure 1: Phase map produced by PARC (880 °C, 500 bars).

High-resolution spectral maps allowed for detailed characterization of run products. Maps were acquired on a Field Emission Gun SEM and processed using a novel software program for automated **Ph**ase **R**ecognition and **C**haracterization (PARC) [Fig. 1]. PARC enabled rapid identification of sub-micron crystals and compositional analysis of all phases by quantitative EDS. Our results shed light on the conditions of crystallization and melt inclusion formation at Mount St. Helens, with implications for the volatile budgets of arc magmas.

Contribution of the reactive mineral surface area on CO_2 mineralization under natural conditions

JEAN RILLARD[1,2] AND PIERPAOLO ZUDDAS[1]

[1]Earth Sciences Department, University of Lyon1 (jean.rillard@etu.univ-lyon1.fr)
[2]INERIS, French National Institute for industrial Environment and RISk- FRANCE

A natural hydrothermal field is considered to be a useful analogue of carbon dioxide mineralization because it integrates the long-term interaction signal. The hydrothermal field of Galicia is characterized fluids resulting from a granit reservoir with pCO_2 from 103 to 105 Pa and pH from 10 to 6. Fluids are characterized by an increase of major elements correlated to pCO_2. We evaluated the effect of deep CO_2 perturbation We evaluated the effects of deep CO_2 perturbation on the fluid-rock interaction system. Mineral reactivity which produces changes in the fluid mineral composition is mainly dependent on the 'real' reactive surface area.

The mineral surface area participating in reactions resulting from this pCO_2 gradient was estimated by an inverse model approach. Input data was based on the chemical composition of the fluids we sampled. The rate of mineral dissolution was estimated by the observed pH and equilibrium conditions.

Moreover, the major elemental concentrations allowed us to quantify the variation of the reactive surface area of minerals involved with the overall water-rock interaction.

The irreversible mass transfer process, ruled by the continuum equilibrium condition, was defined by the overall degree of reaction advancement, using a set of polynomial equations solved independently of time scale.We found that reactive surface area of calcite, albite and K-feldspar increases by 2 orders of magnitude over the entire CO_2 fluid-rock interaction process, while the reactive surface area of biotite increases by 4 orders of magnitude. This shows that fluid neutralisation and consequent CO_2 mineralization under the form of carbonate species is greatly dependent on the behaviour of the reactive surface area of the mineral association in this geological context. We propose that biotite plays a basic role on the pH stabilisation and redox control of environmental perturbation and CO_2 mineralization.

Origin and evolution of ferromanganese crusts from South Altantic

M. RIMSKAYA-KORSAKOVA, I. VVEDENSKAYA AND A. DUBININ

P.P. Shirshov Institute of Oceanology RAS, Moscow, Russia (korsakova@ocean.ru)

Ferromanganese crusts are important tools in palaeooceanography for seawater microelement composition reconstruction and palaeocurrents identification. In this study the trace element content of crusts collected in South Atlantic at Mid Atlantic Ridge (st.2176), Angola Basin (st.2179) and Cape Basin (st.2188 and seamount st.2193) was determined.

We perform the layer-specific chemical analysis to estimate hydrogenous and hydrothermal contribution into crust formation. All crusts surfaces are dominantly hydrogenous that is proved with their chemical composition, namely trace elements enrichment and high positive Ce anomaly. Sample 2176 enriched with iron (up to 27%) and Mn/Fe ratio across the whole crust is about 0.4. We found high Co (up to 0.24%), Cu (0.1%) and As (0.04%) concentrations. Content of typical hydrogenous elements decreases from surface into deep crust layers reflecting changes in origin of matter.

The surface of sample 2179 (Angola Basin) abnormally enriched with Co (0.92%), Th (89 ppm) and Ce (0.29%). The REE composition of the crust upper layers exhibit high Ce anomaly (3.8-5.4) manifesting their hydrogenous signature, in contrast to lower layers with Ce anomaly value about 1.3. The lower layers are also depleted with other trivalent REEs and Y, and enriched with chalcophile elements like Zn and Cu, that indicates the hydrothermal origin of Fe oxyhydroxides.

The crust sample 2193 comes up to 20 kg in weight and characterized with dense texture without visible layers. Preliminary results show the sample enrichment with trace elements (Co – 0.82%, Ni – 0.33%, Pb – 0.22%, Ce – 0.20%, W – up to 170 ppm, Bi – 52 ppm, Th – 47 ppm) and Mn in contrast to other samples. The surface of crust probably undergo the dissolution due to strong near bottom currents flow.

The obtained data reveal a complex history of crusts formation, which origin often associated with submarine weathering (halmyrolysis), hydrothermal transportation reflected in chalcophile elements Cu and Zn concentrations. Subsequent crusts growth supplied with hydrogenous accumulation of matter from seawater.

Marine aerosol oxalic acid from in-cloud oxidation of glyoxal

MATTEO RINALDI[1]*, STEFANO DECESARI[1], SANDRO FUZZI[1], DARIUS CEBURNIS[2], COLIN D. O'DOWD[2], JEAN SCIARE[3], JOHN P. BURROWS[4], BARBARA ERVENS[5,6] AND MARIA CRISTINA FACCHINI[1]

[5]Cooperative Institute for Research in Environmental Sciences, University of Colorado, Boulder, CO, USA
[6]Chemical Sciences Division, Earth System Research Laboratory, NOAA, Boulder, CO, USA

Oxalate was detected in 'clean sector' marine aerosol samples at Mace Head (53°20′N, 9°54′W) and Amsterdam Island (37°48′S, 77°34′E) in concentrations ranging from few ng m^{-3} to tens of ng m^{-3}. Measurements went on in 2006 at Mace Head and from 2003 to 2007 at Amsterdam Island. The oxalate concentration in marine aerosol showed a clear seasonal trend at both sites, with maxima in spring-summer and minima in fall-winter, as other marine biogenic aerosol components (e.g. methanesulfonic acid, non-sea-salt-sulfate and aliphatic amines). These results suggest the existence of a natural source of oxalic acid over the oceans.

Observed oxalate was distributed along the whole aerosol size spectrum, with both a sub and a supermicrometer mode, suggesting the co-exhistence of different formation routes over remote oceanic regions.

Several formation processes can explain the presence of oxalate in marine aerosol. Here, it is proposed that the cloud mediated oxidation of gaseous glyoxal, recently detected over remote oceanic regions in concentrations of the order of 100 ppt, may be an important source of submicrometer oxalate in the marine boundary layer. Supporting this hypothesis, satellite retrieved glyoxal column concentrations over the two sampling sites exhibited the same seasonal concentration trend of marine aerosol oxalate. Furthermore, chemical box model simulations showed that the observed submicrometer oxalate concentrations were consistent with the in-cloud oxidation of typical marine air glyoxal mixing ratios, as retrieved by satellite measurements, at both sites.

Monoterpene emission dynamics from Arctic to Tropics

JANNE RINNE[1], ALMUT ARNETH[2], JÖRG-PETER SCHNITZLER[3] AND ALEX GUENTHER[4]

[1]University of Helsinki, POB 48, 00014 U. Helsinki, Finland (*correspondence: janne.rinne@helsinki.fi)
[2]Lund University, Soelvegatan 12, 22362 Lund, Sweden (almut.arneth@nateko.lu.se)

[4]National Center for Atmospheric Research, POB 3000, Boulder CO 80307, USA (guenther@ucar.edu)

Monoterpene emissions, while globally much smaller than isoprene emissions, can dominate emissions from certain regions and ecosystems [1]. As larger molecules, they are also much more likely to take part in secondary aerosol formation than isoprene.

The traditional monoterpene emission algorithm by Guenther *et al*. [2] was based on an assumption that the monoterpene emission can be described as evaporation from large storage pools. This leads to temperature dependent emission algorithm. However, quite soon it became obvious that monoterpene emission from certain plants and ecosystems showed more or less light dependent behavior [3, 4]. This was taken as indication that a part of the emission originates directly from synthesis. The ^{13}C labeling experiments, in which rapid labeling of a part of monoterpenes is observed, further confirm the linkages between photosynthesis and part of the monoterpene emission [4, 5]. The importance of large storage reservoirs as important source of emission from many coniferous species is indicated by large unlabeled fraction of monoterpene emission from these plants [5]. Thus one can describe the emission using a scheme of parallel emission pathways.

By combining data on monoterpene emissions, content in plant tissue, and labeling patterns reported in literature we can generalize the emission dynamics within plant functional types. This will yield a more comprehensive picture on monoterpene emission dynamics from ecosystems ranging from Arctic to Tropics.

Characterization and identification of minerals in rocks by ToF-SIMS and principal component analysis

S. RINNEN[1]*, C. STROTH[1], A. RISSE[2], C. OSTERTAG-HENNING[2] AND H.F. ARLINGHAUS[1]

[1]Physikalisches Institut, University of Muenster, 48149 Muenster, Germany (*correspondence: stefan.rinnen@wwu.de)

[2]Bundesanstalt fuer Geowissenschaften und Rohstoffe, 30655 Hannover, German (Christian.Ostertag-Henning@bgr.de)

For a variety of geoscientific topics a technique which unambiguously identifies minerals in rock samples would be very advantegous. In addition to optical methods, chemical mapping on the element level with different techniques has gained importance during recent years. For investigating gas-fluid-rock reactions it is important to be able to detect small secondary minerals and mineral alterations formed during the reactions – in combination with a high spatial resolution this could be achieved by mapping the incorporation of isotope labels. Therefore, a method using time-of-flight-secondary mass spectrometry (ToF-SIMS) is being developed that aims at identifying minerals and mineral alterations.

ToF-SIMS has the advantage that the entire mass spectrum is recorded quasi-simultaneously, so that a great number of elemental and molecular ion signals can be used to characterize the minerals. Here, the statistical method of principal component analysis (PCA) is a powerful tool for identifying the ion signals with great differentiation potential between individual minerals. We have used ToF-SIMS and PCA to analyze various rock-forming minerals. A spectral library was produced for all minerals investigated. For this, positive and negative ToF-SIMS spectra were taken from polished grains of rock-forming minerals (silicates, carbonates, sulfates, oxides, etc.). Signals from elemental and molecular ions that allocate to at least one of the minerals were used for the PCA analysis.

Afterwards, we used ToF-SIMS to image areas of rock samples containing unknown minerals. Spectra from individual zones were extracted and used to identify these minerals either by comparing them with the spectral library or by PCA analysis. The data clearly show that the high lateral resolution achievable with ToF-SIMS is very advantageous for the detection and identification of e.g. small newly formed phases of minerals at the edges of other components. Additionally, PCA was successfully used to classify silicates according to their crystal structures by comparing SixOy signal ratios and chemical compositions.

Assessing the factors controlling the temporal variations of weathering fluxes in a tropical watershed: Mule-Hole (South India)

J. RIOTTE[1], J.J. BRAUN[1,2], J.C. MARECHAL, A. VIOLETTE[1], P. DESCHAMPS[1,3], L. RUIZ[4], C. LAGANE[1], M. SEKHAR[2], S. SUBRAMANIAN[2], C. KUMAR[2] AND S. AUDRY[1]

[3]CEREGE, CNRS-Aix-Marseille University, BP80 13545 Aix-en-Provence, France

[4]INRA, UMR1069, SAS, 35000 Rennes, France

We investigated the present-day and long term weathering and erosion fluxes in tropical forested watershed (Mule Hole, South India). The watershed, monitored since 2003, is located in the sub-humid zone (MAR = 1100mm/yr) of a sharp climatic gradient induced by the Western Ghats and mostly fed by the South West monsoon.

The present-day evapotranspiration from the forest accounts for 85% of the annual rainfall, with two major consequences: (1) limitation of groundwater recharge and disconnexion with the stream, and (2) limitation of the stream flow, which is highly ephemeral [1]. However, the stream deconvolution indicates that almost 80% of dissolved species but Na transited through the vegetation as a result of leaf recretion and litter decay. These results emphasis the ambigous role of the vegetation that limits the runoff but enhances dissolved fluxes in the stream.

The present-day denudation rate is 28mm/kyr. It is dominated by erosion, ~25mm/ky, and by groundwater flux, 3mm/kyr, whereas the dissolved flux in the stream is very low, 0.3mm/kyr. The long term -100kyr- denudation rate was measured by ^{10}Be on the stream bedload. It accounts for only one third of the present-day value which means that the watershed experienced much lower erosion fluxes during the last climatic cycle, likeky under drier climate. This is confirmed by the occurrences of pedogenic carbonates in the basin soils. Their U-Th datings reveal the coexistence of several generations, essentially during the Last Glacial Maximum and to a lesser extent during the Holocene [2]. Rainfall conditions during the carbonate formation were semi-arid (MAR= 400 to 700mm/yr), i.e. enough for deepening the weathering front, but not for maintaining erosion fluxes.

Mechanisms for the attainment of sulfide saturation in magmas derived from subcontinental lithospheric mantle

EDWARD M. RIPLEY

Department of Geological Sciences, Indiana University, Bloomington, Indiana, USA 47405 (ripley@indiana.edu)

Magmatic, sulfide-rich, Ni-Cu-(PGE) deposits occur in settings where potential interaction between mantle-derived magma and country is enhanced (and hence a particular significance to subcontinental lithospheric mantle). Although the presence of S-bearing country rocks should not be dismissed when exploring for Ni-Cu-(PGE) deposits, it is clear that immediate country rocks often may have very little to do with the process of ore genesis. For this reason local country rocks may be poor choices for end-members in various types of geochemical mixing calculations, and data collected from the igneous rocks and associated sulfide mineralization must be carefully evaluated to assess the extent of magma interaction with country rocks. In the case of komatiites the introduction of sulfur from relatively local country rocks has been well-documented. For deeper-seated systems the involvement of immediate country rocks as magma contaminants has been more difficult to prove.

Troctolitic intrusions of the Duluth Complex (Midcontinent Rift System) are hosted by sulfide-bearing pelitic rocks which provide a viable source of sulfur in a contamination process. Sulfur isotope values of the mineralized rocks show a strong crustal signature, but their variability also signifies the involvement of multiple sulfide-saturated pulses. In a system of multiple intrusions various pulses may interact with different country rocks in the conduit system, and as a result be characterized by distinct chemical and isotpic signatures. Situations such as these lead to a conclusion that assimilation of crustal S occurred in deeper chambers within the magmatic system.

When the incorporation of S from country rocks is not indicated, the size of the magma system becomes particularly important. Contamination of mafic magmas by silicic country rocks may lead to sulfide saturation and if orthopyroxene crystallizion results rather than olivine, an added benefit is the availability of Ni (D-Ni (pyr) < D-Ni (ol)). However, in cases where S addition has not occurred extremely efficient collection of sulfide, from large masses of magma, is required for the formation of economically viable mineralization.

Long distance electron transmission couples sulphur, iron, calcium and oxygen cycling in marine sediment

N. RISGAARD-PETERSEN[1]* AND L.P. NIELSEN[2]

[1]Center for Geomicrobiology, Department of Biological Sciences, Aarhus University, 8000 Aarhus C, Denmark (*correspondence: nils.risgaard-petersen@biology.au.dk)

[2]Section for Microbiology, Department of Biological Sciences, Aarhus University, 8000 Aarhus C, Denmark (biolpn@biology.au.dk)

Geochemical observations in marine sediment have recently documented that electric currents may intimately couple spatially separated biogeochemical processes (1). When marine sediment rich in iron sulphide was exposed to oxygen we observed how the electric currents resulted in significant geochemical alterations in the upper centimetres of the anoxic sediment:

Sulphides were oxidized to sulphate in anoxic sediment layers. Electrons from this half-reaction were passed to the oxic layers cm above. In this way the domain of oxygen was extended far beyond it's physically presence. Bioelectrical sulfide oxidation leads to electric field formation, sulfide depletion and acidification of the upper centimeters of the sediment. This promoted ion migration and dissolution of carbonates and iron sulfides. Sulfide released from iron sulfides was the major e-donor in the system. Ferrous iron released from iron sulfides was to a large extend deposited in the oxic zone as iron oxides and Ca^{2+} eventually precipitates at the surface as due to high pH caused by cathodic oxygen reduction.

The result show how long distance electron transmission allows oxygen to drive the allocation of important minerals and possibly many trace elements deep in marine sediment.

Alteration of carbonates in saline aquifers due to CO_2 and accessory gases at geological storage conditions

A. RISSE*, K. HEESCHEN, S. STADLER AND C. OSTERTAG-HENNING

Federal Institute for Geosciences and Natural Resources (BGR), Stilleweg 2, D-30655 Hannover, Germany (*correspondence: Andreas.Risse@bgr.de)

The estimation of an environmentally and economically feasible purity of carbon dioxide for geological storage presumes a comprehensive understanding of the geochemical interactions of CO_2, accessory gas components in the separated gas stream, e.g. H_2O, O_2, N_2, SO_x, NO_x, CO, H_2, H_2S, aqueous highly saline fluids and natural minerals.

The main focus of this geochemical subtask within the project COORAL (= CO_2 - Purity for Capture and Storage) is on experimental work with mineral-H_2O-CO_2-electrolyte-(accessory gas, e.g. SO_2, O_2, NO_x)-systems at *in situ* pressure (p) and temperature (T) conditions and the combination with geochemical modeling applying the numerical code PHREEQC.

A literature survey and systematic parameter evaluation demonstrated that some mineral-fluid-gas systems (shown for calcite-H_2O-CO_2-electrolyte) cannot be adequately described as to a partially simplified incorporation into the model, a lack of data at relevant pT conditions, and/or extrapolation-induced errors of the underlying thermodynamic data sets, confirming the need for additional experimental work at elevated pT conditions.

We show natural mineral and fluid alteration data of dissolution experiments of up to 700 h duration in the system calcite-H_2O-CO_2-(SO_2)-NaCl. Results were obtained with a static batch reactor system equipped with chemically inert and flexible gold-titanium-cells at operating conditions of 200 bars and 120 °C. Dissolution data indicate a stronger release of Ca from calcite in the presence of NaCl or/and CO_2 (and acid generating SO_2) in agreement with published findings. Net dissolution rates of calcite at various calcite-H_2O-CO_2-(SO_2)-NaCl systems will be presented and discussed.

While experimental data without CO_2 are well represented by thermodynamic calculations, rather strong discrepancies from measured data are e.g. observed for simulations of experiments in the presence of CO_2. We discuss reasons for deviations and limitations induced by the databases used.

STXM and XAS study of kaolinite conversion into berthierine-like mineral

C. RIVARD[1]*, E. MONTARGES-PELLETIER[1], M. PELLETIER[1], L.J. MICHOT[1], D. VANTELON[2], C. KARUNAKARAN[3], F. VILLIERAS[1] AND N. MICHAU[4]

[2]Synchrotron Soleil, Gif-sur-Yvette, 91192, France
[3]Canadian Light Source, University of Saskatchewan, Saskatoon, SK S7N 5C9, Canada
[4]ANDRA, 1/7 rue Jean Monnet, Parc de la Croix Blanche, 92298 Châtenay-Malabry Cedex, France

Experiments

In the context of radioactive waste repository in geological formation, kaolinite-Fe^0 interactions were investigated at the cristallochemical level. Batch experiments were carried out in anoxic conditions at 90°C, for durations of one, three and nine months, by mixing Georgia Kaolinite (KGa2), powder Fe^0 and aqueous solution (NaCl, $CaCl_2$). Such parameters were chosen to mimic repository conditions.

Results

First results indicated very fast iron metal consumption, morphological changes and iron-enrichment of clay particles.

X-ray diffraction, Fe K- and L-edges microspectroscopy (µ-XAS, STXM) evidence the rapid formation of an iron-rich 7 Å clay phase, with a structure close to that of berthierine or chamosite. At micrometric and nanometric scales, most iron is ferrous and octahedrally coordinated. However, some of the newly formed iron-rich clay particles display significant amounts of Fe^{3+} with variable Fe^{2+}/Fe^{3+} ratio (Figure 1). In order to get further crystallochemical information, iron data were complemented by experiments at both the Si and Al-K edges. Si K-edge spectra display variations mainly due to particles orientation. Al K-edge spectra reveal no change in aluminium status of pristine clay. Although berthierine and chamosite bear both Al^{IV} and Al^{VI}, only Al^{VI} seems to be present in the neoformed iron rich-clays.

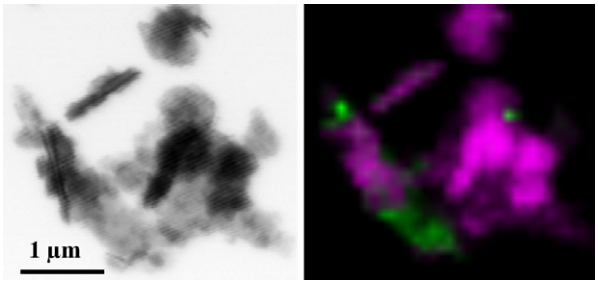

Figure 1: STXM image at 715 eV (Fe L3-edge) and corresponding two components fit (pink Fe^{2+}, green Fe^{3+}).

Li isotopes a powerful tool to trace hydrothermal impact during chemical weathering processes

KARINE RIVÉ[1], SÉTAREH RAD[2], MANUEL GARCIN[2] AND ROMAIN MILLOT[2]

[1]CEGEO, 159 allee chardin, Villeneuve d'ascq, France
[2]BRGM, 3, avenue Claude-Guillemin, Orléans, France

Li isotopes has been recently used to study water-rock interactions at Earth surface. Li is a fluid-mobile element that tends to preferentially partition into the fluid phase during water-rock interaction. The relative mass difference between the two isotopes is considerable, generating large mass dependent fractionation during chemical weathering processes, even at high temperature.

In the present work, the $^{7}Li/^{6}Li$ (expressed as $\delta^{7}Li$) was analyzed in Allier River, one of the major river basins of France. We have undertaken a systematic study of weathering products of the river. The lithology is dominant by granite rocks with current upstream, while it is mainly basaltic and Oligocene sediments in the downstream with hydrothermal manifestation.

Water samples were collected during several field trips. Our results show a large variation in Li isotopes within the catchment from 4.44 ‰ to 23.52 ‰. Li signature show a geographical distribution as it decreases from upstream to downstream over 400km. It appears that the upstream portion of the river present Li signature with higher fractionation with a mean value of 18 ‰ whereas it is only 6 ‰ in the downstream. This last portion of the river is impacted by hydrothermal activity, indeed these values reflect low temperature water-rock interaction in upstream and high water-rock interactions in the downstream, which the lowest values correspond to thermal mineral water plant. Li isotopes can be used here as a tracer of hydrothermalism. Moreover it seems that Li isotopes present a negative correlation with metal elements concentrations, which means that in a natural system hydrothermal activity induce liberation of those elements in the dissolved phase of the river during chemical alteration.

Those promising applications from Li isotopes to better understand chemical weathering processes will be discussed.

Identification of transboundary geothermal aquifers by hydrogeochemistry

N. RMAN[1]*, T. SZŐCS[2] AND A. LAPANJE[1]

[1]Geological Survey of Slovenia, Dimičeva ul. 14, 1000 Ljubljana, Slovenia
(*correspondence: nina.rman@geo-zs.si
[2]Geological Institute of Hungary, Stefánia út 14., 1143 Budapest, Hungary

Problem identification and applied methodology

The transboundary character of the Mesozoic, Miocene and Pliocene geothermal aquifers in the Mura-Zala basin in the SW Hungary and NE Slovenia was investigated by various hydrogeochemical techniques. Chemical analyses of 24 cold- and thermal groundwater samples were performed in 2010 for the T-JAM project, followed by additional sampling in 2011 for the TRANSENERGY project.

Results and discussion

Main components and trace elements analyses confirm the vertical stratification of geothermal aquifers as already suggested by many [1, 2, 3], but also indicate transboundary flow systems. Hydrogeological connections and groundwater age are interpreted from the stable ($\delta^{18}O$, δD, $\delta^{13}C$) and radioactive groundwater isotope (tritium, ^{14}C) analyses.

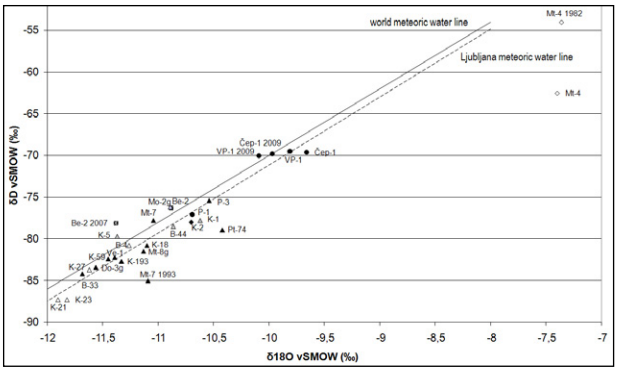

Figure 1: Distribution of $\delta^{18}O$ and δD in the samples.

Organic compounds, dissolved and separated gas, and noble gas analyses indicate differences in evolution and prevalent geochemical processes in the aquifers. Distinction between active and stagnant flow systems is also evident from our results.

Proteogenomics of a marine sediment community dominated by ANME-1

I. ROALKVAM[1], R. STOKKE[1], H. HAFLIDASON[2] AND I.H. STEEN[1]*

[1]Department of Biology, Centre for Geobiology, University of Bergen, 5020 Bergen, Norway (*correspondence: ida.steen@bio.uib.no)

[2]Department of Earth Science, University of Bergen, 5020 Bergen, Norway

Sulfate-reducing methanotrophy by anaerobic methanotrophic archaea (ANME) and sulfate-reducing bacteria (SRB) is a major biological sink of the green house gas methane in anoxic methane-enriched marine sediments. The physiology of a microbial community in the G11 pockmark at Nyegga dominated by free-living ANME-1 was investigated by a proteogenomic approach. Total DNA was subjected to 454-pyrosequencing (829, 527 reads) and 16.6 Mbp sequence information was assembled into contigs Taxonomic analysis supported a high abundance of Euryarchaea (70%) with 66% of the assembled metagenome belonging to ANME-1. Extracted proteins were separated on 1D-SDS-PAGE, and gel slices were in-gel tryptic digested and subjected to liquid chromatography and mass spectrometry (LTQ-Orbitrap XL). Of 356 identified proteins, 245 were expressed by ANME-1. Expression of cold-adaptations and gas vesicle proteins reflects adaptation of the ANME-1 community to a permanently cold environment and possibly to positioning in specific sediment depths, respectively. Furthermore, except N_5N_{10}-methylene-tetrahydro-methanopterin reductase all enzymes in the reverse metanogenesis pathway as well as red-ox protein components homologous to SRB, were expressed by ANME-1. Sulfite reductase and adenosine-5'-phosphosulfate (APS) -reductase in the dissimilatory sulfate reduction pathway were expressed by sulfate reducing δ-proteobacteria. In addition, an APS-reductase affiliated with cluster IV comprising Gram-positive SRB and related sequences [1], was present in the proteome.

[2]US Geological Survey, 400 Natural Bridges Drive Santa Cruz, CA 95060

[3]US Geological Survey, MS 973 Denver Federal Center Denver, CO 80225

[4]Center for Marine Science, University of North Carolina at Wilmington, Wilmington, NC 28409

In this study we report on the use of radiocarbon measurements to investigate growth rates and age distributions of deep-water black corals (*Leiopathes* sp.) in the Gulf of Mexico and the southeastern Unites States. Results from five specimens show that these animals have been growing continuously for at least the last two millennia, with growth rates ranging from 8 to 22 μm yr^{-1}. These results are compared to SEM work to image growth rings and measure relative trace elements concentrations. The counting growth rings counts by two different methods on the SEM images and peaks in iodine concentration are in good agreement (typically within the ^{14}C uncertainty and a 10% counting uncertainty) with the radiocarbon results allowing for the development of independent age models

In this study we also use a multi-proxy approach in order to better understand the combination of biological and physical factors controlling the isotopic and trace element content of deep-sea corals. Both $\delta^{15}N$ and $\delta^{13}C$ signatures along with trace element paleoindicators of eutrophication and oxygen levels (V, Mo, U, Re, Cu and I) can be used to infer changes in surface water conditions related to nutrient loading, eutrophication, and hypoxia in the Gulf of Mexico over the last millennium. Important changes are noted over the last 900 years and over the last century.

Banded iron formations as proxies for Zn

In the transition-metal complement of living cells, zinc plays a central role. It is the most common inorganic co-factor employed by eukaryotic metalloenzymes, and second or equal to iron in prokaryotic metalloenzymes [1]. In Eukarya, many Zn-binding proteins appear to have evolved relatively recently, leading to the proposal that limited marine Zn availability prior to the Neoproterozoic may have impacted the course of eukaryotic evolution [1]. We seek to evaluate this hypothesis by examining sedimentary proxies for the evolution of the marine Zn reservoir over geological time, specifically Precambrian banded iron formations (BIF), younger ironstones and exhalites. By combining the BIF record with experimental results for Fe-Zn-Si co-precipitation we are able account for the competitive effects of silica during absorption. We present estimates of seawater Zn concentrations from the Archean through to the modern; while there appears to be mild enrichment in the Phanerozoic, we extrapolate Archean Zn concentrations that are roughly comparable to modern. These findings have strong bearing on potential consistency between genetic and geological records for the evolution of Earth's surface environment.

Rheological constraints on the deformation of Snake River-type ignimbrites: An experimental study

GENEVIEVE ROBERT[1]*, GRAHAM D. ANDREWS[2], JIYANG YE[1] AND ALAN G. WHITTINGTON[1]

[1]Department of Geological Sciences, University of Missouri – Columbia , Columbia, MO, USA (*correspondence: genevieve.robert@mail.mizzou.edu)

[2]Department of Earth and Environment, Franklin and Marshall College, Lancaster, PA, USA

We have studied the rheology of two ashfall units associated with the eruption of the pervasively rheomorphic Grey's Landing (GL) ignimbrite (a Snake River-type ignimbrite) from the Miocene Rogerson formation, Snake River Plain volcanic province, USA. Lava-like lithofacies of the GL ignimbrite are either crystallized, devitrified, or perlitized, and do not necessarily represent the original material that came out of the vent to be subsequently deposited, welded and deformed by flow (rheomorphism). We therefore chose to use the fused basal co-ignimbrite ashfall tuff (GLB) and the upper co-ignimbrite tuff (GLU) as potential 'starting material' for the GL ignimbrite. The basal ash is laminated, moderately porous (~15%), and contains 10–20% crystals; in contrast the upper ash is massive, nearly aphyric, glassy and contains ~5% porosity.

We measured the apparent viscosity of each unit over ~835-1005°C, a range of temperatures relevant to eruption and deposition of these ignimbrites. The viscosities of the upper and lower units converge in the low-temperature range (~835°C) and diverge at higher temperatures (at 900°C, the viscosity of GLU is $10^{10.3}$ Pa s whereas that of GLB is $10^{10.8}$ Pa s).

Strains ranging from 10 up to 1000 are recorded in the Grey's Landing ignimbrite. However, our viscometry results suggest that dry melts making up the deposit either require unreasonably high stresses (>1MPa) or long deformation timescales (days to weeks) inconsistent with field observations to produce the observed strain in the deposit. It follows that dissolved water reducing the viscosity of the pyroclasts at the deposition temperature and/or strain heating keeping temperatures high or even increasing temperatures during deposition and deformation are necessary to explain the field observations. Models investigating the relative contributions of dissolved water and strain heating in facilitating rheomorphism will be presented.

Potential REE deposits along the Red Sea coast of Egypt

JAMES ROBERTS[1]* AND TAREK IBRAHIM[2]

[1]University of Pretoria, Pretoria, South Africa (*correspondence: james.roberts@up.ac.za)
[2]El Mansoura University, Cairo, Egypt, (elsahabi@yahoo.com)

In Egypt, exploration for heavy mineral deposits with their associated REE minerals has traditionally concentrated on the Mediterranean coast, and large garnetiferous heavy mineral sands have been identified at localities near Alexandria. However, the Red Sea coast is also an ideal environment for the formation of such deposits [1].The Red Sea Coast in the southernmost portion of Egypt has a long geological history of erosion and sediment transportation, and several alluvial deposits rich in economic heavy minerals have been identified in the coastal strip between Ras Banas and the border with Sudan. Accumulations of heavy minerals have been observed along Red Sea beaches at Ras Manazel, Khudaa, Shalateen, Wadi Diit, and along the coastal stretches between these locations. These deposits have formed not only by transport processes related to offshore currents in the Red Sea, but also by drainage networks operating in the Eastern Desert of Egypt. Satellite imagery of the drainage networks indicates that the granites of the Sudanese highlands are the source of the heavy minerals, with minor input from granites in the southern Egyptian highlands. Deposits inland from the current Red Sea coastline may have been formed before the opening of the Red Sea, and subsequent erosion and reworking through flash flooding and other catastrophic transport mechanisms has created more recent deposits along the current coastline. The deposits contain not only illmenite, rutile, magnetite, and garnet, but also large concentrations of radioactive minerals such as thorite, zircon and monazite. Preliminary studies have shown that some of the deposits are extremely rich in REE minerals (1-2% zircon by weight, 0.5% monazite by weight). The mineralogical composition of the deposits matches those of the granites in Sudan and southern Egypt, which have been explored extensively for uranium for the last 10 years. These deposits are thus a viable target for further exploration, with the intent to extract the REE minerals as well as the titaniferous ilmenite.

Rare earth element association with foraminifera

N.L. ROBERTS[1]*, A.M. PIOTROWSKI[1], T.I. EGLINTON[2] AND M.L. LOMAS[3]

[1]Department of Earth Sciences, Downing Street, Cambridge, UK (*correspondence: nr297@cam.ac.uk)
[2]Geological Institute, Sonneggstasse 5, Zürich, Switzerland
[3]Bermuda Institute of Ocean Sciences, St George's, Bermuda

Nd isotopes are becoming widely used as a paleoceanographic tool for reconstructing past changes in water mass source [1]. Recent analysis of Nd isotopes on sedimentary planktonic foraminifera at the Bermuda Rise has proven to be a robust alternative to bulk sediment leachates, for reconstructing bottom water circulation [2]. However, in order to use foraminiferal Nd isotopes as a proxy for bottom water composition, we need to establish how, where and when rare earth elements (REEs) become associated with foraminifera.

We have measured REE concentrations and Nd isotopes on plankton tow and sediment trap foraminifera from the NW Atlantic, and compared with sedimentary foraminifera from marine cores in the same region. This allowed an evaluation of REE association with planktonic foraminifera at various stages of settling through the water column, and diagenesis near the sediment-water interface.

We find approximately 80% of plankton tow and sediment trap Nd is scavenged by particulate organic carbon and metal oxides. These phases are remineralised as particles fall through the water column allowing partial equilibration of foraminiferal Nd isotopes with ambient dissolved sea water. Once at the sediment-water interface, respiration of organic matter between foraminiferal primary calcite layers provides a reducing micro-environment within which diagenetic phases precipitate. These phases increase foraminiferal REE concentrations by ~10 fold through inorganic partitioning from bottom and pore waters.

Calculated partition coefficients suggest manganese carbonate is the predominant diagenetic host for REEs in planktonic foraminifera at the Bermuda Rise. This carbonate phase is difficult to remove during reductive cleaning, and is also resistant to down core REDOX changes, allowing reconstruction of robust bottom water Nd isotope records by measuring mixed planktonic foraminfera. Our findings have important implications for the use of planktonic foraminifera, both for surface and bottom water Nd isotope reconstruction.

Continental growth spurts during supercontinent break-up

NICK M.W. ROBERTS

NERC Isotope Geosciences Laboratory, Kingsley Dunham Centre, Keyworth, Nottingham, NG12 5GG, UK (nickmwroberts@gmail.com)

Accretionary orogens are the primary host of both growth and loss of continental crust, at least since the Archaean. At present-day, growth and loss are balanced globally, leading to a constant continental volume [1]. Retreating accretionary orogens will feature greater continental growth than those in advancing mode (e.g. [2, 3]). Continental growth largely occurs via subdcuction-driven magmatism, whereas continental loss largely occurs via subduction erosion and sediment subduction. Since the latter typically involves partial recycling into magmas, both growth and loss of continental crust are represented in the magmatic record.

Using a global zircon-Hf datset [4], the magmatic record preserved in zircons is examined to determine the relative amount of global continental growth versus recycling. Excursions into positive and negative εHf-time space relative to a global mean, represent increased continental growth and recycling respectively. The data show strong negative excursions at ~2.0-1.7 Ga, ~1.0 Ga, and ~550 Ma, reflecting increased continental recycling during periods of supercontinent amalgamation. Well-defined positive excursions are seen at ~1.7-1.3 Ga and ~0.8-0.6 Ga, interpreted as increased continental growth-rate during periods of supercontinent break-up, and likely reflecting an increased degree of retreating accretionary orogens. The Archaean lacks strong positive or negative excursions, reflecting either a lack of supercontinent formation, or a differing role of accretionary orogenesis during this period.

Preservational bias during the supercontinent cycle may lead to an increased zircon record during supercontinent formation [5]; however, the degree of mantle input recorded by Hf-in-zircon indicates that continental growth-rate is actually increased during supercontinent break-up. Elucidating the exact degree of continental loss through Earth history remains a challenge, but is vital for determining the true nature of continental growth.

Marine controls on atmospheric radiocarbon: The glacial and deglaciation

LAURA F. ROBINSON[1], ANDREA BURKE[2] AND JESS F. ADKINS[3]

[1]Dept. Marine Chemistry & Geochemistry, Woods Hole Oceanographic Institution, 266 Woods Hole Rd. 02543 Woods Hole, MA. USA (lrobinson@whoi.edu)

[3]MC 100-23, 1200 E. California Blvd. Pasadena, CA 91125 (jess@gps.caltech.edu)

Radiocarbon is an important isotope because its radioactive decay provides constraints on the rates and timing of processes today and in the past. It is well mixed in the atmosphere, where its history is reasonably well constrained back through the last 50,000 years. By contrast the radiocarbon content of the ocean varies by about 150 per mil depending on equilibration with the atmosphere and subsequent isolation that allows decay to proceed.

There is evidence for an even greater dynamic range in the marine realm during the last glacial and deglaciation. For example, published records from intermediate waters in the northern hemisphere are up to 500 per mil depleted relative to the contemporaneous atmosphere, and have been used as evidence for a isolated, carbon-rich reservoir in the deep ocean. There is little doubt that interaction with the ocean is a major driver of atmospheric CO_2 and radiocarbon on these timescales, but the mechanisms continue to be debated in the literature. In this abstract we focus on building a coherent compilation of the state-of the-art of marine radiocarbon records, and then use these records to discuss potential mechanisms for abrupt changes in atmospheric carbon and radiocarbon.

Transfer of nutrients and carbon from the Southern Ocean to the Atlantic during the last deglaciation

LAURA F. ROBINSON, ANDREA BURKE AND KATHARINE R.HENDRY

Woods Hole Oceanographic Institution, 360 Woods Hole Rd. 02543 Woods Hole, MA. USA

The interconnection of ocean circulation and nutrient cycling appears to be closely linked to atmospheric carbon dioxide and global temperature. In this abstract we make use of a novel proxy for silicic acid concentration, $d^{30}Si$ in deep-sea sponge spicules, together with new and published ^{14}C records to examine carbon and nutrient cycling in the deep Southern Ocean. We then link this cycling to intermediate and deep locations in the western basin of the Atlantic during the abrupt climate events of the last deglaciation to investigate how circulation, nutrients and CO_2 are coupled.

We have documented little difference between the silicic acid concentration of the deep Southern Ocean at the last glacial maximum compared to the modern. By contrast, it appears that circumpolar deep waters were significantly depleted in radiocarbon during the glacial period, indicative of a build up of carbon. Within the Southern Ocean itself we observe a break down of deep-water stratification during the deglaciation, at around the time of the Bolling Allerod.

Ocean circulation and nutrient cycling in the Atlantic during the three most recent Heinrich events, H2, H1 and the Younger Dryas appear to share certain characteristics, but the CO_2 response is not the same in each case. For example meridional circulation from sedimentary Pa/Th ratios appears to have been somewhat similar during H2 and H1. At the same time there is evidence for northward export of Si and low $^{14}C/^{12}C$ waters into the Atlantic. However in one case atmospheric CO_2 increased markedly, and in the other it did not. During the Younger Dryas when CO_2 was increasing, Pa/Th indicates only a partial reduction in advection but silicic acid and Cd/Ca indicate export of virtually unadulterated circumpolar deep waters throughout the intermediate depths of the Atlantic. Concurrently $^{14}C/^{12}C$ ratios at deep and intermediate depths in the North Atlantic were somewhat depleted, consistent with carbon-rich southern-source waters escaping from the Southern Ocean. We will use these similarities and differences to link our knowledge of the circulation of the ocean to atmospheric carbon records.

Deep subduction of crustal minerals in the mantle: Evidence from ophiolites

P. ROBINSON[1], R. TRUMBULL[2], J.-S. YANG[3] AND A. SCHMITT[4]

[1]Department of Earth Sciences, Dalhousie University, Halifax, Nova Scotia, Canada

[2] Helmholtz Centre Potsdam , GFZ German Research Centre for Geosciences , D14473, Potsdam, Germany

[3] Key Laboratory for Continental Dynamics, Institute of Geology, Chinese Academy of Sciences , Beijing, 100037 China

[4] Department of Earth and Space Sciences, University of California, Los Angeles, Los Angeles, California 90095-1567, USA

Crustal minerals, including zircon, corundum, feldspar, almandine garnet, kyanite, sillimanite and rutile, associated with ultrahigh pressure minerals, such as coesite, diamond, kyanite, and moissanite have been recovered in varying proportions from podiform chromitites of the Luobusa and Donqiao ophiolites of Tibet and the Semail ophiolite of Oman. The UHP minerals, and some of the crustal minerals, have been found in situ; the other grains have been recovered from mineral separates. Zircon is common in all three ophiolites and occurs as rounded to subangular grains, about 50-300 microns across, typically with very complex internal textures. A few euhedral prisms have regular oscillatory zoning indicative of a magmatic origin. $^{206}Pb/^{208}U$ SIMS dates for the Luobusa zircons range from 549±19 to 1657±48 Ma, whereas those from Donqiao have ages of 484±49 to 2515± Ma, all much older than the ophiolites. Sixteen dates on zircons from the Semail ophiolite range in age from 84±4 to 1386±48 Ma. Most zircons from Oman are older than the ophiolite but 3 grains are essentially the same age as the ophiolite (92±4 to 99±5 Ma. These are euhedral prisms with oscillatory zoning. The zircons typically contain a variety of low-pressure inclusions, including quartz, rutile, orthoclase, mica, ilmenite and apatite. In addition, all of the zircons from the three ophiolites have REE and trace element compositions compatible with a crustal origin. The assemblage of crustal minerals, combined with the morphology and age of the zircon, strongly suggest derivation from crustal sediments subducted into the mantle, where they were mixed with UHP and highly reduced phases. The preservation of these minerals can be explained by their occurrence as inclusions in chromite grains.

Southern Ocean nitrogen and silicon dynamics during the last deglaciation

REBECCA S. ROBINSON[1], MATTHEW G. HORN[1], CHARLOTTE P. BEUCHER[2] AND MARK A. BRZEZINSKI[2]

[1]Graduate School of Oceanography, University of Rhode Island, Narragansett, Rhode Island, USA
[2]The Marine Science Institute, University of California Santa Barbara, Santa Barbara, California, USA

The reinvigoration of overturning in the Southern Ocean is hypothesized to have returned CO_2 from the deep ocean to the atmosphere at the end of the last ice age. Large peaks in opal accumulation have been put forward as evidence for an increase in wind driven upwelling between 10 and 15 kyr BP [1]. Here, we use coupled nitrogen and silicon isotope records alongside opal accumulation rates to provide quasi-quantitative estimates of Southern Ocean nutrient supply, by upwelling, and nutrient utilization across this interval. Significant changes in the consumption of N and Si across the two opal accumulation peaks indicate major changes in both upwelling and nutrient demand. We find N and Si consumption to be relatively incomplete during peak opal accumulation. Nutrient supply must have been significantly enhanced. Differences between the Si and N responses during opal peaks may stem from decreasing iron availability across the glacial termination. The reinvigoration of overturning circulation during the deglaciation is hypothesized to cause a transient peak in nutrient supply to the low latitudes [2]. This is supported by our data, which indicate that relatively high macronutrient concentrations were maintained in the Southern Ocean surface waters despite high demand.

A re-compiling of Cretaceous SST proxy data

STUART A. ROBINSON, KATE LITTLER, PAUL BOWN AND JACKIE LEES

Department of Earth Sciences, University College London, Gower Street, London, WC1E 6BT, UK (stuart.robinson@ucl.ac.uk)

The Cretaceous was generally a period of extreme global warmth, most likely caused by elevated atmospheric pCO_2 levels, during which geologically brief (<1 Myr duration) carbon-cycle perturbations were common. Thus, the geological recod of this time period may hold clues as to the mechanics of the Earth system under different conditions to those experienced at the present-day and, also, to the long-term response of the planet to severe environmental perturbation. However, extraction of meaningful inferences about the Earth system from the Cretaceous geological record requires confidence in the proxies used to reconstruct environmental variables, such as temperature and pCO_2.

The last decade has seen significant shifts in the understanding and number of geochemical proxies used to reconstruct sea-surface temperatures (SSTs) in the Cretaceous. The recognition of early bottom-water recrystallization of planktic foraminifera has resulted in the re-appraisal of what is considered ‘excellent’ calcite preservation suitable for oxygen-isotope and Mg/Ca analysis. Organic geochemistry has provided a new proxy, TEX_{86}, that has permitted the generation of SST records in time periods and environments that were previously unobtainable by calcite $\delta^{18}O$. Additional insights have been provided by $\delta^{18}O$ of phoshate from biogenic apatites and new water-phosphate fractionation equations have been defined. These new insights and developments provide the justification for a re-appraisal of the temporal and spatial variability in Cretaceous SSTs. We attempt here to provide an up-to-date synthesis of Cretaceous proxy SST data that is mindful of the lessons and developments of the last decade. Using this new compilation allows us to build a more comprehensive view of Cretaceous palaeoclimates and to explore a number of questions that are pertinent both to Cretaceous palaeoclimatology and wider inferences about the mechanics of the Earth system.

Rapid weathering of arsenopyrite in agricultural soils

T.C. ROBSON*, C.B. BRAUNGARDT AND M.J. KEITH-ROACH

University of Plymouth, Plymouth, PL4 8AA, UK (*correspondence: thomas.robson@plymouth.ac.uk)

Aerially distributed fine mineral waste particles (< 250 μm), the product of mining processes, are an important source of potentially toxic elements (PTEs) in the surface environment. However, there is a paucity of data on the short-term stability of PTE-rich particles in agricultural soils and the associated risk of producing contaminated crops when PTEs are released from mineral matrices.

This study aimed to determine whether sulphide ore minerals undergo geochemical alterations (i.e. oxidation-dissolution) at a rate that is relevant to crop growth (in the order of months – years). Arsenopyrite (FeAsS) was selected for this proof-of-concept experiment due to the toxicity of arsenic at low concentrations [1].

Two soils, contrasting in organic matter content and pH, were spiked with ground FeAsS (1, 600 μmol/kg As), sown with spring wheat (*Triticum aestivum)* and incubated under controlled conditions until the wheat ripened (90 days).

Following the incubation period, soluble (soil water extract) and exchangeable (0.1 mol/L phosphate buffer extract, pH 7.2) arsenic concentrations were significantly ($p<0.05$) higher in spiked soils, compared with controls. Low soluble arsenic concentrations suggested that less than 0.1% m/m of the mineral-bound arsenic had been released and remained present as soluble species. On the other hand, exchangeable As concentrations indicated that up to 9 % m/m (in acid soil, pH 4.5) of the mineral-bound arsenic had been released and loosely bound within the spiked acid soil matrix. The lower exchangeable concentrations extracted from the organic, neutral pH soil (0.5% m/m) were consistent with the reported FeAsS dissolution rate minima at pH 7-8 [2].

Short-term weathering of FeAsS did not yield dangerous arsenic concentrations (4.2-5.3 nmol/g) in edible plant tissues under the test conditions, based on cereal consumption rates [3]. However, this study provides evidence for significant arsenic release from arsenopyrite within an agriculturally relevant, short exposure period. Further experiments are underway, with the aim of determing the alteration rate of FeAsS and other related minerals in agricultural systems.

[4]IAEA, Marine Environment Laboratories, 4 Quai Antoine 1[er], MC-98000 Monaco (J.Scholten@iaea.org)

Recognition of the role played by SGD in the transfer of contaminants to near shore marine environments underscores the need for tools and approaches that will facilitate regional assessments of its environmental impact, including localization, spatial extent and magnitude as well as the provision of uninterrupted chains of evidence that effectively demonstrate links between polluted groundwater sources on land and ecosystem level effects in the coastal zone.

We present an uninterrupted chain of evidence linking groundwater pollution to coastal ecosystem function for a leaky coastal lagoon system. Here, for the first time, this causal link is demonstrated in its entirety for a single ecosystem. The approach used combines Earth observation techniques, hydrological mass balance approaches, conservative, radiogenic and stable isotope tracers, nutrient dynamics along the mixing line and finally, direct physiological indicators of primary producer assimilation of groundwater borne nutrients at the marine end member.

Petroleomics: Past, present and future

RYAN P RODGERS[1], AMY M. MCKENNA[1], CHRISOPHER L. HENDRICKSON[1] AND ALAN G. MARSHALL[2]

[1]National High Magnetic Field Laboratory, 1800 E. Paul Dirac Drive, Tallahassee, FL 32310 USA (rodgers@magnet.fsu.edu, mckenna@magnet.fsu.edu, hendrick@magnet.fsu.edu)

[2]Department of Chemistry and Biochemistry, Florida State Univ., 95 Chieftan Way, Tallahassee, FL 32306 USA (marshall@magnet.fsu.edu)

Advances in mass spectrometry enable identification of tens of thousands of species in petroleum and environmental samples at the molecular level (elemental composition assignment). Current ionization methods amplify the utility of such detailed compositional information through the selective ionization of basic, acidic and aromatic species (± ESI and APPI). The ability to fingerprint, identify and track compositional changes in complex natural mixtures spawned the field of 'Petroleomics'. Although the past and current applications are largely limited to high resolution Fourier transform ion cyclotron resonance mass spectrometry, the future of 'Petroleomics' lies in the expansion and method development on the latest instruments in all areas of analytical chemistry.

Here we present an overview of the birth and development of Petroleomics and highlight the latest developments in our 'petroleomic' research efforts with an emphasis on the diversification of analytical workflows to maximize attainable compositional information. Specifically, microdistillation, 2-D HPLC, GC x GC, LC-TOF, preparative scale LC and FT-ICR MS will be discussed. Geochemical, oil production and refinery applications that include down-hole, deposits, offshore platform, terrestrial production and distillate samples reveal the need for a diversified analytical approach combined with high field FT-ICR mass spectrometry for problem solving and advances in the fundamental knowledge of the composition and behavior of petroleum derived materials.

High-frequency climate cycles in the Westernmost Mediterranean during the last 20,000 yrs

M. RODRIGO-GÁMIZ[1]*, F. MARTÍNEZ-RUIZ[1], F.J. RODRÍGUEZ-TOVAR[2], F.J. JIMÉNEZ-ESPEJO[1] AND E. PARDO-IGÚZQUIZA[3]

[1]Instituto Andaluz de Ciencias de la Tierra (IACT-CSIC-UGR), Granada, Spain (*correspondence: martarodrigo@ugr.es, fmruiz@ugr.es, fjjspejo@ugr.es)

[2]Departamento de Estratigrafía y Paleontología, Universidad de Granada, Granada, Spain (fjrtovar@ugr.es)

[3]Instituto Geológico y Minero de España, Madrid, Spain (e.pardo@igme.es)

High-sedimentation rates in the westernmost Mediterranean (Alboran Sea basin) allow excellent resolution for paleoclimate reconstructions at millennial- to centennial-scales. Here, a novel cyclostratigraphic analysis has been conducted on a marine record, revealing major and secondary peaks related to climate cycles during the last 20,000 yrs. Spectral analysis on time-series corresponds to several multi-proxy groups, including detrital, redox, paleoproductivity, and paleotemperature-paleosalinity, which reveals cycles of different confidence level at particular periodicities. Main periodicities at 1,300, 1,515, 2,000, and 5,000 yrs plus secondary harmonics at 650, 1,087, and 3,000 yrs derive from diverse climate forcing mechanisms. Thus, the 1,300 yr cycle appear to be principally influenced by North Atlantic freshwater inflow. The 1,515 yr cycle, equivalence to the Bond cycle in the North Atlantic, is linked to the North Atlantic thermohaline circulation and changes in the intensity and position of the North Atlantic Oscillation (NAO) and the Inter-Tropical Convergence Zone migrations (ITCZ). Although the 2,000 yr cycle is only punctually registered, it supports a global connection with records distributed at high-, mid-, and low-latitudes, pointing to variations in solar activity as main climate forcing mechanism. In contrast, the cycle at 5,000 yrs is well-registered and presents a direct relationship with orbital forcing responses, also accompanied by monsoonal variations and NAO oscillations. Thus, the obtained spectral periodicities reinforce the evidence on the strong connection between Mediterranean and North Atlantic climates, being climate oscillations mainly forced by solar variations, the NAO and the ITCZ migrations.

Discrimination of sediment samples for forensic application using REE

A. RODRIGUES, A. GUEDES*, H. RIBEIRO, B. VALENTIM AND F. NORONHA

Centro de Geologia da Universidade do Porto e Departamento de Geociências, Ambiente e Ordenamento do Território, Faculdade de Ciências, Universidade do Porto, Rua do Campo Alegre 687, Porto, Portugal (*correspondence: aguedes@fc.up.pt)

The geochemical signature of sediments is currently used as trace evidence in forensic investigations. In this research, geochemical studies have been carried out on Portuguese coastal sands aiming to ascertain its use for forensic purposes.

Rare Earth Elements (REE) concentrations were determined on samples collected on three coastal areas surrounded by different geological contexts, namely limestone, granite and metasediment. Eight sand samples were collected along transects perpendicular to the coastline, in beach and dune from each site. Each sample was manually collected with a plastic spade from the surface sediment, at a depth of approximately 0-5cm. From the sediment samples a standardized particle size fraction of <150 μm was obtained by dry sieving method and subsequently grinded to minimise the variation in the geochemical properties due to particle size.

The REE composition fraction was determined using four acid digestions ultratrace ICP-MS analysis at ACME labs (Canada), and concentrations calculated. Although the measured REEs concentrations can be compared directly for forensic purposes a normalisation reported to condrite meteorites was performed [1].

A REEs normalised concentration and a hierarchical cluster analyses were performed to obtain discrimination between samples. They reveal differences between samples associated with different geological context, and permitted the discrimination between samples surrounded by granite from samples surrounded by limestone and metasediments. It was also possible to discriminate some of the samples based on their REE concentration and profile.

This research was supported by Project PTDC/CTE-GEX/67442/2006 of FCT (Portugal).

Geochemical signatures in detrital tourmalines as indicators for sediment provenance: The Baixo Alentejo Flysch Group, South Portuguese Zone

B. RODRIGUES[1]*, P. DIAS[2], R.C.G.S. JORGE[3] AND P. FERNANDES[1]

[1]CIMA, University of the Algarve, Campus de Gambelas, 8005-139 Faro, Portugal (*correspondence: bmgrodrigues@sapo.pt, pfernandes@ualg.pt)
[2]CIG-R, University of Minho (patriciasdias@gmail.com)
[3]CREMINER LA/ISR, Dep. Geologia, Fac. Ciências da Universidade de Lisboa (rjorge@fc.ul.pt)

Microprobe analyses were made to infer the source of detrital tourmalines from the Mid to Late Carboniferous turbiditic deposits of the Baixo Alentejo Flysch Group (BAFG) of the South Portuguese Zone. A representative group of greywacke samples covering the whole range of the BAFG ages was collected for this study. Tourmalines have brown to brownish gray colors and do not show any optical zonation. In the Fe-Mg-Al diagram, the tourmalines fall into the fields of Ca-poor metapelites, metapsammites and quartz-tourmaline rocks. Microprobe analyses revealed a range of values between schorl and dravite end members, being closer to the latter, with variable contents of X-site vacancies (0.05-0.255 apfu), Ca (0.078-0.2 apfu), Na (0.627-0.924 and Al (5.746-6.622 apfu). The Fe/(Fe+Mg) and Na/(Na+Ca) ratios range from 0.32-0.45 and 0.79-0.91, respectively.

The presence of well-rounded tourmaline grains suggests that they could have derived from a source located at a great distance from the sedimentary basin, or from reworked sedimentary rocks. The occurrence of few euhedral grains indicates minor contribution from first cycle sediments. Together, these data suggest that the detrital BAFG tourmalines derived from multiple sources with the predominance of rocks with a felsic composition.

The role of Mg in the formation of monohydrocalcite

J.D. RODRIGUEZ-BLANCO, P. BOTS, T. RONCAL-HERRERO, S. SHAW AND L.G. BENNING

School of Earth and Environment. University of Leeds. Leeds, LS29JT. UK (earjdrb@see.leeds.ac.uk)

Monohydrocalcite (MHC, $CaCO_3{\cdot}H_2O$) is a calcium carbonate mineral which forms by biological and abiotic processes in a number of environments including caves or lake-bed sediments. MHC often forms in Mg-rich aqueous environments, but is metastable with respect to aragonite and calcite [1]. However, the mechanisms of its formation and the role or effect of Mg on its nucleation and growth are not understood. Hence, using a combination of *in situ* and real-time synchrotron-based scattering and off-line micro-spectroscopic characterization, we followed and quantitatively assessed the formation mechanism of MHC.

Experiments were carried out by mixing equimolar Ca, Mg and CO_3 solutions (0.7:0.3:1) and reacting them at 21°C for 12 hours. The MHC crystallisation reaction was followed *in situ* (1 min/frame) using Small and Wide Angle Scattering (SAXS/WAXS, Diamond Light Source, UK), and equivalent off-line experiments were quenched at various times for solids and solution analysis.

The WAXS profile (Fig. 1 main plot) revealed after ~ 50 minutes MHC crystals grew via a two-step reaction. Step 1 is the transformation of a poorly-ordered amorphous calcium carbonate precursor (inset 1) into MHC nanocrystals (inset 2). This stage is followed by a second growth step after ~8.5 hr of reaction (inset 3) which occurs concomitantly with the formation of minor hydromagnesite (HMg). The combined on- and off-line data have allowed us to elucidate the key role of Mg^{2+} in both the precursor stabilization as well as in the structure, crystallinity and growth mechanisms of MHC.

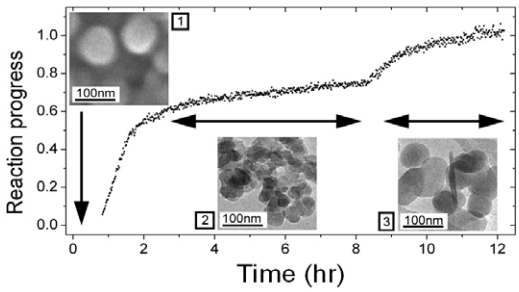

Figure 1: Reaction progress profile (***1***) precursor (***2***) MHC spheres at 3 h (***3***) MHC and HMg (plates) at 11 hr.

The structural dependence of oxide spinel AB_2O_4 compounds (A: divalent cation and B: trivalent cation) under pressure has received a lot of attention, mainly due to their occurrence in many geological settings of the Earth's crust and mantle, as well as in lunar rocks and meteorites. Many AB_2O_4 compounds crystallize in the cubic spinel structure (*Fd*3*m*), exemplified by $MgAl_2O_4$. In this work, we report first-principles calculations of the structural, electronic, and vibrational properties of the cubic spinels $ZnAl_2O_4$ and $ZnGa_2O_4$ compounds under hydrostatic pressure. Besides, we report the variation in the structural parameters under pressure and compare directly with recent experimental

results. Finally, we study the possible pressure induced structural phase transitions for both compounds that have been confirmed from X-Ray diffraction experiments [1] and from *ab initio* studies [2]. Total energy calculations were done within the framework of the density functional theory (DFT) and the projector-augmented wave (PAW) method. The exchange and correlation energy was described within the local density approximation (LDA). We use a plane-wave energy cutoff of 500 eV to ensure a high precision in the calculations. Monkhorst-Pack scheme was employed for the Brillouin-zone (BZ) integrations with dense meshes to ensure convergence. We will report the Raman and IR phonon modes as well as the pressure coefficients and Grüneisen parameters of the spinel structure and the pressure dependence of the Raman and IR active modes in other high-pressure structures.

Colonization of contaminated sediments: Implications in recovery of mass extinctions events

FRANCISCO J. RODRÍGUEZ-TOVAR[1]* AND FRANCISCO J. MARTÍN-PEINADO[2]

[1]Department of Stratigraphy and Paleontology, University of Granada, Spain (*correspondence: fjrtovar@ugr.es)
[2]Department of Soil Science, University of Granada, Spain

Biotic recovery after past bio-events is one of the difficult questions to interpret from mass extinction events. One of the recently proved useful approaches is the comparison with similar unfavourable environmental conditions in recent examples. To interpret the biotic recovery after the K-Pg impact event, characterized by an ejecta layer with high values in Ir as well as by positive anomalies of platinum-group elements and other elements (Zn, As, Cu, Ni, Co, Cr, Fe, etc.), the study of a contaminated area at the Tinto river has been conducted.

The marsh area of the Tinto river, next to the estuary of Huelva (SW Spain), is characterized by high concentrations of heavy metals accumulated in soils and sediments. These elements come from the draining and lixiviation of the river in relation to the Iberian Pyrite Belt, one of the most important polymetallic sulphide formation in Europe that has been exploited by human mining since ancient times. High concentrations of Zn, As, Cu and Tl, were found in the sediments of the marsh areas of two close locations (Palos de la Frontera, and Moguer). Values up to 1688 ppm of Zn, and 125 ppm of As were registered in the surface layer of the sediments; these levels are 2.2 and 2.5-fold, respectively, above the ecotoxicological levels reported in the bibliography. These concentrations should convert the substrate as inhabitable by organisms, but evidences of trace makers were found in this adverse media. Presence of biota colonizing into this high-polluted substrate prevents on a direct interpretation of the dramatic effect of some past bio-events based exclusively in the presence of high levels of toxic components.

The results agree with the recent ichnological evidence of a rapid colonization of the K-Pg boundary ejecta layer, classically interpreted as an inhabitable substrate, by organisms with a high independence with respect to substrate composition.

Paleoarchean barites record microbial reduction of a well-mixed marine sulfate reservoir

DESIREE L. ROERDINK[1], PAUL R.D. MASON, JAMES FARQUHAR[2] AND THOMAS REIMER[3]

[1]Department of Earth Sciences, Utrecht University, The Netherlands (roerdink@geo.uu.nl, mason@geo.uu.nl)
[2]Department of Geology and ESSIC, University of Maryland, College Park, USA (jfarquha@glue.umd.edu)
[3]Bernard-May-Str. 43, Wiesbaden, Germany (tobareim@alice.de)

Bedded barites from the Barberton greenstone belt (South-Africa) preserve a unique record of atmospheric, oceanic and microbial processes involved in the formation and evolution of the Paleoarchean (3.6-3.2 Ga) marine sulfate reservoir [1, 2]. Here, we present multiple sulfur isotope data from the ca. 3.5 Ga Londozi barite deposit in Swaziland, and the ca. 3.4 Ga Vergelegen, 3.26 Ga Stentor and 3.26-3.23 Ga Barite Valley deposits in South Africa. Individual deposits show relatively homogeneous mass-independent signatures ($\Delta^{33}S$, $\Delta^{36}S$) that support a significant contribution of sulfate from photochemical reactions in a low-oxygen atmosphere. Barites are enriched in ^{34}S (average $\delta^{34}S$ = 4.9‰) relative to the inferred composition of atmospheric sulfate ($\delta^{34}S \approx$ -0.5‰), suggesting an important role for global-scale microbial sulfate reduction as a ^{34}S-depleted sink. Modeling shows that variations in $\delta^{34}S$ per deposit can also be linked to active basin-scale biological reduction processes. Observation of relatively constant $\Delta^{33}S$ and $\Delta^{36}S$ in individual deposits and in barites of similar age from other cratons suggests that sulfate accumulated in a well-mixed oceanic sulfate pool, with a residence time similar to or slightly longer than the millenial timescale of barite formation. This global sulfate reservoir fed basins where barite precipitated and sulfate was microbially reduced, with minimal contributions from re-oxidation of sulfide and other sources of juvenile sulfur. Our results demonstrate that sulfate reducing micro-organisms played an important role in the early sulfate cycle similar to modern times, but with considerably less sulfide oxidation than seen in for example the Neoarchean [3].

ID-TIMS as a tool for terrane provenance studies in polyorogenic complexes: A case from the SW-Norwegian Caledonides

CORNELIA ROFFEIS, FERNADO CORFU, ROY H. GABRIELSEN

Department of Geosciences, University of Oslo, Norway (cornelia.roffeis@geo.uio.no, fernando.corfu@geo.uio.no, r.h.gabrielsen@geo.uio.no)

The Caledonian mountain range along the western coast of Norway formed by the collision between Baltica and Laurentia in Silurian times. Several nappe sheets were thrust onto the Baltic basement and built up a mountain range which collapsed during following extensional tectonics and suffered severe erosion. Today the SW-Norwegian Caledonian nappe pile is fragmented into different tectonic units, overlying Baltic basement, without lateral connections.

In this work we look at the provenance of the Hardangervidda-Ryfylke Nappe Complex and its relations to the other nappes in the Caledonides. This nappe complex has been subdivided into three distinct nappe sheets, from bottom to top: the Dyrskard, Kvitenut and the Revsegg nappes. Previous dating with the Rb-Sr method had shown that the rocks formed in the Meso- to Neoproterozoic, but there was considerable uncertainty on the timing of metamorphic overprints and deformation. One specific question is whether the nappes have been emplaced together as one block, or as separate units, during the Caledonian orogeny.

We use ID-TIMS analyses, mainly on single grains of zircon, titanite and rutile from orthogneisses, metavolcanics, neosomes and pegmatites. Some of the main differences emerging at this stage concern the oldest units in the different nappes, which in the Kvitenut nappe point towards 1600 Ma whereas both the Revsegg and the Dyrskard nappes are around 1500 Ma. All three nappes have been affected by the Sveconorwegian orogeny. A most prominent effect is the emplacement of a large granitic body in the Kvitenut nappe at around 990 Ma, coeval with formation of local neosomes and the metamorphism of amphibolite and orthogneiss. The Caledonian overprint was also quite strong in all three nappe segments, disturbing the U-Pb systematics of zircon, forming new rutile, some titanite and local pegmatites. The latter have been affected by regional deformation and hence their age can be used to constrain the dynamics of the Caledonian processes in the region.

Redox-freezing and -melting of carbonates in the deep mantle and the role of transient carbides

A. ROHRBACH[1,2] AND M.W. SCHMIDT[1]

[1]Inst. f. Geochemistry and Petrology, ETH Zürich, Switzerland

[2]Inst. f. Mineralogy, University of Münster, Germany (arno.rohrbach@uni–muenster.de)

The onset of deep melting in the Earth's mantle is likely to be related to small amounts of CO_2/carbonate [1] buried to depths below the 660 km discontinuity as a component in subducted oceanic lithosphere. Thus, we investigate redox processes between oxidized carbonates and the reduced ambient mantle that potentially hosts an Fe, Ni metal phase [2–4]. We locate the carbon/carbonate redox equilibrium in terms of f_{O2} and the solidus temperature of carbonated peridotite at P and T relevant for the transition zone and lower mantle. Experiments were performed on a fertile peridotite composition containing 5 wt.% CO_2 at ETH. At 10–23 GPa, solidi temperatures are in the range of a mantle geotherm implying that small degree carbonatite melting is generally possible through thermal relaxation of subducted lithosphere. f_{O2} controlled experiments indicate that the carbon/carbonate equilibrium is situated ≥2 log units above IW at 10–23 GPa, i.e. ≥2 log units higher than likely f_{O2} conditions of ambient mantle. Consequently, carbonatite melts infiltrating the mantle are unstable and will suffer redox freezing through reduction of CO_2 to diamond causing their immobilization. On a local scale, carbonatite melts will consume Fe, Ni metal to leave a mantle domain that contains all iron as Fe^{2+} and Fe^{3+} in silicates and ferropericlase and all carbon as diamond [5]. The inverse process, carbonatitic redox melting, consuming Fe^{3+} and diamond would occur when such heterogeneities are entrained by upwelling mantle. Such melts cannot travel far within the metal bearing mantle matrix (as they would again reduce at depths > 250 km) and will only escape at less than ~120 km because the ambient f_{O2} remains too low also in metal free mantle to about this depth [6]. We expect a zone of Fe, Ni carbides to form at the boundaries of such domains where the mass of carbonatite is insufficient to oxidize all metal present. Preliminary data indicate that such carbides melt surprisingly at a few 100 degrees below the mantle geotherm.

Compound-specific transverse dispersion in porous media: Darcy-scale experiments and pore-scale modeling interpretation

M. ROLLE[1]*, D. HOCHSTETLER[2], G. CHIOGNA[1], P.K. KITANIDIS[2] AND P. GRATHWOHL[1]

[1]Center for Applied Geosciences, University of Tübingen, 72076 Tübingen, Germany (*correspondence: massimo.rolle@uni-tuebingen.de)
[2]Department of Civil and Environmental Engineering, Stanford University, CA 94305, Stanford, USA

Multitracer laboratory bench-scale experiments and pore-scale simulations in different homogeneous saturated porous media were performed to (i) gain an improved understanding of the role of basic transport processes (i.e. advection and molecular diffusion) at the sub-continuum scale and their effect on the macroscopic description of transverse mixing in porous media; (ii) quantify the importance of compound-specific properties such as aqueous diffusivities for transport of different solutes.

A non-linear compound-dependent parameterization of transverse hydrodynamic dispersion is required to capture the lateral displacement observed in the experiments over a wide range of seepage velocities (0.1-35 m/day). With pore-scale simulations we can prove the hypothesis that the interplay between advective and diffusive mass transfer results in vertical concentration gradients leading to incomplete mixing in the pore channels. We quantify mixing in the pore channels using the concept of flux-related dilution index and show that different solutes undergoing transport in a flow-through system with a given average velocity can show a different degree of incomplete mixing. We conclude that physical processes at the microscopic level significantly determine the observed macroscopic behavior and, therefore, should be properly reflected in up-scaled parameterizations of transport processes such as local hydrodynamic dispersion coefficients. These findings are relevant also for the interpretation of isotopic signatures in groundwater [1] and for mixing-controlled reactive transport. In the latter case, a correct quantification of transverse mixing is of utmost importance to assess the length of contaminant plumes [2].

[4]UMET, Univ. Lille 1, 59655 Villeneuve d'Ascq, France
[5]IDES, Univ. Paris XI, 91405 Orsay, France

Reconstructing past atmospheric CO_2 level and elucidating its link with climate evolution is one of the most fundamental questions in Earth sciences. Boron isotopic composition ($\delta^{11}B$) of marine biocarbonates is considered to be a proxy for ocean pH. This technique has mainly been used in foraminifera and in tropical corals during previous climatic cycles and on longer geological time scales.

Dissolved boron in modern seawater occurs in the form of two species, trigonal boric acid $B(OH)_3$ and tetrahedral borate ion $B(OH)_4^-$, the proportion of which is dependent on pH of the solution. One of the key assumption in the use of $\delta^{11}B$ of carbonates as pH proxy is that only borate ions are incorporated into the carbonate. Here, we investigate the speciation of boron in deep-sea coral microstructures (*Lophelia pertusa* specimen) by using high field magic angle spinning nuclear magnetic resonance (^{11}B MAS NMR) and electron energy-loss spectroscopy (EELS). We observe both boron coordination species, but in different proportions depending on the coral microstructure, i.e. centres of calcification versus fibres. These results suggest that careful sampling is necessary before performing boron isotopic measurements in deep-sea corals. By combining the proportions of $B(OH)_3$ and $B(OH)_4^-$ determined by NMR and our previous ion microprobe boron isotope measurements, we propose a new equation for the relation between seawater pH and boron isotopic composition in deep-sea corals.

The interaction of Pd- and Pt-bearing chloride solutions with sulfide minerals: XPS, SPM and electrochemical study

A.S. ROMANCHENKO[1], O.F. GAYNULLOVA[2] AND YU.L. MIKHLIN[1]

[1]Institute of Chemistry and Chemical Technology SB RAS, K. Marx Str., 42, Krasnoyarsk 660049, Russia (alexrom@icct.ru)

[2]Siberian Federal University, Svobodny Av., 79 Krasnoyarsk 660062, Russia

The majority of platinum group element (PGE) deposits are of magmatic origin, and it has generally been assumed that PGEs are unreactive in aqueous media. However, Pt, Pd, and other metals may be mobile in surface environments, so adsorption and precipitation of PGE at sulfide minerals are of particular interest for the mineral processing, PGE analysis, etc. There are only few studies on this matter in the literature, for example, [1].

In the present work, we examined precipitation of Pd and Pt from aqueous PdCl42- and PtCl62- solutions onto pyrite, pyrrhotite and galena, including those previously reacted under different conditions, applying XPS, AFM, STM/STS, SEM, and cyclic voltammetry. It was found, in particular, that the deposition of Pt is slower than Pd; the quantities of the metals precipitated on pyrrhotite and pyrite are close. Preliminary oxidation of pyrrhotite surface results in an increase in the deposition of Pt, whereas the opposite trend was observed for pyrite. The results were interpreted in terms of the formation of Cl-, O- or S-bearing nanoscale species of Pd and Pt, with their proportion being a function of the reaction time and mineral pre-treatment (Fig. 1). The behaviour of the precipitated Pt and Pd entities was also studied.

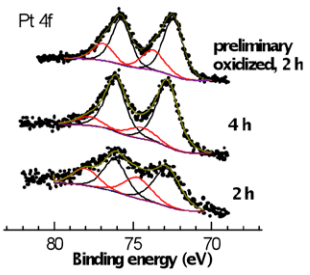

Figure 1: XP spectra from Pt deposited at pyrrhotite under various conditions (room temperature, 1 mM PtCl62-).

$PuO_{2+x}{\cdot}nH_2O$ nanoparticles formation upon Pu(V,VI) sorption onto hematite

A.YU. ROMANCHUK[1]*, A.V. EGOROV[1], Y.V. ZUBAVICHUS[2], A.A. SHIRYAEV[3] AND S.N. KALMYKOV[1]

[1]Lomonosov Moscow State University, Moscow, Russia (*correspondence: romanchuk.anna@gmail.com)

[2]Kurchatov Institute, Moscow, Russia

[3]Frumkin Institute of Physical and Electrochemistry of RAS, Moscow, Russia

Plutonium (IV) as well as most of highly hydrolyzable cations forms intrinsic colloids that is demonstrated in many laboratory experiments mostly at relatively low pH values and high Pu concentrations. The gap of knowledge exists on the possibility and mechanisms of intrinsic colloids formation under conditions more relevant to the environment. The purpose of this study was to define the mechanisms of Pu (V, VI) interaction with hematite colloids including redox reactions and formation of intrinsic colloids.

It was previosly shown [1] that Pu in high valence states is reduced to Pu (IV) upon sorption onto hematite. In case of Pu (IV) at very low total concentrations, e.g. ~10^{-14} M, the fast sorption of monomeric species on hematite occur, while in case of Pu (VI), the sorption is kinetically controlled by slow reduction on the surface. For total concentrations of Pu around 10^{-6} the reduction of Pu (V, VI) upon sorption onto hematite is confirmed by Pu L_{III} XANES. The reduction is accompanied by the formation of PuO_{2+x} crystalline nanoparticles with average size of 1-2 nm that was independently demonstrated by HR-TEM and Pu L_{III} EXAFS measurements.

The most challenging question is concerning Pu behavior at lower concentrations, i.e. around 10^{-9} M and less. Due to the increase of concentration near the surface, Pu (IV) could polymerize even at this relatively concentration that strongly effect both kinetics of sorption and leaching behavior. For the first time it was demonstrated by HRTEM that Pu (V, VI) reduction upon sorption result in the formation of low-crystallinity PuO_{2+x} nanoparticles.

Nitrogen limitation in extremophilic hydrothermal ecosystems of Yellowstone National Park

S.J. ROMANIELLO[1]*, H.E. HARTNETT[1,2], A.D. ANBAR[1,2], J.J. ELSER[3] AND E.L. SHOCK[1,2]

[1]School of Earth and Space Exploration, Arizona State University, Tempe, AZ 85287-1404 (*correspondence: sromanie@asu.edu)

[2]Department of Chemistry and Biochemistry, Arizona State University, Tempe, AZ 85287-1406

[3]School of Life Sciences, Arizona State University, Tempe, AZ

We present the results of ^{15}N assimilation experiments conducted with hydrothermal chemotrophic and phototrophic microbial mats in Yellowstone National Park (YNP), USA. *In situ* ^{15}N incubations were carried out with $^{15}NO_3^-$, $^{15}NH_4^+$, and $^{15}N_2$ during the summer 2009 and 2010 field seasons over a wide range of temperature and pH (50-92°C, pH = 2.1-9.3).

Measured rates of NO_3^-, NH_4^+, and N_2 assimilation vary widely between sites. The highest assimilation rates were generally found in photosynthetic mats. NO_3^--assimilation was detected at some high temperature sites but was conspicuously absent at others, even when these sites exhibited remarkable geochemical simularity. Measurable rates of N_2-fixation were measured in the phototrophic cyanobacterial mats. However attempts to detect N_2 assimilation in high temperature, alkaline, chemotrophic communities were unsuccessful.

NO_3^- assimilation rates determined in 2009 using 1-4 μM initial NO_3^- were generally <10% of 2010 rates using 100 μM initial NO_3^- at reoccupied sites (e.g. Figure 1). These results imply that nitrate assimilation may be strongly understaturated at *in situ* NO_3^- concentrations (<1.5 μM). This suggests that nitrogen limitation may be an underappreciated aspect of hydrothermal ecosystem biogeochemistry.

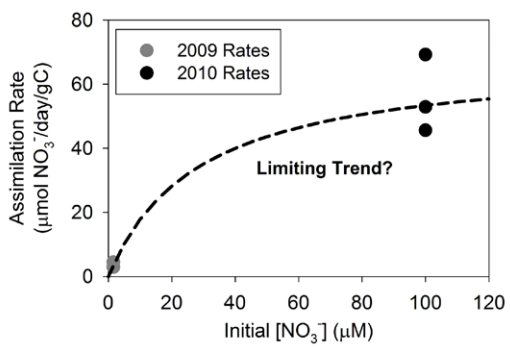

Figure 1: Nitrate assimilation rate as a function of initial NO_3^- concentration at a hot spring near Obsidian Pool, YNP.

Concerning organization of geochemical environment as a study object for geochemistry

S.L. ROMANOV[1]* AND E.M. KOROBOVA[2]

[1]Unitary Enterprise .Geoinformation systems., Belarus National Ac. of Sciences, 220004 Minsk, Surganov Str., 6, Belarus (*correspondence: romanov_s_l@mail.ru)

[2]Vernasky Institute of Geochemistry and Analytical Chemistry, Rus.Ac. of Sci., 119991 Moscow, Kosygin Str., 19, Russia, Korobova@geokhi.ru)

In the light of concepts of theoretical geochemistry the environment is presented by a set of hierarchically ordered and geochemically discontinuous objects such as biosphere or lithosphere which in their part consist of a quantity of the smaller structural units – rocks, gases, proteins. On the molecular level the latter present sets of typical components made of a relatively limited number of chemical elements. In general the environment is treated as the present result of the continuous chemical reactions. However the paradox is that the observed environment can not be interpreted as a result of all the possible chemical reactions. To produce such an object as the World Ocean, or an ore deposit the necessary chemical elements should occur in the corresponding volume, the corresponding form and sufficient quantity. In the other words the physically significant result of interaction of all the substances is characterized by significant masses presented in the particular volume. Therefore the quantity of all the chemical elements present on the Earth may be treated as material bodies of the particular elements such as iron, oxygen or actinium.

Such an approach is logically unrepugnant and permit to formulate an important corollary. All chemical elements and compounds that are in the environment regardless of form, quantity and aggregate state are organized as material bodies which have general and specific properties such as weight, dynamics and space configuration. Furthermore, theirs bodies exhibit characteristics of a three-dimensional fractal.

This assertion does not contradict any of the basic tenets of science and allows us make a more general conclusion. Parameters of the existing geochemical environment at all levels of organization are naturally predetermined by specific interaction of a small number of material bodies, that are stable in time and space and are the basic components of the universe.

If these statements are true (they are at least logically consistent) then the environment can be considered as constantly evolving, naturally organized and well-balanced superposition of special geochemical bodies, which in framework of notions of theoretical geochemistry may become the main object of this science. Such object is in full measure able to provide formal interpretation and comparison of all the existing geochemical data using the means of modern physics and mathematics.

Assessment of arsenic toxicity using bioassays. Application in contaminated soils

A. ROMERO-FREIRE[1], G.N. ANTÚNEZ, F. MARTÍN-PEINADO[1]*, M.O. ESCOTO[2] AND A. ROCA[1]

[1]Soil Science Department. Faculty of Sciences. University of Granada. 18002 Granada, Spain (*correspondence: fjmartin@ugr.es)

[2]Natural Resource Management and Environment. National University of Agriculture. P.C. 9. Catacamas. Honduras

In last decades, arsenic has become a serious environmental problem due to the extensive use and to its potential high toxicity [1]. Arsenic trends to accumulate in soils because its low mobility in this media, although water-soluble fractions are highly bioavailable [2]. Soil toxicity bioassays are based on the evaluation of the toxic effect of the solid phase or the soil solution over a living organism [3].

Potential As toxicity from bioassays with *Vibrio fischeri* and *Lactuca sativa* germination test was estimated. These assays were done in artificially contaminated solutions (ranging from 0.1 to 100 ppm As), and in water extracts from soils spiked with 100 ppm As. Both bioassays had a different response in the artificially contaminated solutions. According to the EC50 values (Table 1), the *Lactuca sativa* test showed higher sensitivity to the toxicity than *Vibrio fischeri* bioassay.

	EC50 (mg/kg)	
	Value	95% CI
Lactuca sativa	2.46	1.36 - 4.48
Vibrio fischeri	12.33	7.83 - 19.42

Table 1: EC50 values in the contaminated solutions. CI: Confidence interval at 95%.

Four soils with different properties were contaminated with 100 mg As kg^{-1} soil. Soil organic matter ranged from 1.2 to 6.8%, calcium carbonate from 0 to 39%, and clay content from 9 to 33%. In all cases the As concentration in soil solutions was below 0.03 mg kg^{-1}. The results of toxicity bioassay with the solutions coming from the contaminated soils indicated no toxic response in the case of lettuce germination test or *Vibrio fischeri* bioassay. Further studies are needed to check the main parameters controlling the reduction of toxicity in relation to soil properties.

Imaging the removal of radionuclides from solution by NZVI using HRTEM

M.E. ROMERO-GONZALEZ[1]*, GABRIELLA KAKONYI[1] AND IAN M ROSS[2]

[1]Cell-Mineral Research Centre, The University of Sheffield, Kroto Research Institute, Sheffield, UK (*correspondence: m.e.romero-gonzalez@sheffield.ac.uk)

[2]Kroto Centre for High Resolution Imaging and Analysis, The University of Sheffield, Kroto Research Institute, Sheffield S3 7HQ, UK

Nano zero valent iron (NZVI) has been promoted as a remedial strategy for a range of contaminants present in the environment. Its applications range from the remediation of chlorinated compounds in sediments to arsenic in groundwater and aquifer material. Its properties such as size, mobility through porous media and reactivity offer advantages for remediation of contaminants under a variety of remedial strategies: used as complement material on iron barriers, direct injection to aquifers and targeted emplacement in subsurface zones.

We explore here the use of NZVI as an external barrier to radionuclide deep nuclear repository waste containment. Rates of removal of U (VI) removal in suspensions of NZVI (nanoFer 25 and 25S) were performed in batch systems in presence of ordinary portland cement (OPC) at pH 9 and 12. All experiments were conducted in an anoxic glovebox free of CO_2. Samples were taken for the quantification of U (VI), Ca and total Fe by ICP-MS. Samples were also analysed using a HRTEM JEOL 2200FSC. The HRTEM provides a maximum 0.05 nm spatial resolution, this allowed the imaging of the reaction products at atomic scale.

The results showed that NZVI can effectively remove uranium (VI) from solution under a range of conditions. The presence of high Ca concentrations reduce the efficiency of NZVI to remove U (VI) when compared to systems without Ca. However, the overall efficiency of the NZVI-cement system was little compromised since U (VI) was effectively removed from solution under all studied conditions.

The HRTEM results indicated mainly a coprecipitation mechanism for the removal of U (VI) from solution at highly alkaline pH. Therefore the potential to use NZVI technology to increase the efficiency of barriers around a deep nuclear waste repository is very promising. Additionally, HRTEM has proven to be a very valuable tool on the investigation of nanoparticle interactions with porous media.

Hydrogen isotopic signatures of algal biomarkers as a proxy of hydroclimatic variability in Lake Isabel, Mexico

L. ROMERO[1]*, H.G. HAUG[1,2], U. KIENEL[1,3] AND D. SACHSE[1].

[1]Institut für Erd- und Umweltwissenschaften, Karl-Liebknecht-Strasse 24, 14476 Potsdam, Germany (*correspondence: romero@geo.uni-potsdam.de)
[2]Geologisches Institut, Department Erdwissenchaften, ETH Zürich, Sonneggstrasse 5, 8092 Zürich, Switzerland
[3]German Research Centre for Geosciences-Helmholtz-Centre Potsdam. Telegrafenberg. 14473 Potsdam, Germany

Based on the observed linear relationships between the isotopic composition of the source water and the δD values of aquatic and terrestrial lipid biomarkers, the analysis of the isotopic signature in these organic molecules preserved in sediments has become a new tool for paleohydrological reconstruction. However the influence of additional factors (i.e. growth rate, salinity, and temperature) on the δD values of algal lipids remains poorly understood. Therefore, sediments from a short core corresponding to the time period 1943-2003 A.D from a hypersaline crater lake located on Isla Isabel, 30km off the Pacific Coast of Mexico, were analysed for lipid biomarker δD values and compared to instrumental climate data. δD values of the 1,15C_{32} diol, a specific biomarker for algal populations, showed a significant relationship with the instrumental record of rainfall amount confirming its potential as a proxy of past hydroclimatic conditions. Unexpectedly, deuterium-enrichment in diols was observed during wetter conditions while these were significantly depleted during drier periods. We hypothesize that under this strongly seasonal climate regime algal growth conditions play an important role in determining algal lipid δD values. This calibration study between the isotopic signatures and the climatic record shows the complexity but also the potential of hydrogen isotope analyses of lipids as proxy to reconstruct the past climatic variability.

The role of inorganic additives in evaporitic carbonate precipitation

T. RONCAL-HERRERO[1,2]*, P. BOTS[2], J.D. RODRIGUEZ-BLANCO[2], S. SHAW[2] AND L.G. BENNING[2]

[1]Department of Geosciences, University of Oslo, PB 1047, Blindern, Oslo, Norway
[2]School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, United Kingdom (*correspondence: eartr@leeds.ac.uk)

Interactions between carbonate-bearing groundwaters and sulphate minerals in evaporitic settings lead to the formation of carbonate deposits [1]. However, our understanding of the reaction kinetics in these processes is still fragmented.

An experimental study following the formation of $CaCO_3$ phases from gypsum (GYP, $CaSO_4.2H_2O$) in the presence of 1 to 100 mM of Mg, Zn, Sr, or PO_4 was carried out at 25°C. GYP (Ø < 420 μm) was reacted with 50 mM Na_2CO_3 at a GYP/liquid ratio of ~ 0.007 in stirred closed reactors. The experiments were run at two different initial pH settings (***a***) pH ≈ 11.4, due to the Na_2CO_3 or (***b***) pH ≈ 6.8, where the solutions was also supersaturated with $CO_{2\ (g)}$. Solids were characterized over time by X-ray diffraction and high-resolution microcopy imaging while changes in aqueous contentrations were determined by ion chromatography.

The results of both sets showed that the dissolution of GYP (release of Ca^{2+}) lead to a relatively fast nucleation and growth of $CaCO_3$ polymorphs. As long as the solution had excess carbonate, the continuous dissolution of gypsum was mirrored by a simultaneous precipitation of $CaCO_3$. In all cases, the first phase nucleating on the gypsum surface was amorphous $CaCO_3$ (ACC). Depending on experimental approach or the presence of additives, ACC transformed gradually to various $CaCO_3$ polymorphs. At condition (***a***) the GYP completely dissolved in ~ 24 h and the initial ACC transformed into calcite within 2 days, while in approach (***b***) GYP took only ~ 5 h to fully dissolve and the carbonate that formed after 30 h was 'stable' vaterite [2]. The presence of additive ions strongly influenced both the reaction kinetics and the nature of the crystalline end products. For example, using approach (***b***) but adding 1 mM Zn produced calcite (instead of vaterite) with Zn becoming incorporated into the calcite structure; conversely, with 100 mM Mg present in the initial solution, ACC transformed to aragonite after 12 h and calcite was not observed. These results revealed that aqueous additives play a fundamental role in controlling the nature and formation pathway of the end product and this has major implications for biomineralization, industrial applications, and CO_2 sequestration.

Re-Os geochronology of the Neoproterozoic Coppercap and Twitya Formations: Implications for the Rapitan-Sturtian glaciation

A.D. ROONEY[1]*, F.A. MACDONALD[2] AND D. SELBY[1]

[1]Earth Sciences Department, Durham University, DH1 3LE, UK (*correspondence: alan.rooney@durham.ac.uk)
[2]Department of Earth & Planetary Sciences, Harvard University, Cambridge MA, 02138

The late Neoproterozoic Windermere Supergroup of NW Canada is a ~7 km thick mixed carbonate-siliciclastic succession deposited on the margin of Laurentia. The Coppercap Formation of the Coates Lake Group consists of ~300 m of TOC-rich limestone that unconformably underlie glaciogenic deposits of the Rapitan Group. U-Pb zircon ages below and within the Rapitan Group in the Yukon constrain the onset of the Rapitan glaciation to ca. 717 Ma. The Rapitan Group is conformably overlain by the Twitya Formation, which is ~900 m thick and consists predominantly of carbonate and siliciclastic turbidites.

A 21 m interval of organic-rich carbonate of the Coppercap Formation yields a Model 1 depositional isochron age of 733 ± 4 Ma. Further Re-Os geochronology of a ~2 m interval of organic-rich carbonate of the Twitya Formation yield a Model 1 depositional isochron age of 655 ± 26 Ma. Combined with U-Pb zircon data, these ages constrain the minimum duration of the Rapitan glaciation to 36 Myrs.

Initial Os isotope composition (Os_i) derived from the Re-Os isotope data of the Coppercap Formation reveals an unradiogenic Os_i (0.14) for seawater prior to the Rapitan glaciation. This unradiogenic Os seawater signal may be derived from the erosion of basalts of the underlying Little Dal Group as well as the Gunbarrel magmatic events, and hydrothermal vents associated with rifting during the break-up of Rodinia. The Os_i data from the Twitya Formation yields a radiogenic composition (~0.83) suggesting that post-glaciation; the crustal Os flux from rivers exerted a strong influence on ocean Os composition. These data are consistent with Sr isotope data, which show a large increase to more radiogenic values across the Rapitan-Sturtian glaciation.

Both the Re-Os isochron age and the Os_i data for the Twitya are identical, within uncertainty, to that of the Aralka Formation, which overlies the glaciogenic Areyonga Formation of Central Australia suggesting that de-glaciation was broadly penecontemporaneous, and that the Sturtian and Rapitan glaciations are correlative. The Re-Os geochronology and Os_i data presented here has profound implications for our understanding of Late Proterozoic ocean chemistry and the Snowball Earth hypothesis.

Synchrotron XAS and XRF study of microbially reduced arsenic and iron in iron-based remediation media

ROBERT A. ROOT[1]*, FERNANDO J. ALDAY[2], SAHAR FATHORDOOBADI[2], WENDELL P. ELA[2] AND JON CHOROVER[1]

[1]Department of Soil, Water and Environmental Science, University of Arizona, Tucson AZ, USA (*correspondence: rroot@email.arizona.edu)
[2]Department of Chemical and Environmental Engineering, University of Arizona, Tucson AZ, USA

Arsenic remediation technologies exploiting the high affinity of ferric (oxy)hydroxides for oxyanion sorption has resulted in a significant increase in the volume of arsenic-bearing solid residuals generated by drinking water utilities. These iron sorbents widely utilized for water treatment may be legally disposed in municipal solid-waste landfills if they pass the USEPA toxicity characteristic leaching procedure (TCLP). However, conditions in a mature landfill are biotic and generally suboxic where iron and arsenic may be reduced and released to the leachate; a consequence not simulated with the TCLP test. To examine the effect of biotically induced reducing conditions, controlled flow through column experiments were used to simulate conditions similar to those found in a landfill. Upflow 30 cm x 2.5 cm reactors were packed with 15 g (dry wt.) ferric arsenate sludge (Fe:As = 20:1; pH 7-8) and 73 g of 0.8 mm glass beads then reacted for 432 days (864 pore volumes) with a synthetic landfill leachate containing nutrients (e.g. components: $[SO_4]$ = 64μM, [Na] = 12 μM, [CO3]= 24 μM etc.) and a consortium of microorganisms from an anaerobic digester sludge collected from a water treatment plant.

Columns were sub-sectioned and investigated with Synchrotron X-ray absorption spectroscopy and fluorescence microprobe (μXRF) to determine the bulk As, Fe, and S speciation and to spatially resolve As and Fe species with energy difference μXRF mapping. Reducing conditions prevail at the inlet of the column and the primary iron phase there is siderite, whereas vivianite, green rust and ferric (oxy)hydroxide form as the conditions become more oxic. Arsenic is present as As (III) and As (V) sorbed to ferric (oxy)hydroxide in suboxic and oxic environments respectively. When the columns are run at sulfate influent concentrations increased from 64 μM to 2.1 mM, the primary iron and arsenic phases are amorphous iron sulfide (FeS) and realgar (AsS), indicating sulfate and iron concentrations are important for As sequestration in landfills.

Contaminated soil diagnosis by electrical resistivity tomography in underground storage tanks of different petrol stations in SE Spain

R.M. ROSALES*, P. MARTÍNEZ AND A. FAZ

Technical University of Cartagena, Cartagena 30203, Spain (*correspondence: rosamaria.rosales@upct.es, p.martinez@upct.es, angel.fazcano@upct.es)

Introduction

Soil contamination could be produced by petroleum products spill and leaks related to activities of refinement and fuel dispensing in Service Stations. Although pipelines and Underground Storage Tanks (UST) are designed to avoid this kind of accidents, the large amount of fuel dispensed at petrol stations during years may cause a very important damage in the surrounding uncontaminated area.Through this research it has been made an environmental diagnosis to identify possible leaks in UST as plumes in the subsoil by applying Electrical Resistivity Tomography 2D (ERT 2D), a non destructive geophysical technique in three petrol stations located in Murcia Region, Spain. Three ERT profiles were carried out in each petrol station per campaign (wet and dry seasons).

Results and discussion

Figure1 shows electrical pseudosections obtained by processing ERT data with PROSYS II and RES2DINV softwares corresponding to one petrol station in wet season.These results may define different confined zones in the subsoil with electrical resistivity values up to 2000 Ω·m, very high values for a natural soil. Hydrocarbons are excellent insulators and exhibit very high values of electrical resistivity [1] around 2500 Ω·m, values assigned to a possible fuel leak [2].

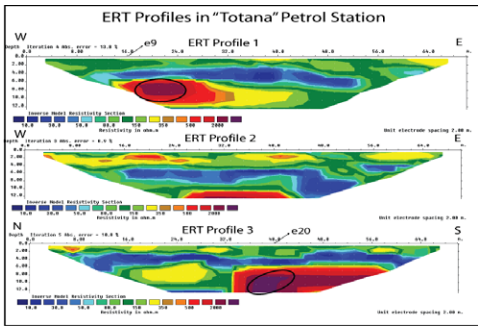

Figure 1: Processed pseudosection from ERT 2D profiles in "Totana" petrol station corresponding to wet season.

On the variability of aerosol intensive optical properties over South America

N.E. ROSARIO[1,2]*, M.A. YAMASOE[1] AND K.M. LONGO[2]

[1]University of São Paulo, São Paulo, Brazil (*correspondence: nrosario@model.iag.usp.br) (akemi@model.iag.usp.br)
[2]National Institute for Space Research, São José dos Campos, Brazil (karla.longo@inpe.br)

The variability of aerosol intensive optical properties, specifically single scattering albedo ($\omega_{o\lambda}$) and asymmetry parameter (g_λ), over South America have been analyzed using data from Aerosol RObotic NETwork [1]. The stations considered in the study are installed in distinct environment: Alta Floresta and Belterra are in the biomass burning regions of the southern and northeast of the Amazon basin, respectively, Cuiaba is in the *Cerrado* area, São Paulo is an urban center in the southeast of Brazil, and Arica and Surinam are coastal sites on the west and north coast of South America, respectively. The variability of aerosol optical properties inter and intra stations is significant, in particular for those located downwind of the biomass burning regions. Further differences emerge when the signal of smoke aerosols from the southern of Amazon basin are excluded from the mean calculation. For instance, São Paulo and Cuiaba locally produced aerosol is more absorbing than the indiscriminate average of optical properties suggests. The smoke transport from the southern Amazonia tends to reduce the heterogeneity that characterizes optical properties elsewhere. A clustering analysis based on the magnitude and spectral dependence of $\omega_{o\lambda}$ and g_λ was performed for each station. The factors associated with the occurrence of the identified clusters vary among the stations. For São Paulo and Cuiaba, as expected, the clusters occurrence are indeed correlated to the smoke transport. In Alta Floresta less absorbing clusters are in general associated with wetter and/or highly polluted conditions. Arica presents the lowest variability in optical properties, although a dependence on the wind diurnal cycle was observed. These results have been analyzed from the perspective of the representation of aerosol intensive optical properties in regional circulation models. Ongoing analysis evaluating the impact of the variability in optical properties on radiative balance using the Coupled Aerosol and Tracer Transport model to the Brazilian developments on the Regional Atmospheric Modelling System [2] are discussed.

Exploring the first steps of iron(III) oxyhydroxide nucleation using a competitive ligand kinetic approach

ANDREW L. ROSE

Southern Cross GeoScience, Southern Cross University, Lismore 2480, Australia
(*correspondence: andrew.rose@scu.edu.au)

Under favourable conditions, nucleation of iron (III) oxyhydroxides (FeOx) is typically rapid compared to subsequent processes. To date, little work has been done to examine the first steps of FeOx nucleation, namely the initial polymerisation of dissolved monomeric iron (III) complexes, which may be rate-limiting in the nucleation process.

I have investigated the kinetics of iron (III) polymerisation over a wide range of pH values using a competitive ligand approach in which the complexation of monomeric iron (III) by desferrioxamine B (DFB) competes with iron (III) polymerisation when conditions conducive to nucleation are induced. Polymerisation was induced by the rapid (< 5 ms) mixing of acidified solutions of dissolved iron (III) with a pH-buffered DFB solution using a micromixer chip. Formation of the orange coloured iron (III)-DFB complex was quantified over time from 100 ms after mixing onwards at concentrations down to ~10 nM with a stopped-flow long (1 m) optical pathlength spectrophotometry system (Figure 1).

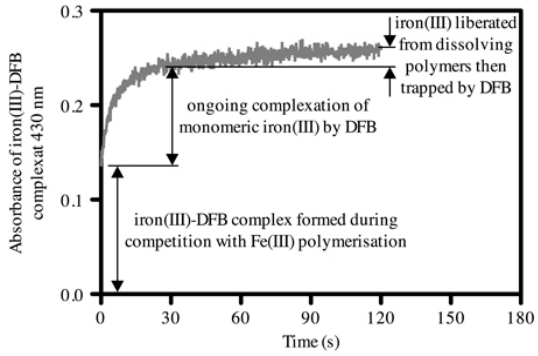

Figure 1: Kinetic traces reveal initial rapid partitioning of iron(III) between the iron(III)-DFB complex and iron(III) polymers, followed by the slow redissolution of polymers.

Kinetic parameters for FeOx polymerisation (obtained by simultaneously fitting data from multiple iron (III) and DFB concentrations at each pH) varied with pH in a manner consistent with control of the initial polymerisation step by the exchange of water bound to monomeric iron (III). The initial steps in FeOx nucleation can thus be interpreted in a similar context to other aquatic chemical processes.

Environmental impact of engineered nanoparticles and nanomaterials through their life cycle

Even though preliminary risk assessments of manufactured nanoparticles (NPs) are emerging, information on NPs bioavailability to aquatic biota and trophic transfer are largely lacking, and early studies have yielded incomplete and contradictory results. Moreover, a considerable confusion exists concerning the distinction between 'nanotechnology' and 'nanomaterial' which are most often considered to be synonymous of nanoparticles. But for most applications nanoparticles can be surface modified and generally are embedded in the final product and therefore do not come into direct contact with consumers or the environment. So what about their toxic effects when surface modified?

The aim of our stufy is to better constrain the transfer, transformation and ecotoxicity of by-products released from nanomaterials during their life cycle. Two examples will be detailed 1) nano-TiO_2 incorporated as UV filter in sunscreens ii) nano-SiO_2 based composite (polymeric matrixes including polyamides, polypropylenes and polyurethanes as bulk materials) to compare impact between by-products and bare nanoparticles. Methodology and experimental issues concerning durability characterisation using accelerated aging protocols, characterisation will be adressed.

The project is supported by the French national programs NANOALTER (INSU/EC2CO/CYTRIX), AGING NANO & TROPH (ANR-08-CESA-001) and the FP7 NEPHH project (CP-FP 228536-2).

Medically-derived ^{131}I as a tracer in aquatic environments

P.S. ROSE[1,2]*, J.P. SMITH[2], J.K. COCHRAN[1], R.C. ALLER[1], R.L. SWANSON[1] AND R.B. COFFIN[2]

[1]SoMAS, Stony Brook University, Stony Brook, NY 11794-5000, USA

[2]Marine Biogeochemistry, Code 6114, US Naval Research Laboratory, Washington, DC 20375, USA (paula.rose.ctr@nrl.navy.mil)

Iodine-131 ($t_{½}$ = 8.04 d) has been measured in Potomac River water and sediments in the vicinity of Blue Plains, the world's largest advanced wastewater treatment plant. It serves all of Washington, DC, treats an average of 1.4 x 10^9 L d^{-1} and has a maximum capacity of >4 x 10^9 L d^{-1}. Concentrations of ^{131}I detected in sewage effluent and in the river suggest a continuous dischage of the isotope from Blue Plains. Surface water ^{131}I ranged from 0.076 ± 0.006 to 6.07 ± 0.07 Bq L^{-1}. Partitioning in sewage effluent and river water suggests that ^{131}I is associated with colloidal and particulate organic material. Iodine-131 was detected in sediments to depths of 5 cm with specific activites between 1.3 ± 0.8 and 117 ± 2 Bq kg^{-1} dry weight. The behavior of ^{131}I in the Potomac River is consistent with the cycling of natural iodine in aquatic environments. It is discharged to the river via sewage effluent, incorporated into particulate matter and deposited in sediments where it is subject to diagenetic remineralization.

Additionally, dissolved ^{131}I showed a strong, postive correlation with $\delta^{15}N$ values of nitrate in the river. Surface water $\delta^{15}NO_3$ values ranged from 8.7 ± 0.3 to 33.4 ± 7.3‰ with dissolved inorganic nitrogen (NO_3+NO_2) concentrations between 0.38 ± 0.02 and 2.79 ± 0.13 mgN L^{-1}. $\delta^{15}N$ in sediments ranged from 4.7 ± 0.1 to 9.3 ± 0.1‰. Sediment profiles of particulate ^{131}I and $\delta^{15}N$ indicate rapid mixing or sedimentation and in many cases remineralization of a heavy nitrogen source consistent with wastewater nitrogen.

Sewage effluent discharges of ^{131}I to surface water can be used to study the rates and mechanisms controlling natural iodine cycling. Iodine-131 coupled with $\delta^{15}N$ can be an excellent tracer for the short-term fate of wastewater nitrogen. The utility of ^{131}I is not limited to the Potomac River. The presence of medically-derived ^{131}I has been documented in several aquatic environments and is readily measureable in sewage effluent. Continuous discharges of this radioisotope in sewage effluent are likely to be widespread. Further study of ^{131}I in receiving waters can provide valuable insight into the fate and transport of this radioisotope in the context of large scale accidental releases.

Volatile abundances and Pb isotopes in melt inclusions from Iwate volcano, Japan

E.F. ROSE-KOGA[1]*, K.T. KOGA[1], M. HAMADA[2], T. HELOUIS[1], M.J. WHITEHOUSE[3] AND N. SHIMIZU[4]

[1]Laboratoire Magmas et Volcans, Universite Blaise Pascal, CNRS, UMR 6524, IRD, R 163, Clermont-Ferrand, France (*correspondence: ekoga@opgc.univ-bpclermont.fr)

[2]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Japan

[3]Swedish Museum of Natural History & Nordic Center for Earth Evolution, Stockholm, Sweden

[4]Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA

The pre-eruptive volatile content of magma is of fundamental importance for understanding melting processes, as well as eruption dynamics. However, since volatiles in magma are largely degassed during subaerial eruptions, it is difficult to estimate their pre-eruptive concentrations based on the measurements of volcanic whole rocks. Melt inclusions trapped in early crystallizing olivine retain dissolved volatiles of magmas at depth (e.g. [1]).

Iwate volcano is located on the volcanic front of the North-east Japan arc on the Honshu Island. The Iwate samples are one of the most undifferentiated rocks on the volcanic front of Japanese island arcs. The olivine hosted melt inclusions of the 1686 eruption of Iwate volcano are basaltic to basaltic-andesitic in composition.

The melt inclusions have Pb isotope compositions $^{207}Pb/^{206}Pb$ (0.836 to 0.850) and $^{208}Pb/^{206}Pb$ (2.079 to 2.094). These compositions are homogeneous and close to MORB values. The volatile contents (H_2O, S) are highly variable and reaches values comparable to that of Izu Oshima melt inclusions (up to 3.57 wt% and 1798 ppm, respectively; [2]). F and Cl concentrations are highly clustered between 113 and 183 ppm and 285 and 408 ppm, respectively. This low F and Cl magma, yet with arc H_2O content, may represent partial melting of a highly depleted mantle wedge with no or little metasomatism.

U/Pb age spectra of detrital rutile as a powerful tool for provenance analysis

DELIA RÖSEL[1], THOMAS ZACK[1], MATTHIAS BARTH[1], ANDREAS MÖLLER[2] AND JEFFREY OALMANN[2]

[1]Institut für Geowissenschaften, Universität Mainz, Becher Weg 21, 55128 Mainz (*correspondence: roeseld@uni-mainz.de)

[2]University of Kansas, Dept. of Geology, Lawrence, KS, 66045, USA

Compared with zircon, rutile is assumed to be unstable during low-grade metamorphic conditions, so that rutile grown under prograde metamorphic conditions should not contain inherited cores of older metamorphic events. Therefore rutile predominantly reflects the age of the latest metamorphic overprint. In general, metamorphic overprint is orogen-wide with similar ages in large areas. We therefore propose that detrital rutile age spectra can be utilized to distinguish between local sources (unimodal age distribution) and continent-wide catchment areas (several age peaks).

As part of a larger project aiming at detrital rutile of sub-greenschist facies meta-psammitic rocks, several samples from the Saxo-Thuringian Zone of the Variscan Orogen have been dated. All detrital rutiles from the Neoproterozoic to Lower Silurian depositional ages show pre-depositional ages indicating that the rutiles are detrital and that the Variscan overprint has not reset the ages. Most samples show an unimodal age distribution, with Pan African ages between 600 and 800 Ma. However, rutiles out of one meta-sandstone with Late Ordovician / Early Silurian depositional age show a multimodal age spectrum. 30 % of the ages are > 1000 Ma and reaching a maximal age of 2200 Ma. This age distribution suggests erosion of other metamorphic domains and transport of the eroded material at the same time and to the same sedimentary environment as those from the Pan African Orogen. The Late Ordovician of the Saxo-Thuringian strata characterizes the transition from rift basin to a passive margin setting on the northern periphery from Gondwana [1]. The age spectrum indicates a direct sedimentary connection between Saxo-Thuringia and Gondwana during that period, perhaps by a continent-wide river system.

Alternatively, another source of multimodal detrital rutiles can be deposits of the Late Ordovician Hirnantian glaciation of Gondwana, which are found stratigraphically below the meta-sandstones [1]. However, this possibility would still imply a sedimentary connection between Gondwana and Saxothuringia.

Reactivity of mafic and ultramafic rocks with CO_2-charged fluids and the autocatalytic reduction of CO_2 to form CH_4

R.J. ROSENBAUER[1]*, C. OZE[2], L.C. JONES[1], B. THOMAS[1], G.I. GOLDSMITH[3] AND J.L. BISCHOFF[1]

[1]US Geological Survey, 345 Middlefield Rd., Menlo Park, CA 94025 (*correspondence: brosenbauer@usgs.gov)

[2]Department of Geological Sciences, University of Canterbury, Christchurch, New Zealand

[3]Department of Chemistry, Bryn Mawr College, 101 N. Merion Ave., Bryn Mawr, PA 19010

Mafic and ultramafic rocks are highly reactive to carbon dioxide (CO_2). They may be potential repositories for sequestering CO_2 because of their capacity for trapping CO_2 in carbonate minerals. They are also capable of reducing CO_2 to form CH_4 via molecular hydrogen (H_2) from serpentinization reactions. Geochemical laboratory experiments, reacting tholeite, picrite, and olivine with CO_2-charged fluids over a range of temperature (50 - 200°C) and pressure (100 - 300 bar) conditions, resulted in a high degree of rock alteration, secondary mineral formation and gas synthesis. In tholeite and picrite experiments, CO_2 is taken up from solution at all temperatures but the maximum extent and rate of reaction occurs at 100°C and 300 bar. The amount of CO_2 uptake at 100°C, 300 bar ranged from 8 wt% for a typical tholeite to 26 wt% for a picrite, where the amount of uptake coincides with the Mg content of the rock as a reaction limiting factor. Although geochemical modeling predicts an equilibrium carbonate alteration assemblage of calcite, magnesite, and siderite, only secondary ferroan magnesite was identified in the residual solids.

An alternate fate for CO_2 when reacted with ultramafic rocks is conversion to CH_4. In olivine hydrolysis experiments (200°C, 300 bar), Fe^{2+} from olivine is incorporated into carbonates more rapidly than Fe^{2+} oxidation (and concomitant H_2 formation) leading to diminished yields of H_2 and H_2-dependent CH_4 production. At carbonate equilibrium or under-saturated conditions, the experimental data suggest that produced magnetite catalyzes the reduction of CO_2 to form CH_4. Rate calculations suggest that the kinetic balance between the production of H_2 and CH_4 in natural systems undergoing serpentinization may serve to discriminate between abiotic and biotic processes.

The Co-precipitation of Ra in a large scale evaporitic system

Y.O. ROSENBERG*[,1], V. METZ[2] AND J. GANOR[1]

[1]Dept. of Geological and Environmental Sciences, Ben-Gurion Univ., P.O.B. 653, Beer Sheva 84105, Israel (*correspondence: yoavoved@gmail.com)

[2]Institute for Nuclear Waste Disposal, Karlsruhe Institute of Technology, P.O.B. 3640, 76021 Karlsruhe, Germany

High concentrations of radium pose environmental and health concerns in natural and industrial aqueous systems. Co-precipitation of Ra^{2+} with barite is an effective process in decreasing its concentration, and was extensively addressed in laboratory experiments. The outcome of such small scale experiments often serves in theoretical risk assessments simulation, but was hardly validated over large field systems.

The co-precipitation of Ra^{2+} with barite was studied in a large scale field system, comprising 6 sequential evaporation ponds, having a total volume of $3.25 \cdot 10^5$ m^3, in which a rejected brine of a desalination plant is evaporated. The non evaporated brine has an ionic strength of 0.7 m, ^{226}Ra concentration of 12 Bq kg^{-1}, and it is oversaturated with respect to gypsum, celestite and barite. Upon its evaporation the ionic strength increases up to 8.4 m, and a total amount of $\sim 4 \cdot 10^6$ kg $year^{-1}$ of sulphate minerals precipitates.

Brine and salt samples were collected and analyzed for their chemical composition and radium isotopes. Precipitation rate of the different ions was calculated by assuming a steady state at each pond. The *apparent* partition coefficient of Ra in barite for pond n was calculated as: $K'_{d,\,n}=ln\{[Ra_n]/([Ra_{n-1}]\cdot EF)\}/ln\{[Ba_n]/([Ba_{n-1}]\cdot EF)\}$, where $[i]$ is the concentration of component i (mol kg^{-1}), and EF is the evaporation factor which corrects for concentration changes due to evaporation. Assuming that Mg is conservative, $EF=[Mg]_n/[Mg]_{n-1}$.

Preliminary results demonstrate that the increase in the amount of ^{226}Ra and Ba in the solid is concurrent and is not correlated with the increase of neither Ca or Sr. This indicates that barite precipitates as a separate phase and that Ra co-precipitates with barite. On the average, K'_d among all the ponds was calculated to be 1.1±0.1 in agreement with laboratory experiments carried out with the same brine (1.04±0.01). However, close examination reveals that K'_d increases by a factor of ~2 from 0.7±0.3 to 1.5±0.1 as barite precipitation rate decreases ~20 fold. This trend suggests that similarly to laboratory observations, kinetic effect lowers Ra co-precipitation.

Constrains given by the above field observations support experimental data, and thus strengthen the validity of the parameters needed for risk assessments.

Solubility of carbon dioxide in aqueous fluids at subcritical pressure: Testing the models

JÖRGEN ROSENQVIST*, ANDREW D. KILPATRICK AND BRUCE W.D. YARDLEY

School of Earth and Environment, University of Leeds, Leeds LS2 9JT, United Kingdom (*correspondence: j.rosenqvist@leeds.ac.uk)

Modelling of CO_2 storage in geological reservoirs indicates that solution trapping will become significant with time. However, there is little direct experimental data for CO_2 solubility in aqueous fluids at subcritical and near-critical pressures. We have therefore performed CO_2 solubility experiments in an intermediate pressure range, and made comparisons with model predictions.

Experiments are conducted at temperatures from RT to 70°C, with absolute pressures ranging from 4 bar to tens of bars. Our experimental setup allows pH-measurements to be conducted at pressure, for pressures ≤ 10 bar. The solution phase can be sampled at any pressure and the CO_2 solubility is determined to within 1% using alkalinity titrations.

Figure 1 shows coupled pH – solubility data at a total pressure of 4 bar. At this pressure the agreement between experiment and PHREEQC modelling is generally good, but anomalously high solubilities are predicted for calcite-bearing assemblages giving relatively high pH fluids. If confirmed at higher pressures, this discrepancy will have important implications for modelling CO_2 storage.

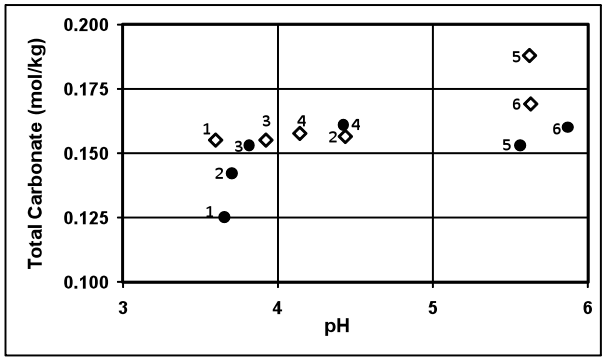

Figure 1: Solid symbols show experimental CO_2 solubility and pH, open symbols show results from PHREEQC calculations. Symbols numbered 1 are for pure H_2O - CO_2, while the others are for H_2O - CO_2 – mineral systems as follows: 2: K-feldspar 3: kaolinite 4: Na-montmorillonite 5: calcite 6: Na-montmorillonite + calcite.

New offset $\delta^{11}B$ isotope reference materials for geochemical and environmental boron isotope studies

M. ROSNER[1,2]* AND J. VOGL[2]

[1]IsoAnalysis UG, 10829 Berlin, Germany
(*correspondence: martin.rosner@bam.de)
[2]BAM Federal Institute for Materials Research and Testing, 12205 Berlin, Germany

The isotopic composition of boron is a well established tool in various areas of science and industries. Boron isotope compositions are typically reported as $\delta^{11}B$ values which indicate the isotopic difference of a sample relative to the internationally accepted isotope reference material NIST SRM 951. A significant drawback of all of the available boron isotope reference materials is that non covers a natural boron isotope composition apart from NIST SRM 951.

To fill this gap of required offset $\delta^{11}B$ reference materials we produced three new solution boric acid reference materials that cover two-thirds of the natural boron isotope variation (-20 to 40 ‰ $\delta^{11}B$) of about 100 ‰. The new reference materials are certified for their $\delta^{11}B$ values. The certified $\delta^{11}B$ values of -20.2 ‰ for ERM-AE120, +19.9 ‰ for ERM-AE121 and 39.7 ‰ for ERM-AE122 have been established by three independent analytical methods (gravimetric, TIMS $Na_2BO_2^+$ and $Cs_2BO_2^+$). The $\delta^{11}B$ reference materials are commercially available through European Reference Materials (http://www. erm-crm. org) or the webshop of the BAM Federal Institute of Materials Research and Testing (http://www. webshop. bam. de).

The newly produced and certified boron isotope reference materials will allow straight forward method validation and quality control of boron isotope data.

Micro-XRD and ICP-MS analysis of sub-milligram sized mineral samples

KIRK C. ROSS AND BALZ S. KAMBER

Laurentian University, Sudbury On Ca (kross@laurentian.ca)

We present a study that combined micro-analytical X-ray diffraction (XRD), emplying the image plate - diffraction image integration software (IP-DIIS) method, with trace element analysis on the very same grain fragment via ultra-low blank solution inductively coupled plasma – mass spectrometry (ICP-MS). The experimental procedure involves three steps. First, trace element homogeneity in the mineral is studied via laser ablation ICP-MS by analysis of multiple spots. Subsequently, a very small fragment of material (typical edge length ~15-25μm) is removed adjacent to the laser ablation pit. This is then mounted in a 114.6 mm Gandolfi camera. An IP is used to quantitatively record the diffraction inter-planar spacing (d-spacing) and intersity (I). The latent image on the IP is digitized through a propietary IP scanner, after which the image plate can be erased and reused. The scanned image is then converted to a digital diffractogram using appropriate not-for-profit software. We demonstrate that simple XRD technique yields a fully quantitative digital diffractogram amenable to Rietveld structural refinement. The accurate and percise crystallo-graphic parameters are thus known for the mineral fragment from the structural refinement. The final analytical step involves ultra-low blank miniaturized mineral acid digestion of the mineral fragments that typically weigh between 0.1 and 1 milligrams. The digests are subsequently analyzed for the trace element suite of interest by solution ICP-MS.

When crystallographic parameters and chemical information are combined in this fashion, it is possible to empirically test the control excerted by the crystal lattice on apparent trace element partition coefficients. In particular, this method allows a test of the theoretically derived and experimentally confirmed crystal lattice strain model (CLSM) [1, 2]) for naturally occuring mineral phases. Namely, the fundamental premise of the CLSM is that isovalent trace element distribution (D) in a mineral is controlled by the size (Ro) and elastic modulus (E) of the substituent crystallographic site. The XRD data can be used to compute Ro while the trace element data can be used to calculate an independent value for Ro from the strain-free admittance of a fictitious atom of radius Ro.

[5]ORNL, Oak Ridge, TN 37831, USA

Water is ubiquitous on the surface of oxide nanoparticles and can exert a profound influence on the thermodynamic properties of the oxide [1]. We have measured inelastic neutron scattering (INS) spectra for several hydrated metal oxide nanoparticles systems, including 6nm SnO_2, 7nm rutile-TiO_2, 16nm Co_3O_4, and 10nm CoO, and determined the isochoric heat capacity and vibrational entropy of the water confined to their surfaces [2-4]. The results from these studies have been combined with complementary calorimetric data and show that the surface energy of the underlying metal oxide particles exerts a strong influence on the heat capacity of the hydration layers. The surface water adsorbed on metal oxide nanoparticles with higher surface energies have lower heat capacities and vibrational entropies. For example, isostructural SnO_2 and rutile-TiO_2 have surface energies of 1.72±0.01 and 2.22±0.07 Jm^{-2}, respectively, with S_{298} values of their hydration layers equal to 37.17 and 32.34 $JK^{-1}mol^{-1}$, respectively [3, 5]. In addition, Co_3O_4 spinel and CoO rocksalt nanoparticles, although chemically similar, have surface energies of 1.96±0.05 and 3.57±0.20 Jm^{-2}, respectively, with S_{298} values of their hydration layers equal to 38.13 and 37.03 $JK^{-1}mol^{-1}$, respectively [4, 5].

The Late Jurassic Andean back-arc volcanism, Northern Chile (26-31°S)

P. ROSSEL[1], V. OLIVEROS[1]*, M.N. DUCEA[2], M. LABBE[1] AND R. CHARRIER[3]

[1]Departamento Ciencias de la Tierra, Universidad de Concepción, Casilla 160-C, Concepción, Chile (*correspondence: voliveros@udec.cl)
[2]Univ. of Arizona, Dept. of Geociences, Tucson, AZ, 85721, USA
[3]Departamento de Geología, Universidad de Chile, Casilla 13518, Correo 21, Santiago, Chile

The configuration of the Andes in southwestern Gondwana during the Jurassic and Early Cretaceous was characterized by abundant primitive arc magmatism, and marine to continental extensional back-arc basins controlled by hemigraben fault systems. Occasional effusion of volcanic material occurred along the eastern flanks of these basins. Between 26°and 31°, two parallel belts of volcanic rocks crop out to the east of the contemporary Upper Jurassic arc. The volcanic rocks located closer to the arc (G1), have a maximum age of 163.2 Ma, range from basaltic-andesite to andesite, with minor rhyolites, and have calc-alcaline affinities but with higher alkali content than the arc rocks. The more distant volcanics (G2) have a maximum age of ca. 153 Ma and are mostly alkaline basalts.

Spider diagrams show enrichment in LILE, usually not higher than 100, relative to the primordial mantle, and concentrations of HREE below 10. The rocks of G1 are characterized by Nb-Ta troughs and La_n/Nb_n ratios between 2.2 and 8.1, while G2 trace elements patterns have a concave-down shape, similar to that of the OIB, and La_n/Nb_n ratios between 1.8 and 2.5 or Nb-Ta anomalies commonly absent. Rocks from both groups have flat REE patterns, with minor negative Eu anomalies for G1, and positive Eu anomalies for some G2 lavas. The Ni concentrations (44-223 vs 20-130 ppm), Dy/Yb (1.8-2.8 vs 1.9-2.1) and La/Yb (7-23 vs 8-17) are higher for the G2 lavas, which is consistent with the greatest distance of this group from the trench, and lower degrees of partial melting of their mantle source. The lower Nb/Yb for the G1 lavas (2-37 vs 3-8) suggests a more depleted source than that of the G2 lavas, but more enriched relative to the source of the arc rocks (0.1-3). Isotopic ratios ($^{87}Sr/^{86}Sr$=0.7035-0.70501, $^{143}Nd/^{144}Nd$=0.512455-0.512742, $^{206}Pb/^{204}Pb$=18.4-19.34, $^{207}Pb/^{204}Pb$=15.6-15.67, $^{208}Pb/^{204}Pb$= 38.43-39.0) are indicative of an enrichment in the magma source from the arc eastwards; the spatial and temporal geochemical variations suggest progressive increase of lithospheric contributions to the back-arc magmatism.

Large-scale simulation of molecular structure and electron transfer in microbial cytochromes

KEVIN M. ROSSO[1]*, PIOTR ZARZYCKI[1], MARIAN BREUER[2], JOCHEN BLUMBERGER[2], LIANG SHI[1], DAVID J. RICHARDSON[3], THOMAS A. CLARKE[3], MARCUS EDWARDS[3], JULEA BUTT[3], JOHN M. ZACHARA[1] AND JIM K. FREDRICKSON[1]

[1]Pacific Northwest National Laboratory, Richland Washington, USA (*correspondence: kevin.rosso@pnl.gov)
[2]University College London, London, UK
[3]University of East Anglia, Norwich, UK

This research seeks to understand rates and molecular mechanisms used by microbial multiheme c-type cytochromes (c-Cyts) for mediating extracellular Fe valence transformation, an important biogeochemical process affecting the availability and supply of reactive Fe (II) in subsurface environments. The structure of MtrF, an outer-membrane decaheme c-type cytochrome from an iron-reducing bacterium, has been determined by synchrotron diffraction measurements. Results show that the ten hemes of MtrF are organized into a unique 'wire cross', in which a staggered 65 Å octa-heme chain transects the length of the protein and is crossed at the middle by a 45 Å tetra-heme chain. Each heme is within 7 Å of its nearest neighbors, in principle permitting rapid interheme electron transfer.

Large-scale molecular dynamics simulations are being carried out to understand the free energy landscape for electron hopping along various trajectories of the wire cross. Using the technique of thermodynamic integration, relative redox potentials of all possible intraprotein electron transfer steps have been computed, which shows that upon possible electron entry into heme 5, only a 0.84 kcal/mol (1.4 kT) activation free energy barrier for electron transfer to heme 4 opposes otherwise net thermodynamically downhill heme-to-heme conductance to hemes 2, 7, and 10 at the protein-environment interface. It is therefore proposed that heme 5 is the input site of electrons from partner proteins MtrDE up the electron transport chain, and that MtrF transfers electrons down the chain directly to Fe (III)-oxides via highly solvent-exposed heme 10. The combined experimental and computational simulation activity is collectively providing a comprehensive understanding of bacterial outer-membrane c-Cyt functioning at the level of individual heme redox potentials, heme-to-heme electron transfer rates across the protein, and insights into dynamical effects of protein fluctuation and solvent reorganization on overall electron transfer conductance.

Reactive Fe(II) and electron exchange dynamics in iron oxides

K.M. ROSSO[1]*, P. ZARZYCKI[1], C.I. PEARCE[1], J. KATZ[2], B. GILBERT[2], R.M. HANDLER[3], M.M. SCHERER[3] AND P. MEAKIN[4]

[1]Pacific Northwest National Laboratory, Richland WA, USA (*correspondence: kevin.rosso@pnl.gov)
[2]Lawrence Berkeley National Laboratory, Berkeley, CA, USA
[3]University of Iowa, Iowa City, IA, USA
[4]Idaho National Laboratory, Idaho Falls, ID, USA

Ferrous-ferric electron exchange is central to the biogeochemical cycle of iron and determines iron forms and availability in the subsurface. For most environmentally relevant conditions this exchange involves interaction between soluble ferrous iron and solid-phase iron oxides and oxyhydroxides, with complex involvement of solid-state charge migration. Examples include Fe (II)-catalyzed transformation of Fe (III)-oxides and oxyhydroxides, and spinel ferrite nanoparticles acting as a mineralogic source and sink for reactive Fe (II) due to their topotactic solid-solution property and stable multi-valent nature. This presentation focuses on the interdependence of Fe (II) fluxes at these mineral-water interfaces with structural and electronic properties of mineralogic iron oxide forms. Using combined experiment and computational molecular simulation, we examine the underlying mechanisms of observed complete iron atom exchange without change in mineralogy, crystallinity, crystal size or shape between an aqueous Fe (II) pool and well-defined goethite (FeOOH) crystallites, the accessibility of solid-state Fe (II) in titanomagnetite ($Fe_{3-x}Ti_xO_4$) nanoparticles in which the structural Fe (II)/Fe (III) ratio is intentionally tuned by the Ti (IV) content, and the highly time-resolved dynamics and fate of Fe (II) electrons photoinjected into maghemite ($Fe_{8/3}O_4$) nanoparticles. Aspects covered will include thermodynamic energy requirements for bulk crystal conduction and possible free energy sources sustaining bulk currents, ferrous iron adsorption energies at iron oxide surfaces and the kinetics of interfacial electron exchange, the structural dependence of ferrous-ferric electron exchange in the solid, and internal charge compensation mechanisms. These lines of research are collectively converging on a picture of rapid electron exchange dynamics between aqueous ferrous iron and iron oxides, with broad-reaching implications for the biogeochemistry iron in the subsurface.

New approaches to assess the responses of phytoplankton to ocean acidification

BJÖRN ROST

Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany (Bjoern.Rost@awi.de)

Global Change will affect phytoplankton in many ways, altering the complex balance of biogeochemical cycles and climate feedback mechanisms. Hence, predictions of how phytoplankton may respond to these perturbations at the cellular and ecosystem levels are a major challenge in global change research. In this presentation, I will outline the expected physico-chemical changes in the marine environment (e.g. ocean acidification, light regime, nutrients supply) and describe how these may affect different phytoplankton groups. Focusing on coccolithophores, diatoms, dinoflagellates and cyanobacteria, results from laboratory and field studies will be analyzed in view of the overall sensitivity (e.g. elemental composition, growth rate, productivity) to ocean acidification. To go beyond this descriptive level, methods on cellular processes are increasingly applied in the context of global change research. They yield information about underlying mechanisms causing processes like photosynthesis, calcification or N_2 fixation to be responsive to ocean acidification.

Overall results indicate major species- and taxa-specific differences in the sensitivity towards ocean acidification. While some species are not responsive at all, others will clearly benefit or have to face detrimental effects. The presented data will stress, however, that responses to ocean acidification are strongly modulated by other environmental conditions, such as light or nutrient levels. As these factors are also influenced in the framework of global change, the combined effects have to be considered. Some of the observed responses can meanwhile be related to species- or taxa-specific physiological traits. Next to *direct* CO_2 effects (e.g. on processes like the CO_2 concentrating mechanism), the aspect of energy allocation between physiological processes seems to play an crucial role in causing *indirect* CO_2 effects (e.g. on processes like N_2 fixation). As the cellular changes imposed by ocean acidification likely influence the competitive abilities of species, implications for the natural phytoplankton communities and biogeochemical cycling may be even be larger than indicated from results obtained in mono-specific incubations.

Wetland extension on the Russian Plain over the past 40 kyr: A biomarker approach from the Black Sea

F. ROSTEK* AND E. BARD

CEREGE, Univ. Aix-Marseille, CNRS, IRD & College de France, Technopole de l'Arbois BP 80 13545 Aix-en-Provence Cedex 04, France
(*correspondence: rostek@cerege.fr, bard@cerege.fr)

The Black Sea is a catchment basin for large areas of the European Russian Plain, the Alps and southeastern Europe. In order to study the hydrological changes in this basin over the last 40 kyr, we measured a continous series of terrestrial long-chain *n*-alkan-2-ones and *n*-alkanes as paleoclimate proxies in well dated glacial lacustrine to Holocene marine sediments from the NW Black Sea.

Two specific molecules of these homologuous series are normalized to total organic carbon (TOC), respectively Ket27/TOC for *n*-alkan-2-ones and C23/TOC for n-alkanes and interpreted as characteristic biomarkers for *Sphagnum* mosses, a dominant vegetation component in wetlands. Decreased concentrations of *Sphagnum* biomarkers are found for the North Atlantic icebergs surges and cooling events known as Heinrich Events, the Last Glacial Maximum and the Younger Dryas. These drops are pointing to low erosional input to the Black Sea with cold and dry climate conditions. Increased biomarker inputs characterize the mild climate phases known as Dansgaard/Oeschger Interstadials, pointing to increased erosion due to permafrost degradation and/or wetland extension on the Russian Plain.

The final retreat of the Fennoscandian ice sheet is concomitant with Heinrich Event 1 and expressed by increased biomarker concentrations in the so-called Red Layers, a typical series of deglacial clay layers. The two biomarker signals are decoupled at the start of the Bølling/Allerød: C23/TOC is decreasing whereas Ket27/TOC variations are in phase with the major climate events like the Bølling/Allerød, the Younger Dryas event and the early Holocene. The paleoclimatic record is interrupted by the final reconnection of the Black Sea with the Mediterranean Sea which led to marine conditions.

Halogen composition of the early Solar System inferred from meteoritic apatites

J. ROSZJAR[1]*, T. JOHN[2], M. WHITEHOUSE[3], G. LAYNE[4] AND A. BISCHOFF[1]

[1]Institut für Planetologie, WWU Münster, Germany (*correspondence: j_rosz01@uni-muenster.de)
[2]Institut für Mineralogie, WWU Münster, Germany
[3]Laboratory for Isotope Geology, Naturhistoriska Riksmuseet Stockholm, Sweden
[4]Department of Earth Sciences, Memorial University, St. John's, NL Canada

The volatile halogens are important tracers in constraining Solar System processes, such as degassing, and as abundant anionic components in fluids they are also useful in deciphering fluid-rock interactions. So far, there is limited information about halogen ratios and the $\delta^{37}Cl$ isotope composition of planetary reservoirs, such as the chondritic reservoir, depleted Earth mantle or bulk silica Earth.

The halogen budget of individual meteorite samples appears dominantly controlled by apatites that preferentially incorporate halogens. To constrain the halogen budget of the early Solar System planetesimals we determined F, Cl, Br, and I concentrations, and the $\delta^{37}Cl$ of individual apatite grains in meteoritic materials - including ordinary and Rumuruti chondrites, primitive achondrites, eucrites, and iron meteorites. Phosphate grains were documented by SEM and their mineral chemistry was determined by EPMA. Halogen concentrations and $\delta^{37}Cl$ were determined using a Cameca IMS 1280 (NORDSIMS). Mass balance calculations were carried out to evaluate the potential of apatite to act as a probe for the halogen chemistry.

$\delta^{37}Cl$ values of different meteorite groups span a range from about -1 ‰ to +1 ‰ [1; this study]. We found an evolutionary trend in $\delta^{37}Cl$ from chondritic through differentiated material, with the latter probably being balanced by silicate-bearing iron meteorites, such as Campo del Cielo. This trend is also seen for F/Cl of apatites from different meteorite groups, which ranges from ~100×10^{-3} in chondritic material to ~32, 500×10^{-3} in differentiated meteorites. I/Cl range from ~0.6×10^{-6} to 6×10^{-6}, - except for eucrites, which have I/Cl two orders of magnitude higher. Br/Cl vary from ~0.02×10^{-3} in ordinary chondrites to ~1.7×10^{-3} in iron meteorites. This implies discernible variation of halogens among different meteorite groups but, compared to Earth's halogen reservoirs, a relatively homogeneous halogen composition for the early Solar System.

Inherited ^{142}Nd anomalies in the Nuvvuagittuq supracrustal belt

A.S.G. ROTH[1], B. BOURDON[2], T. KLEINE[3], S.J. MOJZSIS[4] AND M. TOUBOUL[5]

[1]Institute of Geochemistry and Petrology, ETH Zurich, 8092 Zurich, Switzerland (antoine.roth@erdw.ethz.ch)
[2]ENS Lyon, UMR 5276, CNRS, France
[3]Institut für Planetologie, Universität Münster, 48149 Münster, Germany
[4]Department of Geological Sciences, University of Colorado, Boulder, CO 80309-0399, USA
[5]Department of Geology, University of Maryland, College Park, MD 20742, USA

The short-lived ^{146}Sm-^{142}Nd chronometer is a sensitive tool to trace early silicate Earth differentiation. Mantle depletions prior to ~4.2 Ga are documented as positive ^{142}Nd anomalies in Eoarchean rocks [e.g. 1]. O'Neil *et al*. [2] reported evidence for an early enriched reservoir from negative ^{142}Nd anomalies in pre-3750 Ma rocks of the Nuvvuagittuq supracrustal belt (NSB) in Québec. These authors derived a ^{146}Sm-^{142}Nd isochron with a 4.28 Ga age and concluded that the NSB may be the oldest crust.

We present new coupled $^{147, 146}Sm$-$^{143, 142}Nd$ systematics for six different NSB lithotypes. Samples yield a range of $^{147}Sm/^{144}Nd$ ratios from about 0.07 to 0.17. Nd data were collected on a Triton (TIMS) at ETH; repeat measurements of the JNdi-1 standard yield an external precision of ±4 ppm (2 SD) for the $^{142}Nd/^{144}Nd$ ratio (n=39). We reproduced negative ^{142}Nd anomalies for sample powders reported in [2], and for a cummingtonite amphibolite from the mapped area in [3]. A mafic (tonalitic) gneiss and a quartz-biotite schist from an Inukjuak supracrustal enclave NE of the NSB show $^{142}Nd/^{144}Nd$ ratios lower than the terrestrial standard ($\varepsilon^{142}Nd$ = -0.08 to -0.13). Taken together, these negative ^{142}Nd anomalies are uncorrelatable with $^{147}Sm/^{144}Nd$ for mafic or felsic lithologies and do not produce a ~4.28 Ga isochron as in [2]. In ^{147}Sm-^{143}Nd isochron diagrams our NSB whole rock samples define an array with an imprecise age of ~3.75 Ga similar to ages from U-Pb ion microprobe zircon geochronology [3]. Data indicate that the NSB rocks suffered a complex protracted history and that the Sm-Nd system is disturbed. We conclude that the absence of concordant ages in the ^{143}Nd-^{142}Nd system suggests that the negative ^{142}Nd anomalies were inherited from an early enriched reservoir and do not represent the age of the formation of the NSB rocks.

Use of TGA/DSC-IR to assess the effect of Cr on struvite stability

ASHAKI A. ROUFF

School of Earth and Environmental Sciences, Queens College, CUNY, Flushing NY 11367, USA (Ashaki.Rouff@qc.cuny.edu)

A TGA/DSC-IR hyphenated technique was used to evaluate the effect of sorbed Cr on the thermal properties of struvite ($NH_4MgPO_4 \cdot 6H_2O$, MAP). MAP occurs in guano deposits, peat, and lake sediments [1, 2]. It is also found in agroecosystems as a fertilizer decomposition product, and as a component of animal manure and poultry litter [3]. These systems can have high metal content, including Cr, which may substitute for P in MAP. Simultaneous thermal analysis has been used to determine the effect of Cr on the thermodynamic properties and stability of phosphate minerals [3, 4]. Addition of IR spectroscopy allows direct identification and quantification of decomposition products. Cr-MAP solids were generated from solutions with 0-100 μM Cr (III) and Cr (VI). DSC indicated an endothermic peak for all solids at 127 ± 0.5 °C, accompanied by >50% sample weight loss based on TGA, due to evolution of H_2O (g) and NH_3 (g) as identified by IR. The enthalpy, weight loss, and moles of evolved gases varied with initial Cr oxidation state and concentration. This was suggestive of diverse sorption complexes and mechanisms, further investigated using FT-IR and XAFS. The overall effect of sorbed Cr was to increase the structural H_2O content of MAP and to reduce the enthalpy of the endothermic transition. This indicates that Cr reduces the stability of MAP, increasing susceptibility to decomposition and thus release of the metalloid. This has implications for cycling of Cr, P and N in MAP-bearing natural and agricultural systems.

After the accident at the Chernobyl Nuclear Power Plant in april 1986, 12.10^{18} Bq of radionuclides (RN) were released in the atmosphere and most of them were redeposited around the facility. To prevent atmospheric resuspension, about 800 trenches were dug on site to dispose contaminated material (debris, organic matter, topsoil containing reactor fuel particles). Since 1999, the EPIC (Experimental Platform In Chernobyl) project has been set to study migration of radionuclides from one of these trenches, the trench T22, through the unsaturated and saturated zone. A plume of ^{90}Sr was identified downstream from the trench. The aim of this study is to contribute to the understanding of the migration of ^{90}Sr and other RN in groundwater. Water stable isotopes indicate winter recharge and groundwater stratification. Major elements show an increase in concentration with depth, linked to mixing and/or water-rock interaction processes. Preliminary results in $^{36}Cl/Cl$ show ratios in the order of those observed in concrete of proton-accelerator facilities [1] and 2 to 3 orders of magnitude higher than the theoretical ratio in precipitation. The source of this contamination may be contaminated particles released during the explosion and/or background activity and/or waste buried in the trench. Characterization of transport processes will be further investigated based on $^{235}U/^{238}U$, $^{86}Sr/^{88}Sr$ and $^{87}Sr/^{86}Sr$ ratios and additional $^{36}Cl/Cl$ measurments.

Energy content of soil organic matter as studied by bomb calorimetry

PERE ROVIRA* AND RITA HENRIQUES

Forest Sciences Center of Catalonia (CTFC), Solsona, Spain (*correspondence: pere.rovira@ctfc.cat)

Calorimetry has been applied to the study of soil organic matter for decades. Differential scanning calorimetry (DSC) has been the most widely used technique: this method submits the soil sample to a controlled temperature increase (often, 10°C per minute), and records the energy released by the combustion of organic matter. The components of organic matter (cellulose, lignin, polyphenolics, etc) have contrasting ignition temperatures; thus the graph of energy released *versus* temperature characterizes a given substrate [1]. In spite of the obvious attractive of this technique, it has the problem that during the temperature increase (and as a consequence of it) some components of the sample may volatilize before being affected by combustion, a fact that may result in underestimations of the amount of energy stored within the structure of the organic matter under study.

Bomb calorimetry is an alternative procedure. This technique does not allow a detailed study of the release of energy along a range of temperatures, because it gives just a single value, the total energy released by the combustion of the sample. Nevertheless, since the combustion occurs within a closed vessel, no losses of material occur. Therefore, the recorded release of energy reflects the amount of energy stored in the sample probably better than DSC techniques.

We applied bomb calorimetry to quantify the energy stored in soil organic matter in a set of mediterranean forest soils, under *Pinus halepensis* and over calcareous substrates (limestones, marls, etc). Methodological problems were observed; for instance, for soil samples below 7% of OC it was not possible to start a combustion by the standard method (electrical flash in the O_2-saturated vessel), and a comburent was needed.

The amount of energy released was linearly related to the organic carbon content. The relationship was very close, with r^2 values higher than 0.9. Translated to stored energy per unit of organic matter, the obtained values were around 34 Joules per mg C. This ratio, however, was not constant, for it increased with the total organic matter of the sample. In soil horizons very rich in organic matter (some OH horizons) it can reach almost 40 Joules per mg C, whereas it may drop down to less than 30 in mineral soil horizons. The relationships between energy stored and characteristics of the soil organic matter are under study.

Basaltic magmatism and mantle metasomatism in the Rio Grande Rift

M.C. ROWE[1]*, J.C. LASSITER[2] AND B.M. SCHMANDT[3]

[1]Washington State University, School of Earth and Environmental Sciences, Pullman, WA 99164, USA (*correspondence: mcrowe@wsu.edu)
[2]University of Texas at Austin, Jackson School of Geosciences, Austin, TX 78712, USA
[3]University of Oregon, Department of Geological Sciences, Eugene, OR 97403, USA

The Rio Grande Rift in the southwest United States provides an excellent opportunity to investigate temporal and spatial variations in mantle sources and basaltic magmatism in an active continental rift setting. The Rio Grande Rift, extending from northern Mexico to northwest Colorado, has undergone varying amounts of extension, with extension decreasing to the north. Prior rheological studies have indicated that metasomatism and hydration may have a significant effect on the strength of the lithospheric mantle. Here we combine primitive melt inclusion geochemistry (major-, trace-, and volatile elements), whole rock Sr-Nd-Pb isotopic analysis, and tomographic imaging to examine potential mantle metasomatism and its effects on basaltic magma compositions in the Rio Grande Rift.

Melt incusions and whole rock compositions are screened for potential crustal contamination based on negative correlations between Cl/K and Ba/Nb as described by Rowe & Lassiter [1]. Here we focus on Cl variations in melt inclusions, specifically variations in Cl/Nb, to identify mantle metasomatism. The only significant temporal variation along the rift in Cl/Nb is in the southernmost region where the highest Cl/Nb ratios are observed in olivine-hosted melt inclusiosn from a ~37Ma basalt (~150 Cl/Nb) compared to melt inclusions from a young (<50ka) basalt (~10 Cl/Nb). Correlations between age of magmatism, Cl/Nb, and whole rock $^{143}Nd/^{144}Nd$, particularly in the southern rift segment, indicates changes in Cl/Nb are likely related a transition from lithospheric to asthenospheric melting over time.

For basaltic volcanism younger than 5 m. y. the highest Cl/Nb ratios are in the central Rio Grande Rift, suggesting little systematic Cl/Nb fluctuations along the rift (N to S). However, for young volcanics, tenative correlations between whole rock Pb isotopes and mantle seismic velocity models (Vs/Vp at 60-100km depth) may further support diverse mantle sources for basaltic magmatism.

The Fe L_3-edge as a probe for Fe oxide speciation

A.N. ROYCHOUDHURY[1]*, B.P. VON DER HEYDEN[1], M. FRITH[2] AND S.C.B MYNENI[2]

[1]Dept. of Earth Sciences, Stellenbosch University, Stellenbosch 7602, South Africa (*correspondence: roy@sun.ac.za)

[2]Dept. of Geosciences, Princeton University, Princeton, NJ 08544, USA

L-edge XANES spectroscopy has been used to identify the speciation of Fe in natural samples. The majority of previous analyses are limited to the identification of Fe (II) versus Fe (III) speciation in complex natural samples however, these spectra are rarely used to identify different mineral phases in soils and sediments. Using the fine spectral variations between different crystalline and amorphous Fe phases, we developed a technique to evaluate the local co-ordination environment of Fe in natural samples. The technique makes use of splitting of the main electronic transitions in the L_3 edge (ΔeV) region, and the ratio of their peak intensities. These spectral parameters are sensitive to the valence state, electronegativity of the coordinated ligands and the degree of distortion of the polyhedra of Fe. We collected L-edge XANES spectra of several synthetic Fe-oxides and oxyhydroxides, and also compiled the spectra of several published spectra in the literature.

When compared for the characteristic ΔeV values and intensity ratio values; the common Fe (III) minerals, goethite, akaganeite, lepidocrocite, amorphous Fe, hematite, and maghemite fall within their own discreet oblong fields, with minor overlap between some of the phases. Similarly, the Fe (II) rich phases occupy their own positions on the plot characterized by greater intensity ratios. The differences in the characteristic intensity ratio values of the fields for the ferric standards is defined predominantly by the number of hydroxyls co-ordinating, and the characteristic ΔeV values are governed predominantly by the magnitude of the ligand field splitting. The arrangement of the fields is also a function of the polyhedral linkages and this is reflected in the average metal-metal distances. However, this analysis is limited by the saturation effects, an artifact of the XANES analysis of thicker and Fe-rich particles.

Details of these spectral analyses, the effects of cation substitution in Fe-oxides that influence these spectral parameters, and an application of this technique to study the natural samples will be presented.

Redox stratification of the White Sea sediments

ALEXANDER ROZANOV

P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences, Moscow (rozanov@ocean.ru)

Redox stratification is formed by the consequence of biogeochemical reactions of oxidation and reduction of organic and inorganic components of the sediments. Organic matter on the surface of the White Sea sediments is oxidized by oxygen dissolved in bottom water. However, in the subsurface horizons the oxygen is rapidly disappearing and other carriers of oxygen, namely, oxygen compounds of nitrogen, manganese, iron and sulfur serve as oxidants. The most striking manifestation of diagenesis is an extremely high content of Mn^{2+} in the pore water (sometimes more than 500 μM), which determines its flux from the sediments to the bottom water and oxidation at the contact with oxygen to form oxyhydroxides MnO_2, enriching the surface layers of the sediments. In lesser extent, migration and oxidation are characteristic of iron. After exhaustion of oxygen in the surface layer at the stage of anaerobic diagenesis newly formed oxyhydroxides (MnO_2 and FeOOH) themselves become oxidants of organic matter. Estimation of the diffusion flux of manganese from the sediments (280 μM/(m2day) and the corresponding amount of MnO_2 formed, compared with the opposite flux of oxygen to the sediments (1-10 mM/(m2 day), shows that over 10% of the organic matter of the surface layer of the sediments can be oxidized with MnO2. The role of other oxidants of organic matter (FeOOH and SO_4^{2-}) is prominent in the deeper horizons. In the upper package of sediments (0 - 100 cm) 61% of the anaerobic oxidation of Corg accounted for MnO2, the proportions of FeOOH and SO_4^{2-} are 14 and 25% respectively. At the same time in the topmost surface layer (0-5 cm) MnO_2 is practically 100 per cent oxidant agent, and at 100 cm the 100-percent oxidizer is SO_4^{2-}. A detailed calculation of the balance of reduction process shows the higher consumption of organic matter in diagenesis of surface sediments than gives a direct determination of Corg. The most active processes of redox diagenesis end at 25-50cm. Layers of manganese enrichment in the deeper horizons are in the nature of metastable relics of the surface accumulation (pobably, manganese nodules), subject to gradual dissipation withtin the sediment column.

Core formation in the Earth and the terrestrial planets

D.C. RUBIE[1]*, D.J. FROST[1], D.P. O'BRIEN[2], F. NIMMO[3], A. MORBIDELLI[4] AND H. PALME[5]

[1]Bayerisches Geoinstitut, Univ. Bayreuth, D-95440 Bayreuth, Germany (*correspondence: dave.rubie@uni-bayreuth.de)
[2]Planetary Science Institute, Tucson, AZ 85719, USA
[3]Dept. of Earth and Planetary Sciences, University of California, Santa Cruz, CA 95064, USA
[4]Observatoire de Nice, F-06304 Nice Cedex 4, France
[5]Forschungsinstitut und Naturmuseum Senckenberg, D-60325 Frankfurt am Main, Germany

Accretion of the terrestrial planets occurred through a series of impacts/mergers with smaller differentiated embryos and planetesimals (e.g. [1]). In addition to adding Fe metal to proto-planets, impacting bodies provide sufficient energy to cause large scale melting, the establishment of deep magma oceans and therefore episodes of metal-silicate segregation. In our recent model of multistage core formation [2], collisions result in an impactor's core partially or fully equilibrating in a magma ocean before merging with the planet's proto-core. Compositions of metal and silicate that result from the equilibration process are determined from the bulk composition by a novel approach involving mass balance combined with element partitioning. In the case of the Earth, model parameters (e.g. metal-silicate equilibration pressures) are determined by a least squares regression based on constraints provided by the concentrations of major and trace elements in the Earth's mantle. Results show that accretion of the Earth was heterogeneous: early accreting material was highly-reduced and volatile-poor and later accreted material was more oxidized and volatile-rich. This is consistent with dynamical simulations which suggest that late-accreting material originates from greater heliocentric distances and should thus be more volatile rich [1]. Oxygen fugacity and the FeO content of the mantle both increase during accretion due to (a) the dissolution of Si into the core by a reaction that releases oxygen and (b) the late addition of oxidized material. In contrast to early models of heterogeneous accretion, equilibration at pressures up to 60-80 GPa and a significant degree of disequilibrium both play a critical role.

The model is currently being integrated with N-body accretion simulations [1] in order to investigate the chemical evolution of all the terrestrial planets simultaneously. Some simulations suggest an increase in mantle FeO contents (e.g. from 4 to 14 wt%) and a decrease in mantle Mg/Si ratios and core mass fractions as heliocentric distance increases from 0.5 to 2 AU [3]. Finally, the model is used to investigate the causes of ^{182}W anomalies in planetary mantles.

Do erupted mafic lavas accurately reflect mantle magmatic timescales?

K.H. RUBIN

Dept. of Geology & Geophysics, Univ. of Hawaii, Honolulu, HI 96822 USA (krubin@hawaii.edu)

Mantle melting and melt transport encompass a range of processes that vary in duration, magnitude and length scale, and depend upon variables such as tectonic setting, volcano maturity, volcano spacing, and mantle physical characteristics (e.g. thermal state, composition, lithology, upwelling rate). Multiple compositional attributes of mantle derived magmas provide information on melting processes and conditions. The U-series nuclides are nearly unique in their ability to provide information about rates of such processes because chemical fractionation creates radioactive disequilibria between decay chain nuclides, which then decay away on characteristic timescales once fractionation ceases. Some surprising results from this literature suggest that the duration of melting is highly variable over short temporal and spatial scales in the mantle, and that melt transport is generally quite fast. But how trustworthy are these interpretations? Early studies were content to use the presence or absence of radioactive disequilibria in magmas to crudely estimate the duration of magma generation and transport in the mantle. Yet since the 1970s, development of much more sophisticated melting models and of analytical methods for nuclide activity measurements with 100-fold precision improvements have led to more specified time scale assessments in the U-series literature. Despite these refinements, the geological errors introduced by the melting and melt transport processes in the mantle place severe and often underestimated limits on our ability to tell time with these tracers in erupted magmas. Situations such as multiple melting lithologies, magma mixing, fluid-addition (at convergent margins) and reactive transport create a large amount of non-uniqueness to the way U-series data sets can be interpreted. Add crustal/magma chamber processes to this list and the challenge of deriving a unique temporal solution to the duration of magmagenesis and transport using a combined U-series, major/trace element and radiogenic isotope data set is nearly insurmountable. Nevertheless, results from U-series studies have much to tell us about magmatic timescales so long as data are not over-interpreted or modeled with a false sense of precision to the parameterization. This presentation will discuss the current state of the art and successful strategies for limiting the uncertainty of timescale assessments from magma chemistry, and present examples where results are generally consistent with independent geological and geophysical observations.

Local and regional magmatic modulators to mantle signatures in erupted mid-ocean ridge lavas

K.H. RUBIN[1]*, JOHN MACLENNAN[2], JOHN SINTON[1] AND ERIC HELLEBRAND[1]

[1]Dept. of Geology & Geophysics, Univ. of Hawaii, Honolulu, HI 96822 USA (*correspondence: krubin@hawaii.edu)
[2]Department of Earth Sciences, University of Cambridge, CB2 3EQ, UK

Although nearly all mid-ocean ridge magmas are formed in the mantle and inherit local compositional characteristics of the mantle source, a range of processes that occur between melt generation at depth and eruption on the sea-floor modulate the chemical signals of mantle heterogeneity that is sampled by ridge volcanoes. Increased time-integrated magma supply from mantle to crust is one characteristic that dramatically impacts (reduces) true mantle compositional variance in MORB by promoting coupled magma mixing and differentiation in the crust (e.g. [1]) Studies at local and regional spatial scales underscore the importance of geological conditions for interpreting mantle signatures in erupted lavas and provide a means for studying non-steady-state aspects of magma transport and crustal construction on decadal to millennial timescales. The inherent complexity in MORB compositions reflects the processes and rates of magma delivery to and accumulation in the crust, as well as the extent of mixing and heat loss prior to eruption, with implications for the spatial scales of mantle compositional variation thereby recorded in MORB. This talk will discuss global variations in MORB compositions and new results of recently conducted local/regional studies at a range of spreading rates where there are melt supply 'anomalies' along axis (e.g. from hot spots) and clear short-term differences in magma supply and eruptive activity at neighboring ridge segments. In general, these studies demonstrate that short term fluctuations in magma supply are driven by mantle heterogeneity, and that globally inferred linkages between magma supply, mantle compositional variance, and differentiation degree hold at these shorter spatial and temporal scales as well. They also demonstrate the importance of understanding geological context of lava samples, the need to have a sufficiently well sampled eruptive unit, and the preference for less differentiated (generally, high MgO) lavas in order to begin to decipher mantle compositional variation patterns in MORB.

Intermediate water $\Delta^{14}C$ off Brazil between 3-40 ka BP

M. RUCKELSHAUSEN[1]*, R. KOWSMANN[2], J.M. GODOY[4], G.M. SANTOS[3] AND A. MANGINI[1]

[1]Heidelberger Akademie der Wissenschaften, Im Neuenheimer Feld 229, 69120 Heidelberg, Germany (*correspondence: mario.ruckelshausen@iup.uni-heidelberg.de)
[2]Petrobras-CENPES, Cidade Universitaria, Quadra 7, Ilha do Fundao, CEP 21949-900, Rio de Janeiro, RJ, Brazil
[3]Keck-CCAMS Facility, Earth Systems Science, B321 Croul Hall, Univ. of California, Irvine, CA 92697-3100, USA
[4]Instituto de Radioprotecao e Dosimetria, Barra da Tijuca, CEP 22643-970, Rio de Janeiro, RJ, Brazil

The Southern Ocean is thought to play a key role in understanding the atmospheric rise of CO_2 at the end of the last glacial period accompanied by a decline of atmospheric $\Delta^{14}C$. Here we present reconstructed marine $\Delta^{14}C$ activities from corals of intermediate depth off Brazil. The corals stem from two new sediment cores in the direct vicinity to our cores already reported in [1]. This new dataset expands the older one and encompasses now the ages from 3-40 ka BP. First measurements validated our $\Delta^{14}C$ findings already published in [1]. The new data show that the continuous $\Delta^{14}C$ decline starting in our previous study with the Younger Dryas (YD) extends to 5 ka BP reaching an absolute minimum with an apparent ventilation age of over 6200 ^{14}C years. These observations are compatible with the scenario suggesting the existence of an abyssal reservoir in the Pacific Ocean that was isolated for several thousand years from the atmosphere before deglaciation. The observed continuous $\Delta^{14}C$ decline during Heinrich Stadial 1 (HS1) and the YD would then suggest a further weakening of ventilation of the deep water and the injection of this old carbon dioxide signature from the deep Pacific reservoir into the Circumpolar Water around Antarctica that is the source of Atlantic Intermediate Water. This follow-up study also attempts to trace back the history of the $\Delta^{14}C$ activity beyond HS1 (HS2, HS3 and HS4). First results lead to the conclusion that even during HS4 (38-35 ka), the water on the continental shelf off Brazil was highly depleted in ^{14}C with apparent ventilation ages of 4.84±1.35 ka (2σ). Recurring events of old water masses advance at intermediate depth off Brazil indicate a coupling between the intensity of deep water formation in the North Atlantic and the ventilation of the deep Pacific Ocean.

Statistical sampling of mantle heterogeneity

JOHN F. RUDGE[1]*, JOHN MACLENNAN[2] AND ANDREAS STRACKE[3]

[1]Bullard Laboratories, Department of Earth Sciences, University of Cambridge, Madingley Road, Cambridge, CB3 0EZ, UK (*correspondence: rudge@esc.cam.ac.uk)
[2]Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge, CB2 3EQ, UK (jcm1004@cam.ac.uk)
[3]Institut für Mineralogie, Westfälische Wilhelms-Universität Münster, Corrensstraße 24, 48149 Münster, Germany (stracke.andreas@uni-muenster.de)

The Earth's mantle is chemically, isotopically, and perhaps even lithologically, heterogeneous. This heterogeneity provides key information on Earth's evolution through time. Unfortunately much of this information is destroyed and overprinted by the melting and melt mixing processes that occur during the formation of basalt, which is then sampled at the Earth's surface.

The aim of this study is to better understand how mantle heterogeneity is filtered to produce the heterogeneity we observe in basalts. Since the physical processes of melting, melt mixing, and melt extraction are complex and still poorly understood, we focus here on developing simple statistical models of the sampling process. In these models we consider the melting of a two lithology source consisting of an enriched, more fusible, lithology (e.g. pyroxenite), and a more depleted, less fusible, lithology (e.g. peridotite). We fractionally melt these two lithologies, and then mix the resultant fractional melts together to form a sample, i.e. an erupted basalt.

There are many different ways in which the fractional melts can be mixed together to produce a sample, and we compare a number of different models for this mixing process. We focus in particular on the effects of biasing the mixing according to the different depths at which the fractional melts are generated. To constrain our models we compare the results with isotopic, major, and trace element observations of both whole rocks and melt inclusions from tightly constrained regions (e.g. Theistareykir, NE Iceland [1, 2]). Models in which deep melts mix more thoroughly than shallow melts can account for several key characteristics of these geochemical observations. We suggest that mixing of deep melts occurs during melt generation and migration in the mantle, prior to extensive mixing in lower crustal magma chambers.

A novel proxy links CAMP volcanism with end-Triassic mass extinction *and* early Jurassic evolution

M. RUHL*, C.J. BJERRUM, R. FREI AND C. KORTE

Nordic Centre for Earth Evolution, University of Copenhagen, Oester Voldgade 10, DK-1350 Copenhagen K, Denmark (*correspondence: micharuhl@gmail.com)

Phanerozoic mass extinctions are marked by global marine and terrestrial biodiversity loss and often linked to the formation of large igneous provinces (LIPs). Large-scale greenhouse gas release during these major volcanic events had a profound impact on the global exogenic carbon cycle, initiating strong perturbations in $\delta^{13}C$ records. Hence, they can be regarded as natural deep-time analogues of global environmental change. However, high resolution stratigraphic correlation between LIP formation, biotic crises and isotopic perturbations are poorly constraint. Here we present a novel proxy for volcanic activity, based on relative abundance changes of Lu, Hf, Y and Nb trace elements (ratio: $^{(Lu/\ Hf)}/_{(Y/\ Nb)}$), in a marine sedimentary record across the Triassic-Jurassic boundary. We show that peak ($^{(Lu/\ Hf)}/_{(Y/\ Nb)}$) values exactly match up with consecutive continental flood basalt emplacements in the Central Atlantic Magmatic Province (CAMP). The observed ($^{(Lu/\ Hf)}/_{(Y/\ Nb)}$)-peaks also coincide with the end-Triassic mass extinction, one of the largest Phanerozoic extinctions (at ~201.38 Ma), *and* with early Jurassic recovery patterns, suggesting that volcanism also governs (the speed of) early Jurassic evolution. Hence, this proxy for the first time allows very detailed causality studies on increased volcanic activity, disruption of global geochemical cycles and global biodiversity/ ecosystem turnovers, in unprecedented stratigraphic resolution. We furthermore test this method on the end-Permian mass extinction, the largest extinction event in earth history. Furthermore, the abundance of these trace elements in different CAMP basalt units, suggests a transition in magmatic source for the flood basalts. Lu/Hf and Y/Nb values in the oldest CAMP units are similar to the upper crust and gradually change (within ~600 kyr) to MORB values in the youngest CAMP units. In addition, highly reactive iron and trace element (Mo, U etc.) data allow interpretation of water column conditions in terms of oxic vs. anoxic and ferruginous vs. euxinic conditions. Periods of ocean anoxia/ euxinia (based on increased Fe-HR/Fe-T, Fe (Py)/Fe-HR, Mo values) coincides with the CAMP volcanic phase, but a direct link to individual CAMP pulses is yet less clear.

Reduction of biogenic uranyl phosphate nanoparticles by three metal-reducing bacteria

X. RUI[1], M.I. BOYANOV[2], M.J.KWON[2], E.J.O'LOUGHLIN[2], S. DUNHAM-CHEATHAM[3], J.B. FEIN[3], B.A. BUNKER[1] AND K.M. KEMNER[2]

[2]Bioscience Division, Argonne National Laboratory, Argonne, IL 60439
[3]Department of Civil Engineering and Geological Sciences, Univserity of Notre Dame, Notre Dame, IN 46556

The transformations of U in subsurface environments are controlled by a number of bacterially-driven precipitation and redox reactions. We examined the ability of three dissimilatory metal-reducing bacteria (*Anaeromyxobacter dehalogenans* strain K, *Geobacter sulfurreducens* PCA, and *Shewanella putrefaciens* CN32) to reduce U (VI) in three forms: hydrogen uranyl phosphate (HUP) nanoparticles on the cell wall of *Bacillus subtilis* bacteria precipitated by passive cell wall biomineralization; abiotically precipitated HUP; and aqueous uranyl ion. The reduction experiments were conducted at pH=6.8 with presence and absence of bicarbonate and phosphate. X-ray Absorption Fine Structure spectroscopy (XANES and EXAFS) showed varied reduction extent of U (VI) by the three bacteria. The biogenic HUP mineral was consistently more easily reduced than the abiotic HUP under the same experimental conditions. Higher extent of reduction was observed in the presence of bicarbonate. Reduction experiments under conditions that inhibited the HUP dissolution (i.e. high phosphate concentrations) showed smaller extents of U (VI) reduction. These results indicate reduction of the dissolved U (VI) species in the system, as opposed to direct electron transfer to the HUP mineral. EXAFS analysis shows that the reduced U (IV) species are consistent with mono-and bi-dentate phosphate complexation of the U (IV) atoms, as found in the $U^{IV}Ca(PO_4)_2$ mineral ningyoite.

Radioactive element abundances, paleo-heat flows, and the internal evolution of Mars

JAVIER RUIZ[1]*, ALBERTO JIMÉNEZ-DÍAZ[1], VALLE LÓPEZ[2,3], PATRICK J. MCGOVERN[4], JEAN-PIERRE WILLIAMS[5], BRIAN C. HAHN[6] AND ROSA TEJERO[1,3]

Lithospheric strength, crustal and mantle lithosphere composition and orbital measurements of radioactive element abundances can be used together to estimate paleo-heat flows for Mars (e.g. [1]), which help us to constrain the thermal evolution of this planet. In this work we present estimates of paleo-heat flow for several martian regions of different periods and geological context, derived from lithospheric strength and regional radioactive element abundances obtained with the *Mars Odyssey* Gamma Ray Spectrometer. The obtained surface heat flows are in general lower than the equivalent radioactive heat production of Mars in each time, suggesting a limited contribution from secular cooling to the heat flow during the majority of the history of Mars. This is contrary to the predictions from the majority of thermal history models [2], but it would be consistent with an inefficient cycling of volatiles to and from the mantle [3], as might be expected for Mars, which has lacked a plate tectonic cycle.

Dissolution/precipitation processes during low-temperature mineral weathering

E. RUIZ-AGUDO[1]*, M. UROSEVIC[1], C.V. PUTNIS[2], C. CARDELL[1], C. RODRIGUEZ-NAVARRO[1] AND A. PUTNIS[2]

[2]Institut für Mineralogie, Universität Münster, Germany

Low-temperature weathering of rock-forming minerals is critical for understanding earth-surface geochemical processes. Many of these minerals are reported to dissolve non-stoichiometrically, i.e. the elemental ratios in the solid are different to those in the fluid. This phenomenon is commonly called *incongruent dissolution*, and it is attributed to the preferential release of certain cations to the solution (due to differences in the bonding strength of the mineral components), leading to the formation of the so-called *leached layers* [1]. In this study, chemical analysis of the output solutions during mineral dissolution (dolomite, as an example of a mineral that reportedly dissolves 'incongruently' [2]) and in situ, nanoscale observations of the reacting surfaces using AFM are combined with the aim of establishing a realistic mechanism for the reaction. From our observations of the reacting surface we found no experimental evidence that supports the hypothesis of a preferential release of any of the cations. Moreover, our AFM results clearly indicate that the 'incongruent' behavior is the result of a dissolution-precipitation process, with the formation of a Mg-rich precipitate on dolomite dissolving surfaces. This process seems to be controlled by the composition of a boundary layer at the carbonate-fluid interface. Dissolution of the carbonate causes this fluid boundary layer to become supersaturated with respect to the secondary phase, which then precipitates.

Optimized hydrofluoric acid demineralization for quantitative isolation of soil organic matter

M. RUPPENTHAL[1]*, Y. OELMANN[1] AND W. WILCKE[2]

[1]Institute of Integrated Natural Sciences, Department of Geography, University of Koblenz, Germany (*correspondence: ruppenthal@uni-koblenz.de)
[2]Soil Science Group, Geographic Institute, University of Berne, Switzerland

Many analytical methods for chemical characterization of soil organic matter (SOM) require a precedent separation of SOM and soil mineral matrix [1]. For example, δ^2H measurements of SOM are hampered by the interference of constitutional water of clay minerals [2]. During demineralization of soil samples with hydrofluoric acid (HF), the hydrolyzed fraction of SOM is frequently discarded. Moreover, neoformed fluorides after HF treatment are often removed with highly concentrated acids resulting in additional SOM hydrolysis. Particularly from subsoil horizons considerable amounts of SOM are lost because of demineralization (losses of organic carbon [C_{org}] up to 70%).

In order to increase the C_{org}-recovery after HF treatment of soil samples and to minimize chemical alterations of SOM induced by the acid attack, we demineralized soil samples from three depth profiles. We used a new method involving density fractionation or dilute acid washings to reduce the amount of neoformed fluorides in SOM concentrates. Furthermore, we recovered the SOM dissolved in HF via precipitation of dissolved metals as hydroxides in the presence of sodium pyrophosphate to avoid coprecipitation of dissolved organic matter, followed by desalting the supernatant by means of dialysis.

Our results show that the new method allows for a better demineralization compared to established procedures, especially for subsoil horizons. We were able to minimize hydrolysis of SOM, double the C enrichment factors (ratio of C_{org} concentration after to that before treatment) and reduce C_{org}-losses to below 15%. We will discuss potential effects of the demineralization method on δ^2H values of SOM.

Magma mixing and the assembly of complex eruption sequences

PHILIPP RUPRECHT AND TERRY PLANK

Lamont-Doherty Earth Observatory, Columbia University, 61 Route 9W, Palisades, NY 10964, USA (*correspondence: ruprecht@ldeo.columbia.edu, tplank@ldeo.columbia.edu)

Elemental diffusion in plagioclase and olivine [1, 2] can provide an integrated timescale of the sequence of magma mixing until eruption. For example, at Quizapu volcano (Chile) textural observations and Mg diffusion in plagioclase constrain a succession of magma recharge, mixing and eruption to a few days to three weeks [3]. One major caveat in using elemental diffusion, however, is the potential competing effect of crystal growth, which may lead to similar normal zoning patterns when magma mixes, cools and crystallizes with more evolved compositions.

In order to deconvolve crystal growth from diffusion, we have obtained by LA-ICPMS multi-element zoning patterns for olivines from the 1963-5 eruption of Irazu volcano (Costa Rica) for elements that span a wide range of diffusivities (Fe-Mg, Mn, Li, Ca, P, Sc, Ti V, Cr, Mn, Fe-Mg, Co, Ni, Zn). The 1963-65 eruption is characterized by phreatomagmatic deposits of basaltic andesites (54-57 wt% SiO_2, [4]). In three samples spanning a large sequence of the eruption we identify olivines of different origin (Fo70-91, crustal olivine cumulates and mantle-derived recharge olivines). Some olivines are dominated by growth signatures (primarily based on P profiles) and others record the timing of magma mixing through their diffusion profiles (Fe-Mg, Ni). The initial phase is dominated by mantle-melt derived olivines with a thin low Fo growth rim consistent with decompression growth over a few weeks in a mixed magma and a slightly normal zoned interior (Fo84-90) resulting from an extended time of diffusive exchange (months to years) at evolving but still mafic compositions. The later eruptive sequence shows much larger variety of olivines that records the syn-eruptive addition of distinct magmas that wax and wane through the eruption, though olivines still present from the early stage have much thicker growth rims indicating longer residence prior to eruption. Thus, multi-element zonation profiles record crystal growth during magma ascent and diffusive exchange during crystal storage, as an eruptive system evolves.

Core Formation in Partially Molten Planetesimals

The segregation of metallic cores from silicate mantles is one of the earliest, and most important, differentiation process involved in the evolution of terrestrial planetary bodies and reconciling our estimates of primary bulk silicate mantle with candidate planetary bulk compositions requires an understanding of the different regimes in which core forming material may have been mobile. This includes regimes that are dynamic and may result in transient states of high stress due to impact. Recent scenarios of core formation in planetesimals using calculations from extinct radionuclides (e.g. ^{26}Al, ^{60}Fe) call for segregation of a metal liquid (core) from partially molten silicate – a silicate mush matrix. This segregation scenario requires growth of molten core material into blebs large enough to overcome the strength of the mush matrix so that separation can occur. However, currently there is no satisfactory explanation as to how or why metallic liquid blebs in the presence of silicate melt actually grow. Experimental work has suggested deformation and shear can help coalesce metallic blebs. Here, we have developed an innovative approach that combines textures in experimental deformation experiments on a partially molten natural meteorite with complex network analyses. This approach can elucidate and quantify the growth of metallic blebs in regions where a silicate mush matrix is present and help predict separation.

Fate of nutrients in the fresh-saline water interface in coastal aquifers

A. RUSSAK[1,2]*, O. SIVAN[1], Y. YECHIELI[2], B. LAZAR[3] AND B. HERUT[4]

[1]Department of Geological and Environmental Sciences, Ben Gurion University of the Negev, Beer Sheva, Israel (*correspondence: russak@bgu.ac.il, oritsi@bgu.ac.il)
[2]Geological Survey of Israel, Jerusalem, Israel (yechieli@gsi.gov.il)
[3]Institute of Earth Sciences, Hebrew University, Jerusalem, Israel (boaz.lazar@huji.ac.il)
[4]Isreal Oceanographic and Limnological Research, National Institute of Oceanography, Haifa, Israel (barak@ocean.org.il)

The fresh-saline water interface (FSI) is the transition zone between fresh and saline groundwater in coastal aquifers. Major ions composition indicate if the FSI deviates from conservative mixing between fresh and saline end-members, mainly attributed to cation exchange.

This study aims to quantify the changes in nutrient concentrations (NH_4^+, NO_3^-, NO_2^-, PO_4^{3-} and $Si(OH)_4$) across the FSI at the Israeli coastal aquifer due to freshening and salinization processes. In addition to field sampling in boreholes at the coastal aquifer, experimental studies were conducted to simulate salinization and freshening events using sediment columns and a flow-through system.

The field results show that the FSI acts as a redoxcline. The oxidized fresh groundwater zone is charecterized by relatively high NO_3^- and low NH_4^+ and NO_2^- concentrations, while the saline groundwater is almost anoxic with high NH_4^+ and low NO_3^- and NO_2^-. Within the FSI NO_2^- was enriched.

During the experiments the nutrients behavior was not conservative as well. This was attributed to denitrification, adsorption/desorption and dissolution processes, similar to the field observations.

$\delta^{18}O$ zoning in eclogite garnet

A.K. RUSSELL*, K. KITAJIMA, A. STRICKLAND, L.G. MEDARIS JR., M.J. SPICUZZA AND J.W. VALLEY

Department of Geoscience, Univ. of Wisconsin, Madison, WI 53703, USA (*correspondence: akrussell@wisc.edu)

Metamorphic garnets record history and can preserve evidence, through chemical zoning, of chemical changes and fluid interactions. O isotope ratios in minerals are valuable as monitors of fluid interactions. Secondary Ion Mass Spectrometry (SIMS) allows the measurement of $\delta^{18}O$ at 10 μm scale in garnet with a precision of ±0.3‰ (2sd) [1].

Nine garnets from eight different eclogite localites across Europe were analyzed for $\delta^{18}O$ zoning. Samples are from the Saxothuringian and Moldanubian Zones of the Variscan Bohemian Massif; Trescolmen, Alps, and the Scandian-age Nordfjord region, Norway. Analyzed by laser fluoination, eight garnets had bulk $\delta^{18}O$ values between -0.41 and 3.75‰, and the ninth, 8.18‰ [2].

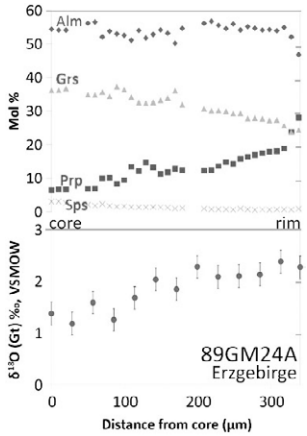

Figure: $\delta^{18}O$ and major element zoning from core to rim in garnet from the Erzgebirge[4].

This first detailed study of $\delta^{18}O$ zoning in eclogite garnet reveals a common pattern: low $\delta^{18}O$ in the core with higher $\delta^{18}O$ rims (Figure). Seven out of nine garnets analyzed have this type of zoning, independent of garnet size, geological setting, peak metamorphic conditions, age, and garnet composition.

Our results are consistent with an inherited low $\delta^{18}O$ core derived from hydrothermally altered mafic protoliths formed at an oceanic spreading center. Due to small oxygen fractionations at high T between garnet and other minerals [3], and the refractory nature of garnet, we conclude that the increase of $\delta^{18}O$ toward the rims represents interaction with a high $\delta^{18}O$ reservoir at high pressures.

[2]Department of Environmental Science, University of Virginia, Charlottesville, VA 22904, USA

[3]Pacific Marine Environmental Laboratory, NOAA, Seattle, WA 98115, USA

Oceans cover two-thirds of the Earth's surface, and the particles emitted by waves breaking on the ocean surface provide an important contribution to the planetary albedo. The contribution of sea salt particles to atmospheric aerosol has been recognized and qualitatively understood for almost a century. The quantity, size distribution, and composition of submicron particles released into the atmosphere from bubble bursting remains unknown because measurements of particle production in controlled conditions have never fully explained open ocean observations. This presentation compares ambient-observed and artificially-generated composition, size, and production of marine particles.

In addition to physical measurements of particle number distributions, chemical analyses are used to illustrate the important role of surface seawater composition in forming particles. Filter samples were analyzed using Fourier transform infrared (FTIR) spectroscopy to determine the functional group composition and total organic mass (OM) of the ambient and generated marine particles. Positive matrix factorization (PMF) of the ambient particle FTIR spectra was used to separate the marine and anthropogenically-influenced sources of OM in ambient observations. Samples from marine aerosol bubbling generation showed similar organic compositions to those determined from ambient marine factors, all showing high fractions of hydroxyl functional groups. Number concentrations of artificially-generated particles were also related to the properties of the seawater from which they were generated.

To evaluate the role of organic and inorganic components of seawater in forming particles, we also investigated particle production from laboratory bubbling in controlled conditions with simple seawater model solutions. These experiments serve to illustrate the important role of sea surface components in the film bursting process that leads to particle production.

Magma degassing processes during Plinian eruptions of La Montagne Pelée (Martinique, F.W.I.)

LORRAINE RUZIÉ* AND MANUEL MOREIRA

Équipe de Géochimie et Cosmochimie, Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Univ. Paris Diderot, UMR 7154 CNRS, F-75005 Paris, France (*correspondence: ruzie@ipgp.jussieu.fr)

Magma degassing process is the driving force behind explosive eruptions. To assess our knowledge on this phenomena, we have measured noble gas abundances and isotopic ratios in pumices produced by fragmentation of volatile-enriched magma.

Ruzié et Moreira (2009) [1] conducted analyses on pumice samples coming from worldwide Plinian eruptions. All samples are characterized by a systematic enrichment in neon over argon, a depletion of krypton relative to argon and an isotopically fractioned $^{38}Ar/^{36}Ar$ ratio. These features do not depend on geological setting, or on pumice age, or eruption intensity. However, they are similar for pumices from the same eruption. A correlation is observed between $^{84}Kr/^{36}Ar$ and $^{38}Ar/^{36}Ar$ ratio. This illustrates that only one physical process is at the origin of the fractionation. We therefore proposed a model of kinetic magma degassing before fragmentation to explain the elemental and isotopic fractionation. Noble gases diffuse in a magma shell surrounding a preexisting bubble with constant radius. The model explains measurements and shows the rapidity of the magma degassing process in the conduit (few hundreds of seconds).

We apply a more elaborate model taking into account bubble growth in pumices coming from La Montagne Pelée volcano (Martinique), which produced Plinian eruptions with various intensities. A detailed stratigraphic study for the last three Plinian eruptions is still in progress.

Regime of volatile components in magmatism of LIP (Siberian traps)

I.D. RYABCHIKOV

Institute for Geology of Ore Deposits, Russian Academy of Sciences, 119017, Moscow, Russia (iryab@igem.ru)

To assess the formation conditions of Siberian traps we investigated melt and fluid inclusions in the phenocrysts of these rocks, which were analyzed for major and trace elements (EMPA and SIMS methods).

Ion microprobe data for reheated melt inclusions show relatively low concentrations of water by comparison with non-volatile components of comparable incompatibility (H_2O/Ce=4.5 vs 170 for MORB). Similar decoupling of H_2O and light REE was found for OIBs which belong to EM2 mantle reservoir. This has been interpreted as diffusive dehydration of the EM2 source during its storage in a drier ambient mantle (Workman *et al*. 2006). Similar mechanism of diffusive loss of water to the surrounding mantle may be proposed for magmas in Siberian Trap Province. Fluorine whose partition coefficients for major minerals of mantle rocks are similar to those of water is characterized in the investigated melts by close correlation with its non-volatile analogue (F/Nd=17 vs 21 for MORB+OIB). Concentrations of volatiles other than water in the mantle source of Siberian magmas are similar to the estimates for the sources of OIB magmas.

Low concentration of H_2O and moderate contents of other volatiles imply that the estimates of near-solidus temperature based on comparison with volatile free systems would not be changed significantly. Comparison of the estimated from melt inclusion data pressures with experimental data shows that the temperature of rising plume material was ca 400°C higher by comparison with the convecting upper mantle at the same depth. This proves that plume material arrived from deep levels in the mantle below certain thermal boundary layer.

Predicting the properties and behavior of multiphase materials in disposal environments

J.V. RYAN*, C-W. CHUNG, R.E. WILLIFORD, L.A. TURO, N.M. WASHTON AND A.L. WARD

Pacific Northwest National Laboratory (*correspondence: joe.ryan@pnl.gov)

Multiphase materials such as cement, ceramics, metals, glasses, and glass-ceramics, are being considered for stabilization of primary and secondary radioactive wastes. These materials are hydrophysically, chemically, and structurally complex with properties varying across multiple length scales. Hydrophysical properties exert control over percolation processes that help to define the relationship between microstructure and transport properties. Chemically, each form contains several components and phases, some of which can be amorphous or poorly crystalline with metastable solid-solution compositions varying over a fairly wide range. Transport properties are generally not well understood; their dependences on microstructure are non-unique such that empirical relations cannot be universally applied with confidence and modeling of interactions is under-constrained. In addition, the characteristics, and thus performance, of multiphase materials will change as the system evolves and degrades. Prediction of these changes is necessary for an improved understanding of service life in the disposal environment. A direct consequence of this complexity is that the evolution and degradation of waste form systems (comprised of the waste form and the near-field environment) are difficult to measure and, consequently, long-term performance is difficult to predict.

This research uses an integration of computational materials science, multiphase hydraulics, and geophysical techniques with careful experimentation to develop the tools necessary for analyzing and predicting the changes accompanying the evolution and degradation of multiphase waste form systems. Two waste form systems have been chosen for analysis: corroded HLW glass and cementitious cast stone. Both subject materials are multi-scale in their heterogeneity, with variations in microstructure from nanometers to millimeters. Inverse modeling techniques are coupled with physically-realistic composite physico-chemical models to determine critical parameters. These are then investigated with targeted experiments utilizing a suite of experimental techniques covering the range of scales of interest to these particular problems, including nuclear magnetic resonance, electron microscopy, x-ray tomography, and impedance spectroscopy.

Intra-transform magmatism; Melt migration and two-component mantle

A.E. SAAL, A.N. NAGLE, R.C. PICKLE AND D.W. FORSYTH

Brown University Department of Geological Sciences, Providence, RI (asaal@brown.edu)

Oceanic intra-transform magmatism is not supported by long-lived magma chambers or along-axis transport of melt from other parts of the spreading system, thus providing well-defined locations of melt delivery and crustal formation. Intra-transform basalts therefore represent pre-aggregated melts and their compositions provide insight into models of melt generation and transport processes beneath mid-ocean ridges. The Quebrada/Discovery/Gofar (QDG) transform fault system offsets the fast-slipping East Pacific Rise (3°-5°S) by approximately 400km and is composed of 8 active intra-transform spreading centers ranging in length from 5 to 70 km. Forty-seven dredges of young intra-transform basalts were collected and geochemically characterized from this area.

QDG basalts exhibit varying degrees of differentiation, which correlate with the estimates of crustal thickness of each ridge segment derived from gravity models. The incompatible trace element ratios (e.g. Th/La) of these lavas range significantly from depleted to enriched compositions at similar MgO content, and the level of enrichment correlates well with indicators of depth of melt segregation (e.g. Sm/Yb). Overall, the chemical variation of these basalts is greater than that previously found in fracture zones (such as Siqueiros and Garrett FZ) and is similar to the compositional range defined by northern EPR seamounts.

A simple geochemical model reproducing the trace and isotopic data of QDG basalts suggest that melting of a two-mantle component and the effect of melt migration can easily explain the compositional range observed at mid-ocean ridges.

Arsenic in siliceous deposits formed from geothermal water

A. SABITA[1], K. YONEZU[2], Y. OKAUE[1] AND T. YOKOYAMA[1]*

[1]Faculty of Science, Kyushu University, Fukuoka 812-8581, Japan (*correspondence: yokoyamatakushi@chem.kyushu-univ.jp)

[2]Faculty of Engineering, Kyushu University, Fukuoka 819-0395, Japan

Arsenic in geothermal power plants

Geothermal water, which discharges from deep underground, contains various harmful elements since it is volcanic origin. Especially, arsenic (As) concentration of geothermal water is outstanding and is generally several ppm. Therefore, the geothermal water after water/vapor separation for electric generation has been returned into deep underground again through re-injection wells at geothermal power plants. On the other hand, siliceous deposits, which are formed from geothermal waters, have been discharged into environment as industrial wastes. However, they are possible to take up As from geothermal water during the formation. Whereas, the uptake mechanism of As by siliceous deposits formed from geothermal water and its chemical state have never been investigated. In this study, the uptake mechanism of As by siliceous deposits in geothermal water at a geothermal power plant and change in the chemical state of As during the formation of siliceous deposits was investigated.

Results and Discussion

From the correlation analysis between elements in siliceous deposits formed from geothermal water at the Hatchobaru geothermal power plant, Japan and rare earth element pattern of the geothermal water, As can be concluded to be taken up by coprecipitation with hydrous iron (III) oxide. Although the siliceous deposits were formed from oxidizing geothermal water, the inside of the deposits was considered to be in reducing environment because of the conversion of hydrous iron (III) oxide to pyrite. No As was contained in the pyrite. Due to the conversion, the As may immigrate from Fe phase to silicate phase based on the result of chemical leaching treatment.

[4]Department of Basic Sciences, Islamic Azad University, Khurasgan Branch, P.O. Box 81595-158, Isfahan, Iran

New Method and Discussion

Speleothems are a kind of secondary minerals that form in caves. These deposits have different landscapes and mineralogy properties. In this research, the Khas-e-Tarash Cave, which is in the northeast of Isfahan, centeral Iran, is studied and introduced for the first time. We considered 59 stations in the cave and all of 19 speleothem samples are studied. Results of the scanning electron microscope (SEM) and X-ray powder diffraction (XRD) analyses indicate that calcite ($CaCO_3$), aragonite ($CaCO_3$) and the other minerals are gypsum ($CaSo_4.2H_2O$), thenardite, halite and in some cases quartz minerals are formed by groundwater along joints, fractures and main cave saloons (A sample of XRD figure 1).

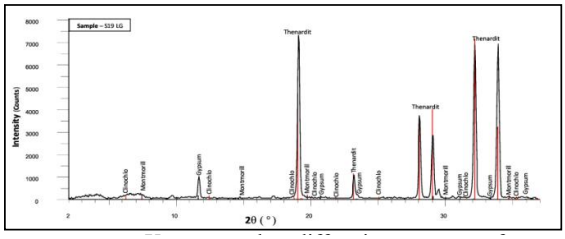

Figure 1: X-ray powder diffraction pattern of one sample, it shows that minerals are sulfates with clay minerals.

A new method, in AAS analyses, stransium Measured and the results show some samples only consist of carbonate. This survey shows that carbonate speleothems have calcite and aragonite. The evaporite minerals consist of different shapes in gypsum minerals (very fine to coarse), halite and thnardite. Silicon observed is in some cave deposits that indicate a change in groundwater composition. Later erosion and solution by groundwater have deformed old speleothems.

These minerals contain from four different chemicals classes; carbonates, sulfates, halides and silicates that sometimes stained by clay minerals and Iron oxide.

The tectonic setting where faults allowed the ascension of hydrothermal solutions and the deposition of the quartz minerals.

These minerals precipitated in low-temperature vadose solutions (calcite, aragonite, hydromagnesite, etc.).

Preliminary results of magnetic fabric of the Gole-zard pluton, Aligoodars, Iran

M. SADEGHIAN, S. BADALLOI* AND M. SHEIBI

Faculty of earth Science, Shahrood University of Technology, Shahrood, Iran (*correspondence: simin_badallo@yahoo.com, Sadeghianm1386@yahoo.com, Sheibi58@gmail.com)

A magnetic fabric study was performed on the Gole-zard pluton in an attempt to understand its emplacement history. Gole-zard granitoidic body (~20 km^2) is located in the north of Aligoodarz cities (SW of Iran), Sanandaj-Sirjan structural zone and ranges compositionally from granodiorite-granite to leucogranite. The pluton intruded in middle Jurassic metapelitic rocks and base on age determinations on the Sanandaj-Sirjan magmatic and metamorphic belt, it belongs to middle Jurassic (155-175 Ma). The presence of metaplitic and metasandstone enclaves, silica veins xenoliths with metamorphic origin, xenocrysts of andalusite and garnet confirm its S-type character. According to the geochemistry data, the rocks are peraluminous and calc-alkaline.

The mean magnetic susceptibility obtained from different rock groups are as follows: granodiorites (225 μSI), leucogranites (56 μSI), and chloritized granodiorites (510 μSI). Obtained results characterize that granodiorites (the main part of this pluton) associated with leucogranites are belong to paramagnetic granitoids (0<Km<500) which is accommodates with S-type granite. Km values increase in proportion to abundance of biotite and ilmenite. Km values reduce from granodiorites to leucogranites and finally tourmaline bearing leucogranites. In spite of distribution of magmatic microstructures in all parts of pluton, the eastern part show some evidences of solid state deformation microstructures including alteration of biotite to muscovite, chlorite and hematite; kinked biotite; mechanical twining in plagioclase and chessboard pattern in quartz.

Anisotropy percentage (P %) and shape parameter of magnetic ellipsoid (T) values vary from 1 to 3, and -0.43 to, in respectively. With respect to variation of (P) and (T) values and microstructural evidences, eastern parts of Gole -Zard g pluton have undergone more intensive deformation.

Magmatic evolution of Azna-Aligoudarz granitoidic plutons, SW of Iran: A typical example of S type granitization

M. SADEGHIAN, S. BAGHBANI* AND M. SHEIBI

Faculty of earth Science, Shahrood University of Technology, Shahrood, Iran
(*correspondence: Shiva.baghbani@gmail.com, Sadeghianm1386@yahoo.com, Sheibi58@gmail.com)

Darreh Bagh, Gol-e Zard and Azna plutons located in the Sanandaj- Sirjan zone, SW Iran. Based on mineralogy and geochemistry, these plutons are S -type granites with compositional range from granodiorite to leucogranite. Special characteristics of them are: presence of andalusitic xenocrysts, andalusite bearing metapelitic enclaves, xenolithic silica (quartz fragments), metasandstone and micaschistic enclaves, microgabbroic (or basaltic) dikes cutting Gol- e- Zard granitoid pluton. Field relationships show evidences for intrusion of basic – intermediats magmas (with gabbro to diorite compositions) into metapletic rocks (slate, phyllite, micashiste and garnet micashist) and resulted in contact metamorphism and converting the metapletic rocks to cordierite hornfels, andalusite hornfels and silimanite hornfels. With increasing temperature, migmatites appeared and produced granitoidic melt. Then, they ascended to higher levels in the upper crust. More differentiated members including pegmatite and leucogranites dikes, tourmaline veins and veinlets, and tourmalinites cut granitic- granodioritic rocks. Since these plutons are believed that belong to the tectonomagmatic events in Sanandaj-Sirjan zone and subuction of neothethys, basic – inter mediate magmas derived from melting oceanic slab undergoing or mantle source. In conclusion, it seems interval time between emplacement of basic – intermediate and felsic magmas is not so long.

Microstructural and AMS investigation of Darre Bagh granitoidic pluton (SW Iran)

M. SADEGHIAN, S. SHEKARI* AND M. SHEIBI

Faculty of earth Science, Shahrood University of Technology, Shahrood, Iran
(*correspondence: Shekari_2002@yahoo.com, Sadeghianm1386@yahoo.com, Sheibi58@gmail.com)

Darre Bagh granitoidic pluton (60 km^2) is located in the north of Azna-Aligoodarz cities (SW Iran) and in Sanandaj-Sirjan structural zone. The pluton intruded in middle Jurassic metapelitic rocks and base on age determinations on the Sanandaj-Sirjan magmatic and metamorphic belt, its age is obtained 169-170 Ma. This pluton compositionally ranges from granodiorite, granite to leucogranite. Small tourmaline bearing pegmatites are also observed in some parts of the studied pluton. The presence of metaplitic and metasandstone enclaves, xenolithes of silica veins with metamorphic origin, xenocrysts of andalusite and garnet, ubiquitous presence of biotite association with metapelitic host rocks confirm peraluminous and S-type granite nature of the studied rocks.

This pluton has been examined by anisotropy of magnetic susceptibility method (AMS) for the first time. Based on our investigations in 86 stations (249 cores and 854 fragments), average of measured mean magnetic susceptibility (Km) for different rock groups are as follows: granodiorites (Km=248.5 μSI), leucogranites (Km=52.6 μSI), migmatites (Km=415.1 μSI) and enclaves (Km=391.3 μSI). Obtained Km values (in Geomagnetic Lab of Shahrood University of Technology) indicate that main part of this granitoidic pluton (biotite bearing granodiorites) belong to paramagnetic granitoids (0<Km<500 μSI). Mean magnetic susceptibility is decreased from granodiorites to leucogranites which accommodates with decrease of ferromagnesian minerals (in particular biotite). The other magnetic behavior carriers are sphene, ilmenite and tourmaline. Therefore, there is a direct and logical relationship between lithological and mineralogical compositions and Km values. Hence, we can use Km values with reliable, for interpretations of compositional evolutions of granitoidic rocks.

Submagmatic and high to medium temperature subsolidus microstructures are visible in most of the thin sections prepared from core samples. The most interesting features of deformation in Darreh Bagh pluton are as follow: subgraining of quartz, plagioclase, orthoclase and biotite; mechanical twining in plagioclase; producing kinked biotite, chessboard pattern and undulose extinction in quartz, plagioclase and orthoclase; myrmekite rim along the margin of plagioclase; alteration of biotite to muscovite and chlorite and neoformation of secondary sphene and finally sericitization of orthoclase and plagioclase. The percentage of anisotropy (P%) values vary from 2 to 10 and show positive correlation with degree of deformation. Shape parameter of magnetic ellipsoid (T) values varies from 0.78 to -0.58 and most of magnetic ellipsoids are oblate.

Deciphering the significance of hopanoids in the marine geologic record

JAMES P. SÁENZ[1,2,3], STUART G. WAKEHAM[4], TIMOTHY I. EGLINTON[3,5] AND ROGER E. SUMMONS[2]

[1]MPI-CBG, 01307 Dresden, Germany (saenz@mpi-cbg.de)

Hopanoids are pentacyclic triterpenoids produced by some bacteria that have been dubbed bacterial 'sterol surrogates.' Hopanoids have been broadly applied in the marine sedimentary record as taxonomic markers for certain groups of bacteria and their associated biogeochemical processes. However, our ability to rigorously interpret the significance of hopanoids in the geologic record has been greatly limited by a dearth of knowledge surrounding the sources of hopanoids in marine environments. Despite the ubiquity of hopanoids in modern and ancient marine sediments, their precise provenance in the modern oceans is largely unknown. In this study, we present a survey of bacteriohopanepolyols (BHPs) in a diverse selection of marine and proximal marine environments. Our work establishes the presence and ubiquity of hopanoids in the oceans, and provides fresh insight on the environmental sources and biogeochemical significance of hopanoids in marine sediments. We observe pronounced heterogeneity in the spatial and temporal distribution of BHPs, indicating the potential for the application of hopanoids as biomarkers for biological processes in the upper ocean and as tracers for organic matter input to sediments. In particular, BHPs appear to be relatively abundant and structurally diverse in low oxygen and oligotrophic environments and in particulate organic matter (OM) transported by rivers from terrestrial environments. Given the rich structural diversity of BHPs in terrigenous OM, interpretations of the sedimentary record of hopanoids in coastal marine settings must resolve inputs from marine pelagic and terrestrial sources. Furthermore, BHPs produced in suboxic and anoxic pelagic environments likely represent an important input to the sedimentary hopanoid inventory in upwelling environments and anoxic marine basins.

The Shatsky Rise supervolcano

WILLIAM W. SAGER[1], TAKASHI SANO[2] AND JUN KORENAGA[3]

[1]Texas A&M University, College Station, TX 77843, USA (*correspondence: wsager@tamu.edu)
[2]National Museum of Nature and Science, Tokyo 169-0073, Japan
[3]Yale University, New Haven, CT, 06520, USA

Oceanic plateaus are igneous mountains constructed by massive eruptions of basalt and related igneous rocks. Because they are hidden beneath remote parts of the oceans, the structure and evolution of these mountains are poorly known. Shatsky Rise, in the northwest Pacific, is an oceanic plateau that formed during the Late Jurassic and Early Cretacous (~145-125 Ma) near a triple junction of spreading ridges. It consists of three large volcanic massifs and a narrow volcanic ridge. It is inferred that eruptions began with the largest massif (Tamu Massif) and waned through time through the formation of the other massifs. Tamu Massif is a supervolcano, i.e. a single volcanic edifice, like a seamount, but much bigger. It has an area similar to Olympus Mons on Mars, the largest volcano in the solar system. Geophysical data show that Tamu Massif has a central summit, and a shape that is symmetric across its axis. Volcanic slopes are low, implying long, low viscosity lava flows. A seismic profile across the volcano axis shows lava flows flowed outward from the axis. Seismic profiles in some spots over these axes show normal faulting that imply volcanic rift zones. Coring on Integrated Ocean Drilling Program (IODP) Expedition 324 recovered basalt flows of two types: pillows and massive flows. Pillows are indicative of normal seamount volcanism at low effusion rates whereas the massive flows imply high volume lava flows with high effusion rates. Massive flows are typical of continental flood basalts and are also found on other large plateaus. On Shatsky Rise, thick massive flows are found on Tamu Massif, whereas pillows and thin massive flows characterize the other massifs. This trend supports the idea that Tamu Massif was formed by an initial massive eruptive event and afterwards volcanism waned as other massifs were erupted. Shallow water fossils and depth-diagnostic rocks and sediments indicate that the summits of Shatsky Rise massifs were near sea level at the time of formation. Expedition 324 cores recovered hyalo-clastites and volcanic sedimentary rocks implying that explosive volcanism was significant near the volcano summit. Heavy alteration of rocks from the shallower parts of the volcanoes suggests that warm fluids flowed through the volcano summit rocks. In sum, the structure and evolution of Tamu Massif appears much like that of a typical seamount, except that it is much bigger and was built by correspondingly larger and widespread eruptions.

Environmental impacts of abandoned VMS deposits: An example case from NE Turkey

E.S. SAĞLAM[1]*, M. AKÇAY[1] AND D.N. ÇOLAK[2]

[1]Dept. of Geology, Karadeniz Technical University, 61080, Trabzon, Turkey (*correspondence: ssaglam@ktu.edu.tr, akcay@ktu.edu.tr)

[2]Dept. of Biology, Karadeniz Technical University, 61080, Trabzon, Turkey (dilsatcolak@hotmail.com)

The eastern Black Sea Region (NE Turkey) is well known for massive sulphide deposits. The abandoned mines near Espiye (Giresun, NE Turkey) are characterised by widespread slag disposed of along valleys into streams and tributaries causing serious environmental pollution. This study presents physical and chemical features of stream and spring waters and their degrees of pollution based on a sampling programme in August, 2010.

In the Ficklin diagram [1], three groups of samples collected from highly polluted mine effluent (along Acısu tributary), areas of slag disposal sites and upstream from the mine effects plot in high acid-extreme metal and high acid-high metal fields, acid-high metal field and near neutral-low metal field, respectively. The water samples from the zones near the effluent are highly polluted and contain extremely anomalous values of S, Fe, Cu, Zn, As, Cd, Pb with values as high as 1375, 1130.12, 71.37, 53.08, 2.15, 0.21, 0.1 mg/L, respectively. After about a km downstream from the effluent, these values are diluted to a great extent, especially for Pb, Fe and As. Elevated levels of other elements continue further. In contrast, the waters of tributaries draining slag piles have much lower levels of heavy metals, with some elements such as As and Fe having undetectable concentrations.

In the Acısu tributary, SO_4 is highly enriched (up to 5410 mg/L) due to microbial oxidation of sulfides. 16S rRNA analyses on water samples from this area indicates presence of *Acidithiobacillus ferrooxidans* at 98% precision.

The sediments are in compliance with this, and are enriched in As, Mo, Pb, Cu, Cd, Zn, Hg and Fe based on geoaccumulation (I geo) values [2]. These values are significantly high and denote heavy contamination in stream sediments along the Acısu tributary. The sediments with the surface waters are potentially hazardous to the environment adjacent to the abandoned Karaerik mine and thus are in need of remediation.

Prograde P-T path of a ~3.2 Ga tectonometamorphic event from Assegaai greenstone belt, SE Kaapvaal Craton

L. SAHA[1]*, A. HOFMANN[2] AND H. XIE[3]

[1]School of Geological Sciences, UKZN, Durban, SA (*correspondence: saha.lopamudra@gmail.com)

[2]Department of Geology, UJ, Johannesburg, SA

[3]Beijing SHRIMP Center, Beijing, China

P-T pseudosections are being used extensively in modern petrological studies not only to determine the P-T conditions of peak metamorphism but to establish how these conditions have been achieved, i.e. the tectonic scenario related to such processes [1]. In the present study we have used P-T pseudosection to determine the prograde P-T path from amphibolite facies garnet-staurolite-chlorite-albite-quartz-ilmenite-bearing pelitic schist from the Archaean Assegaai greenstone belt, SE Kaapvaal craton.

The pelitic schist forms part of a supracrustal sequence consisting of amphibolite, BIF, talc-tremolite schist, quartzite and calc-silicate. Within the metapelite, garnet and staurolite form the peak metamorphic assemblage and are replaced by chlorite. Absence of inclusions of any prograde mineral within garnet and staurolite porphyroblasts hinders application of any conventional thermobarometry to determine the prograde and peak metamorphic conditions.

Pesudosection analysis reveals that the garnet and staurolite assemblage was formed along a clockwise P-T path by breakdown of chloritoid: Fe-Chloritoid = almandine + Fe-Staurolite, a common reaction in pelitic rocks under amphibolite-facies conditions. Peak P-T conditions are estimated at~ 8 kbar, 600-625°C. Chlorite and albite were formed during post-peak decompression and cooling by breakdown of garnet-staurolite and paragonite, respectively.

Zircon crystallisation ages ($^{207}Pb/^{206}Pb$, SHRIMP) obtained from syntectonic quartzofeldspathic veins derived from partial melting reveal that peak metamorphism occurred ~3.18 Ga. The clockwise P-T path from the metapelite indicates a collisional tectonic event similar to that reported from other greenstone belts of SE Kaapvaal craton [2, 3], that marked stabilisation of the craton at ~3.2 Ga.

Geochemical and age of collision-related volcanism following the closure of the Neotethys Ocean (Lesser Caucasus, Armenia)

L. SAHAKYAN[1]*, D. BOSCH[2], M. SOSSON[3], O. BRUGUIER[2], Y. ROLLAND[3], GH. GALOYAN[1] AND A. AVAGYAN[1]

[1]Institute of Geological Sciences, National Academy of Sciences, 24[a] Baghramyan avenue, Yerevan, 0019, Armenia (*correspondence: lilitsahakyan@yahoo.com)
[2]University Montpellier 2, Place Eugene Bataillon 34095, Cedex 05, France (bosch@)gm.univ-montp2.fr)
[3]University of Nice-Sophia Antipolis, UMR Geoazur, OCA, 250 rue A Einstein 06560 Valbonne 2, France

In the Lesser Caucasus in Armenia, collision of the South-Armenian Block (SAB) and Eurasia started during the Paleocene and was forming the Amasia-Sevan-Akera Suture zone (ASASZ). Magmatism covering the suture zone occurred during this collision and is particularly widespread since Middle Eocene. Moreover magmatism occurred after the Arabian plate collision with Eurasia since Miocene. In order to add constraints to the geodynamic context of these magmatisms, an extensive geochemical study (major & trace elements, isotopes) and geochronological study has been developped on 19 magmatic rocks. Only scarce geochemical and geochronological data are available on the Middle to Late Eocene volcanism which is associated to calc-alkaline to alkaline mildly alkaline compositions.

12 zircon grains extracted from a rhyodacite sample from SAB have been dated by U-Pb laser ICP-MS ablation which gives a well-concordant middle Miocene age of 14.6±0.2 My.

The rocks are overall characterized by enrichment in large ion lithophile elements (LILE) and show significant enrichment in light rare earth elements (LREE) compared to heavy rare earth elements (HREE) with $(La/Sm)_N$ evolving from 2.2-7.3 and $(La/Yb)_N$ ratios ranging between 2.5 and 16 and up to 47 for the rhyodacite. Extended rock-patterns of the ASASZ samples show positive anomalies in Pb, Sr, Ba associated to negative Nb and Ta spikes typical of subduction or back-arc environments. A more continental character is evidenced for trachyandesites of late Eocene and rhyodacite of middle Miocene ages due to possible slab retreat, a break off and continental crust heating by rising of the astenospheric mantle (Sosson *et al*. 2010).

Geochemical reactivity of submarine tailings from the Batu Hijau Mine

ALI SAHAMI[1], JORINA WAWORUNTU[2] AND SKYA FAWCETT[1]

[1]Lorax Environmental Services Ltd, 2289 Burard Street, Vancouver, British Columbia, Canada (alis@lorax.ca, Skya.Fawcett@lorax.ca)
[2]PT Newmont Nusa Tenggara, Jl Sriwijaya 258, Mataram, NTB, Indonesia (Jorina.Waworuntu@nnt.co.id)

Batu Hijau is an open pit mine, located in south-western Sumbawa, Indonesia, with economic mineral recovery achieved through sulphide flotation and copper-gold concentrate production. Mine tailings are discharged to Senunu Submarine Canyon via an engineered deep sea tailings placement (DSTP) system. The tailings pipeline terminus is at a water depth of 125 meters from which solid tailings flow down the canyon slope to settle at depths approximately 2,000-4,000 meters. The ore processed at Batu Hijau is categorized as fresh ore from the pit, medium and low grade, with the majority of the latter two reporting to the ore stockpile where they may be stored for several years prior to processing. The fresh ore tailings contain primarily unreactive gangue material and residual sulphides. Extensive global scientific research as well as site-specific data has conclusively demonstrated that fresh sulphidic tailings are geochemically stable when permanently stored under a water cover due to greatly reduced sulphide oxidation rates arising from the limited availability and diffusibility of oxygen in water as compared to air. Conversely, the stockpiled ore is exposed to oxygen and rain prior to processing resulting in the partial oxidation of precursor sulphides and formation of secondary weathering and oxidation products. Disposal of oxidized minerals within the tailings to the marine environment may result in the reductive dissolution of oxide and oxyhydroxide phases potentially resulting in an increase in mobility of metals to overlying seawater. Field experiments were conducted in 2010 to assess the geochemical reactivity of tailings derived from processing of fresh and partially oxidized ore in the marine environment. Redox sensitive parameters and trace metals in tailings porewater and the overlying seawater were measured at high spatial resolution through the use of dialysis arrays (peepers). Mobility of contaminants of concern and the geochemical reactions governing the reactivity of submarine tailings were assessed from the porewater geochemical data. Copper efflux rates of less than 0.7 $\mu g/cm^2$/year were calculated for both types of tailings from the porewater chemical profiles.

Studying soft X-ray absorption edges under extreme conditions

CHRISTOPH J. SAHLE[1], CHRISTIAN STERNEMANN[1], ALEXANDER NYROW[1], KOLJA MENDE[1], MAX WILKE[2], CHRISTIAN SCHMIDT[2], JULIEN DUBRAIL[2], METIN TOLAN[1], LAURA SIMONELLI[3], VALENTINA GIORDANO[4] AND JOHN S. TSE[5]

[5]Department of Physics, University of Saskatchewan, Saskatoon S7N0W0, Canada

The study of absorption edges has proven a powerful tool to investigate the local and electronic structure of materials. [1] Absorption edges of medium or high Z elements can be accessed using X-ray absorption spectroscopy even under extreme conditions. However, the *in situ* study of low Z elements absorption edges under extreme conditions, i.e. high temperature and high pressure, is not feasible using soft X-rays or electrons as probe. Here, non-resonant X-ray Raman scattering (XRS) as an energy loss technique enables one to choose the energy of the primary X-ray beam freely and thus gives access to shallow absorption edges even in highly absorbing sample environments such as diamond anvil cells. [2]

In this contribution we enlighten the approach of XRS as a tool to access shallow absorption edges under extreme conditions and present first results of *in situ* studies of solids and liquids under high temperature and high-pressure conditions. In particular, the Ba N_{45}- and Si L_{23}-edges of the silicon clathrate Ba_8Si_{46} was studied at pressures up to 19.4 GPa. Data of the Si and Al L_{23}-edges of hydrous sodium silicate and alumosilicate glasses are presented and compared to the first *in situ* high pressure - high temperature data on hydrous silicate melts. In addition, the O K-edge of supercritical water was studied to acquire insights into its local structure. Finally, the potential of XRS for determining the Fe oxidation state from the Fe L and/or M-edge is explored.

[3]Dept. Earth Science, Univ. California, Riverside, CA, USA
[4]Sch. Earth Sc. & Res., Univ. Geosciences, Beijing, China
[5]Dept. Chem/Biochem, Arizona State Univ. Tempe, AZ, USA

Complex multicellular organisms including early metazoans appeared in the Ediacaran Period shortly after the termination of the late Cryogenian (Marinoan) glaciation about 635 million years (Myr) ago. Given that metazoans have high respiratory demands, it has been speculated that the termination of the Marinoan glaciation, the rise of oxygen, and evolution of complex life forms were casually linked. Previously published geochemical data, however, suggest that a major increase in the extent of ocean oxygenation did not happen until the middle Ediacaran Period, 50 Myr after the first appearance of animal fossils. This later oxygenation is arguably linked to the termination of a much less severe Gaskiers glaciation around 580 Myr ago. Here we report new geochemical data from early Ediacaran (ca. 632 Myr ago) organic-rich black shales of the basal Doushantuo Formation in South China. Iron speciation and sulfur isotope data indicate pervasive deep-water euxinia (anoxic and sulphidic) and an increase in the marine sulphate reservoir from the oxidative weathering of crustal sulphides. High molybdenum (Mo) and vanadium (V) enrichments (Mo: 120 parts per million [ppm] and V: 6000 ppm) in these shales record an increase in the oceanic Mo and V reservoirs and hence point toward a significant post-glacial oxygenation event. Our data provide evidence for co-evolution of marine redox conditions and early animals in the immediate aftermath of the Marinoan glaciation.

Inventory of particulate matter from all possible major sources for air quality forecasting during Commonwealth Games 2010 in Mega City Delhi

S.K. SAHU* AND G. BEIG

Indian Institute of Tropical Meteorology, Pune-411008 India (*corresponding author: saroj@tropmet.res.in)

Mega city Delhi, is facing large urban agglomerations which is one of the largest urban concentrations in South Asia and a fast growing economic center. Adverse impact of air pollution on human health, welfare and ecosystem is a key environmental problem in Indian mega cities as well as worldwide. High resolution emission inventory (EI) is one of the important and essential critical input to air quality modeling and should be as latest as possible. As part of the System of Air quality Forecasting and Research (SAFAR) project developed for air quality forecasting during the Commonwealth Games (CWG) – 2010, a high resolution emission inventory of PM_{10} and $PM_{2.5}$ have been developed for the mega city Delhi for the year 2010. The comprehensive inventory involves detailed activity data and developed for a domain of 70km×65km with a 1.67km×1.67km resolution covering Delhi and surrounding region using Geographical Information System (GIS) based statistical modeling. Developed high resolution EIs of PM_{10} and $PM_{2.5\ for}$ the air quality forecasting includes the technological specific activity data for different sectors were collected from primary source through one year field campaign as well as from secondary source which is first of its kind of attempt have been made in this work not only to fill the gap but also improve the understanding, uncertainty and accuracy of inventory.. It has been found that total emission of PM_{10} and $PM_{2.5}$ over the study area is found to be 236 Gg/yr (as shown in Fig.1) and 94 Gg/yr respectively. The contribution of windblown road dust is found to be as high as 131 Gg/yr for PM_{10} which is unusual. The relative contributions of different sectors are discussed with possible target for mitigation.

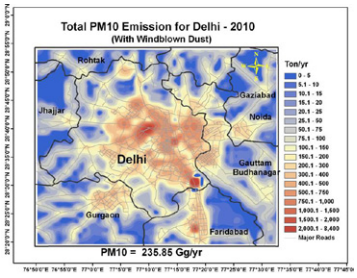

Figure 1: PM_{10} emission from different sources over Mega city Delhi.

Positive Ce anomalies and U-enrichment in Archean volcanics: Implications for oxygenated oceans

N. SAID[1]*, R. KERRICH[2] AND C. MANIKYAMBA[3]

[1]School of Earth Sciences, University of Western Australia, Western Australia 6011 (*correspondence: nsaid@cyllene.uwa.edu.au)

[2]Geological Sciences, University of Saskatchewan, Canada S7N 5E2 (robert.kerrich@usask.ca)

[3]NGRI, Hyderabad 500 007, India (cmaningri@yahoo.com)

Inference of reducing conditions in the Archean are mostly based on local evidence such as paleosols. Accordingly, new data from the scale of ocean basins is presented. Boninites in unweathered volcanic sequences of the 2.7 Ga Gadwal greenstone terrane, Dharwar craton, India, record systematic positive anomalies of U relative to Th on primitive mantle normalised diagrams, where Th/U spans 0.9-2.1 versus ~ 4 in tholeiitic basalts [1]. Such patterns are present in Phanerozoic forearc boninites where oxygenated fluids are released from the subducting slab into forearc mantle wedge. Adakites, interbedded with pillow basalts, of the ~ 2.6 Ga Hutti greenstone terrane, Dharwar craton, record Ce/Ce* ~ 1.2-1.3 with Th/U ratios <4 consistent with additions of Ce and Th from oxygenated ocean waters. Systematic positive anomalies of Ce, where Ce/Ce* spans 2.1 to 11.4, are present in basalts and rhyolites of a 2.9 Ga submarine volcanic sequence, Murchison Province, Western Australia; these are true Ce anomalies as Pr/Pr*<1. These extreme anomalies are attributed to a stratified ocean, with oxygenated surface waters but reduced bottom waters, in which Ce^{4+} was sequestered, then co-precipitated with Fe-, Mn-oxides and hydroxides distal to a submarine hydrothermal system that generated the Golden Grove Zn-Cu VMS deposit. Archean BIF of the Dharwar craton preserve negative Ce anomalies, complementary to the positive anomalies in volcanic sequences. Collectively, these observations, at the scale of ocean basins, preserve the record of an oxygenated marine environment ~ 400 Ma before the so-called great oxidation event (GOE) at ~ 2.4 Ga.

Spectroscopic estimation of SiO_2 for characterizing clays in the Brahmaputra river sediment

BHASKAR J SAIKIA

Department of Physics, ADP College, Nagaon -782 002, India (vaskar_r@rediffmail.com)

We report here the characterization of sediments from the Brahmaputra river. The samples were collected along the stretch of the Brahmaputra river channel. Analysis of the sediment is presented with the help of FTIR and XRF spectroscopic methods. Clay mineral analyses provide evidence for diagenesis. The maturity index of sediment and extinction coefficient of SiO_2 inclusion reflects the nature of erosion quality of the river.The major constituents of the samples are silica, alumina, which confirms the chemical analysis of clay. The LOI was determined at 800°C. The relatively large difference in the LOI values between 9.87 wt % and 22.21 wt % indicates that greater loss on ignition took place during the calcination step. This is largely due to the giving off of structural hydroxyl water and volatile organic components. The samples showed SiO_2 contents between 34.77 and 56.41 wt%. The grain size of the sediment samples are measured from the SiO_2/Al_2O_3 (wt %) ratio. The maturity index is invalidating with gain size of the samples, which indicate that the maturity increases with the decrease of quartz content and grain size. The correlation of the K_2O, TiO_2, Na_2O and MgO with Al_2O_3 indicate that these compounds of the sediment samples are completely associated with detrital phases of erosion process of the river. The region 400-800 cm^{-1} represents generally the bands assigned to the O-Si-O and O-Al-O bending region. The region 800-2000 cm^{-1} contains the Si-O and Al-O stretching modes and the region 2600-4000 cm^{-1} represents the OH stretching modes. In the O-Si-O and O-Al-O bending region of the infrared spectra of the studied samples are complex and there is a significant overlap between the quartz and kaolinite bands. The deposition of kaolinite in the sediment samples of the different stages of the river track can be differentiated on the basis of its quartz content. Comparison between the maturity index and extinction coefficient of the sediment samples shows a marked increase of SiO_2 content.

Spectroscopic characterization of olivine due to Fe/Mg in Dergaon H5 chondrite

BHASKAR J. SAIKIA[1], G. PARTHASARATHY[2] AND R.R. BORAH[3]

[1]Department of Physics, ADP College, Nagaon -782 002, India (vaskar_r@rediffmail.com)

[2]National Geophysical Research Institute (CSIR), Hyderabad-500 007, India (gpsarathy@ngri.res.in)

[3]Department of Physics, Nowgong College, Nagaon -782 001, India (rashmirekha_b@rediffmail.com)

The effect of the Fe and Mg ratio of olivine group $[(Mg_nFe_{2-n})SiO_4]$ in the Dergaon H5 chondrite has been investigated by Fourier Transform infrared (FTIR) and X-ray florescence (XRF) analysis. The change of peak positions of the SiO_4 tetrahedra in the stretching region have been observed with the Fe, Mg contents. The special interest is given in systematic band shifts in forsterite- fayalite series. The SiO44– tetrahedra are isolated in the structure and linked by cations Fe^{2+} or Mg^{2+} in octahedral positions. The cation positions in the structure can be filled with iron and magnesium in all possible ratios and sometimes it is occupied by Ca^{2+} or Mn^{2+}. The iron and magnesium (Fe/Mg) ratio in olivine is expressed as the forsterite content, and is calculated from the atomic percentage of Fe and Mg in the measurements. The variation of fosterite and fayalite compositions are Fo 66-89 and Fa 10-33 mol % respectively. The plot of Fo and Fa against the corresponds wavenumbers for the bands 1to5 of olivine group of the meteorite sample shows a linear variation for Fo and Fa in a different direction. The factors responsible for the frequency decrease of the absorption bands with an increase in iron may be the effects of replacing an ion of smaller radius (Mg^{2+} of radius 0.66Å) with a larger one (Fe^{2+} of radius 0.74 Å). The infrared bands in the 10mm region of the meteorite sample exhibits good agreement with the XRF results. In the 600 - 400 cm^{-1} region, the pyroxene shows a ‘V’ shape in the infrared spectra. This band shape depends upon the Mg/Fe ratio in the sample.

Spectroscopic studies of silicate minerals from North-Eastern India

BHASKAR J SAIKIA[1] AND N C SARMAH[2]

[1]Department of Physics, ADP College, Nagaon -782 002, India (vaskar_r@rediffmail.com)
[2]Department of Physics, Dibrugarh University, Dibrugarh-786 004, India (ncsdu@yahoo.com)

The samples we reported here are collected from North-Eastern region of India in their almost pure form of quartz crystal and silicates. Here an overview of the basic morphological, physico-chemical and crystallographic characteristics of the silicates is given. Particular emphasis is given to make a catalogue of silicates on the basis of structural classifications. The colour of the quartz crystal of these locations indicates the inclusion of the trace elements present in the host rocks. The compositional and structural studies were carried out at room temperature by using X-ray fluorescence (XRF), electron microprobe (EPMA) analyses and Fourier transform infrared (FTIR) spectroscopic techniques. Differential thermal analysis (DTA) and thermo gravimetric studies were also performed. The results of the compositional analysis of the samples are comparable to the standard literature. The compositional analysis of the samples exhibits that the major trace elements are Fe, Al, Ca and Mg. The optical properties are compared with the standard literature and the results are found to be satisfactory. An attempt to identify the minerals using the FTIR spectroscopy and to classify them according to their structural characteristics is performed. The crystallinity investigation throws light on the dependency on temperature and pressure during formation. The purity and distributions of the samples can also helps on the economic and industrial values of the silicates of the study region.

A rough idea about the silicate minerals of the study area can be lead from this investigation. Since silicates are known as rock forming mineral, one can have a fairly good idea about the rocks found in these areas.

Complexation of Eu^{3+} with humic substances studied by time-resolved laser fluorescence spectroscopy and parallel factor analysis

TAKUMI SAITO[1]*, STEVEN LUKMAN[1], NOBORU AOYAGI[2], TAKAUMI KIMURA[2] AND SHINYA NAGASAKI[1]

[1]The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, 113-8656, Japan (*correspondence: takumi@flanker.n.t.u-tokyo.ac.jp, stevenlukman@flanker.n.t.u-tokyo.ac.jp, nagasaki@nucler.jp)
[2]Japana Atomic Energy Agency, 2-4 Shirakatashirane, Tokai-mura, Ibaraki 319-1195, Japan (aoyagi.noboru@jaea.go.jp, kimura.takaumi@jaea.go.jp)

Humic substances (HS) are heterogeneous and ill-defined organic nanoparticles widely found in soil and aqueous environments. HS are known as effective complexants for inorganic and organic contaminants, mediating their migration through geosphere. Although many researches have been devoted to study binding of metal ions to HS mostly in terms of macroscopic binding amounts, detailed information on the binding processes are still limited, because of the heterogeneity and variety of HS from different origins. In this research, we investigated the binding of Eu^{3+} to various HS by time-resolved laser fluorescence spectroscopy (TRLFS) hyphnated with parallel factor analysis (PARAFAC). TRLFS is an analytical technique sensitive to physico-chemical forms of a target fluorescent metal ion, which can be further reinforced by combining with a powerful multivariate data analysis, PARARAC [1].

Binding of Eu^{3+} to HS purchased from the International and Japanese Humic Substances Societies was examined by TRLFS as a function of pH. A series of TRLFS data obtained for a certain HS were processed by PARAFAC to determine the number, spectra, decays and relative concentrations of factors. Except for one HS, three factors were necessary and enough to describe the variations in the data sets. These factors were distinctive with each other and could correspond to different Eu^{3+} species bound to HS. Each of the factors has some similarity among different HS, suggesting the presence of similar binding environments in different HS. It was further revealed that there were systematic trends between the spectra, decays and concentrations of the factors and the physical and chemical properties of HS. The observed trends will be used to deduce the characteristics of the different binding environments for Eu^{3+} in HS.

Viscosity measurements of FeO-rich silicate melts and its implication for the lunar crust formation

R. SAKAI*, I. KUSHIRO, H. NAGAHARA, K. OZAWA AND S. TACHIBANA

Department of Earth and Planetary Science, The University of Tokyo, 7-3-1 Hongo, Tokyo 113-0033, Japan (*correspondence: rsakai@eps.s.u-tokyo.ac.jp)

The anorthite crust of the Moon has been thought to be the product of large-scale differentiation in the cooling lunar magma ocean, and the bulk composition of the Moon has been estimated to be richer in FeO than the bulk silicate Earth (e.g. [1]). The FeO content is a critical parameter for density and viscosity of silicate melt, and precise determination of those parameters is important for quantitative evaluation of the lunar curst. Contrary to the density, viscosity of silicate melts show complicated dependence on pressure and composition. Hence, experimental determination of viscosity of FeO-rich silicate melts is important. We have carried out viscosity measurements with the falling sphere method for silicate melts suitable for the lunar magma ocean.

The starting materials are glasses with three different compositions, which are fractionated in terms of mantle minerals to the first appearance of anorthite from the bulk silicate Earth with FeO-enrichment with various degrees.

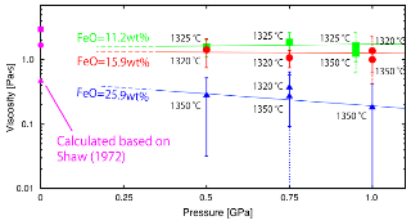

Figure 1: Viscosity of silicate melts responsible for differentiation of the Moon.

The results are shown in Figure 1, which shows weak (or slightly negative) dependence of viscosity on pressure and clear negative dependence on the FeO contents.

Figure 1 suggests little pressure dependence of viscosity for the lunar magma ocean melt at least to P>1GPa (~ 100km). The little or weak negative pressure dependence of the melt of the magma ocean in addition to high density due to high FeO contents result in effective flotation of anorthite, that is, effective formation of the anorthite crust. Our quantitative model predicts that the initial FeO content of the Moon that finally generated the anorthosite crust with the thickness of 45km was 10 - 13 wt%, which is more than the bulk silicate Earth.

Continuous marine sediment cores during 5 myrs in the Bowers Ridge (Sites U1340 and U1341) and continental slope of the Aleutian Basin (Sites U1341, U1343, and U1344) of the Bering sea obtained by the IODP expedition 323 in 2009. Age models of the drilled cores are constructed using oxygen isotope stratigraphy, bio- and magneto-stratigraphy with astronomical calibration of non-destructive XRF core measurements (TATSCAN-F2). Estimated sedimentation rates during interglacials are two to three times higher than that of glacials.

Marine primary productivity, Si/Al ratio measured using TATSCAN-F2 representing biogenic silica content, exhibits large glacial-interglacial cycles during the Plio-Pleistocene. and. The productivity is relatively high, similar to that of today's 'green-belt', during the interglacial periods with increasing glacial-interglacial variability after NHG, and even larger amplitude variations during last 500 kyrs. Changes of biological productivily were closely related to terrigenosu inputs representing by K/Al and Fe/Al ratio that those elements derived from the Alaskan large rivers during the past 5 myrs.

Geochemical studies in Piraeus port sediments, Greece

F. SAKELLARIADOU

Dept of Maritime Studies, University of Piraeus, 18532 Piraeus, Gr (fsakelar@unipi.gr)

Introduction and methodology

Piraeus port surface sediments were geochemically studied. Total metal content and metal partitioning [1] were determined by Atomic Absorption Spectrophotometry. Metal partitioning is presented as percentages in pie diagrams. The DOM aqueous extracts were characterized by fluorescence spectroscopy for distinguishing different classes of organic components. Mono dimensional spectra [2] and contour plots (EEMS) are given.

Discussion of Results

Sediments show a high metal enrichment, especially in the outer part of the central port for Fe, Pb, Zn, Cu, Cd and Sn while seawards the outer cargo terminal for Mn, Ni, Cr and Zn. In all samples there are significant easily hydrolyzed Zn, Cu and Cd components, easily available to the biota. A carbonate related contribution of Mn and Ni was found. More than half of Cu is either bound to various forms of organic matter and/or present in sulphide minerals.

DOM consists of either simple aromatic units [2, 3] (phenolic- like, hydroxyl substituted benzoic and cinnamic acid derivatives, coumarins and alkaloid-like hydroxyquinolines) or compounds such as humic- and fulvic-like moieties and protein derived materials [4].

Iron isotope composition of the Middle Eocene ooidal-oncoidal ironstones and the associated lateritic paleosols from the Bahariya Depression, Western Desert, Egypt

W. SALAMA[1]*, S. WEYER[2], R. GAUPP[3] AND M.M. EL AREF[1]

[1]Department of Geology, Faculty of Science, Cairo University, Giza 12613, Egypt (*correspondence: walidsamir@daad-alumni.de)

[2]Institute of Mineralogy, Leibniz University Hannover, Callinstr. 3, 30167 Hannover

[3]Institute of Earth Sciences, Friedrich Schiller University, 07749 Jena, Germany

The Middle Eocene ironstones of the Bahariya depression, Western Desert, Egypt are subdivided into two marine sequences. The lower ironstone sequence consists mainly of peritidal stromatolitic and ooidal-oncoidal ironstone facies that were later subjected to subsurface alteration by acidic hot groundwater. The upper ironstone sequence consists mainly of mud-ironstones. The upper surfaces of these ironstone sequences were exposed to subaerial weathering processes, along which lateritic iron ores and paleosols were formed.

Iron isotope measurements were used to differentiate between the subaerial and subsurface alteration processes affecting the original marine ironstones. The iron isotope composition of the lateritic paleosols displays low δ^{56}Fe values of -0.15‰ to -0.85‰, while the stromatolitic and ooidal-oncoidal ironstones have high δ^{56}Fe values of +1.14 ‰ to +2.28 ‰. The negative δ^{56}Fe values of the paleosol are compatible with the simple internal redistribution of originally light (i.e. organically- bound) iron by dissolution-reprecipitation processes in a closed system. Multiphase iron recycling through multiple oxidation and reduction steps may have resulted in lower δ^{56}Fe [1, 2]. The negative δ^{56}Fe may have been preserved by complete or near-complete oxidation of low δ^{56}Fe aqueous Fe^{2+}. The positive δ^{56}Fe values of the marine ironstones are most probably related to a secondary subsurface alteration by ascending acidic groundwater. The acidity and the redox gradient of the groundwater resulted in the oxidation of pyrite pockets of the Cenomanian glauconitic clastics. This process involved transport of aqueous Fe^{2+} through the marine ironstone sequences. The production of high δ^{56}Fe values can be attributed to partial oxidation of low δ^{56}Fe Fe^{2+}_{aq} in a close proximity to an aqueous anoxic-oxic boundary. The high δ^{56}Fe values for oxides indicate an open system with respect to Fe [3]. Our findings indicate that the application of iron isotopes may provide important information about environmental conditions dominated during the Middle-Eocene ironstone formation and helps to determine precisely the paleoweathering surfaces within the marine ironstone sequences.

Development of steady-state surface topography and the determination of dolomite dissolution rates

G.D. SALDI[1]*, D. DAVAL[1], M. XU[2], S.R. HIGGINS[2] AND K.G. KNAUSS[1]

[1]ESD, LBNL, Berkeley CA 94720, USA (*correspondence: gdsaldi@lbl.gov)
[2]Department of Chemistry, WSU, Dayton, OH 45435, USA

The knowledge of the elementary mechanisms controlling the reactivity of mineral surfaces which undergo dissolution is critical to the development of rate-models that can accurately describe the processes occurring at the mineral/water interface. The correct interpretation of experimentally measured steady-state dissolution rates is affected by the duration of the experiments and by the development of a steady-state surface morphology, particularly at conditions close to equilibrium [1, 2].

Dolomite dissolution has been studied by hydrothermal atomic force microscopy (HAFM) on fresh-cleaved crystal surfaces as a function of the chemical affinity from 60 to 100 C, while a parallel series of experiments has been performed on a mineral powder of the same origin, under the same conditions, using a mixed-flow reactor.

The microscopic observations show the development of rectangular-shaped etch pits at mildly acidic pH's and a progressive decrease of the step velocities accompanied by a concurrent rounding of the acute step morphology when a carbonate-rich solution is introduced in the AFM cell. This change required several hours to be clearly manifested and effectively slow the rates of dissolution. Depending on the previous history of the sample, the same morphological steady-state may even require a few days to be attained. The results obtained from bulk experiments confirm the inhibiting effect of both carbonate species and aqueous Ca on dissolution and indicate that this drastic decrease of the rates is the consequence of a lower etch pit density.

Biologically enhanced silicate mineral dissolution for CO_2 sequestration

S.S.S. SALEK[1], R. KLEEREBEZEM[1], H.M. JONKERS[2] AND M.C.M. VAN LOOSDRECHT[1]

[1]Delft University of Technology, 2628BC Delft, The Netherlands
[2]Delft University of Technology, 2628CN Delft, The Netherlands

During the past two centuries release rate of CO_2 to atmospheric reservoir has been increased by combustion of fossil fuels [1]. The consequence of CO2 accumulation in the atmosphere is reflected as global climate change which is one of the main challenges facing humanity today [2]. CO_2 fixation as carbonates has been introduced as one the most sustainable and promising mitigation methods [3]. The efficiency of this method however is mainly limited by the raw material availability (Ca or similar divalent cations) [4]. Naturally occurring alkaline silicates are rich in divalent cations and have large reservoirs on earth; however with low dissolution rate. In the present study we describe dissolution enhancement of an alkaline silicate (wollastonite) during microbial anaerobic fermentation producing organic acids. Fermentation is an intermediate step in the anaerobic digestion process, a common process used for industrial or domestic purposes to manage waste and/or to release energy. Integration of wollastonite in an anaerobic fermentation process can result in release of Ca to the solution and neutralization of the process. ICP-OES and HPLC measurements showed an increase of dissolution rate by both proton release resulted from dissociated organic acids and complexation of Ca with these organic-products. Upon subsequent degradation of the organic acids to biogas, inorganic CO2 will be sequestered as carbonate mineral. This work could provide an alternative route to reduce climate impacts from waste treatment plants.

TIMS U-Pb dating of bastnäsite, calzirtite and tantalite as a powerful tool for timing of rare-metal granites and carbonatites (Eastern Siberia)

E.B. SALNIKOVA*, S.Z. YAKOVLEVA, A.B. KOTOV AND YU.V. PLOTKINA

IPGG RAS, St.Petersburg, Russia
(*correspondence: katesalnikova@yandex.ru)

Complex Ti, Nb-Ta and Zr oxides, primary HFSE hosts like baddeleyite, zirconolite, perovskite, pyrochlore are well known minerals appropriated for U-Pb dating of carbonatites, phoscorites as well as granitic pegmatites of the rare-element class. We propose to extend this list with calzirtite, tazheranite and bastnäsite.

Bastnäsite ((LREE)(CO_3)F) is a typomorphic mineral of siderite carbonatites from the Karasug (REE, Ba, Sr, F, Fe) deposit (Tuva Republic) Concordant U-Pb age at 118±1 Ma was obtained for bastnäsite which is in good agreement with Sm–Nd and Rb–Sr ages [1]. The minerals of this group are widespread and, in particular, represent the major economic LREE minerals in the deposits related to nontraditional carbonatite complexes, as well as occur in highly alkaline pegmatites, alkaline granites and scarns.

Tazheranite ($CaTiZr_2O_8$) and calzirtite ($Ca_2Zr_5Ti_2O_{16}$) are the characteristic accessory minerals in alkalic and ultramafic complexes associated with carbonatites. A Tazheran (SW Lake Baykal) calzirtite and tazheranite yielded a Concordia U-Pb ages at 466±2 Ma and 464±2 Ma respectively which are consistent with zircon U-Pb age at 471±5 Ma [2] as well as perovskite U-Pb age at 462.8±2.5 Ma [3].

For the first time U-Pb isotopic analyses were carried out on tantalites from three suites of pegmatites in East Sayan large-scale rare-metal province. The ages of 1838±3 Ma 1824±7 Ma and 1738±5 Ma have been obtained. These data demonstrate that mineralization is just for 30-100 Ma younger than country post-collisional Sayan granites (1858±20 Ma) [4].

Our study advertises bastnäsite, calzirtite, tazheranite as well as tantalite as promising tool for U-Pb timing of mineralization related to plumasitic type rare-metal granites and some of carbonatites.

A new debate on the origin of granitoid rocks from Dehnow area (NE Iran), based on isotopic data

R. SAMADI[1]* AND N. SHIRDASHTZADEH[2]

[1]Science and Research Branch, Islamic Azad University, Tehran, Iran
(*correspondence: ramin_samadi@hotmail.com)
[2]Department of Geology, University of Isfahan, Isfahan, Iran

Introduction

Magma origin of Dehnow tonalite was always under debate. [1] revealed valuable isotopic data for these rocks and suggested that they are S-type. [2] introduced them I-type based on whole rock geochemistry (e.g. Zr & Zn vs. SiO_2 plots, etc) and mineralogy. In this work, we try to illuminate the fact by putting isotopic values from [1] on figure below.

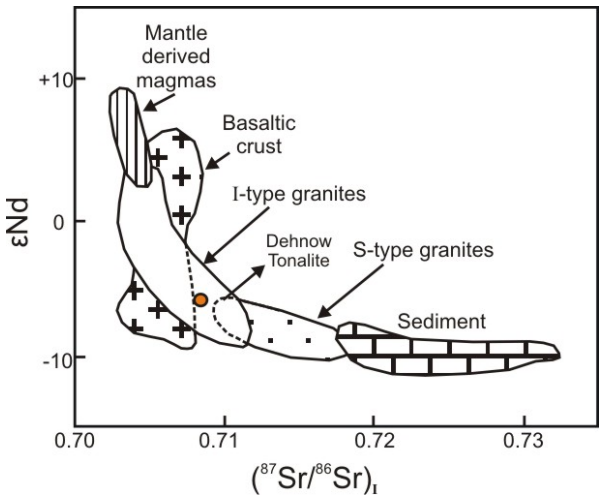

Figure 1: εNd vs. Sr isotope ratio [3, 4].

Discussion

In fact, according to figure 1, isotopic data of [1] ($^{87}Sr/^{86}Sr$=0.7079-0.7085 and εNd=-6.63 to -5.90) completely confirm the results by [2] and simply underline I-type granitoids nature of these rocks.

XPS analysis of corrosion products formed on mild steel surface

A. SAMIDE[1], B. TUTUNARU[1]* AND C. NEGRILA[2]

[1]University of Craiova, Calea Bucuresti 107i, Craiova, Romania (*correspondence: tutunaruchim@yahoo.com)
[2]National Institute of Materials Physics, Bucharest, Romania

Methods of investigation

Effect of an antibacterial drug, sulfacetamide (SA), on the composition of corrosion products formed on mild steel surface in 1.0 M HCl solution has been investigated using potentiodynamic polarization, electrochemical impedance spectroscopy and XPS analysis. Fig.1 shows XPS spectra.

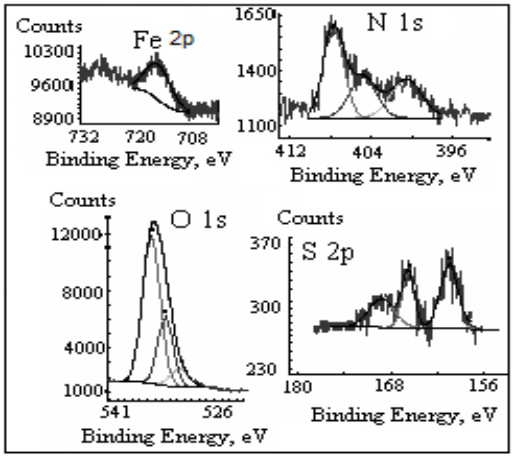

Figure 1: XPS spectra of mild steel surface corroded in 1.0 M HCl solution containing 4 mM sulfacetamide

Discussion of Results

In presence of SA, the surface layer consists of FeO (OH) rather than pure oxide [1, 2], adsorbed molecules of SA [2] and inorganic compounds (sulfides, carbonates, sulphates, nitrates) which were obtained by electrochemical decomposition of sulfacetamide [2]. More or less hypothetical compound such as schwertmannite, an iron-oxyhydroxysulfate mineral with an ideal chemical formula of Fe_8O_8 $(OH)_6$ $(SO_4)\cdot nH_2O$ or $Fe^{3+}{}_{16}O_{16}$ $(OH, SO_4)_{12\text{-}13}\cdot$10-12 H_2O may be formed. It can be considered that the SA acts as an incipient 'rust transformer' and favors the formation of a 'superficial closed layer'.

The authors thank for the financial support to the IDEI/Grant-Program, 422/2008 competition.

Stable isotope constraints on fluid flow in the Cascadia accretionary prism: Evidence for large flow transients during recent deformation

J.C. SAMPLE[1]* AND A. TRIPATI[2]

[1]SESES, Northern Arizona Univ., Flagstaff, AZ 86011, USA (*correspondence: james.sample@nau.edu)
[2]Earth and Space Sciences, UCLA, Los Angeles, CA 90095 (ripple@ess.ucla.edu)

The Cascadia subduction zone is a site of significant earthquakes with a recurrence interval of 240 to 530 years [1]. ODP drilling near the deformation front and on Hydrate Ridge has revealed pervasive deformation, and the formation of abundant gas hydrate, and in addition carbonate cements and veins [2]. The carbonates are proxies for fluid characteristics during he most recent active deformation and perhaps extending back to 2 Ma bp. Conventional and ion microprobe isotopic studies have shown that several fault horizons preserve carbonates with δ^{18}OVPDB values as low as -22‰, substantially out of equilibrium with modern pore water isotopic compositions and temperature. The values can be explained by transient flow events bringing in fluids from several kilometers remote from the drill sites, with substantially different isotopic compositions and temperatures. At one of the drill sites, δ18O values are consistent with precipitation temperatures of >100°C at a depth of only 67 meters below seafloor (mbsf). Conventional and ion microprobe analyses cannot distinguish between fluid isotopic and temperature causation of the carbonate isotopic anomalies. We are planning to measure samples using the technique of clumped isotope analysis, which relies on the correlation between the prevalence of ^{13}C-^{18}O-^{16}O isotopologues (Δ47 measurements) in carbonate with temperature during carbonate formation, to determine temperature and oxygen isotopic composition of fluids. The new data presented here will bear on our model of periodic, nonsteady-state fluid migration in the Cascadia accretionary prism. These transient flow events likely occur at time scales of less than a year, and may be related to periodic large-magnitude earthquakes. Widespread pulses of warm fluids could potentially destabilize clathrates at Hydrate Ridge and result in release of large quantities of methane into the overlying water column and atmosphere.

Study of Naryn river (Central Asia) runoff formation by stable isotope

A.A. SAMSONOVA[1]* AND I.V. TOKAREV[2]

[1]IWPH NAS KR, Bishkek, 720033 Kyrgyz Republic (aasamson@yandex.ru)
[2]SPbSU, Sredniy 41, of. 519, Saint-Petersburg, 199004 (*correspondence: tokarevigor@gmail.com)

Monitoring of the isotope composition ($\delta^{18}O$, $\delta^{2}H$) of precipitations, Naryn river and its tributaries, groundwater, and Toktogul reservoir was carried out in 2007-2009. Isotope composition of precipitations vary from $\delta^{18}O$ = -1.2 and $\delta^{2}H$ = -17 ‰ to $\delta^{18}O$ = -26.5 and $\delta^{2}H$ = -206 ‰ and fits the global meteoric water line. Mean seasonal composition of precipitation in summer (Jun.-Jul.-Aug.) is $\delta^{18}O$ = -9.5 and $\delta^{2}H$ = -70 ‰; in spring (Mar.-Apr.-May) is $\delta^{18}O$ = -11.6 and $\delta^{2}H$ = -83 ‰, in autumn (Sep.-Oct.-Nov.) is $\delta^{18}O$ = -11.0 and $\delta^{2}H$ = -79 ‰, in winter (Dec.-Jan.-Feb.) is $\delta^{18}O$ = -17.3 and $\delta^{2}H$ = -130 ‰.

End-member isotopic compositions varies: a) Naryn river head $\delta^{18}O$ = -15.2 and $\delta^{2}H$ = -134 ‰ to $\delta^{18}O$ = -10 and $\delta^{2}H$ = -82 ‰; b) middle reach of Naryn river and its tributaries $\delta^{18}O$ = -10.9 and $\delta^{2}H$ = -79 ‰ to $\delta^{18}O$ = -14.5 and $\delta^{2}H$ = -104 ‰; c) Toktogul reservoir $\delta^{18}O$ = -14.1 and $\delta^{2}H$ = -103 ‰ to $\delta^{18}O$ = -11.8 and $\delta^{2}H$ = -84 ‰; d) groundwater $\delta^{18}O$ = -17 and $\delta^{2}H$ = -126 ‰ to $\delta^{18}O$ = -13 and $\delta^{2}H$ = -94 ‰. The average isotopic composition of Naryn river just before flowing into the Toktogul reservoir is $\delta^{18}O$ = -13.0 and $\delta^{2}H$ = -93.2 ‰, and in the reservoir itself – $\delta^{18}O$ = -13.0 and $\delta^{2}H$ = -94.4 ‰; both are close to the mean annual precipitation $\delta^{18}O$ = -12.8 and $\delta^{2}H$ = -92.5 ‰. Consequently, there is strong averaging of precipitations in the some reservoirs, and averaging increases with runoff.

Naryn river runoff practically has no the glacier water, because of a) isotopic composition of water in rivers is weighted in summer and lighted in winter; b) water isotopic composition in the middle reaches is heavier, than in river head, where water has moreover fingerprint of cryogenic metamorphism in isotope composition; c) river water significantly differs from the isotopic composition of ice cores on the Inylchek glacier $\delta^{18}O$ = -16.5 and $\delta^{2}H$ = -105 ‰.

In conclusion, Naryn river runoff is formed at the expense of winter and spring precipitations. Summer precipitations can be neglected, as their volume is insignificant, and at altitudes to 1600 m precipitations are completely absorbed by evaporation. Disappearance of glaciers won't render essential influence on a river Naryn runoff.

The breakup and chemical equilibration of metal diapirs in terrestrial magma oceans

HENRI SAMUEL

Bayerisches Geoinsitut, Universitaet Bayreuth (henri.samuel@uni-bayreuth.de)

The early history of the Earth is most likely marked by at least one global magma ocean stage. During this time window, iron diapirs of various sizes delivered by differentiated impactors may have plunged through a few hundred kilometer thick silicate magma ocean. Understanding the breakup of metallic cores in such context is key to constrain the degree of metal-silicate equilibration processes.

To address this problem, I have conducted a series of numerical experiments where I follow the sinking of iron diapirs until breakup. These models include an accurate treatment of surface tension, inertial effects, stress and composition dependent viscosity. The influence of rheological properties and diapir sizes was systematically investigated. Scaling laws for the conditions of diapir breakup have been derived and are used to determine the stable size of sinking iron bodies in a silicate magma ocean.

Using these relationships I investigate the conditions and timing for metal-silicate chemical equilibration in terrestrial magma oceans.

Determination of U-Th and Pb isotope ratios in crude oil, kerogen and asphaltenes: Potential application for dating age of expulsion of crude oil from the rock source

GEORGIA SANABRIA[1], CHRISTOPHE PECHEYRAN[1]*, SYLVAIN BERAIL[1], ALAIN PRIZHOFER[2] AND OLIVIER F.X. DONARD[1]

[1]LCABIE, IPREM UMR 5254, CNRS – Université de Pau es des Pays de l'Adour, 64053, Pau cedex 9, France
[2]IFP, Direction Géologie-Geochimie, 1 et 4, Av. de Bois Préau, 92852 Rueil Malmaison Cedex, France

The Pb-Pb, U-Pb and Th-Pb methods of dating have become in geochromometers widely used to determine ages of minerals and rocks. However, there is scarce information about their application for dating hydrocarbon samples.

A simplified concept for U-Th-Pb geochronometers is proposed to estimate the expulsion age of crude oil from the source rock. Elemental isotopic ratio U/Pb and Th/Pb were determined by Q-ICPMS after sample acid digestion. Due to the matrix composition, classical anion exchange procedures used for lead isolation in inorganic samples (like sediments, minerals or rocks) can not be applied directly in crude oil, kerogenes and asphaltenes samples. Therefore purification procedures were evaluated in-depth for experimental optimal conditions and the optimized method was compared with a new developed method which consists in a two purification steps: first Pb ethylation with $NaBEt_4$ and solvent extraction followed by second separation stage in a gas chromatograph coupled to the MC-ICPMS. This new approach providing limited sample preparation is an efficient alternative to conventional geochimical procedures, with a great potential for micro geochemical samples.

Isotopic ratios results were used for dating hydrocarbon accumulation of two petroleum basin. These results were in good agreement with the theoretical model, hence, representing a new potential tool in petroleum prospection.

Root litter decomposition and stabilisation in three different soil depths related to microbial community dynamics and enzyme activity

M. SANAULLAH[1], A. CHABBI[1,2], P.A. MARON[3], A. SARR[3], E. BLADOTSKAYA[4] AND C. RUMPEL[1]

[3]INRA, Dijon, France
[4]Uni Bayreuth, Bayreuth, Germany

Subsoil horizons located below the A horizon are known to store important amounts of organic carbon characterised by high mean residence times. Microbial biomass and activity in these horizons are most probably contrasting to those of topsoil horizons and thus influence root litter degradation in different soil depths [1]. The aim of this study was to follow ^{13}C labelled root litter degradation in three different soil depths during a three year field incubation experiment and to establish a relation to the dynamics of microbial communities analysed by DNA fingerprinting and enzyme activities.

Our results showed contrasting decomposition dynamics in top- and subsoil horizons despite similar stabilisation processes [2]. Subsoil horizons showed a lag phase during the first months of incubation, but this retard in decomposition was compensated at the end of incubation probably by slightly better abiotic conditions at depth [2].

Enzyme activities showed distinct dynamics in different soil depths. Chitinase was the only enzyme that showed similar activity in top-and subsoil horizons; all other enzyme activities were much higher in topsoil. Activity of the enzyme involved in the N-cycle was evident in subsoil only within a short period after plant litter addition.

Dynamics of microbial populations evolved with time especially in the first year of the experiment. Thereafter changes in community composition were less pronounced. Stucture of microbial communities showed a depth gradient with the lowest soil layer being most different from the other two. This was mainly related to the first six months, where fresh root litter input obviously caused drastic changes.

We conclude, that microbial biomass and activity at soil depth are more limited by lack of fresh plant litter than by physical conditions. Both parameters can rapidely be stimulated and reach topsoil level in the first few months after root litter addition. However, these changes were only transient at 90 cm depth.

Funding was provided by the french science foundation ANR (project DIMMIMOS) and EGIDE (program PROCOPE).

Microbial Fe(III)-reduction in highly calcareous agricultural soils

I. SÁNCHEZ-ALCALA[1], K.L. STRAUB[2]*, M.C. DEL CAMPILLO[1], S.M. KRAEMER[2] AND J. TORRENT[1]

[1]Departamento de Ciencias y Recursos Agrícolas y Forestales, Universidad de Córdoba, Edificio C4, Campus de Rabanales, 14071 Córdoba, Spain
[2]Department of Environmental Geosciences, University of Vienna, Althanstraße 14, 1090 Vienna, Austria (*correspondence: kristina.straub@univie.ac.at)

Although iron is the fourth most abundant element in the Earth's crust, plants may develop iron deficiency symptoms (iron chlorosis) due to low iron bioavailability. Iron chlorosis symptoms include insufficient leave chlorophyll content, poor growth and low crop yield. In particular, plants grown on calcareous soils of arid and semi-arid regions are prone to iron chlorosis because calcium carbonate buffers pH at high pH values where iron solubility is low and soil acidification strategies of diverse plant families – which would otherwise increase iron solubility and hence availability – are compromised. Agronomic practices to alleviate iron chlorosis include the application of inorganic iron fertilizers or synthetic iron chelators. Occasionally, temporary flooding of soils was shown to increase iron phytoavailability; it was speculated that microbial iron reducing activities mobilized iron during such flooding events. However, information on microorganisms with Fe(III)-reducing capabilities inhabiting calcareous soils is scant. To study flooding effects in relation to microbial activity in greater detail, we incubated soil slurries prepared from twenty-four different calcareous soils from southern Spain in the laboratory and monitored changes in iron mineralogy. The concentration of ferrous iron remained constant in control experiments with sterilized soils. In contrast, native soils produced significant amounts of ferrous iron from soil ferric minerals and the extent of ferrous iron production correlated well with native contents of dissolved organic carbon. The addition of organic acids that are typically found in root exudates further increased the production of ferrous iron. Comparative examination of soil samples suggests significant microbial mobilization of both poorly crystalline and crystalline soil iron oxides. Threshold values required for adequate iron nutrition of tolerant plants were reached in 18 slurries of native soils and 22 of the native soils that had been amended with organic acids. Microbial mechanisms that probably contributed to the mobilization of iron include respiration, fermentation and sulfur-cycle mediated reduction of soil iron minerals.

Distribution of branched tetraether lipids in a Black Sea sediment core: Insights into continental temperature evolution in Central Europe over the past 40000 years

L. SANCHI*, G. MENOTAND E. BARD

CEREGE, Univ. Aix-Marseille, CNRS, IRD & College de France, Technopole de l'Arbois BP 80, 13545 Aix-en-Provence Cedex 04, France (*correspondence: sanchi@cerege.fr, menot@cerege.fr, bard@cerege.fr)

The MBT/CBT proxy based on the relative distribution of branched tetraether membrane lipids found in peat bogs, soils and ancient sediments is a promising tool for past annual air temperature and soil pH estimations. The first studies support its application in marine sediments (e.g. [1, 2]). Nevertheless the uncertainties on the source of the biomarkers (producing organisms and/or possible aquatic production) and the need of new calibration datasets clearly speak for more studies.

We present the first paleo-record of branched tetraether lipids in Central Europe from a sediment core retrieved in the Black Sea, over the past 40000 yrs BP. As the Black Sea encountered a transition from a lacustrine to a marine stage at the beginning of the Holocene period, we could explore the MBT/CBT proxy in the two realms. During the marine stage and especially during the reconnection of the Black Sea to the Mediterranean Sea, MBT/CBT-derived temperature profile seems to be biased possibly due to the major reorganization in the water column and/or the salinity shifts. However, using the MBT/CBT global lake calibration [3], the core-top yields reconstructed temperatures similar to the instrumental spring temperature in the Black Sea basin and to the present mean annual atmosphere temperature registered above the core.

Whatever calibration datasets, the Holocene/LGM reconstructed temperature drop is consistent with existing paleo datasets from the area. Furthermore, the temperature profile of the last glacial period shows synchronous variations with major climatic events recorded elsewhere in the Northern Hemisphere.

$CaCO_3$ polymorph growth and stabilization in water-ethanol mixtures

K.K. SAND[1]*, J.D. RODRIGUEZ-BLANCO[2], E. MAKOVICKY[3], L.G. BENNING[2] AND S.L.S. STIPP[1]

[1]Nano-Science Center, Dept. of Chemistry, University of Copenhagen, Denmark (kks@nano.ku.dk)

[3]Dept. for Geography and Geology, University of Copenhagen, Denmark

Alcohol-water mixtures can control the mode of precipitation and morphology of crystalline $CaCO_3$. However, these two characteristics are sensitive to experimental parameters such as concentration, calcium source, temperature, precipitation method and mixing speed. An understanding of the growth of $CaCO_3$ in alcohol-water mixtures is important because control of the precipitating polymorph and its morphology are two central parameters for successful biomineralization of $CaCO_3$.

We used a simple, homogeneous precipitation method, where we fixed temperature (24 °C) and total concentration of $CaCl_2$ and Na_2CO_3 (25 mM) and varied the proportion (10 and 50%) of alcohol, shaking speed, type of alcohol (ethanol, 1-propanol and 2-propanol) and reaction time (1 h to 4 m). Diffraction and imaging results show that shaking speed and alcohol concentration are the determining parameters for vaterite and aragonite stabilization. They also control vaterite morphology, which varies from cauliflower shaped aggregates to dendrites (Figure 1). We also present an equation for controlling the synthesis of aragonite:vaterite and aragonite:calcite ratios.

The evolution of the precipitates over time lead us to conclude that this system is described by classical growth with twinned aragonite and spherulitic vaterite and aragonite. Solutions with a low water activity can be used as a switch for control of polymorph and morphology and thus define new possible pathways for biomineralization processes.

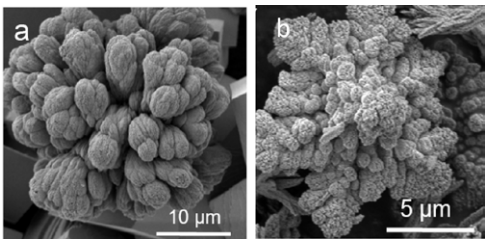

Figure 1: Vaterite precipitated in (a) 10% and (b) 50% alcohol under vigorous shaking. With gentle shaking, vaterite did not form in experiments with 50% alcohol.

Electron donating properties of humic substances and implications for pollutant phototransformation

MICHAEL SANDER[1]*, MICHAEL AESCHBACHER[1], JANNIS WENK[1,2], SILVIO CANONICA[2], URS VON GUNTEN[1,2,3], ELISABETH SALHI[2] AND RENÉ P. SCHWARZENBACH[1]

[1]Institute of Biogeochemistry and Pollutant Dynamics, Swiss Federal Institute of Technology, ETH Zurich (*correspondence: michael.sander@env.ethz.ch)
[2]Water Resources and Drinking Water, Swiss Federal Institute of Aquatic Science and Technology, eawag
[3]Civil and Environmental Engineering, Ecole Polytechnique Fédérale de Lausanne (EPFL)

Humic substances (HS) play a key role in many biogeochemical and pollutant electron transfer reactions. Past research primarily focused on HS redox properties under anoxic conditions. This contribution will present the results of a systematic characterization of the electron donating properties of a diverse set of HS under oxic conditions and, for selected HS, relate their antioxidant properties to inhibitory effects on the indirect phototransformation of organic pollutants.

Electron donating capacities (EDCs) were measured by electrochemical oxidation using 2, 2'-azino-bis (3-ethylbenz-thiazoline-6-sulphonic acid) radicals to mediate electron transfer from HS to the working electrode [1]. The number of oxidizable moieties at constant pH and applied reduction potential, E_h, increased from microbial to terrestrial HS and was highest for mixed aquatic-terrestrial HS. For a given HS, EDC values increased with increasing pH and E_h. Strong positive correlations of EDC with HS titrated phenol contents and, for mixed terrestrial-aquatic HS with aromaticities indicates that phenols and hydroquinones are the major electron donating moieties in HS.

HS may decrease indirect phototransformation rates of organic pollutants by donating electrons to oxidized reaction intermediates [2]. Combined electro- and photo-chemical experiments with anilines as model pollutants showed that the inhibition efficiencies of HS on pollutant phototransformation increased with their EDCs. Furthermore, the inhibition efficiency for a given HS increased with increasing pH, in parallel with increasing EDC. Pre-treatment of HS with chemical oxidants, including ozone and chlorine dioxide, reduced the number of electron donating moieties, reflected by significant reduction in both inhibition efficiency and EDC values. These results suggest that EDC and inhibition efficiency on organic pollutant phototransformation are determined by the number and potential distribution of hydroxybenzene moieties present in HS.

Sulfur isotope data from Beaver Brook Antimony deposit, Central Newfoundland, Canada: A hint for the source of mineralization?

DIRK SANDMANN*, THOMAS SEIFERT AND JENS GUTZMER

Department of Mineralogy, TU Bergakademie Freiberg, Brennhausgasse 14, D-09596 Freiberg, Germany (*correspondence: dirk.sandmann@mineral.tu-freiberg.de, thomas.seifert@mineral.tu-freiberg.de, jens.gutzmer@mineral.tu-freiberg.de)

The Beaver Brook Mine exploits one of the largest antimony deposits in the Americas. It has a current production level of 12,000 metric tons antimony concentrate (grading around 65% Sb) per year with current reserves sufficient for an estimated ten-year operating life. The mineralization (dominantly stibnite with traces of pyrite as well as quartz and carbonate gangue) is hosted by meta-sedimentary rocks of Ordovician to Silurian age and structurally controlled by faults and breccia zones. The conditions of formation of the deposit remain unknown, but it has characteristics similar to other Sb-dominated hydrothermal deposits that form at variable temperatures (100-400°C).

Stable sulfur isotope data of ten monomineralic stibnite samples were analyzed at the Department of Mineralogy, TU Bergakademie Freiberg. $\delta^{34}S_{VCDT}$ values for the stibnite samples occupy a very narrow range from -6.6 to -6.0‰ with an total analytical error of ≤ ±0.3‰. The narrow range of $\delta^{34}S$ values of stibnites from Beaver Brook suggests stable physico-chemical conditions as well as a large well-mixed sulfur reservoir. Obolensky *et al*. [1] suggest that mixing of neutral or alkaline metal-containing solutions with H_2S-bearing fluids sourced from sulfide-rich host rocks are well-suited for stibnite ore deposition. Accordingly, we suggest that the sulfur contained in the Beaver Brook deposit was provided by meta-sedimentary host rocks. The metal source, on the other hand, remains unconstrained [2, 3].

Sediment-water nutrient and Oxygen fluxes in two Antarctic continental shelf areas differently affected by climate change

E. SAÑÉ[1]*, E. ISLA[1] AND A. GRÉMARE[2]

[1]Instituto de Ciencias del Mar (ICM-CSIC), 08003 Barcelona, Spain (*correspondence: sane@icm.csic.es)

[2]UMR EPOC, Université Bordeaux 1- CNRS, Station Marine d'Arcachon, 33120 Arcachon, France

Larsen A and B ice shelves, in the Eastern Antarctic Peninsula (EAP), collapsed in 1995 and 2002, respectively. In 2006, during Antarctic expedition ANTXXIII/8, respiration experiments were carried out onboard R/V Polarstern to measure nutrient and oxygen water-sediment fluxes beneath the extinct Larsen ice shelves and off of the Northern Antarctic Peninsula (NAP), a region which has been free of ice shelves in the last 1000 years [1, 2]. Nutrient and oxygen water-sediment fluxes in EAP were studied to investigate how Larsen ecosystems evolved from a situation of negligible primary production and negligible vertical flux of organic matter to the sea floor under ice shelves [3] to a situation of ongoing primary production after Larsen ice shelves collapse [4]. We found higher nutrient and oxygen fluxes in NAP than in EAP probably related to the higher concentration of particulate organic matter found in NAP sediments [5]. Studies on benthic recolonization after iceberg scouring events suggested that the recovery time for an Antarctic mature benthic community is comprised between 230 and 500 yr [6, 7], with early recovery stages that may take up to 10 yr long, presumably like those found in the EAP benthic ecosystem [8].

Equation of state of water and melting curve of Ice VII based on simultaneous measurements of sound velocity and X-ray diffraction of Ice VII to 19 GPa and 873 K

L. SANG[1]*, D.L. FARBER[2,3], C.R. ARACNE[2], J. ZHANG[1], V. PRAKAPENKA[4], I. KANTOR[4], S. TKACHEV[4], K. ZHURAVLEV[4] AND J.D. BASS[1]

[1]Department of Geology, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801, USA (*correspondence: sang1@illinois.edu)
[2]University of California, Lawrence Livermore National Laboratory, Livermore, California 94550, USA
[3]University of California, Santa Cruz, Santa Cruz, California 95064, USA
[4]GSECARS, Advanced Photon Source, Argonne National Laboratory, Argonne, Illinois 60439, USA

We have measured the sound velocity of H_2O by Brillouin spectroscopy using membrane-style diamond anvil cell with resistance heating at elevated temperatures and pressures up to 873 K and 19 GPa. The unit cells of Ice VII and Au were determined by synchrotron X-ray diffraction, using Au as an *in situ* pressure gauge. All our samples were contained within and chemically insulated from the Re-gasket hole by a gold liner. Measurements of the sound velocity in liquid water have been extended to 8.0 GPa and 873K. We observed, generally, lower velocities (up to 10% at 723 K) than those given by previous studies [1, 2]. The melting of Ice VII was determined by monitoring the sound velocity drop and the disappearance of diffraction pattern of Ice VII upon melting. Our determination of the melting temperatures differ significantly from those given by previous studies [3, 4], with an observed discrepancy of 130 K at 8 GPa. Given the care taken in the present experiments to avoid potential contamination of the water sample due to reactions at high temperatures between the sample and the gaskets and/or pressure gauges, our new measurements likely provide the first measurements on pure water which displays an extended stability field of the solid phase. Thus, our new measurements suggest that the melting curve of H_2O at high pressure needs to be reevaluated.

Solid - liquid Equilibria in the quaternary $K_2B_4O_7$-K_2SO_4-KCl-H_2O system at 323 K

SHI-HUA SANG*, XIAO ZHANG AND DAN WANG

College of Materials and Chemistry & Chemical Engineering, Chengdu University of Technology, ChengDu 610059, P.R. China (*correspondence: sangsh@cdut.edu.cn)
Mineral Resources Chemistry Key Laboratory of Sichuan Higher Education Institutions, ChengDu 610059, P.R. China

Introduction

A huge store of underground brine was discovered in Sichuan western basin of China. Sodium chloride, potassium and boron are the major chemical compositions of the underground brines. For exploiting brine resources of the underground brines, the measurement of mineral solubilities at different temperatures is used widely.

Discussion of Results

The solid - liquid equilibria in the quaternary system $K_2B_4O_7$-K_2SO_4-KCl-H_2O at 323 K were studied experimentally using the method of isothermal solution saturation. Solubilities and densities of the solution of the quaternary system were measured experimentally. In the phase diagram of the quaternary system $K_2B_4O_7$ -K_2SO_4-KCl-H_2O at 323 K, there are one invariant point E and three univariant curves E1E, E2E and E3E, and three crystallization fields corresponding to KCl, $K_2B_4O_7{\cdot}4H_2O$ and K_2SO_4 in the studied quaternary system. The experimental results show that K_2SO_4 has the biggest crystallization field (E2EE1 field) in the phase diagram (Figure 1).

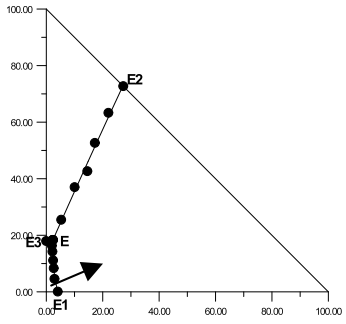

Figure 1: Phase diagram of the quaternary system $K_2B_4O_7$ - K_2SO_4-KCl-H_2O at 323 K(KB: $K_2B_4O_7{\cdot}4H_2O$)

Density measurements

The physical and chemical properties of molten iron play a key role in core formation, the largest chemical differentiation event in the early evolution of the Earth [1]. We have performed density measurements of molten iron containing an appropriate amount of light elements (5.7 wt.% carbon) up to 8 GPa using the *in situ* X-ray absorption technique [2, 3].

Discussion of the results

A liquid–liquid transition is identified by a significant compressibility increase in the vicinity of the δ-γ-liquid triple point at 5.2 GPa [4]. The observed increased compressibility of the melt is consistent with the reported molar volume difference between δ and γ phases that increases by a factor of 2 along the Fe melting curve between 0 and 5 GPa [5].

This transition pressure coincides with a marked change in the pressure evolution of the distributions of nickel, cobalt and tungsten between liquid metal and silicate melt that form a cornerstone of geochemical models of core formation. The identification of a clear link between molten metal polymorphism and metal-silicate element partitioning implies that reliable geochemical core formation models will need to incorporate the effects of these additional liquid metal transitions.

Insolation is an important meteorological parameter and a primary determinant of the Earth's climate system. The historical record of insolation in tropical and sub-tropical regions is short. Moreover, it remains difficult to extract solar radiation from a past marine environmental proxy, even though past seawater temperature [1], salinity [2], pH [3], and nutrients [4] were successfully estimated from geochemical data of biogenic marine carbonates such as coral skeletons, foraminifera tests, and mollusk shells. Herein, we describe the precise analysis of Sr/Ca ratio by using a NanoSIMS [5] with 2 micro-meter resolution in a cultivated giant clam shell exhibiting striking diurnal variations, elevated as high as 25% relative to the mean, associated with regional hourly solar radiation. This is the finest proxy among all data ever published. Annual variation of the Sr/Ca ratio is also observed in the sample by a 10 micro-meter spot with 50 micro-meter interval, again correlated with daily insolation record with similar amplitude. Light enhanced calcification and elemental transportation processes in giant clam and symbiotic algae may explain these diurnal and annual variations. Therefore, the Sr/Ca ratio of a giant clam shell might be a useful paleo-chemical-pyrheliometer.

An attempt to trace the redox state of the post Marinoan glaciation (≈635Ma) ocean at the Araras platform (Brazil)

P. SANSJOFRE[1,2]*, M. ADER[1], R.I.F. TRINDADE[2], M. REUSCHEL[3] AND A.C.R. NOGUEIRA[4]

[1]Institut de Physique du Globe de Paris, Univ Paris Diderot, UMR 7154 CNRS, F-75005 Paris, France (*correspondence: sansjofre@ipgp.fr)

[4]Universidade Federal do Pará, CEP 66.075-110, Belém, Brazil

Oceans and atmosphere oxidation in the Ediacaran paved the way for one of the biggest evolutionary leaps in Earth's history – the dawn of animals. In an attempt to trace such a major oxidation event, we investigated carbonate layers deposited at the base of the Ediacaran period which cap Marinoan glacial deposits in central Brazil. The stratigraphic section in the Araras Group comprises 13 meters of pink dolostone overlain by 25 meters of gray limestone, separated by a transition zone of gray dolostone with higher organic carbon content. Well-preserved sedimentary structures along the section indicate a transgressive tract from shallow marine to deep water deposition environments. Applied redox proxies show two different oxidation states along the sedimentary column: oxic in the dolomitic part and dysoxic-anoxic in the limestone, suggesting that respective carbonates have formed in a redox stratified water column. In the transition zone between oxic and dysoxic-anoxic environments, nitrogen, vanadium, manganese, iron and sulfur show successive variations in their concentrations or isotopic compositions. These variations likely record the succession of nitrogenous, manganeous, ferruginous and sulfidic zones, thus indicating a progressive upward transition from oxic to anoxic conditions. However, some geochemical proxies (e.g. Ce anomaly, Ni/Co) as well as the classical iron speciation redox indicator FeHR/FeT show contradictory results, providing thus conflicting interpretations for our dataset. We explain the different interpretations of the data in terms of either a paleo-redox state for the post Marinoan Ocean, or a diagenetic overprint.

Metamorphic evolution recorded by amphiboles in the metadolerites from the Frido Unit ophiolites (Southern Apennine-Italy)

MARIA T. CRISTI SANSONE[1], GIACOMO PROSSER[1], GIOVANNA RIZZO[2], PAOLA TARTAROTTI[3]

[1]Dipartimento di Scienze Geologiche-Università degli Studi Della Basilicata
[2]Dipartimento di Chimica-Università degli Studi Della Basilicata
[3]Dipartimento di Scienze della Terra- Università degli Studi di Milano

Metadolerites of the Frido Unit Ophiolites have different kinds of texture reflecting various degree of *crystallinity*. Primary clinopyroxene is replaced by brown and green amphiboles interpreted as being of oceanic origin; brown amphiboles show Mg-hastingsite, edenite, pargasite, Fe-hastingsite, Mg-horneblende and tschermakite compositions, whereas green amphiboles show Mg-hastingsite, hastingsite, edenite, Mg-horneblende, tschermakite and Fe-tschermakite compositions. The blue amphibole rims of the brown amphibole has a winchite and barrowisite compositions; we infer that it crystallized during the early stages of the orogenic metamorphism, likely under static conditions. The different composition of amphiboles occurring in the metadolerites suggest that the ophiolitic rocks from the Frido Unit has been affected by both ocean-floor metamorphism in the amphibolite to greenschist facies conditions and subsequent orogenic metamorphism under HP/LT conditions.

Multidisciplinary study of Santa Eulalia Plutonic Complex (Central Portugal): Preliminary insight

H. SANT'OVAIA[1]*, J. CARRILHO LOPES[2] AND P. NOGUEIRA[2]

[1]DGAOT, Centro de Geologia, FCUP, Portugal (*correspondence: hsantov@fc.up.pt)
[2]Dep. Geo., Univ. Évora, Centro de Geologia UL, Portugal

The Santa Eulália Plutonic Complex (SEPC) is a late-Variscan calcalkaline granitic body that occupies an area of 400 km^2 and is located in the Variscan Iberian sector. The host rocks of the complex are composed by metamorphic formations from Proterozoic to Lower Paleozoic. The SEPC has two main facies which present different compositions and textures. From the rim to the core, there is a medium- to coarse-grained pinkish granite (G0) involving large masses of mafic to intermediate rocks and a central gray monzonitic granite (G1). The central facies can be divided into a porphyritic facies (G1A) and a central medium-grained facies (G1B). Multidisciplinary studies that include petrography, mineral and whole-rock chemistry, Anisotropy of Magnetic Susceptibility (AMS) and microstructural analyses were carried out. Besides petrographic and mineral chemistry data, whole-rock analytical results reveal clear differences between these two main granitic facies. G0 granites represent more evolved liquids (>SiO_2 wt.% and <MgO wt.%), plot closer to metaluminous and A-type fields, and present negative Eu anomalies, while G1 facies are typically monzonitic granites with a strong peraluminous character. The AMS study was based on 50 sampling sites. The magnetic susceptibility ranges between 55.09 and 7343.67 x 10^{-6} SI. Two major groups can be established: facies G0, with Km > 10^{-3} SI which supports the presence of magnetite, and the central facies (G1A, G1B) with Km< 10^{-4} SI. In the central facies the paramagnetic behaviour is due to ferromagnesian minerals, such as biotite, and ilmenite. Magnetic anisotropy ranges between 2.2 and 18.2% being in mean >5% in facies G0 and <4% in the central facies. The high P% in G0 facies may be caused by the magnetic bearer, magnetite. Nevertheless, microscope observations show signs of a post-magmatic deformation in G0. These preliminary data support that the facies G0 and the central facies (G1) have a distinct magnetic behaviour which may suggest different redox conditions in magma genesis.

Fe(II) and organic exudates interaction in seawater

J. MAGDALENA SANTANA-CASIANO*, ARIDANE G. GONZÁLEZ, NORMA PÉREZ AND MELCHOR GONZÁLEZ-DÁVILA

Departamento de Química, Facultad de Ciencias del Mar, Universidad de Las Palmas de Gran Canaria, Campus de Tafira, 35017 Las Palmas, Spain

Fe(II) oxidation kinetic was studied in seawater and in seawater enriched with exudates excreted by *Phaeodactylum tricornutum*. The exudates produced after 2, 4 and 8 days of culture at $6.21 \cdot 10^7$ cell/L, $2.29 \cdot 10^8$ cell/L and $4.98 \cdot 10^8$ cell/L were selected. The effects of the pH (7.2-8.2), temperature (5-35°C) and salinity (10-36.72) on the Fe(II) oxidation rate were studied. All the data was compared with the results for seawater without exudates (seawater control). The Fe(II) rate constants decreased as a function of culture time and cell concentration at different pH, temperature and salinity. The experimental data was fitted to a polynomial function in order to quantify the fractional contribution of the organic exudates from the diatoms to the Fe(II) oxidation rate in natural seawater. Experimental results showed that the organic exudates excreted by *Phaeodactylum tricornutum* affect the Fe(II) oxidation, increasing the life time of the Fe(II) in seawater. A kinetic model approach was carried out in order to account for the speciation of each Fe(II) species together with its contribution to the overall oxidation rate.

Biomineralization of Mn oxides by Mn(II)-oxidizing fungi

C.M. SANTELLI[1,2]*, S.M. WEBB[3], A.C. DOHNALKOVA[4] AND C.M. HANSEL[2]

[1]Smithsonian Institution, Washington, DC 20560, USA (*correspondence: santellic@si.edu)

[4]Environmental Molecular Sciences Laborary, PNNL, Richland, WA 99352, USA (Alice.Dohnalkova@pnl.gov)

Manganese (Mn) oxides are environmentally abundant, highly reactive mineral phases that play important roles in the biogeochemical cycling of nutrients, contaminants, carbon, and numerous other elements. The oxidation of Mn(II) to these sparingly soluble, nanocrystalline Mn(III/IV) oxide phases is believed to be largely driven by microbiological activity. The majority of studies thus far have focused on the contributions of bacteria to the biogeochemical cycling of Mn, however recent studies have suggested that fungi may substanially contribute to the biomineralization of Mn oxide minerals in some environments. Understanding the environmental impact of these fungally precipitated mineral phases requires detailed analysis of their size, composition, and structure.

Several species of Mn(II)-oxidizing Ascomycete fungi were isolated from metal-contaminated and freshwater environments. A microscopic examination of these fungi revealed that the patterns of Mn oxide deposition varied amongst the different species. In this study, representative Mn(II)-oxidizing fungi were grown under the same chemical and physical conditions to determine if the species of fungus impacts the size, morphology, or structure of Mn biooxides. A combination of electron microscopy annd synchrotron radiation X-ray absorption spectroscopy (SR-XAS) were utilized to characterize the Mn oxide phases produced by these representative fungal species.

Our study reveals that the initial phase produced by different species of Mn(II)-oxidizing fungi grown under the same conditions is a highly disordered, nanocrystalline phyllomanganate similar to δ-MnO_2. Amongst the different species, however, differences in mineral size, morphology, and secondary products are observed. Changes in solution chemistry (e.g. Mn concentration) further impacts the structure of these biominerals, which could translate to large influences on biogeochemical processes in the environment.

Changes in the Fe(II)/Fe(III) ratio by bacterial activity according to dynamics of an acid pit lake

E. SANTOFIMIA[1], E. LÓPEZ-PAMO[1], E. GONZÁLEZ-TORIL[2] AND A. AGUILERA[2]

[1]Instituto Geológico y Minero de España, Ríos Rosas 23, Madrid, España
[2]Centro de Astrobiología, Torrejón-Ajalvir road km 4, Torrejón de Ardoz, Madrid, España

Nuestra Señora del Carmen acidic pit lake (Iberian Pyrite Belt) generally presents a chemical stratification, differentiating two layers: 1) a thin upper layer of ~2 m depth, pH between 2.5-2.7, EC from 2 to 8 mS/cm and Eh 820 mV, which corresponds to oxic conditions where iron is predominantly Fe(III), and 2) a thick bottom layer from 2 m to 35 m depth, homogeneous in depth, with pH ~2.5, EC 9 mS/cm, anoxic (<0.2 mg/L) and Eh between 640-680 mV, where Fe is both Fe(II) and Fe(III). Microbial community composition was analyzed by 16S and 18S rRNA gene cloning and sequencing in this layer, detecting oxidising bacteria (*Leptospirillum*) and the facultative iron-reducing bacteria such as *At. ferrooxidans* and *At. ferrivorans*.

Occasionally at the beginning of some winters, a period of mixing and total homogenization was observed in entire water column, being this process favoured by dry autumns. The pit lake recovered the chemical stratification after intense episodes of rainfall (strong inflow of runoff). An unusual mixing process happened during summer 2009 as a result of intense evapoconcentration that took place in the upper layer.

High average concentrations of SO_4 (8.5 g/L), Mg (1.0 g/L) and metals (Fe 760 mg/L, Al 230 mg/L, Mn 88 mg/L and Cu 29 mg/L) were measured in the homogeneous pit lake during the winter mixing. In this process the dissolved oxygen is introduced from surface to depth, but it is rapidly consumed by the bacterial oxidation of ferrous iron, decreasing the Fe(II)/Fe(III) ratio. This ability is normal in these types of microorganisms as could be checked during the winter mixing of entire water column in November 2008 or partial mixing of summer 2009, in which had a decrease of the Fe(II) and a increase of the Fe(III) as a result of aerobic bacterial oxidation. These bacterial species have revealed metabolic versatility, being able to reduce ferric iron in anoxic conditions. This ability is less common but it was registered in the anoxic bottom layer during stratification periods (Fe(II) increased and Fe(III) dropped). Extremophile bacteria respond to changes in environmental conditions and its versatility seems to control the evolution of the redox species of iron in the bottom layer of this pit lake.

Deep ground water migration in Brazilian Federal District based on isotope geochemistry

R.V. SANTOS*, W. PACHECO AND L.H. MANCINI

Instituto de Geociências, Universidade de Brasília, Campus Darcy Ribeiro, 70910-900 Brasília – DF (*correspondence: rventura@unb.br)

The young capital of Brazil is placed geographically in the Brazilian Central Plains, where the average altitude is close to a 1,000 m above sea level. The area includes drainages that flow to three of the most important river basins of the country: the Paraná, the Amazon, and the São Francisco river basins. Because population has already reached more than 2 million people and continues to grow, policy makers increasingly use groundwater reservoirs.

In order to evaluate the geochemical stability of these reservoirs, we performed an 18 month detailed monitoring of is $\delta^{13}C$, $\delta^{18}O$, δD and $^{87}Sr/^{86}Sr$ isotopic composition. The isotopic data revealed two main behaviors of these reservoirs: 1) those that present a narrow range of isotopic variation; and 2) those that present a wide range of isotopic variation. While the former were interpreted as isotopic equilibrated water-host rock reservoirs, the later were interpreted as reservoirs that did not reached isotopic equilibrium due to the young age of their waters. We further show that isotopic fluctuation observed in these reservoirs may be related to changes in hydrostatic pressure induced by seasonal variations of rainfall amount.

Biogeochemical and microbial controls of ^{129}I mobility in groundwater

PETER H. SANTSCHI[1], ROBIN BRINKMEYER[1], KATHLEEN A. SCHWEHR[1], SAIJIN ZHANG[1], CHEN XU[1], HSIU-PING LI[1] DANIEL I. KAPLAN[2], CHRIS YEAGER[2] AND KIMBERLY A. ROBERTS[2]

[1]Texas A&M – Galveston, Galveston, Texas
[2]Savannah River National Laboratory, Aiken, South Carolina

Due to its long half-life (17 My), high mobility, and biophilic properties, ^{129}I, a major by-product of nuclear fission, is one of the three major risk drivers at nuclear disposal sites. In aquatic environments, iodine (I), mainly exists as I^-, IO_3^- and organic iodine (OI). Field and laboratory batch and column studies were established to understand the inter-conversion of I species in an ^{129}I-contaminated plume located in F-area of the Savannah River Site (SRS), by determining speciated ^{129}I and stable ^{127}I using GC-MS [1]. These studies demonstrated that the mobility of I species greatly depended on the I concentration used [2, 3]. It was found that bacteria isolates can accumulate I^- at environmentally relevant concentrations (0.1 μM I^-); some isolates were also found to oxidize I^- to IO_3^- [*4*]. When the hypothesis that I^- mobility can be controlled through an engineered barrier system was tested, results showed that while the majority of I (as ^{127}I and ^{129}I) existed as I^- near the source term, iodide transformed into iodate and organo-I downgradient [5], and was removed through the formation of immobile particulate OI and partly released as mobile OI [6], depending on aromaticity and relative hydrophobicity; the greater the aromaticity, the greater the uptake of iodine [7].

Low oxygen fugacity mantle derived auriferous fluids for Archaean Orogenic Gold deposit of Ajjanahalli, Chitradurga Schist belt, Dharwar Craton, India

S. SARANGI[1]*, A. SARKAR[2], V. BALARAM[3] AND R. SRINIVASAN[3]

[1]Department of Applied Geology, ISM-Dhanbad, India (ssarangi2@Rediffmail.com)
[2]Dept of Geology and Geophysics, IIT-Kharagpur, India
[3]National Geophysical Research Institute, Hyderabad

The BIF hosted Ajjanhalli gold deposit of Chitradurga Schist Belt, Dharwar Craton, India has been grouped under Orogenic type of gold deposit in an Archaean set up [1]. Recently magma/mantle origin has been proposed [2] for the source of CO_2 rich aurifereous fluids based on $\delta^{13}C$ values of carbonates (-5.1±1.4‰) and the fluid (-5.81±1.14‰). We present here the REE compositions of same carbonates from the auriferous quartz-carbonate veins (QCVs) and compare them with our previous obtained isotope data to understand the source of the mineralising fluid.

Both the chondrite and PAAS normalized REE plots of the carbonates of QCVS shows distinct positive Eu anomaly. As positive Eu anomaly is seen under low oxygen fugacity condition of fluids [3], we propose that the auriferous fluids responsible for gold minerlisation at Ajjanhalli could be from a oxygen depleted source. The $\delta^{13}C$ values of carbonates of these carbonates have also indicated a mantle or a felsic magmatic source of auriferous fluids [2]. Though felsic magma source has also been believed for the ultimate source of auriferous fluids [4], positive Eu anomaly of QCVs goes against such a possibility as granitic magma generated hydrothermal fluids could have shown a negative Eu anomaly. We therefore suggest that auriferous fluids could be from a mantle reservoir under a low oxygen fugacity condition.

Since the Orogenic gold deposit at Ajjanahalli deposit is spatially located on a crustal scale shear zone [1] possibility of a mantle derived auriferous fluids cannot be ruled out.

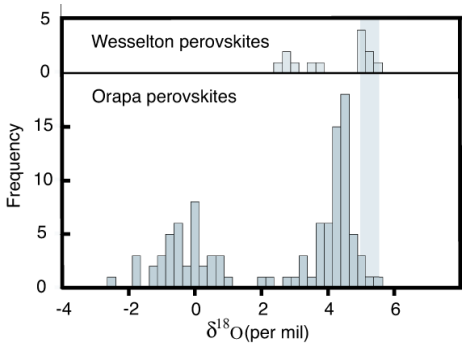
Oxygen isotopes in perovskites from kimberlites

CHIRANJEEB SARKAR[1]*, C.D. STOREY[2], C.J. HAWKESWORTH[3] AND R.S.J. SPARKS[1]

[1]Department of Earth Sciences, University of Bristol, Bristol, BS8 1RJ, UK (*correspondence: C.Sarkar@bristol.ac.uk)
[2]School of Earth & Environmental Sciences, University of Portsmouth, Portsmouth, PO1 3QL, UK
[3]University of St Andrews, Scotland, KY16 9AJ, UK

Isotopic data (Sr, Nd and Hf) obtained from groundmass perovskites ($CaTiO_3$) within kimberlites have been shown to more accurately reflect the unaltered signature, which has besieged whole rock studies. However, recent studies have questioned their suitability to represent primary kimberlite magma. *In situ* trace elements along with Sr and stable O isotope data have been employed to assess the effects of contamination on perovskites from Orapa and Wesselton kimberlite. Crustal contamination had a minimal role as the samples have an extended range in La/Yb and Sr/Yb rather than scatter around low values. Moreover, lack of any perovskites with elevated $\delta^{18}O$ also suggests minimal interaction with upper crustal material.



The $\delta^{18}O$ values from Orapa perovskites show two distinct peaks (around +3.6‰ and -0.6‰). Wesselton perovskites in contrast are clustered around $\delta^{18}O$ values of +4‰. Perovskite in equilibrium with the mantle has lower $\delta^{18}O$ than other common upper mantle minerals. One group of Orapa perovskites and the Wesselton perovskites are interpreted to reflect the $\delta^{18}O$ of uncontaminated upper mantle derived kimberlite magma (4.2‰). The negative $\delta^{18}O$ values from the second group of Orapa perovskites are attributed to crystallisation of perovskite after magma degassing, rather than to crustal assimilation, magma mixing, cooling or hydrothermal alteration. The Wesselton sills, however, did not suffer significant degassing, at least to the extent to deplete the magma in ^{18}O.

Synthesis of lithium ion-sieves using biogenic birnessite as a precusor

K. SASAKI, E. MORIOKA AND Q. YU

Department of Earth Resource Engineering, Kyushu University, Fukuoka, Japan (keikos@mine.kyushu-u.ac.jp)

Lithium (Li) is regarded as one of the most important elements in advanced industries, and its concentration in geothermal water is around 10 mg/L at the maximum corresponding to about 50 times larger than in seawater [1]. In the present work, synthesis of lithium ion-sieve was investigated using biogenic Mn oxides. Biogenic Mn oxides were produced by a Mn-oxidizing fungus, *Paraconiohyrium sp*.WL-2 strain at pH 6.5 [2].

After biogenic birnessite was suspended in LiCl solution, the solid phase was obtained by evaporation at 80 °C for 24 hours and then calcined at 450 °C for 4 or 8 hours. The calcined product was washed with 0.1 mol/L HCl to exchange with Li^+ to obtain a sorbent as a template for Li^+ ions. To compare with biogenic birnessite, several types of synthesized Mn oxides, that is, acidic birnessite, ramsdellite, Mn_3O_4, cryptomelane, were investigated as the starting materials in the same manner.

Based on XRD results, $LiMn_2O_4$ was detected in three products of five before acid washing, that is, derived from biogenic birnessite, acidic birnessite and ramsdellite. The minimum calcination time was required to obtain a pure $LiMn_2O_4$ phase using biogenic birnessite as a starting material. XRD peaks assigned to $LiMn_2O_4$ were maintained even after Li^+ ions were extracted by acid washing.

While products from acidic birnessite sorbed little Li^+, the products from biogenic birnessite and ramsdellite sorbed Li^+ more effectively. Some release of Mn^{2+} was observed during sorption of Li^+ ions on the product derived from ramsdellite. Products derived from biogenic birnessite showed the most effective performance to sorb Li^+ ions.

Very alkaline condition is required to synthesize ramsdellite, while biogenic birnessite can be produced around neutral pH values. Therefore, biogenic birnessite is a promising geomimetics as starting materials for synthesis of the effective lithium ion-sieves.

Sorption of Sr^{2+} on hydroxyapatite from calcined fish bones at different temperatures

K. SASAKI*, S. TSURUYAMA, S. MORIYAMA AND T. HIRAJIMA

Kyusyu University, Fukuoka 819-0395, Japan (*coresspondance: keikos@mine.kyushu-u.ac.jp, s-tsuruyama09@mine.kyushu-u.ac.jp, s-moriyama09@mine.kyushu-u.ac.jp, hirajima@mine.kyushu-u.ac.jp)

Hydroxyapatite was produced by calcination of fish bones at different temperatures (400- 1100 °C). Higher calcination temperatures reduced the organic matter content but also provided better crystallized hydroxyapatite and larger crystal sizes with less lattice strain. Higher calcination temperatures also decreased the specific surface area and increased the ion-exchange capacity hydroxyapatite. Sorption of Sr2+ as a surrogate for radionuclides was investigated with hydroxyapatite calcined at different temperatures. These results demonstrated that lattice strain affects ion-exchange properties at nano-domain level relatively more as compared to its effects on the surface area.

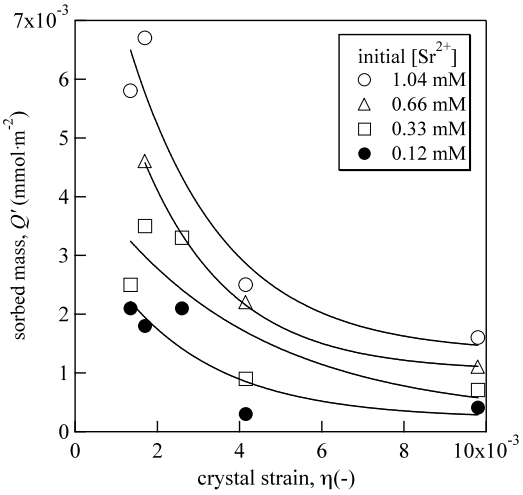

Figure 1: Sorption capacity of Sr^{2+} on hydroxyapatite with different lattice strain.

Study of deep subsurface microbial community under changing redox conditions using quantitative method

Y. SASAKI[1]*, T. ASANO[2], Y. AMANO[3], T. SATO[1], T. IWATSUKI[3] AND H. YOSHIKAWA[1]

[1]Geological Isolation Research and Development Directorate, Japan Atomic Energy Agency, Tokai, Ibaraki, Japan (*correspondence: sasaki.yoshito@jaea.go.jp)
[2]Environmental Business Division, Bio-Business Promotion Department, CHUGAI TECHNOS Corporation, Nishi-Ku, Hiroshima, Japan.
[3]Geological Isolation Research and Development Directorate, Japan Atomic Energy Agency, Horonobe, Hokkaido, Japan

Microbial activity is one of controlling factor for geochemical condition and the change during excavation and backfilling of underground facility. This study aims to evaluate the role of microbes on geochemical evolution around underground facility. We investigate microbial community and redox condition in the borehole drilled from 140m depth gallery of underground research laboratory (URL) in Horonobe area of Hokkaido, Japan.

Redox potential (ORP_{obs}) of groundwater changed from oxidized condition (+180mV) to reducing condition (-480mV) in 10 days. Total microbial count also decreases from $6.6x10^5$ cells/ml to $3.2x10^4$ cells/ml. Quantification analysis using both 16S rRNA and functional genes with real-time PCR shows that the biomass decreased constantly; domain bacteria (16S rRNA), Nitrate reducers (*nirS*), denitrifires (*nosZ*), Metal reducers (Geobacteraceae 16S rRNA) and Methane oxidizers (*pmoA*). On the other hand, the biomass increased in 5 days and then decreased or be maintained approximately-constant. ; domain archaea (16S rRNA), nitrate reducers (*nirK*), sulfate reducers (*dsr*), methanogens (*mcrA*). The change corresponded with redox potential change. These groups would have ecological relationship. Microbial community quickly changes according with redox condition change in deep subsurface.

This study was performed as a part of the 'Project for Assessment Methodology Development of Chemical Effects on Geological Disposal System' funded by the Ministry of Economy, Trade and Industry of Japan.

Air quality over India: Weekly periodicities and long term trends

S.K. SATHEESH[1,2]*, K. KRISHNA MOORTHY[3], S.S. BABU[3], N. SRIVASTAVA[1] AND V. VINOJ[4]

[1]Centre for Atmospheric and Oceanic Sciences, Indian Institute of Science, Bangalore-560012, India (*correspondence: profsks@gmail.com)
[2]Divecha Centre for Climate Change, Indian Institute of Science, Bangalore-560012, India
[3]Space Physics Laboratory, Vikram Sarabhai Space Centre, Thiruvananthapuram-695022, India
[4]Pacific Northwest National Laboratory, Richland, WA 99352, USA

Air quality degradation is emerging to be an issue of major concern in India. This is mainly attributed to unplanned urbanization and industrial growth. Central Pollution Control Board is executing a nation-wide programme of ambient air quality monitoring. This network consists of 342 monitoring stations covering 127 cities in India. In addition, Indian space Research Organisation (ISRO) is maintaining 33 climate observatories across the country namely ARFINET (Aerosol Radiative Forcing over India Network). In this study, we have used multi-year observations of particulate mass (PM) concentration, aerosol black carbon (BC) mass concentration and aerosol optical depth (AOD) from these network observatories to make assessment of ambient air quality over India and its radiative impact. It has been observed that both column AOD and ground-level measurements (BC and PM) exhibit a weekly cycle with low aerosol concentrations on weekends. In comparison to the weekdays, the weekend reductions of AOD, BC and PM were ~15%, 25% and 24%, respectively. Aerosol trends indicates conflicting trends at different regions of India, thereby reflecting the complex factors behind the impact of growth on environment. While an increasing trend in aerosol has been observed in many cities, some cities show a decreasing trend during the last few years. Aerosol radiative impact assessment was made using ground-based radiometers and is compared with that simulated by radiative transfer models (which employ measured aerosol microphysics). One striking inference from this effort is the large discrepancy between observed and modelled aerosol surface radiative impact. Potential sources of such discrepancies are discussed in this presentation. The CHIMERE chemistry-transport model was used to simulate PM, BC and AOD over India and are compared with measurements. Evaluation of CHIMERE output shows that while diurnal and seasonal trends are captured reasonably by the model, absolute magnitudes differ substantially.

(*correspondence: Kei.Sato@usp.br)
[2]Universidade Federal de Ouro Preto, DEGEO, MG, Brasil
[3]Universidade Estadual do Rio de Janeiro, DGPI, RJ, , Brasil

Measurements

Several fragments of MG xenotime were mounted in epoxy disk (2.54 cm). Temora, FC and GJ standards were used as reference. The analytical conditions were: RF = 1200 Watts, Cooling gas = 15 L/min, Aux gas = 0.70 L/min, Sample gas flow = 0.75 L/min. Detector configuration: $^{202}Hg = IC_3$, $^{204}Hg + ^{204}Pb = IC_4$, $^{206}Pb = L_4$, $^{207}Pb = IC_6$, $^{208}Pb = L_3$, $^{232}Th = H_2$ and $^{238}U = H_4$, where IC = MIC, L (low) and H (high) are Multi Faraday Cups. The intensity to ^{80}Ar for stable condition was around 10V (aux gas =0.77 L/min and He gas = 0.65 L/min). The Laser analytical conditions to get the best ablation rate were: wavelength = 193 nm, Energy = 6mJ, Repetition rate = 10Hz, He gas flow = 0.65 L/min, spot size = 38 mm.

Results

The MG crystal shows Th concentration ranging from 300 to 2000 ppm with low common Pb ($^{204}Pb/^{206}Pb$ ratio <0.0001). The Th/U ratio ranges from 0.9 to 4.5. The GJ show low ^{232}Th intensity (~2 mV) but high ^{238}U (150 mV) intensity while MG shows high ^{232}Th (150mV) and normal ^{238}U intensity (90mV). Also the $^{232}Th/^{238}U$ ratios on GJ zircon standard range from 0.012 to 0.022, while in the MG ratio are much higher ranging from 0.7 to 4.7. The ^{232}Th intensity on GJ zircon standard range from 0.7 to 3 mV, while MG presents 130 mV (gray portions) to 900 mV (brown portions). Electron microprobe analyses, indicate high contents of Dy_2O_3 (3 – 6%), Er_2O_3 (3-4%), Yb_2O_3 (2-3%) and Lu_2O_3 (0.3 – 0.8%) for MG. The $^{206}Pb/^{238}U$ weighted average age of 445.8 +-4.5 Ma using GJ1 as standard, is lower than the TIMS age of 492Ma (1). This difference must be investigate but here it is suggested to be related to matrix effect.

Conclusions

The MG xenotime present a high U content, permitting precision measurements which is very helpful for the beam focusing during the LA-ICP-MS pre-adjustment set up. Therefore its high REE and Th concentrations, require matrix corrections of several percent for data from most zircon samples.

Effects of non-supercritical CO_2 on leaching of potential microbial substrates from macromolecular organic matter

PATRICK SAUER*, CLEMENS GLOMBITZA AND JENS KALLMEYER

University of Potsdam Institute for Earth- and Environmental Sciences Karl-Liebknecht-Straße 24, 14476 Potsdam, Germany (*correspondence: sauer@geo.uni-potsdam.de)

The storage of CO_2 in underground reservoirs is discussed controversly in the scientific literature and the public. The worldwide search for suitable storage formations also considers coal bearing strata. In addition, injection of CO_2 into coal formations is already applied for enhanced gas recovery of coal bed methane. Nevertheless, processes resulting from increased CO_2 concentration especially in organic matter rich formations are rareley investigated.

Depending on reservoir pressure and temperature, the injected CO_2 will dissolve in the porewater causing a decrease in pH [1] and resulting in acidic formation waters.

Recent investigations outlined the importance of potential substrates (e.g. low molecular weight organic acids) stored in organic-rich litologies such as coals [2]. Huge amounts of these substrates are chemically bound to the macromolecular matrix and may be liberated by hydrolysis within the acidic porewater. Therfore, injection of CO_2 into coal formations may result in an enhanced nutrient supply for microbial metabolism.

To study the effects of high dissolved CO_2 concentrations on macromolecular organic matter, we developed an inexpensive, high-pressure high-temperature incubation system. It allows not just controlling hydrostatic pressure and temperature but also the concentration of dissolved gases. Furthermore the system can be used for both static and flow through experiments and also allows subsampling during the experiment without depressurization.

We will present results from leaching experiments of low molecular weight organic acids such as formate and acetate with CO_2 saturated water at variing temperature and pressure conditions on coal samples of different thermal maturity.

Aerosol particle phase state measurement technique using a low pressure impactor

E. SAUKKO*, H. KUULUVAINEN AND A. VIRTANEN

Department of Physics, Tampere University of Technology, Tampere, FI-37720, Finland
(*correspondence: erkka.saukko@tut.fi)

The phase state of aerosols has impact on the behaviour of atmospheric aerosols. Recently published results show that the atmospheric biogenic SOA particles can adopt amorphous solid phase [1]. Existing methods to resolve solvent absorption induced phase change, such as tandem differential mobility analysis rely on the size change of particles related to solvent uptake.

To study the particle phase and phase change induced by size-preserving processes e. g oxidation, a new method has been developed. The method relies on impaction of particles on a smooth substrate and subsequent counting of bounced particles by condensation particle counter [2].

An example data of bounce probability with varying relative humidity is given in Figure 1. An ammonium sulphate aerosol was cycled through the system and an almost step-like transition was seen on the bounce probability at around 80% relative humidity. This corresponds well with the known deliquescence relative humidity of 80% [3].

The bounce probability can not at present be quantitatively linked to mechanical properties of particles, but it is qualitatively informative. The method has been applied on nebulised laboratory aerosols as well as on SOA.

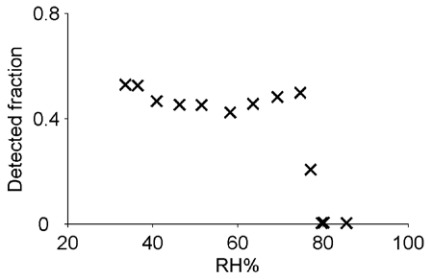

Figure 1: Fraction of 91nm ammonium sulfate particles detected after impaction with varying humidity

Gold mobility in the mantle: Constraints from sulfides in pyroxenites and lherzolites

J.E.J. SAUNDERS*, N.J. PEARSON AND SUZANNE Y. O'REILLY

GEMOC/CCFS, Macquarie University, NSW, 2109, Australia
(*correspondence: james.saunders@mq.edu.au)

Sulfides are the host for gold in the mantle [1], yet there is a scarcity of reliable Au analyses for sulfides from different mantle rock types. As a result, the geochemical behaviour of Au in the mantle is still poorly understood. In this study Au has been measured along with major and trace elements in sulfides in the well-characterised peridotite and pyroxenite xenoliths from Qilin, southeastern China. The peridotites are spinel and amphibole-spinel lherzolites, and the pyroxenites are basaltic melts that have re-equilibrated to spinel and garnet websterites in the upper mantle [2].

Pyrrhotite with very limited variability in major-element geochemistry is the dominant sulfide in the pyroxenites. The sulfides in the lherzolites include polyphase assemblages of mainly monosulfide solid solutions (MSS) with minor millerite, hazlewoodite and cubanite. The lherzolite-hosted sulfides have substantial variation in Fe, Ni and Cu contents. Interstitial and enclosed sulfides in these samples are mineralogically and chemically identical.

There are significant differences in the Au content of the pyroxenite- and lherzolite-hosted sulfides. Most pyroxenite sulfides have Au concentrations below lower limits of detection (<200 ppb), whereas the Au concentrations in lherzolite-hosted sulfides are several times higher than detection limits. There is no systematic difference between the Au content of sulfides in samples that have been modally metasomatised (amphibole-bearing), and sulfides in amphibole-free samples.

The lherzolites are quite fertile (equivalent to ~10% melt removal [3]), but there is no consistent trend in the PGEs (average Pd_{PUM}/Os_{PUM} = 1.49). However Au in these samples does appear to be depleted compared with the PGEs (average Au_{PUM}/Os_{PUM} = 0.25). This trend in the lherzolites strongly contrasts with the Au/Os ratio in the pyroxenites, where Au is relatively enriched. This comparison between Au in pyroxenite- and lherzolite-hosted sulfides suggests that Au can be transported by melts, and these melts may play a significant role in Au enrichment in the mantle.

Silicon isotopes in granitoid rocks

PAUL S. SAVAGE[1]*, R. BASTIAN GEORG[2], HELEN M. WILLIAMS[3], KEVIN W. BURTON[1], ALEX N. HALLIDAY[1] AND BRUCE W. CHAPPELL[4]

[1]Department of Earth Sciences, Oxford University, Oxford, UK (*correspondence: Paul.Savage@earth.ox.ac.uk)

[3]Department of Earth Sciences, Durham University, Durham, UK
[4]Earth and Environmental Sciences, University of Wollongong, NSW, Australia

Granites (and other felsic lithologies) constitute ~50% of the mass of the upper continental crust [1] and play a major role in global weathering [2], yet little information exists on their Si isotopic composition and systematics. In principle, S-type granites (that is, those with a pelitic sedimentary affinity [3]) should be isotopically light, as weathering enriches sediment in the lighter Si isotopes, whereas 'igneous' granites (I- and A-type) should be isotopically heavier. Previous work [4] reveals relatively large Si isotopic variation in granitoid rocks, but no systematic differences between granite types - however, the large uncertainties associated with these data makes interpretation difficult.

Here we revisit this problem and provide a Si isotopic perspective on granite petrogenesis with the benefit of high-precision techniques. We have analysed a representative suite of over 30 I-, S- and A-type granitoid samples and mineral separates, using a HF-free alkali fusion method and high-resolution MC-ICP-MS [5].

The data fall between δ^{30}Si = -0.41 and -0.11 ± 0.06‰ (2 s. d. external precision), although the variation within each batholith is small, providing evidence of a strong source control. However, Si isotopes do not distinguish between I- and S-type granites; both groups display a similar range of isotopic compositions. In contrast, the data for A-type granites are more restricted and comparable to extrusive felsic material [6]. A strong negative correlation with initial $^{87}Sr/^{86}Sr$ provides evidence that Si isotopic variation in both I- and S-type granites can be explained by contamination of an 'igneous' source region magma by an enriched (high Rb/Sr) end-member, possessing a light δ^{30}Si signature, such as sediment derived from continental crust.

Volcanic ashes as the source of dissolved calcium in seawater

A.V. SAVENKO* AND V.S. SAVENKO

Moscow M.V. Lomonosov State University, 119991, Moscow, Russia
(*correspondence: Alla_Savenko@rambler.ru)

The geochemical balance of carbon in the modern ocean indicates that 487 million ton of C_{org} annually oxidizes and form Ca–Mg carbonates. The reaction of carbonate formation requires 1 628 million ton of Ca (Mg) from silicates. Volcanic terrigenous ashes coming into the ocean possess of great specific surface and can pretend to the role of significant source of labile Ca (Mg). It was tested experimentally.

Variable amounts of ashes were placed into artificial 35‰ seawater containing no borates and salts of weak acids with the exceptions of carbonate. Hermetically closed contents were mixed during a month, and filtered through 0.22 μm filters. Values of pH, Alk, and concentrations of Ca, Mg, and Si were determined both in filtrates and the initial seawater.

Concentrations of calcium and silicon in all experiments increase in direct relation to the solid/water mass ratio (table). Maximal calcium mobilization was observed for the Koryaksky volcano ashes containing 2.1% S_{tot}. High sulfur content in this sample accounted for dramatic pH and Alk reduction. But pH and Alk reduction was observed also in the experiments with low-sulfur ashes from Kamchatka. This indicates that other reactions may affect acid-base equilibrium. Magnesium concentration except the Karymsky volcano ashes also increases with the solid/water mass ratio increase, but lesser than calcium concentration. Dissolved calcium and magnesium coming into the ocean can possibly bind dissolved inorganic carbon formed by oxidation of C_{org} of continental runoff in the ocean.

Tracing deep slab recycling via study of boron isotopes of volcanic rocks from hotspot (OIB) settings

I.P. SAVOV[1,2]*, S.B. SHIREY[2], S. TONARINI[3], J.G. RYAN[4] AND E. HAURI[2]

[1]University of Leeds, School of Earth and Environment, Leeds LS2 9JT, United Kingdom (*correspondence: i.savov@see.leeds.ac.uk)
[2]DTM-Carnegie Institution of Washington, 5241 Broad Branch Road, Washington DC 20015, USA.
[3] Istit.Geosci.Georisorse, CNR, Via Moruzzi 1, Pisa, Italy
[4]Geology Department, University of South Florida, 4202 E.Fowler Ave, SCA 528, Tampa, FL 33620, USA

Boron and B isotopes have potential to be among the best tracers of fluids and crustal components in the deep mantle because isotopically light B, strongly fractionated at the slab or isotopically heavy B, imprinted in the wedge could be recycled. Analytical challenges in basaltic rocks are presented by low B concentrations, and only limited high precision B isotope ratios are reported for OIB volcanic suites [1, 2]. Hence B and B isotopes have not been widely used to quantify potential slab and crustal contributions to hotspot magmas. Here we report LA-ICP-MS and TIMS δ^{11}B ratios and SIMS B concentrations for OIB lavas from key hotspot sites representing end-member components of the various mantle reservoirs. The B contents are always low (generally <5 ppm) and the δ^{11}B ratios are as follows: Society Isl. (+1.3 to -7.7‰; n=10); French Polynesia-Samoa Isl. (+2.8 to -9.1‰; n=10); Mt.Erebus/McMurdo Group/Crary Mts. (+2.3 to –10.4 ‰; n=10); St.Helena Isl. (+19 to -3.8‰; n=5); Reunion Isl. (-1.4 to -10.2‰; n=2) and Gough Isl. (-3.9 to -8.1‰; n=7). Interestingly, our new B and B isotope dataset often shows large deviations from currently accepted intraplate B and B isotope values for the deep mantle [3]. We shall evaluate the impact of processes such as assimilation of seafloor-altered basement and ancient subduction-related metasomatism as possible causes for the observed isotope variations. The overall negative B isotope results, combined with mantle-like Sr and Nd isotope ratios, indicate very sufficient and large volume B losses during the initial (shallower) stages of subduction, confirming the fluid mobile nature of this important slab tracer.

Seasonal dynamics of sulfide oxidation processes in Tokyo Bay dead zone sediment

M. SAYAMA

National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba 305-8569, Japan (m.sayama@aist.go.jp)

Sulfide (H_2S) pool in Tokyo Bay dead zone sediment changed dramatically according to the season (Fig. 1). In early fall with hypoxic bottom water, sediment surface was covered with *Beggiatoa* massively, indicating biological H_2S oxidation with NO_3^-. During winter with oxic bottom water, ascorbate-extractable-iron oxide (Asc-Fe(III)), that reflects ferrihydrite (high reactivity towards H_2S, insulative), showed a seasonal maximum, indicating chemical H_2S oxidation with Fe(III). During late fall, oxalate-extractable-Fe(III) (Oxa-Fe(III)), that reflects magnetite (low reactivity towards H_2S, conductive), showed a remarkable increase with a unique pH signature, pH maximum at oxic-anoxic interface (Fig. 2). Those results suggest that the main process for H_2S oxidation during transition period from hypoxic to oxic bottom water was probably bioelectrochemical reactions with O_2. H_2S oxidation processes in Tokyo Bay dead zone sediment are dynamically shifting in response to O_2 conditions in the bottom water.

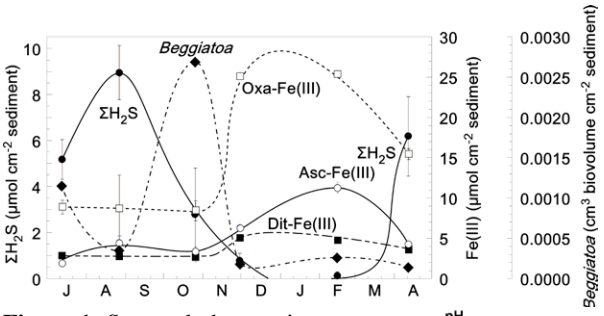

Figure 1: Seasonal changes in depth integrated (0-30mm) pool size of H_2S, *Beggiatoa* and iron oxides in Tokyo Bay dead zone sediment.

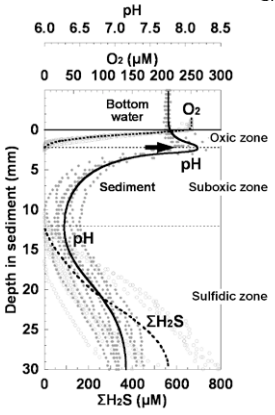

Figure 2: Microprofiles of O_2, pH and H_2S at sediment-water interface during transition period from hypoxic to oxic bottom water (November 30) in Tokyo Bay dead zone sediment.

The role of impurity atoms in forming cation vacancies in the pyrrhotite

A.M. SAZONOV* AND V.V. ONUFRIENOK

Siberian Federal University, Krasnoyarsk, Russia
(*correspondence: anatoly.sazonov@yandex.ru)

Synthetic pyrrhotites (Fe_nS) not containing interstitial atoms in the crystal structure and natural pyrrhotites of the 'Blagodatny' mine containing interstitial point defects have been investigated in the stable phase The phase and chemical composition was monitored by using the methods of X-ray diffraction (XRD) and X-ray spectrum analysis (XRS).

As a result of comparison of the crystal structure and the phase composition of the synthesised samples with natural pyrrhotites the influence of the inclusion atoms on the concentration of cation vacancies has been established.

The influence of impurity atom on the concentration of the cationic vacancies was considered on the basis of calculating the thermodynamic potentials using the Bose-Einstein quantum statistics. The theoretical calculations were compared with X-ray analysis data (Table 1).

The results of the X-ray analysis (XRS and XRD)		The results of the theoretical calculations of the number of defect on point of lattice		
S/Fe ratio	defects mass, %	sum of defects	impurity atom	cationic vacancies
1.130	0.160	0.1038	0.0020	0.1018
1.140	0.168	0.1185	0.0021	0.1164
1.147	0.151	0.1284	0.0021	0.1213

Table 1. Results of theoretical calculations on the basis of X-ray analysis of samples (XRS and XRD).

As it is shown in the table, tendency to increase of concentration cationic vacancies with increase impurity atom is calculated on the basis of experimental results.

The influence of S on silicate melt structure: An experimental and spectrocospic approach

B. SCAILLET[1]*, Y. MORIZET[2], I. DI CARLO[1] AND M. PARIS[3]

[1]Institut des Sciences de la Terre d'Orléans, UMR CNRS 6113, 1a rue de la Férollerie, 45071 Orléans (France) (*correspondence: bscaille@cnrs-orleans.fr)

[2]Laboratoire de Planétologie et Géodynamique de Nantes (LPGN), UMR CNRS 6112, 2 rue de la Houssinière, 44300 Nantes (France)

[3]Institut des Matériaux Jean Rouxel (IMN), UMR CNRS 6502, 2 rue de la Houssinière, 44300 Nantes (France)

Sulfur is one important volatile element after C and H in magmatic systems, however its effects on silicate melt structure and magmatic physical properties are poorly addressed. We present preliminary result of the effect of sulfur on silicate melt structure based on an experimental approach and spectroscopic measurments.

Glasses of HPG8 and An-Di eutectic compositions were synthesised at 300 MPa and 1250°C and under oxidising conditions (ΔFMQ+3.0) using IHPV. Starting compositions were equilibrated with a fluid phase composition: S (0 to 5 wt.%) and H_2O (5 wt.%). Recovered glasses were characterised using EMPA to determine S solubility, FTIR for H_2O solubility, Raman and Solid State NMR for glass structure.

S solubility determined in glasses changes from 0 to 1100 ppm and 0 to 8700 ppm for HPG and An-Di, respectively. The increase in S solubility is accompanied by the decrease in the H_2O content from ~5 to 4 wt.% H_2O. S is directly correlated to the initial S content traducing the change in the fluid phase composition.

Analyses of fluid inclusions suggest S is present as SO_2 and metallic S in HPG and An-Di glasses and additional H_2S has also been identified in some inclusions for An-Di glasses. The S speciation within the glasses is only represented by $M^{n+}SO_4$ groups (M^{n+} is Ca^{2+} in An-Di, Na^+ in HPG) consistent with the oxidising conditions of the experiments.

Raman and NMR analyses of the glass structure show subtle changes upon S dissolution. We observe 1) a slight polymerization with increasing S content, 2) a decrease in ^{VI}Al in An-Di and 3) a change in the H environments with increasing S content. The observed changes may be the result of decreasing H_2O content. However, the subtles changes remain very small suggesting that S will produce only minor changes to the melt strucutre in comparison to H_2O effect. Hence, the change in magmatic viscosity upon S dissolution is likely to be small.

Subducted serpentinites are the boron reservoirs for arc magmatism

MARCO SCAMBELLURI[1] AND SONIA TONARINI[2]

[1]Dipartimento per lo studio del territorio e delle sue Risorse, Università di Genova, Corso Europa 26, Genova - Italy
[2]Istituto di Geoscienze e Georisorse-CNR, Pisa, Italy

Serpentinites are key players in volatile and fluid-mobile element cycles in subduction zones. Their dehydration represents the main event for fluid and element flux from slabs to mantle, though no direct proof of this fact yet exists. For this purpose, B isotopes are known markers of fluid-assisted element transfer during subduction. Until recently, the altered oceanic crust has been considered the main ^{11}B reservoir for arc magmas, which largely display positive $\delta^{11}B$. However, slab dehydration below fore-arcs transfers ^{11}B to the overlying hydrated mantle and leaves the residual mafic crust very depleted in ^{11}B below sub-arcs. The ^{11}B-rich composition of serpentinites candidate them as the heavy B carriers for subduction. Here we present high positive $\delta^{11}B$ of Alpine high-pressure (HP) serpentinites recording subduction metamorphism: we show a connection among serpentinite dehydration, release of ^{11}B-rich fluids and arc magmatism. In general, the $\delta^{11}B$ of these rocks is heavy (16‰ to + 24‰ $\delta^{11}B$). $^{87}Sr/^{86}Sr$ ranges from 0.7044 to 0.7065, i.e. lower than oceanic serpentinites formed from seawater. Our data suggest two implications. 1st, the analyzed HP serpentintes are ^{11}B reservoirs for subduction. They maintain high ^{11}B down to a first fluid release event, thus the $\delta^{11}B$ of olivine-veins, that fingerprint the composition of released fluids, justify the positive values observed in many arc lavas. Fluids released by dehydration of such HP serpentinites by full antigorite breakdown should have up to + 20‰ $\delta^{11}B$. The comparable ^{11}B fingerprint of serpentintes, their fluids and arc lavas provides a strong link between serpentinite subduction and arc magmatism. 2nd, the combination of δD, $\delta^{11}B$, $^{87}Sr/^{86}Sr$ of the HP serpentinite apparently favour their location above the subducting slab. This implies that serpentinites were formed by low-T fluids likely arising from a subducting lower plate.

A new Br isotope analytical protocol: Constraints on the global Br cycle

BRUCE F. SCHAEFER

GEMOC, Earth and Planetary sciences, Macquarie University, Sydney NSW, 2109, Australia

Bromine possesses a chemistry broadly comparable to that of Cl and F, however its heavier mass and lower abundance results in slightly different behaviours in the geochemical cycling. Hence it is disproportionately enriched in sea water with respect to Cl, and unlike F possesses isotopes which may be fractionated by geological processes. These isotopes are ^{79}Br (50.686%) and ^{81}Br (49.314%).

Br can be considered to be a 'hydrophile' element, and hence its behaviour is in many ways analogous to that of water. Therefore environmental (low temperature) aqueous processes, particularly transpiration, weathering and evaporation are likely to produce fractionations in $\delta^{81}Br$ of the order of ~3.5‰ [1]. These signatures may be inherited by hydrous fluids derived from subducted slabs in regions where extensive hydrothermal alteration and/or carbonate deposits are present in the downgoing slab.

This study has developed new chemical extraction, and most significantly, new mass spectrometric protocols for Br isotopes on silicates and waters using N-TIMS methodologies. Existing CF-IRMS methodologies offer internal precision of ~0.3‰ (1SD, [1]), whereas N-TIMS measurements of laboratory HBr and seawater standards produce external reproducibility of <0.07‰ (1SD) over a 6 month period with internal precision typically <0.06‰ (1SD) on single analyses.

Southern Hemisphere Pacific Ocean Water (SHPOW) records $^{81}Br/^{79}Br$ significantly lower (0.9627) than the IUPAC canonical ratio (0.9729; a difference of ~10‰).

Protocols for mitigation of PO_3^- polybaric interferences on $^{79}Br^-$ will also be presented, as will $\delta^{81}Br$ data for depleted Island Arcs Tholeiites.

High-precision ^{10}Be-dating of moraines and the exploration of pro-glacial bedrock as climate archive using the new *in situ* ^{14}C/^{10}Be tool

JOERG M. SCHAEFER[1], IRENE SCHIMMELPFENNIG[1], BRENT GOEHRING[2], ROBERT C. FINKEL[3] AND DYLAN H. ROOD[4]

[1]Lamont-Doherty Earth Observatory/Columbia University, Palisades, NY-10964, USA
[2]Department of Geosciences, Pennsylvania State University, University Park, Pennsylvania, USA
[3]Earth and Planetary Science Department, University of California-Berkeley, Berkeley, California, USA
[4]Lawrence Livermore Natl Lab, Ctr Accelerator Mass Spectrometry, Livermore, CA 94550 USA

Methodological and analytical progress in cosmogenic nuclide techniques has surged in recent years, fueled in part by the CRONUS inititatives. One example is the increase in sensitivity of the ^{10}Be and the *in situ* ^{14}C methods that affords new perspectives on glacier fluctuations in response to past climate change. Moraine records around the globe can now be dated with unprecedented precision and pro- and subglacial bedrock can be explored as climate archive for past warm periods.

Here we present published and unpublished glacier chronologies from southern and northern mid-latitudes. The chronologies show centennial resolution of past glacier advances. The proglacial bedrock data yield complementary informations about periods of smaller-than-today glaciers.

We discuss the climatic implications of these data sets, focusing on (i) the chemical and analytical protocols behind this advance, (ii) the high internal consistency of the chronologies and the underlying reasons, and (iii) perspectives towards further methdo progress and its relevance for climate science.

Modeling of alteration processes in the Ringelbach granitic research catchment (Vosges, France)

T. SCHAFFHAUSER, B. FRITZ, F. CHABAUX, B. AMBROISE, A. CLÉMENT AND Y. LUCAS

LHYGES, Université de Strasbourg/EOST, CNRS, France (thiebaud.schaffhauser@etu.unistra.fr)

A geochemical modeling approach has been used to characterize the nature of weathering processes occuring within the Ringelbach granitic catchment (Vosges, France). The main springs were regularly sampled over the 2004-2006 period and analysed for major and trace element concentrations and Sr and U isotope ratios. Water samples from two 150-m deep boreholes drilled within the watershed were also used and analysed for this study; Geochemical characteristics of the waters are systematically different among the springs (depending on their elevation along a same slope) and deep boreholes (Chabaux *et al*. this issue).

The coupled transport/reaction model KIRMAT [1, 2] allows us to discuss and constrain the origin of such a systematic geochemical variation. The KIRMAT model combines geochemical reactions and one dimension mass transport equations to simulate the reactive transport of a fluid through a rock along a given water pathway. It was also designed to incorporate ideal solid solutions for the precipitation of clay minerals [3]. In the case of the Ringelbach weathering, the model simulates the transport of rainwaters along a 1-D water pathway crossing the different weathering levels of the granitic bedrock, from the surface saprolite level to the deep fresh granite. The long-term simulations (30ky) lead to weathering mineralogical sequences and to porosity evolution of the granitic bedrock consistent with field observations. They also point out that the geochemical characteristics of the water samples collected on the Ringelbach catchment depend on both the lithological level in wich the waters circulate and on the duration of the water transfert within each lithological level. The latter is certainly a key parameter to be further addressed in future studies.

Formation of seconday minerals A lysimeter approach

F. SCHÄFFNER[1]*, D. MERTEN[1], G. DE GIUDICI[2], P.C. RICCI[2] AND G. BÜCHEL[1]

[1]Friedrich-Schiller-University, Jena, Germany (*correspondence: franziska.schaeffner@uni-jena.de)
[2]University of Cagliari, Cagliari, Italy

Heavy metal contamination of large areas due to uranium mining operations poses a serious long-term environmental problem. In Ronneburg, in eastern Thuringia, Germany, leaching of low grade uranium bearing ores (uranium content < 300g/t) proceeded from 1972 to 1990 using acid mine drainage (AMD; pH 2.7-2.8) and diluted sulphuric acid (10g/l). Secondary mineral phases like birnessite, todorokite and goethite occure as natural attenuation process associated with enrichment of heavy metals, especially Cd, Ni, Co, Cu and Zn due to a residual contamination even after remediation efforts.

To reveal the processes of secondary mineral precipitation in the field a laboratory lysimeter approach was set up under similar conditions than in the field. Homogenated soil from the field site and quartz were used as substrates. Water supply was just from the bottom by a mariott´s bottle using contaminated groundwater from the field. Evaporation processes were accepted to allow continuous flow of water. This leads to precipitation of epsomite and probably aplowite on the top layer equal to field investigations. *In situ* measurements of redox potentials showed in general high oxidizing conditions (200-750 mV) due to different redox couples in the groundwater. After 4 weeks first secondary minerals became visible. Although Eh/pH data does not support formation of manganese minerals, SEM-EDX data show microorganisms in organic rich phases together with the occurrence of manganese, oxygen and nickel, indicating manganese oxides enriched in nickel. Infrared (IR) spectroscopy give hints for todorokite of being the secondary manganese mineral. Soil water samples were used for monitoring behavior of metals within the lysimeter. Hence saturation indices (SI) for different secondary minerals were calculated with PHREEQC. Clay minerals (e.g. kaolinite, illite) show SI values up to 5 indicating precipitation. This is coincided with a nearly completely depletion of aluminum in the soil water after entering the lysimeter and XRD measurements. The SI of goethite also shows oversaturation with respect to the soil solution. SEM-EDX analyses and IR spectroscopy confirm the formation of goethite. Data revealed that the formation of goethite is mainly dominated by Eh/pH processes in this system and that heavy metals like Zn and U could be enriched.

Are Large Igneous Provinces net-sinks for CO_2?

MORGAN F. SCHALLER[1], JAMES D. WRIGHT[1] AND DENNIS V. KENT[1,2]

[1]Earth and Planetary Sciences, Rutgers University, Piscataway, NJ (*correspondence: schaller@rutgers.edu)
[2]Lamont Doherty Earth Observatory, Palisades, NY

Continental flood basalts are subaerially erupted Large Igneous Provinces (LIPs), often covering significant continental areas with millions of cubic kilometers of lava. Recent evidence from the Central Atlantic Magmatic Province (CAMP) record in the Eastern North American (ENA) Newark Rift Basin demonstrated that LIPs may result in a transient doubling of atmospheric pCO_2, followed by a ~300 ky falloff to near pre-eruptive concentrations (*1*). We use the pedogenic carbonate paleobarometer in the corollary Hartford Basin to confirm findings in the Newark, and to test the million-year scale effect of the CAMP eruptions.

We find that the Hartford basin pCO_2 record is consistent with observations from the Newark, where a ~4400 ppm pCO_2 peak is identified just after each volcanic episode. The significantly longer post-extrusive Portland formation of the Hartford Basin shows a fourth CO_2 pulse to ~4500 ppm, about 250 ky after the last lava recorded in the ENA section, which may correlate to a later basalt in the Central High Atlas Basin of Morocco. The Hartford record also shows a rapid post-eruptive decrease in pCO_2, reaching pre-eruptive background concentrations of ~2000 ppm in <~300 ky, consistent with observations from the Newark Basin. Furthermore, the Hartford post-extrusive section exhibits a long-term decrease in pCO_2 to levels below the pre-CAMP background over the subsequent 1.5 My following the final apparent episode of eruptions.

We use a simple geochemical carbon-cycle model to demonstrate that the rapidity of these decreases, and the fall to concentrations below background may be accounted for by a 1.5-times amplification of continental silicate weathering due to the presence of the CAMP basalts themselves. If basalt has 10-times the chemical reactivity of continental crust, such an amplification would require eruption of lavas over an aerial extent of ~8.3 x10^6 km^2, well within independent estimates of the CAMP at 1.1 x 10^7 km^2. Together, these results indicate that continental flood basalts result in an extreme short-term perturbation of the carbon system, followed by a long-term decrease in pCO_2 to below pre-eruptive levels, implying they may have an overall net-cooling effect on global climates.

Alkaline mantle melts pinpoint late Triassic thinning of the Southern Alpine lithosphere (Ivrea Zone, Italy)

U. SCHALTEGGER[1]*, O. MÜNTENER[2], A. ULIANOV[2], M. OVTCHAROVA[1], I. PEYTCHEVA[1,3], M. ANTOGNINI[4] AND F. GIRLANDA[4]

[2]Mineralogy and Geochemistry, University of Lausanne, Switzerland
[3]Bulgarian Academy of Sciences, Sofia, Bulgaria
[4]Museo Cantonale di Storia Naturale, Lugano, Switzerland

Following granulite facies metamorphism and abundant mafic magmatism in the Permian lower crust, the European – Adriatic continental crust thermally equilibrated prior to upper Triassic to lower Jurassic rifting and exhumation. During this process, decompressional partial melts from the asthenosphere intruded into the lower continental crust and locally triggered partial melting and rejuvenation of isotopic systems. Such features have been described from the Ivrea zone [1, 2].

We studied Na-rich peralkaline leucocratic pegmatoid lenses within the ultramafic Finero body (N-Italy/S-Switzerland) at the eastern end of the Ivrea zone. These pegmatoids are composed of nepheline, plagioclase, biotite, zircon, apatite, sodalite and corundum. High-precision U-Pb ID-TIMS age determinations on single crystals, fragments and on a transect through a one centimeter sized zircon, combined with *in situ* laser ablation ICP-MS data, as well as initial Hf isotopes provide evidence that zircon grew episodically between 210 and 190 Ma from melts originating from an enriched mantle source. Variations in trace element composition and in age - up to 2 million years within one zircon crystal - are compatible with a first emplacement of plagioclase/albite and nepheline megacrystal bearing pegmatoids that are subsequently brecciated by a K, REE and trace element rich, fluid-saturated liquid. Both liquids are zircon saturated. The pulsed zircon growth is interpreted to reflect episodes of enhanced crustal stretching and thinning, producing a low-percentage of mantle melting. Our data may explain why the granulite-facies parageneses in the Ivrea zone have been locally overprinted and rejuvenated, solving the decennial controversy on the age of the regional granulite-facies event.

Estimating stable isotope signatures of core formation

EDWIN A. SCHAUBLE

UCLA, Los Angeles CA 90095 USA

The geochemical separation of isotopes at equilibrium is a process driven by material dynamics, chiefly the zero-point energy of vibrations (phonons). Isotopic signatures caused by this process might be useful for understanding the composition and conditions of formation of the Earth's core, as well as metal-silicate segregation elsewhere in the solar system [1-5]. This presentation will discuss recent progress in using first-principles models to understand isotopic fractionation caused by dissolution into metal alloys at high temperatures and/or pressures, as well as complementary techniques including spectroscopy-based modeling, experiments, and empirical calibration. Estimates of H, C, N, O, Si, S and Cr isotope fractionations in iron-rich metallic melts are calculated with density functional theory, via models of iron-rich crystals with bonding environments analogous to liquid alloy, e.g. dhcp-FeH, Fe_3C-cohenite and $Fe_{15}Cr$. Alloying atoms in these crystals are completely coordinated by iron. Equilibrium fractionation is assumed to be driven by the reduction of vibrational frequencies when heavy isotopes are substituted – though mass-independent fractionation may become significant for very heavy elements (e.g. platinum group elements, Pb). Quasiharmonic methods approximate the effects of high pressure and thermal expansion – in the case of silicon-isotope fractionation it appears that pressure effects of bond compression and increased cation coordination in silicate melts roughly cancel each other along the mantle liquidus. Stronger pressure effects are possible for other elements. The calculations suggest that iron alloys will usually be depleted in heavy isotopes, relative to other planetary materials, by as much as ~100‰/amu at 2000 K in the case of D/H fractionation between FeH and water, or as little as ~0.1‰/amu in the case of $^{53}Cr/^{52}Cr$. Isotopic signatures appear to be largest for light elements (H >> C, N, O > Si > S, Cr), and at low temperatures. All of the light-element systems studied could show isotopic separations large enough to measure, suggesting that significant core partitioning could perturb the bulk silicate Earth isotopic composition. Experimental and empirical determinations of Si-isotope and C-isotope fractionations broadly agree with theoretical models.

Modeling isotopic signatures of nebular chlorine condensation

EDWIN A. SCHAUBLE[1] AND ZACHARY D. SHARP[2]

[1]UCLA, Los Angeles CA 90095 USA
[2]University of New Mexico, Albuquerque NM 87131 USA

Recent measurements of $^{37}Cl/^{35}Cl$ in bulk chondrites and the silicate Earth suggest a relatively homogenous distribution of chlorine isotopes[1], but significant variation has been found in other planetary samples. In order to assess the potential for stable chlorine isotope ratio measurements to constrain the origin and transport of chlorine in chondritic parent bodies and other planetary precursors, and more broadly in minerals and ices, we calculated equilibrium $^{37}Cl/^{35}Cl$ isotope fractionations between gas-phase HCl and the crystalline phases $HCl.3H_2O$, NaCl (halite), KCl (sylvite) and $Na_4Al_3(SiO_4)_3Cl$ (sodalite) using a combination of experimental vibrational frequencies and electronic structure (DFT) models. Sodalite is estimated to have ~0.7‰ lower $^{37}Cl/^{35}Cl$ than HCl at ~950 K, the expected 50% condensation point for silicate-hosted chloride. This fractionation is in the same direction, but somewhat smaller than, the ~1.3‰ $^{37}Cl/^{35}Cl$ depletion observed in primitive sodalite inclusions in Allende[1]. Calculated halite-sodalite fractionation at 1098 K is also of the same sense but smaller than an experimental calibration (0.02‰ vs. 0.3‰) [1]. In contrast, $HCl.3H_2O$ hydrate is predicted to have 3-6‰ higher $^{37}Cl/^{35}Cl$ than coexisting HCl gas in equilibrium at temperatures relevant to low- pressure gas/crystal partitioning (roughly 140-160 K). This enrichment in ice is opposite in sense to what would be expected in a general rapid condensation process — more mobile ^{35}Cl-bearing molecules with weaker H-Cl bonds should react faster and thus ^{35}Cl should be enriched in the rapid condensation product. It is also opposite in sense to predicted and observed equilibrium isotope fractionation between HCl vapor and liquid water [2], but may overlap fractionation associated with disequilibrium evaporation. These results suggest that it may be possible to distinguish between icy [3] and silicate sources of chloride to planets and planetary precursors, so long as chlorine condensation in not quantitatively complete. Acid hydrate-derived high $^{37}Cl/^{35}Cl$ signatures, if found, could additionally indicate a post-condensation origin of chlorine-bearing minerals in chondrite minerals, and would be consistent with correlated high chlorine abundances and hydration in CI chondrites.

Modes of interaction between inorganic engineered nanoparticles and biological and abiotic surfaces

G.E. SCHAUMANN[1]*, P.M. ABRAHAM[1], A. DABRUNZ, R. SCHULZ[1] AND L. DUESTER[1,2]

[1]University Koblenz-Landau, Institute of Environmental Sciences, Germany
(*correspondence: schaumann@uni-landau.de)
[2]Department of Aquatic Chemistry, Federal Institute of Hydrology, Koblenz, Germany

Engineered nanoparticles are subjected to various aging and transformation pathways when they are emitted into the environment. One important pathway is connected to their attachment to biological or inorganic surfaces (e.g. planktonic invertebrates, plant leaves, biofilms or soil and sediment particles).

In this study the attachment of $n\text{Ag}^0$ and $n\text{TiO}_2$ to daphnia, plant leaves and organic as well as to inorganic model surfaces was studied, with the objective to understand the physicochemical interactions, in order to examine a possible link between (eco)toxicological effects and the attachment of the nanoparticles.

Surface-nanoparticle interactions were investigated in ecotoxicological test systems and in laboratory sorption experiments. The model surfaces were chosen to cover a wide range of intermolecular interactions considering van-der Waals interactions as well as proton donor and acceptor interactions. Samples were analysed quantitatively by ICP-MS and qualitatively by microscopic techniques (optical microscopy, environmental scanning electron microscopy and atomic force microscopy including nanomechanical properties).

In ecotoxicological test systems, attachment of nanoparticles to *Daphnia magna* occurred in large nanoparticle clusters and inhibited the molting of inidividuals. The deposition mechanism is in these systems determined by aggregation processes. In contrast, sorption of individual nanoparticles occured from stable suspensions. The sorption coefficient was determined by the chemical nature of the model surfaces as well as by the surfaces accessible for the nanoparticles.

The current results show that attachment is determined by an interplay between physicochemical nanoparticle-surface interactions, colloidal stability and physical characteristics.

Growth conditions of stalagmites derived from noble gas concentrations in fluid inclusions

Y. SCHEIDEGGER[1,2], N. VOGEL[1,2], S. FIGURA[1], M. BRENNWALD[1], R. WIELER[2], D. FLEITMANN[3] AND R. KIPFER[1,2]

[1]Eawag, Water Resources and Drinking Water, Dubendorf, Switzerland
[2]ETH Zurich, Institute for Geochemistry and Petrology, Zurich, Switzerland
[3]Geological Insitute, University of Berne, Switzerland

Stalagmites are increasingly used as climate archives to reconstruct past climate conditions over long time intervals and in wide ranges of continental regions. We analysed noble gases in 43 holocene samples from 2 tropical stalagmites (D1, P3) from Socotra Island, Yemen. Kr and Xe concentrations in many of the samples are explained as binary mixtures of noble gases from air-saturated fluid inclusion water and atmospheric noble gases released from air inclusions ('excess air'). After 2-component deconvolution, equilibrium concentrations of noble gases in the fluid inclusion water are calculated, from which in turn noble gas temperatures (NGTs) are deduced [1]. NGTs are assumed to reflect the ambient cave temperature at the time of the last gas exchange.

Many NGTs in D1 and P3 agree with the modern cave temperature (28°C). However, we observe relatively large NGT variations over short timescales, which cannot reflect actual cave temperature variations. We attribute these variations to changing conditons during air-water partitioning between inclusion water and the local cave atmosphere. An occasional enrichment in CO_2 around the stalagmite would lower the partial pressures of Kr and Xe and thus reduce their equilibrium concentrations in the inclusion water leading to spuriously high NGTs.

Our analyses also provide a record of the water content and allow to determine the amount of excess air in the samples. D1 shows a statistically significant regime shift at ~1.5 ka BP (see [2] for age model) both in the water content and in the amount of excess air. The regime shift coincides with the most negative excursion in the $\delta^{18}O$ record of the calcite [2]. Thus, growth conditions of stalagmite D1 changed dramatically at this time, possibly in response to a reduced drip rate, which lead to a major change in the amount of air and water inclusions incorporated in the stalagmite.

Chromium isotopes in Saanich Inlet sediments and waters

K. SCHEIDERICH[1]*, C. HOLMDEN[1] AND R. FRANCOIS[2]

[1]Saskatchewan Isotope Lab, Univ. of Saskatchewan, Saskatoon, SK S7N 5E2, Canada (*correspondence: kas373@mail.usask.ca, ceh933@mail.usask.ca)
[2]Earth and Ocean Sciences, Univ. of British Columbia, Vancouver, BC V6T 1Z4, Canada (rfrancoi@eos.ubc.ca)

Saanich Inlet is a classic locality for study of anoxic sedimentation and sulfidic water column processes. Organic-rich sediments from the inlet are enriched in Cr relative to the detrital background. Water column sulfide develops in the summer months as a result of stratification and high primary productivity and restricted deep water renewal. Thus, Saanich Inlet provides an excellent opportunity to uncover the modern behaviour of Cr isotopes, which show promise as a tool for paleoenvironmental analysis with respect to redox cycling. Cr isotopes are fractionated through reduction of soluble Cr(VI) to relatively insoluble Cr(III), enriching the Cr(III) in the lighter Cr isotopes. This study will be the first to assess the fractionation between Cr in contemporaneous waters and sediments in an anoxic setting.

Preliminary results for total Cr in the water of Saanich Inlet (100 m depth) show a $\delta^{53}Cr$ of +0.30‰ (normalized to SRM 979), with a total Cr concentration of 0.11 μg/L. This is a lower concentration than open ocean seawater (North Atlantic Seawater; 0.26 μg/L), suggesting that there may be removal of Cr from the water column. At the time of collection (August 2010), the water column was sulfidic below ~80 m depth. Open ocean Cr [1] has a $\delta^{53}Cr$ of +0.45 to +0.71‰, which suggests that Cr in the sulfidic water column of Saanich Inlet is being reduced and removed to the sediments. The Cr leached from the organic component of Saanich sediments was -0.17‰, while bulk marine sediments average -0.03‰ [2]. This system does not conform to the results of groundwater and laboratory experiments performed by others, which yielded large fractionation factors of ~+3.5‰ and predicted sedimentary $\delta^{53}Cr$ values of ~-3‰. One possibility is that reduction goes to completion on only a small fraction of the available Cr, perhaps facilitated by water column particulates or processes operating at the sediment-water interface.

The biogeochemistry of phytosiderophores in the rhizosphere in relation to Fe uptake

W. SCHENKEVELD[1], E. OBURGER[2], M. DELL'MOUR[3], C. STANETTY[3], M. WALTER[3], S. HANN[3], M. PUSCHENREITER[2] AND S. KRÄMER[1]*

[1]Universität Wien, Dept. of Environmental Geosciences Althanstraße 14, 1090 Wien, Austria (*correspondence: stephan.kraemer@univie.ac.at)
[2]University of Natural Resources and Applied Life Sciences, Dept. of Forest and Soil Sciences, Tulln, Austria
[3]University of Natural Resources and Applied Life Sciences, Dept. of Chemistry, Wien, Austria

Phytosiderophores (PS) are naturally occuring chelators, which are exuded by graminaceous plant species for the sake of iron acquisition (Strategy II) [1]. PS are highly efficient in mobilizing Fe from soil [2], and upregulation of PS exudation is the key iron deficiency stress response mechanism for graminaceous plants [1].

Despite the extensive research on the mechanism of action of PS, the understanding of the biogeochemistry of PS in the rhizosphere is still limited. The vast majority of studies have been carried out under conditions quite remote from those present in the rhizosphere (e.g. with hydroponic systems).

A lack of adequate analysis and sampling techniques, the complicated acquisition of PS from root exudates and the biodegradation of PS by rhizosphere microorganism are among the principal problems, prohibiting a more detailed study of PS in relation to soil-grown plants.

Our research project addresses several of these issues, amongst others through synthesis of PS ligands, development of new analytical methods suitable for measuring PS and metal-PS complexes in soil solution, and application of novel rhizosphere sampling techniques with rootboxes and microsuction cups.

The overall aim of the projects is an integral quantification of the source and sink terms determining PS concentrations in the rhizosphere. Both reaction kinetics and thermodynamic equilibrium aspects will be considered. Processes that will be examined include adsorption, desorption, mobilization of iron and other metals from the soil, biodegradation, PS exudation and PS-facilitated iron uptake.

Hydrothermally induced changes of electrical rock conductivity and permeability in porous feldspar-rich materials

A. SCHEPERS* AND H. MILSCH

Deutsches GeoForschungsZentrum, 14473 Potsdam, Germany (*correspondence: schepers@gfz-potsdam.de)

Due to the extraction of heat during geothermal energy production from deep sedimentary reservoirs, dissolution and/or precipitation reactions may be induced which potentially alter the pore space properties of the reservoir rocks. In this study hydrothermal batch and flow-through experiments were conducted with feldspar-rich porous materials at temperatures up to ~160°C, under hydrostatic pressure conditions, and durations up to 4 months to investigate the influence of such reactions on electrical rock conductivity (σ_r) and permeability (k).

Sample materials were feldspar-rich Rotliegend sandstone samples and granular analogue materials composed of quartz, K-feldspar, and plagioclase grains. The temperature range applied in the experiments pertains to a low enthalpy geothermal energy production scenario. The starting fluids ranged from deionised H_2O to 2 mol/L $NaCl_{aq}$ solutions. σ_r was continuously monitored while k was measured at irregular intervals throughout the flow-through experiments. In the batch experiments electrical fluid conductivity (σ_f) was measured at irregular intervals.

Chemical fluid analyses were performed on the resulting fluids with respect to the major ions of the system H^+, Na^+, Al^{3+}, Si^{4+}, K^+, Ca^{2+}, OH^-, Cl^-, and SO_4^{2-}. Aliquots of the solid materials were characterised prior and after the experiments with XRD, BET, Hg-porosimetry, SEM, and EMPA. Sub μm sized structures on altered grains were also investigated with TEM. One sandstone sample was analysed with X-ray CT with a resolution of ~2 μm prior and after a flow-through experiment to image the pore space *in situ*.

Dissolution features were common on the altered solid materials while precipitates were rarely observed. Precipitates were sub μm sized amorphous particles occurring mainly on plagioclase surfaces. The transient increases of concentrations of dissolved ionic species, of σ_f, and σ_r indicate a kinetically controlled dissolution process. Concurrently k decreases in the course of the flow-through experiments. The k decrease is mainly due to thermo-mechanical effects but may also result from the observed dissolution and precipitation reactions which lead to an alteration of the geometrical properties of the pore space.

The speciation of Au, Ag, Hg, Th and U in peat polluted by acid mine drainage

I.N. SCHERBAKOVA*, E.V. LAZAREVA, M.A. GUSTAYTIS AND S.M. ZHMODIK

Institute of Geology and Mineralogy SB RAS, Pr. Koptug, 3, Novosibirsk, 630090, Russia (*correspondence: sherbachok@ngs.ru)

The peat substance is one of the more popular natural sorbents that is used to recovery of elements from aqueous solutions including other similar materials. Ursk's sulfide-bearing waste piles (Ursk, Kemerovo region, Russia) have been formed more 50 years ago. The wastes of the cyaniding primary Cu-Zn-polymetallic ores and these of the oxidation zone have been dumped as a two piles. The natural stream draining the waste piles has been transformed in acid mine drainage (AMD). The wastes have not been fixed and hence ravine's swampy territory below the tailings piles have been covered with the derived waste matter. The interactions between the bog peat substances, AMD and wastes pore solutions have occurred for 50 years. It have been established the elements precipitation and concentration on peat substance. The Zn, Cu, Pb, Zn concentrations in peat samples are comparable to these in the wastes. The ore contained 4 ppm of Au. The contains of Au in waste covering the peat substance range from 0.2 to 1.7 ppm. It have been obtained that the concentrations of Au in the peat that is contacting with sulfide-bearing waste are 0.3-14.3 ppm. The Fe hydroxides, sulfides, jarosite, gypsum are established there.

The speciation of Au, Ag, Hg, Th and U in peat material has been determined using the selective extraction technique. It have been identified the following elements forms in peat substances: the water-soluble forms, these associated with organics/sulfides and with the Fe(III) hydroxides/oxides and residue. The part of all being studied elements is partially attributed to the water-soluble compounds (0.1 Au, 0.6 Hg, 0.08 Th, 0.5 U ppm). Gold is partly presented as organ-complexes ore sulfides (up to 1.4 ppm). In places where the gold concentration is in reaches 10 ppm, it appears mostly in the native form. The submicrometer gold Cu-bearing grains are observed among secondary minerals of Fe and are formed on the detrital material. Silver may enters as isomorphic admixture in the jarosite and mainly presets in contamineted peat as Fe(III) hydroxides/oxides fraction. Mercury as organ-complexes and/or as the secondary sulfide of Hg has been registered in peat samples. The major unit of U is associated with organic material and Th is with residual fraction.

Organic and inorganic $scCO_2$-rock interactions – Results from laboratory experiments

ANN-KATHRIN SCHERF*, HANS-MARTIN SCHULZ, ANDREA VIETH-HILLEBRAND AND KETZIN-GROUP

German Research Centre for Geosciences – GFZ, Telegrafenberg, 14473 Potsdam (*correspondence: scherf@gfz-potsdam.de)

Mineralogical changes in the reservoir in the cause of CO_2 injection and its propagation may provide information on e.g. CO_2-induced geochemical interactions and are of great importance for the estimation of potential risks of geological CO_2 storage. To overcome the gap of direct observations, experimental studies at simulated reservoir conditions are an important tool to study all types of potential CO_2-fluid-rock interactions *ex situ* on mineral phases or real reservoir samples.

In this broad experimental study, our aim was to examine the role of supercritical CO_2 ($scCO_2$) on the mobilization of organic compounds from mineral phases as well as the changes in elemental and mineralogical composition of reservoir and cap rock samples due to the defined temporal exposure to $scCO_2$ under variing p-T-conditions. For this purpose several flow-through experiments using $scCO_2$ have been performed [1] on real rock samples of different lithologies from an real CO_2 storage site: the Ketzin site in Germany.

$ScCO_2$-extracts as well as untreated and $scCO_2$-treated rock samples were analysed using a variety of organic and inorganic geochemical, mineralogical and microscopic techniques to detect changes compared to untreated twin samples.

Generally, organic matter mobilization – mainly the low molecular weight organic acids formate and acetate - occurred linearly within the first 8 hours, then continued with decreasing extraction yields. XRD and XRF analyses revealed no quantitatively distinguishable changes in elemental and mineralogical composition between $scCO_2$-treated and untreated twin samples. However, SEM images indicated blastesis and corrosion effects on mineral surfaces as well as a partly loss / destruction of primary cements due to the exposure to $scCO_2$.

Re-Os constraints on gold mineralisation events in the Neo-archaean Storø supracrustal belt, Southern West Greenland

ANDERS SCHERSTÉN[1], KRISTOFFER SZILAS[2], ROBERT A. CREASER[3], TOMAS NÆRAA[2], JEROEN VAN GOOL[4] AND CLAUS ØSTERGAARD[5]

[5]21st North, Kullinggade 31, DK-5700 Svendborg, Denmark

The Storø supracrustal belt in Godthåbsfjord, southern West Greenland, hosts gold mineralization that is associated with arsenopyrite along a contact between lithological units and along the axial plane of a large fold core. Here we present new arsenopyrite Re-Os and zircon U-Pb data to constrain the age of the debated Storø gold deposit. Arsenopyrite from a stratiform mineralisation yield a 2.71 ±0.05 Ga isochron and model ages for highly radiogenic arsenopyrite form a bimodal distribution with peaks at 2.66 Ga and 2.71 Ga respectively. The older population combined with the isochron result yields a weighted mean of 2.707 ±0.008 Ga (MSWD = 0.57, n=4). A 2.64 ±0.02 Ga isochron from arsenopyrite from the axial plane of the fold core indicate a two-stage mineralisation process. The 2.64 ±0.02 Ga isochron is in perfect agreement with U-Pb zircon data (Nutman *et al*. 2007. Prec. Res. 159, 19-32), which are best explained by orogenic mineralisation during amphibolite facies metamorphism along structural weak planes. The initial $^{187}Os/^{188}Os$ value of 0.56 ±0.16 for the 2.64 ±0.02 Ga isochron indicates a crustal source for the metals, whereas the initial $^{187}Os/^{188}Os$ = -0.1 ±0.6 for the 2.71 ±0.05 Ga isochron remains unconstrained. Nevertheless, these data are best explained by relatively short crustal residence times of less than 0.1 Ga, wherein the Os, and associated metals, were extracted from the mantle after 2.8 Ga, and in which the 2.64 ±0.02 Ga stage formed by mobilisation of an earlier mineralisation around 2.72 Ga. Such a model is corroborated by detrital zircon constraints, which imply that volcanism and the first mineralisaton stage is ≤2.8Ga. Finally, the ~2.63 Ga amphibolite facies metamorphic event in the Storø supracrustal belt was important for the redistribution of gold bearing sulphide minerals.

Marcasite in clastic sediments – Formative processes and deep time stability

JUERGEN SCHIEBER AND MICHAEL CHESHIRE

Department of Geological Sciences, Indiana University, Bloomington, Indiana 47405, (jschiebe@indiana.edu)

Marcasite occurs in marine and brackish water shale, claystone, and sandstone units from multiple locations and ages (Proterozoic through Eocene). Textural observations, such as differential compaction around marcasite concretions, indicate that these marcasites formed during early diagenesis in surface sediments. In marine shales and sandstones, textural studies suggest that marcasite precipitation is intimately associated with corrosion and destruction of framboidal pyrite for the former, and with destruction of reworked early diagenetic pyrite concretions for the latter. Marcasite formation in association with pyrite destruction is consistent with a scenario whereby earlier formed diagenetic pyrite is re-oxidized in surface environments to produce the low-pH conditions required for marcasite formation.

In brackish water claystones, marcasite occurs as radial fibrous masses along the margins of burrows that penetrated into reducing sediments. Soil science research that associates marcasite formation with water-logged acid sulfate soils in coastal settings suggests that this marcasite as well formed because oxidation of pre-existing iron sulfides provided favorable conditions for marcasite growth.

Marcasite concretions from both marine and brackish water settings show multiple generations of marcasite growth, and $\delta^{34}S$ values were measured from successive generations in micro-drilled samples and by ion-probe. The data show the lowered $\delta^{34}S$ values indicative of microbial sulfate reduction in surface sediments, as well as a wide range of $\delta^{34}S$ values suggestive of variable degrees of system closure (marine) and salinity fluctuations (brackish).

The studied samples range from approximately 50 million to 1.6 billion years in age and were all collected from unmetamophosed sediments. Marcasite is considered metastable and thought to invert to pyrite over time. Our observations indicate that this conversion proceeds very slowly at low temperatures (<200ºC). In general, partial conversion of marcasite to pyrite is minor to absent for fine grained sediments (shales and claystones), and common and completed to various degrees in sandy sediments.

High precision Ca isotope analysis using MC-ICPMS and TIMS

M. SCHILLER*, C. PATON AND M. BIZZARRO

Centre for Star and Planet Formation, Natural History Museum of Denmark, University of Copenhagen, DK-1350 Copenhagen, Denmark (*correspondence: schiller@snm.ku.dk)

Calcium is a refractory lithophile element and a major rock-forming constituent of rocky planets. Whereas most Ca isotopes are synthesized during hydrostatic and explosive nucleosynthesis in massive stars, the synthesis of ^{48}Ca is unique, as it is only efficiently produced in a low entropy environment most likely achieved in a type-Ia supernova [1]. Thus, high-precision Ca isotope measurements of meteorites and their components allow for a better understanding of the nature of the various stellar sources that contributed matter to the nascent solar system.

However, there are several challenges for the precise measurement of Ca isotopes. The natural abundance of the six stable isotopes (40, 42, 43, 44, 46 and 48) of Ca varies by a factor of >24000 (40 to 46), providing an obstacle for the simultaneous measurement of all Ca isotopes. In addition, there is a 20% mass difference between ^{40}Ca and ^{48}Ca, which produces a large mass dispersion beyond the geometry of either of the mass spectrometers used in our study. To overcome these issues we used a combination of TIMS and MC-ICPMS, where the low mass range (40-44) was measured using a Triton TIMS, while the overlapping high mass range (42-48) was measured using a Neptune MC-ICPMS. To precisely analyse ^{46}Ca using the MC-ICPMS we measured in high-resolution ($m/\Delta m \sim 6500$) and at total beam intensities of >5000 V. To further avoid direct isobaric interferences from Ti and Sr, we also established an improved chemical separation of Ca effectively eliminating especially Ti and Sr.

Repeated analyses of rock standards relative to the NIST SRM915b Ca-standard demonstrate that our approach allows the measurement of ^{40}Ca/^{44}Ca, ^{43}Ca/^{44}Ca, ^{46}Ca/^{44}Ca and ^{48}Ca/^{44}Ca to 50, 2.5, 50 and 12 ppm (2 sd), respectively, when normalized to ^{42}Ca/^{44}Ca. This represents a 100-fold improvement compared to previous studies for the less abundant isotopes of Ca. Using this improved resolution, we have re-investigated the extent of Ca-isotope heterogeneity in the solar protoplanetary disk by analyzing a suite of strategically-selected inner solar system objects.

Inhibition of calcite dissolution kinetics during direct liming of acid surface waters

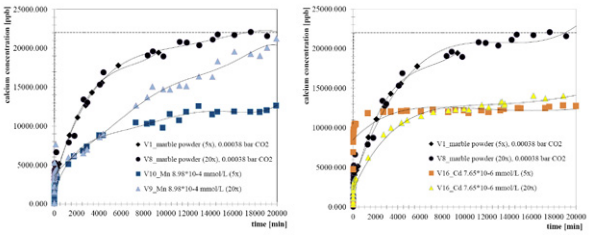
M. SCHIPEK* AND B.J. MERKEL

TU Bergakademie Freiberg, Chair of Hydrogeology, 09596 Freiberg, Germany (*correspondence: schipek@geo.tu-freiberg.de)

Dissolution kinetics of pure calcite is well investigated, e.g. [1, 2]. But, composition of natural carbonates, as well as the constituents in mine waters, have a strong influence on the solution kinetics and may inhibit dissolution processes during lake liming.

The reactivity of synthetic marble powder and industrial products was investigated. Significant differences in reactivity was obvious at $p_{CO2} > 3.8 \bullet 10^{-4}$ atm. Ions typical for acid mine drainage (e.g. Mn^{2+}, Cd^{2+}, SO_4^{2-}) do have different effects on the kinetic of carbonate dissolution. Manganese ions (c = $8.98 \bullet 10^{-4}$ mmol/L) inhibit calcite dissolution. Experiments with 5-times excess of calcite results in 66.4% of dissolved calcium compared to experiments without inhibitor. Providing a surplus of calcite particles (20-times excess) results in 92.7% of the equilibrium concentration and a significant time-shift in reaching equilibrium (20, 000 min instead of 12, 000 min).

Cadmium has as well a significant influence on dissolution and kinetics. Only 58.2% of the calcium concentration was reached with cadmium as inhibitor (c = $7.65 \bullet 10^{-6}$ mmol/L) compared to the dissolution in pure water. Using carbonate 20 times in excess revealed a slightly higher dissolution reaction (63.8%).



Increased CO_2 partial pressure might be used to compensate inhibtion by material impurities and/or water constituents.

The microbiology and biogeochemistry of sulfidic mine dumps

AXEL SCHIPPERS

Federal Institute for Geosciences and Natural Resources (BGR), Geomicrobiology, Stilleweg 2, 30655 Hannover, Germany (axel.schippers@bgr.de)

The microbiology and the relevant biogeochemical processes in the dumps and heaps are reviewed and have to be understood for improving copper heap leaching operations and to develop and control countermeasures for the formation of acid mine drainage (AMD). Pyrite or pyrrhotite oxidation is the most relevant biogeochemical process in sulfidic mine waste dumps and heaps and different techniques have been applied to measure reaction rates: column experiments, humidity cells, heat flow measurements, or oxygen consumption measurements. Acidophilic Fe(II)-and sulfur-oxidizing microorganisms are most relevant for metal sulfide oxidation. Anaerobic biogeochemical processes in sulfidic mine dumps and heaps are Fe(III)- and sulfate reduction, but little is known about the reaction rates. Fe(III)-reducing microorganisms dissolve Fe(III)(hydr)oxides and may thereby release adsorbed or precipitated metals. Sulfate-reducing microorganisms precipitate and immobilize many metals. Mainly culturing approaches were used to study the microbial communities in sulfidic mine dumps and heaps. More recently, molecular biological techniques have been applied to investigate the microbial diversity and to quantify and monitor particular microorganisms.

Bioremediation strategies to inhibit salt-enhanced stone weathering

MARA SCHIRO[1]*, ENCARNACION RUIZ-AGUDO[1], FADWA JROUNDI[2], MARIA TERESA GONZALEZ-MUÑOZ[2] AND CARLOS RODRIGUEZ-NAVARRO[1]

[1]Dept. Mineralogy and Petrology, Univ. of Granada, Spain (*correspondence: mschiro@gmail.com)

[2]Dept. Microbiology, Univ. of Granada, Spain

Salt weathering is an important mechanism contributing to the degradation and loss of carved stone and historic stone buildings. Stone monuments in the presence of salt and water, suffer from salt-enhanced physical and chemical weathering. It has been observed that weathering rates of rocks in nature, as well as building stones, are slowed down by naturally occurring or artificially produced patinas. These tend to be bacterially produced, durable mineralized coatings that lend some degree of protection to the underlying stone surface [1].

Our research shows that bacterially produced carbonate coatings can be quite effective at reducing both physical and chemical weathering of stone by soluble salts. The calcite-producing-bacteria used in this study were isolated from stone monuments in Granada, Spain [2] and cultivated in an organic-rich culture medium on a variety of artificial and natural substrates (including limestone, marble, sandstone, quartz, calcite single crystals, glass cover-slips, and sintered porous glass). Scanning electron microscopy (FESEM) was used to image bacterial calcite growth and biofilm formation. *In situ* atomic force microscopy (AFM) enabled calculation of dissolution rates of untreated and treated surfaces. 2D-XRD showed the mineralogy and crystallographic orientation of bacterial calcium carbonate.

Results indicate that bacterially produced calcite crystals form a coherent, mechanically resistant surface layer in perfect crystallographic continuity with the calcite substrate (self-epitaxy). These calcite biominerals are more resistant to chemical weathering by salt-enhanced dissolution, apparently due to the incorporation of organics (bacterial exopolymeric substances, EPS). Conversely, on silicate substrates, non-oriented vaterite forms, leading to limited protection. Organic films formed on treated substrates appear to promote salt crystallization at reduced supersaturation [3], thus reducing salt crystallization pressure and minimizing physical damage. These preliminary results indicate that bacterial treatments have tremendous potential to protect built cultural heritage.

Mineral assemblages and metamorphic history of granulites in the Rychleby Mts., Bohemian Massif

KATEŘINA SCHLÖGLOVÁ*, SHAH WALI FARYAD, DAVID DOLEJŠ AND HELENA KLÁPOVÁ

Institute of Petrology and Structural Geology, Charles University, Albertov 6, 128 43 Praha 2, Czech Republic (*correspondence: schloglo@gmail.com)

Relics of high-pressure metamorphic rocks are preserved in various crustal and mantle segments of the Variscan orogen in central Europe. These rocks may provide important insights into early stages of plate convergence and burial as well as exhumation mechanisms. We use mineral assemblages and chemistry to reconstruct the pressure-temperature (*P-T*) paths of high-pressure granulites in the Rychleby Mts., Bohemian Massif. Mafic granulites consist of garnet, omphacite, kyanite, two feldspars, and quartz with accessory rutile and zircon. The peak assemblage was partly replaced by pargasitic amphibole and biotite during exhumation. Garnet grains are zoned from $Gr_{36}Py_{10}Alm_{54}$ (core) to $Gr_{20}Py_{38}Alm_{42}$ (rim), and host inclusions of phengite, omphacite, unmixed feldspars, kyanite, and rutile. Omphacite composition varies from $Di_{44}Hd_{14}Jd_{42}$ (inclusions in garnet) through $Di_{63}Hd_{20}Jd_{17}$ (porphyroblasts) and $Di_{63}Hd_{24}Jd_{13}$ (symplectitic intergrowths with plagioclase). Reintegrated composition of the feldspar porphyroblasts is $Or_{43}Ab_{53}An_{04}$. Felsic granulite variety is composed of garnet, kyanite, two feldspars, quartz, accessory rutile, and zircon. Garnet preserves zoning from $Gr_{32}Py_{10}Alm_{68}$ (core) to $Gr_{25}Py_{24}Alm_{51}$ (rim), and it contains inclusions of phengite, sometimes replaced by biotite and zoisite. We have applied various univariant equilibria in order to estimate the *P-T* conditions of inclusion entrapment, porphyroblast growth as well as matrix recrystallization during exhumation. The phengite-garnet pairs indicate pre-peak temperatures of 840-860 °C. Ternary feldspar solvus and Zr concentrations in rutile (with a maximum at 1400-1900 ppm Zr) indicate 830-910 and 850-890 °C, respectively. The corresponding pressure, constrained by garnet-omphacite-kyanite-quartz and garnet-feldspar-kyanite-quartz equilibria, ranges between 15 and 18 kbar. Exchange equilibria between omphacite and garnet reveal peak temperatures as high as 950-980 °C, followed by decompression to 900 °C and 14 kbar associated with the formation of amphibole. Crystallization of biotite, at the expense of garnet, occurred near 740 °C possibly after a melt loss, which facilitated preservation of peak mineral assemblages. The reconstructed pressure-temperature path is consistent with extrusion of bimodal calc-alkaline igneous suite from orogenic root.

Biochemical characterization of single weathering hyphae of *Paxillus involutus* using CLSM and synchrotron based μFTIR

A. SCHMALENBERGER[1,2], A.W. BRAY[3], A.L. DURAN[4,1], J.R. LEAKE[4,1], S.A. BANWART[1], L. TATIC[1], G. CINQUE[5], M.D. FROGLEY[5], J. FILIK[5], J. PIJANKA[5], S. BONNEVILLE[3], L.G. BENNING[3] AND M.E. ROMERO-GONZALEZ[1]*

[3]School of Earth and Environment, University of Leeds, UK
[4]Animal and Plant Sciences, The University of Sheffield, UK
[5]Diamond Light Source Ltd, Didcot, UK

The mycelium of symbiotic ectomycorrhizal fungi (EM) increases nutrient uptake by the plants through fungal secretion of low molecular weight organic acids that can accelerate mineral dissolution. This EM weathering with pine trees plays a key role in nutrient mobilization processes and pedogenesis. Here we report first insights into the chemical variability of the weathering mycelium when studied on a micrometer scale using Confocal Laser Scanning Microscopy (CSLM) and synchrotron based micro Fourier Transform Infrared (μFTIR) spectroscopy.

Pine seedlings ectomycorrhizal with *Paxillus involutus* were grown in microcosms containing wells with olivine, quartz, basalt, granite and limestone. CLSM analysis of EM hyphae with the molecular probe SNARF4F in contact with basalt and limestone revealed a pH below or at 4.6 while the pH of EM in contact with granite identified pH values that varied from pH 4.6 to 6.5 with variations observed within single cells. Chemical μFTIR maps of single hyphae at a resolution of 5x5 μm identified variabilities within the spatial distribution of lipids, amides and carbohydrates. Particular distinctions in intensities of carbohydrates and lipids were discovered on a single cell level.

We conclude that mineralogy has a significant impact on the biochemistry of colonizing symbiotic EM mycelia, individual hyphae and cells. Earlier studies showed that exudation of oxalate is increased in the presence of basalt and limestone[1] and here we report the corresponding biochemical changes that take place on a single hypha scale.

Growth- and post-growth behavior of major and trace elements in garnets, a case study

ALEXANDER SCHMIDT, MATTHIAS KONRAD-SCHMOLKE AND PATRICK J. O'BRIEN

Department of Earth & Environmental Science, University of Potsdam (alexander.schmidt@geo.uni-potsdam.de, mkonrad@geo.uni-potsdam.de, obrien@geo.uni-potsdam.de)

The distribution of major and trace elements in the mineral garnet plays an important role in the interpretation of ages deduced by e.g. Lu-Hf and Sm-Nd garnet geochronology. A common understanding is that Lu and other heavy rare earth elements (HREE) have high partition coefficients for garnet, hence will be enriched in early formed garnet cores, while on the other hand light rare earth elements (LREE), such as Sm, will be incorporated during late growth into garnet rims. Further, distribution patterns of HREE in garnet are important indicators for processes during metamorphism as they might point to episodic and multi-generation garnet growth, as well as to mineral reactions producing distint enrichment peaks during garnet growth (e.g. amphibole- & epidote-out reactions).

In this study we investigate these distribution patterns of major and trace elements in a variety of garnets from chemically different host rocks, and discuss the influence of e.g. diffusion on the preservation of growth zoning.

The first results show that nearly all single-generation garnets indeed preserve element distribution profiles with an enrichment of Lu and other HREE in garnet cores. Interestingly diffusion often seems to play a negligible role for the HREE compared to the major elements. Distinct Lu peaks in garnet cores do on the one hand correspond to well-preserved Mn peaks, but also Lu enrichments together with flat Mn patterns are observed, which indicates that Lu (and presumably other HREE) are less prone to diffusional resetting compared to e.g. the major elements. One of the major aims of this study will be to constrain how explicitly diffusion can influence and alter major and trace element distribution profiles in garnets and how these are interrelated with each other. With this information it hopefully will be non-ambiguous to interpret geochronological data of garnets from the Lu-Hf and Sm-Nd isotope systems.

Role of fluid flow conditions on denitrification rates in sediments during managed groundwater recharge

CALLA M. SCHMIDT[1]*, ANDREW T. FISHER[1], ANDREW J. RACZ[1], BRIAN S. LOCKWOOD[2] AND MARC LOS HUERTOS[3]

[1]University of California, Santa Cruz, Santa Cruz, California 95064 (*correspondence: cschmidt@ucsc.edu)

[2]Pajaro Valley Water Management Agency, Watsonville, California 95076

[3]California State University, Monterey Bay, Seaside, California 93955

We measured *in situ* denitrification during infiltration through saturated sediments to develop a mechanistic understanding of controls on denitrification rates. Sampling and measurements were completed below a managed aquifer recharge pond, providing strong constraints on initial nitrate and carbon concentrations, flow rates, and other controlling parameters. Co-located thermal measurements were used to determine flow rates with time, and chemical and isotopic methods were used to assess denitrification progress. Zero order denitrification rates of 3 to 300 μmol L^{-1} d^{-1} were measured during infiltration. Denitrification was not detected at times and locations where the infiltration rate exceeded a threshold of approximately 0.9 m d^{-1}. Pore water profiles of oxygen and nitrate concentrations indicated a deepening of the redoxocline at higher flow rates, which reduced the thickness of the zone favorable for denitrification. Below the threshold infiltration rate, denitrification rates were positively correlated with infiltration rates, suggesting that for a given set of sediment characteristics an optimal range in infiltration rate exists for achieving maximum nitrate load reduction. This study has implications for managing water resources to achieve the greatest possible nitrate load reduction by denitrification in both natural and manipulated settings including recharge ponds, wetlands, and hyporheic zones in streams.

Zircon as a Raman spectroscopic pressure sensor

C. SCHMIDT[1], M. STEELE-MACINNIS[2] AND M. WILKE[1]

[1]Deutsches GeoForschungsZentrum (GFZ), Telegrafenberg, 14473 Potsdam, Germany (hokie@gfz-potsdam.de, max@gfz-potsdam.de)

[2]Department of Geosciences, Virginia Tech, Blacksburg, VA 24061, USA (mjmaci@vt.edu)

Experiments using diamond-anvil cells have been crucial in understanding minerals and fluids at high pressure (*P*) and temperature (*T*) because sample properties can be studied *in situ*. Pressure in these cells must be determined indirectly, e.g. from the shift in wavenumber of a Raman line of a phase inside the sample chamber. The 464 cm^{-1} Raman line of quartz has frequently been applied as pressure sensor because of its fairly large shift with *P* ($\partial\nu/\partial P$ ~9 cm^{-1}/GPa) and relatively small shift with *T* ($\partial\nu/\partial T$ ~-0.014 cm^{-1}/K) [1]. However, its use is limited by phase transitions and high solubility of quartz in many fluids and melts. In such situations, zircon represents an option because it is stable over a larger range in *P*, *T*, and fluid composition (e.g. [2]).

In this study, we calibrate the shifts in wavenumber of the ν_3-SiO_4 (~1008 cm^{-1}) Raman band of fully crystalline synthetic zircon with *T* and *P*. The relationship between wavenumber and *T* from 22 to 950 °C is described by the equation ν (cm^{-1}) = $7.26*10^{-9}*T$ (°C)^3 - $1.58*10^{-5}*T$ (°C)^2 - $2.893*10^{-2}*T$ (°C) + 1008.64. At ~25 °C, the $\partial\nu/\partial P$ slope to 6.6 GPa is 5.69 cm^{-1}/GPa, and that to 2 GPa is 5.81 cm^{-1}/GPa. The latter does not significantly change with temperature, as determined using a Bassett-type hydrothermal diamond-anvil cell [3], with the pressure based on the EoS of H_2O [4]. The observed $\partial\nu/\partial P$ slopes are 5.88 cm^{-1}/GPa for the 700 and 600 °C isotherms, and 6.08 cm^{-1}/GPa along the 500 °C isotherm. The zircon pressure sensor was used to obtain isochores for aqueous fluids with 6 wt% $NaAlSi_3O_8$, 16 wt% $Na_2Si_2O_5$, 28 wt% $Na_2Si_{1.3}O_{3.6}$, or 64 wt% $Na_2Si_3O_7$ to 800 °C and 1.43 GPa. Except of the experiment with H_2O + 6 wt% $NaAlSi_3O_8$, these isochores were at significantly higher pressures (by up to ~700 MPa) than calculated from the liquid-vapor homogenization temperature using the EoS of H_2O [4]. The actual sample temperature should be well known for accurate determination of *P* using this sensor ($\partial\nu/\partial T$ ~-0.038 cm^{-1}/K).

Fractionated enrichment of Zr-Hf and Nb-Ta in ferromanganese crusts

K. SCHMIDT, MICHAEL BAU AND ANDREA KOSCHINSKY

Jacobs University Bremen, Earth and Space Sciences, 28759 Bremen, Germany (k.schmidt@jacobs-university.de)

The very slow growth rate of and the high adsorption capacity attracting dissolved elements from seawater makes marine hydrogenetic ferromanganese (Fe-Mn) crusts generally suitable for the investigation of environmental and paleooceanographic conditions in the past. However, a detailed unterstanding of enrichment processes and possible fractionation mechanisms of elements and isotopes during the accumulation of the crusts is required. Here we report on the distribution of the geochemical twin elements Zr-Hf and Nb-Ta in ferromanganese crusts from the Northern and Southern Central Pacific, the Eastern North Atlantic and from the hydrothermal vent field Logatchev-1. Recent studies [e.g. 1] dealing with the distribution of Zr-Hf and Nb-Ta in the Pacific Ocean show a fractionation of these elements relative to chondritic values throughout the water column, with distinct signatures in different water masses. Our investigated depth profiles of ferromanganese crusts cover up to 20 Ma and are characterized by highly variable distributions of Zr, Hf, Nb, and Ta, accompanied by changing and fractionated Zr/Hf and Nb/Ta ratios. The Zr/Hf ratios in crust surfaces are always lower compared to the range of Zr/Hf ratios in modern deep seawater. Thus, ferromanganese crusts do not inherit the Zr/Hf (and Nb/Ta) signature of the water mass at the location of crust formation and the ratios cannot be used as paleooceanographic tracers. The elements are almost exclusively bound to the Fe oxyhydroxide fraction of the crust and are probably enriched via surface precipitation. While the Fe oxyhydroxide colloids and particles accumulating in the crusts may have formed away from the crust location and would then carry a different, integrated signal [2], the always lower than seawater Zr/Hf ratios in the crusts also indicate the preferred enrichment of Hf relative to Zr during accumulation in the crust and thus a fractionation of the dissolved seawater Zr/Hf ratio. Seawater data for Nb-Ta are scarce, but a preferential enrichment of Nb in the Fe-Mn crusts can be suggested. The different particle reactivity of the geochemical twin elements is related to the different electron structure causing differences in complex stabilities and the type of chemical bonding. Further, the contribution of hydrothermal Hf to the marine Hf budget will be discussed.

Centennial-scale sea surface temperature and salinity change in the Florida Straits during the early Holocene

M.W. SCHMIDT[1]*, W. WEINLEIN[1], F. MARCANTONIO[2] AND J. LYNCH-STIEGLITZ[3]

[1]Department of Oceanography, Texas A&M University, College Station, TX 77843, USA (*correspondence: schmidt@ocean.tamu.edu)
[21]Department of Geology and Geophysics, Texas A&M University, College Station, TX 77843, USA
[3]School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta, GA 30307

Previous studies showed that sea surface salinity (SSS) in the Florida Straits [1] as well as Florida Current transport [2] covaried with changes in North Atlantic climate over the past two millennia. However, little is known about earlier Holocene variability in the Florida Straits. Here, we combine Mg/Ca-paleothermometry and stable oxygen isotope measurements on the planktonic foraminifera *G. ruber* (white variety) from Florida Straits sediment core KNR166-2 JPC51 (24° 24.70′N, 83° 13.14′W, 198m deep) to reconstruct a high-resolution (~35 yr/sample) early to mid Holocene record of sea surface temperature and $\delta^{18}O_{SEAWATER}$ ($\delta^{18}O_{SW}$, a proxy for SSS) variability. In addition, we also measured Ba/Ca ratios in the same shell material as a proxy for riverine input into the Gulf of Mexico over the same time interval. After removing the influence of global $\delta^{18}O_{SW}$ change due to continental ice volume variability, our $\delta^{18}O_{SW}$ record suggests early Holocene surface salinity enrichments caused by increased evaporation/precipitation ratios in the Florida Straits associated with periods of reduced solar output [3], increased ice rafted debris in the North Atlantic [4] and the development of more permanent El Niño conditions in the eastern equatorial Pacific [5]. When considered with previous high-resolution reconstructions of early Holocene tropical atmospheric circulation changes, our results provide evidence that solar output variability over the Holocene can have a significant impact on the global tropical hydrologic cycle.

Rare earth element variation in hydrothermal Fe-oxide Cu-Au systems

ANDREAS SCHMIDT MUMM AND CRISTIANA CIOBANU

School of Earth and Environmental Sciences Cooperative Research Centre for Deep Exploration Technologies, The University of Adelaide Adelaide, South Australia 5005 (andreas.schmidtmumm@adelaide.edu.au, Cristiana.ciobanu@adelaide.edu.au)

Mineral deposits of Cu-sulphides and gold paragenetically associated with hematite and magnetite may also contain variable, in some cases economic levels of uranium and rare earth elements. The size of these deposits, e.g. Olympic Dam with an ore body in excess of 3x5x2km implies large, crustal scale fluid processes. Alteration of the host rock of these deposits is variable but distinct alteration mineral facies can be distinguished. The commonly identifed regional geochemical footprint of these REE anomalous deposits is a pronounced sodic alteration (albitisation) with accompanying formation of calc-silicate / magnetite / Fe-amphibole breccias and metasomatism. On the depositional side of the mineralising system we can distinguish two types of alteration asociated with Cu and Au mineralisation: i) a pyrite/magnetite dominated assemblage with pronounced potassic (biotite, K-spar) alteration and a predominance of chalcopyrite ± bornite, locally and variably overprinted by hematite + bornite + covellite + chalcocite. ii) a hematite dominated assemblage with bornite + covellite + chalcocite and much less chalcopyrite. Gold content appears related to sulphide abundance but Au rich zones with low sulphide grades are present. The different alteration/mineralisation zones have distinct REE patterns. The regional albitisation zone, which is seen as the source region of the metal components displays a path of initial depletion of LREE followed by an overall REE depletion as the involved rock is progressively converted to an albitite. Intermediate sections dominated by magnetite / biotite / K-spar alteration can have intense enrichment of REE including the formation of discrete RE minerals (allanite) but this appears to be most related to a late stage of the mineralising process. A pronounced enrichment of the REE occurs in the hematite / sericite dominated section, with REE rich barite and fluorite as well as RE minerals such as bastnaesite, florencite, monazite and xenotime. On the mineral grain scale enrichment of REE and U is pronounced in the hematite / sericite dominated part of the system.

Growth rate effect on Sr/Ca and Mg/Ca partitioning between calcite and fluid: *In situ* data

A.K. SCHMITT[1]*, R.I. GABITOV[1], A. SADEKOV[2] AND A.LEINWEBER[1]

[1]University of California, Los Angeles, CA, 90095, USA (*correspondence: axel@oro.ess.ucla.edu)
[2]University of Edinburgh, Edinburgh, *EH9 3JW, UK*

Sr/Ca and Mg/Ca (Me/Ca) abundances in speleothems, foraminifera, coccolith, and mollusks have been extensively used as paleotemperature proxies. However, inconsistencies exist between different Me/Ca-temperature calibrations which imply disequilibrium exchange of Sr/Ca and Mg/Ca between fluid and calcite, thereby jeopardizing their use as paleoclimate proxies unless the overriding physico-chemical and biological effects on elemental partitioning can be calibrated.

This study complements existing experimental data on Sr and Mg partitioning that are mostly based on bulk analysis of calcite precipitated at different rates. In our alternative approach, the advancing rate of the crystal surface was determined by sequentially spiking calcite-precipitating fluids with rare earth element (REE) dopants. *In situ* secondary ion mass spectrometry (SIMS) analyses of Me/Ca were performed on single crystals of experimentally grown calcite at relative external reproducibilities for both ratios of ~1 % (1s. d.). REE patterns reveal concentric domains of calcite growth. The growth rate of calcite generally decreases with time - i.e. crystal rims advanced at slower rates than cores. Fluids were sampled periodically for Me/Ca, dissolved inorganic carbon, and pH.

SIMS profiles across individual calcite crystals displayed depleted Sr/Ca and elevated Mg/Ca at crystal rims relative to interiors. The partition coefficient of Sr/Ca ($K_d^{Sr/Ca}$) increases by ~100±2% with increasing growth rate over the range of 1 to 8 μm/day (at 25°C). In contrast, $K_d^{Mg/Ca}$ decreases by ~33±16% over the same range.

Our results suggest that Sr (Mg) are enriched (depleted) in the near-surface region of calcite relative to the bulk crystal lattice. This observation is consistent with previous *in situ* data and the surface entrapment model [1, 2], which underscores that Sr/Ca and probably Mg/Ca in natural carbonates are not a direct proxy for marine and terrestrial temperature, and require corrections for the dependency of partitioning behavior on crystal growth rate.

Zircon rim response to metamorphic and hydrothermal regime-change

D.A. SCHNEIDER[1] AND A.K. SCHMITT[2]

[1]Earth Sciences, University of Ottawa, Canada, K1V 6N5
[2]Earth & Space Sciences, University of California-Los Angeles, USA 90095

A significant advance in zircon geochronology is the recognition of different types of neoblastic growth and recrystallization during tectonism and mineral-fluid interaction. Such domains can form in zircon and other accessory minerals as a consequence of alteration and dissolution-precipitation processes across a range of P-T conditions, and as low as ~200 °C particularly when in the presence of fluids. Distinct chemical and isotopic signatures associated with these alteration regimes can reveal valuable geological information regarding the timing and source of fluid influx, as well as mineral-fluid interaction at the sub-grain level. Application of SIMS depth-profiling now permit unparalleled spatial resolution analysis (down to ~0.2 μm) of these thin alteration zones. Complementary LA-ICPMS depth-profiling allows detection of geochemical changes accurately down to ~5 μm. Depth-profiling of unpolished zircon or other accessory crystal species measures changes in radiogenic (U-Pb), stable isotopic ($\delta^{18}O$) and chemical (REE) signatures that translate into concentration-depth profiles as drilling progresses into the crystal's interior. One application is to resolve the source and timing of fluid-flow responsible for lode Au deposits of the Canadian Abitibi Province. Depth-profiling techniques successfully uncovered <3 μm alteration domains in wall-rock zircon, occurring as light REE-enriched "rims", and Th/U and ^{18}O values suggest that alteration involved limited crustal recycling. Zircon rim ages are significantly younger than host rock ages, and correlate to intensely mineralized and deformed quartz-carbonate-Au shear veins. Subsequent zircon alteration correlating to thin, shallow-dipping and less altered and mineralized vein networks occurred 20 m.y. later, and represents a late hydrothermal fluid pulse at the end of retrograde metamorphism. A similar approach revealed an episode of Eocene metamorphism (metasomatism?) in the western Cyclades of the Aegean, an area known for iron- and sulfide-ore skarn deposits. A dominant zircon population had a spongy structure created by complete recrystallization of the pre-existing crystal, possessing low Th/U and flat and depleted HREE patterns, and yielding Eocene ages with $\delta^{18}O$ ~7‰. Detailed pre- and post-analytical imaging is necessary to document crystal structures and mineral outgrowths. Depth-profiling on zircon is a successful, yet nascent application for the dating of mineral deposits and fluid flow.

A multi-component reactive transport model assessment of microbial processes and trace metal cycling across a gradient in sulfate reduction rates along the California Margin

A. SCHNEIDER MOR[1], C. STEEFEL[2] AND K. MAHER[1]

[1]Department of Geological and Environmental Sciences, Stanford University, Stanford, CA, 94305, USA (*correspondence: ayaschm@stanford.edu).
[2]Earth Sciences Division, Lawrence Berkeley National Laboratory Berkeley, CA 94720 USA

Sediments and pore water from 4 ODP Leg 167 sites along the California Margin (1011, 1017, 1018 and 1020) were used to compare biogeochemical processes across a gradient of sulfate reduction (SR) rates with the purpose of studying the processes that control these rates and how they affect trace metal redistribution. Measurements of the trace element composition of pore water and sediment along with $\%CaCO_3$, %biogenic silica, wt% carbon and $\delta^{13}C$ of Total Organic Carbon (TOC) were used to constrain the multicomponent reactive transport model CrunchFlow. The rates of sulfate reduction, methanogenesis and anaerobic methane oxygenation (AMO) were constrained by fitting the model to the measured concentration profiles. The sites are distinguished by the depth of AMO: a shallow zone is observed at sites 1018 (14 to 19 mcd) and 1017 (23 to 27 mcd), while deeper zones occur at sites 1011 (45 to 55 mcd) and 1020 (97 to 113 mcd). In general, the sulfate reduction rates are faster (on the order of $9\text{-}9.9*10^{-17}$mol/L/yr) for the shallow zones, compared to $1\text{-}1.4*10^{-17}$ mol/L/yr for the deeper zones. AMO rates are also faster at the shallow belt $2*10^{-7}$ mol/L/yr compared to $3*10^{-8}$ mol/L/yr at the deeper sites. Sites with shallow sulfate reduction zones appear to have high rates of AMO resulting in high alkalinity concentrations close to the sediment-water interface. The dissolved metal ion concentrations also varied between the sites, with Fe (0.01-7uM) and Mn (0.01-57uM) concentrations highest at Site 1020 (water depth 3000m) and lowest at site 1017 (water depth 950m). The highest Fe and Mn concentrations occurred at various depths, with no direct correlation to sulfate reduction and alkalinity maximum values. Modeling of the dissolved and solid SiO_2, Ca, Mg, K, Mn and Fe is used to establish the relationship between the biogeochemical reactions and trace metal variations and to better constrain the parameters that influence the trace metal distributions in the sediment column.

Dissolved reactive mangenese at pelagic redoxclines

B. SCHNETGER[1]* AND O. DELLWIG[2]

[1]Institute for Chemistry and Biology of the Marine Environment, University of Oldenburg, Germany (*correspondence: schnetger@icbm.de)
[2]Marine Geology Section, Leibniz Institute for Baltic Sea Research, Rostock, Germany

Experiments with suboxic freshwater and seawater suggest a dissolved reactive manganese fraction (dMn_{react}) that completely oxidizes within 36 h, mainly by microbial activity. The fast redox cycle of Mn drives the 'Mn pump' transporting metals into anoxic basins. A difference method can be used to determine dMn_{react}. One aliquot of a water sample is directly filtered and represents the total dissolved Mn. A second aliquot is aged under atmospheric oxygen and app. 20°C and filtered after 36 h representing the residual dissolved Mn(II). The concentration of dMn_{react} is calculated as difference of both aliquots.

Application to the Black Sea revealed dMn_{react} profiles comparable to published Mn(III) patterns analysed with a polarographic method. Both methods show that the upper part of the suboxic zone consists exclusively of dMn_{react} or Mn(III). dMn_{react} is a half quantitative measure of dissolved M(III), an unknown fraction of i) autocatalytic oxidation of dissolved Mn(II) by readily produced MnO_x and ii) microbial Mn(II) oxidation. Thus, the present method helps to assess the full potential for oxidation of dissolved Mn within an aquatic environment. The method has the advantage that sample preparation can be easily done on site, followed by analysis of dissolved Mn by conventional methods in the lab.

dMn_{react} was also detected in the Landsort Deep (Baltic Sea) with values distinctly increasing from the outer regions towards the central part (max. 3 μM). Similar to the Black Sea, dMn_{react} concentrations increase in the suboxic transition zone separating oxygenated and H_2S containing waters. In contrast, almost no dMn_{react} was present in the Gotland Basin (Baltic Sea). Pronounced lateral currents and turbulence in the Gotland Basin prevent the formation of a stable suboxic zone, a prerequisite necessary for accumulation of dMn_{react}. Such intrusions supply trace amounts of O_2 and H_2S thus causing either immediate oxidation/reduction of dMn_{react} or deteriora–tion of its stabilising ligands.

Analysis of dMn_{react} in the seasonally anoxic Lake Dagow (Germany) revealed maximal concentration of 6 μM. This value significantly exceeds the level of the Landsort Deep most likely due to the stable stratification of this lake during sampling.

[7]Institute for Geology, Mineralogy and Geophysics, Ruhr-University Bochum, Germany

We present high-resolution $\delta^{18}O$, $\delta^{13}C$ and trace element profiles for stalagmite HBSH-1 from Hüttenbläserschacht-höhle, western Germany. The major part of the sample grew between 130 and 80 ka providing a climate record with decadal to centennial resolution for Marine Isotope Stage (MIS) 5. The record shows three growth interruptions during this period coinciding with the Greenland Stadials suggesting that stalagmite growth in this area is a very sensitive proxy for cool and dry conditions in the northern hemisphere.

We interpret stalagmite $\delta^{18}O$ as a proxy for past temperature changes, whereas stalagmite $\delta^{13}C$ rather reflects changes in the hydrologic balance. The $\delta^{13}C$ record shows three pronounced negative peaks during MIS 5, and the timing of those is in agreement with MIS 5e, 5c and 5a. This suggests warm and relatively humid climate in western Germany for these phases.

During the Last Interglacial, the evolution of $\delta^{18}O$ and $\delta^{13}C$ is opposite. Whereas the $\delta^{18}O$ signal suggests the warmest conditions around 125 ka followed by a gradual decrease, the $\delta^{13}C$ signal indicates wetter conditions towards the end of the Last Interglacial. This 'decoupling' of temperature and humidity during MIS 5e is also visible in a series of snapshot simulations performed using the general circulation model FAMOUS. The decoupling is probably related to the change in solar insolation, which influences the atmospheric dynamics and storm activity in the region.

Mumia vera – vera mumia?

BARBARA M. SCHOLZ-BÖTTCHER[1]*, ARIE NISSENBAUM[2] AND JÜRGEN RULLKÖTTER

[1]ICBM, University of Oldenburg, D-26111 Oldenburg, Germany (*correspondence: bsb@icbm.de)
[2]Dep. Environmental Science and Energy Research, Weizmann Institute of Science, Rehovot 76100, Israel

The drug *mumia vera* has a long tradition not only in Arabian but also in ancient European medicine. The knowledge in antiquity of the curativeness of asphalt combined with the belief in the magics of death made *mumia vera* a precious ingredient of medications with a very broad spectrum of indications. Since the 16th century it was even used as paint pigment. The export of mummies is supposed to have started in the 12th century and the drug was still available in 1924. Because the export of mummies was banned by the Arabs since the 17th century a more or less macabre market of substitutes developed.

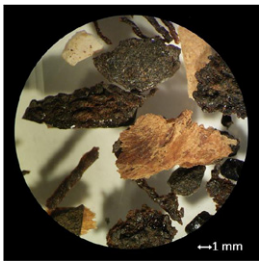

Figure 1 Reflected-light microscopy of the sample analysed

A small amount of ground *mumia vera* from a pharmaceutical vessel of the early 18th century was analysed on a molecular level. A number of diverse particles were hand-picked under the microscope and analysed separately via CP-pyrolysis GC-MS. Extracts were analysed by GC-MS. The ingredients of all particles exhibited a close relation to authentic ancient mummy material and published data in this field [1, 2, 3]. Besides fibres of linen and wood as well as embalming material (cedrium, pistacia turpentine, beeswax, Dead Sea asphalt) pieces of most probably human tissue and a wax-like substance (possibly a kind of adipocere) were found. Some inconsistencies in the data point to a mixture of material most plausibly due to occasional refilling of the vessel. Genuine mummy material milled as a whole obviously was used as medicine in the present case.

Experimental constraints on Ag isotope fractionation during planetary core formation

M. SCHÖNBÄCHLER[1]*, K.J. THEIS[1] AND B.J. WOOD[2]

[1]SEAES, The University of Manchester, M13 9PL, UK (*correspondence: m.schonbachler@manchester.ac.uk)
[2]Department of Earth Sciences, University of Oxford, Parks Road, Oxford, OX1 3PR, UK

A recent study [1] proposes a heterogeneous accretion scenario for the Earth, which is for the first time based on isotopic constraints from the short-lived Pd-Ag, Mn-Cr and Hf-W decay systems. The study concludes that the Earth inherited the major part of its moderately volatile element depletion from its building blocks. The model also requires a late addition of volatile-rich material while core formation was still active. These findings are in good agreement with work based on elemental abundances of the BSE (Bulk Silicate Earth) and partitioning experiments (e.g. [2]) as well as dynamic models of the accretion and planet formation [3]. The late addition of volatile-rich material is mainly required by the Pd-Ag decay system to explain the identical Ag isotope compositions but different Pd/Ag ratios of CI chondrites and BSE.

The need for a late volatile-rich addition can be relaxed by proposing that the true BSE Ag isotope composition is more radiogenic (~ +1.2 epsilon^{107}Ag/^{109}Ag) than the measured value (-2.2 ± 0.7 [1]), because the latter was modified by extraction of light Ag into the Earth's core. To explore this possibility, we performed experiments on mixtures of silicate, sulphide and metal in a piston-cylinder apparatus at 1.5 GPa and 1800 K. Metal and silicate phases of the run products were manually extracted and analysed for Ag isotopes on a MC-ICPMS following the protocol of [4]. The Ag isotope compositions obtained for metal and silicates were identical within the analytical uncertainty (± 0.5 epsilon). This demonstrates that Ag isotope fractionation is negligible at the investigated conditions. Isotope fractionation generally decreases with T^{-2} at the temperature range considered for metal-silicate equilibration in a deep magma ocean. Therefore it is likely that Ag isotopes do not fractionate at conditions predicted for terrestrial core formation (higher T and P). Moreover, the experimental results also show that Ag partitioning into the metal increases with sulphur content.

Evidence of mantle heterogeneity underneath slow-spreading ridges? Case study at 45°N mid-Atlantic ridge

N SCHROTH[1]* AND B.J. MURTON[2]

[1](*correspondence: ns2r07@noc.soton.ac.uk)
[2](bramley.murton@noc.soton.ac.uk)

Axial volcanic ridges (AVR) are a ubiquitous feature along mid-oceanic ridges. Although numerous studies have been performed on their structure and volcanic activity, many questions still remain unanswered, e.g. do AVR basalts have a common parental magma, and are the basalts derived from different magma chambers erupting at different times?

During cruise JC24 in 2008, nearly 300 basaltic samples were collected with the ROV ISIS in order to answer some of these questions.

A large dataset has now been compiled and some preliminary results will be presented. Rare earth element (REE) data coupled with trace element data of 30 samples revealed three different groups of samples. Group I is charaterized by low La/Yb, incompatible element concentrations between normal and enriched mid-oceanic ridge basalt (N- and E-MORB). Group III has highly elevated La/Yb ratios, and a pattern of incompatibles that is more enriched in light REE than E-MORB. Group II lies in between but shows clear gaps to both other groups.

As REEs are not available for all samples yet, the incompatible and alteration-resistant elements Nb-Zr-Y were used to extend the grouping to a further 230 samples analysed by XRF. The results are coherent with the REE groupings. In addition, groups II and III could be subsequently split into subgroups.

The most enriched samples occur on (1) flat-topped volcanoes, situated off-AVR, (2) in the median valley near these volcanoes, (3) in the median valley walls on the western side as well as in the western axial floor, and (4) at the northern tip of the main AVR structure. Group II occurs on the axial floor north and west of the AVR, in the western median valley wall, and at the northern and southern tips of the AVR.

It is the aim of this study to reveal connections between volcanic structures, as well as to define the various melt sources.

Wider implications of this study are insights into the magma storage and plumbing underneath the AVR, and a detailed geochemical map of a (typical) mid-Atlantic ridge segment.

Lessons to learn from amino acid distribution in POM of Lake Baikal

CARSTEN J. SCHUBERT[1], JUTTA NIGGEMANN[2], MICHAEL STURM[1], BENTE LOMSTEIN[3] AND MATTHEW D. MCCARTHY[4]

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, SURF, Kastanienbaum, Switzerland (carsten.schubert@eawag.ch)
[2]Forschungsgruppe der Max-Planck-Gesellschaft - Marine Geochemie - Carl von Ossietzky Universität, Oldenburg, Germany
[3]Department of Biological Sciences, Section for Microbiology, University of Aarhus, Aarhus, Denmark
[4]Ocean Sciences Department, University of California, Santa Cruz,

Lake Baikal offers a unique opportunity to study water column processes in a freshwater system with conditions similar to oceanic systems. With a maximum water depth of ~1640 m, Lake Baikal is the deepest lake on Earth and due to efficient vertical mixing, oxygen concentrations are high throughout the water column.

Furthermore, although Lake Baikal receives considerable input of suspended particles via rivers, primary production in the surface waters is the major source of carbon and energy for organisms in deeper water layers and in the sediments.

Sediment trap material from Lake Baikal, collected at 18 different water depths (50-1350 m), has been investigated for total hydrolysable amino acids (THAA) and amino acid D- and L-enantiomers. The THAA flux decreased by 50% in the upper 500 m and remained constant below this depth, indicating that organic matter (OM) degradation was mostly restricted to the upper water column.

We additionally measured nitrogen isotopes on THAA (POM) from different water depths that allowed for determination of source and food web changes.

The dependence of ^{222}Rn air-water partitioning on water temperature and water salinity

MICHAEL SCHUBERT AND ALBRECHT PASCHKE

Helmholtz Centre for Environmental Research – UFZ, Permoserstr. 15, 04318 Leipzig, Germany

Radon (^{222}Rn) is used as natural aquatic tracer for many applications. A prominent example is its use as indicator for submarine groundwater discharge (SGD) processes.

On-site radon-in-water detection is performed by means of a mobile radon-in-gas monitor and radon extraction from the water into a closed circulating air volume. For converting the detected radon-in-air concentration into radon-in-water values the water/air partition coefficient ($K_{w/air}$) needs to be known.

$K_{w/air}$ depends on two water parameters that are easily attainable on site: temperature and salinity. Possible values for $K_{w/air}$ cover a range between about 0.50 (cold fresh water) and 0.03 (hot saline water). The temperature dependence of $K_{w/air}$ applies for all environments (terrestrial and marine) and is generally taken into consideration. The 'salting out' of radon, however, is often underestimated or not accounted for at all, potentially leading to an erroneous data interpretation.

Theoretical considerations that are based on reported data as well as on an extensive own dataset resulted in the easily applicable equation shown below. The equation allows for uncomplicated consideration of the dependence of $K_{w/air}$ on both, temperature (T [K]) *and* salinity (S [‰]) (see Fig. 1).

$$\ln\beta = -56.90 + 92.49\left(\frac{100}{T}\right) + 22.24\ln\left(\frac{T}{100}\right) + S\left\{-0.219 + 0.138\left(\frac{T}{100}\right) - 0.022\left(\frac{T}{100}\right)^2\right\}$$

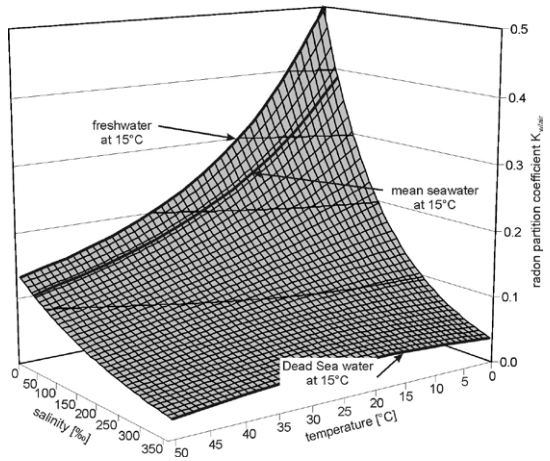

Figure 1: Dependence of the air/water partitioning coefficient ($K_{w/air}$) of radon on water temperature and salinity (*cf.* Eq. 1)

Exploring micro-scale stable isotope variations using femtosecond laser ablation MC-ICP-MS

J.A. SCHUESSLER AND F. VON BLANCKENBURG

German Research Centre for Geosciences GFZ, Section 3.4, Earth Surface Geochemistry, Potsdam, Germany (jan.schuessler@gfz-potsdam.de)

We present advancements in micro-scale analyses of non-traditional stable isotopes using a second generation custom build femtosecond laser ablation system coupled to a multicollector ICP mass spectrometer.

The heart of our laser ablation system is based on the latest generation Ti-Saphire regenerative amplifier system *Spectra Physics Solstice*, which produces 100 fs infrared (IR) laser pulses with up to 3.7 mJ/pulse. Non-linear optics are used to convert the fundamental IR wavelength into the UV with a wavelength of 196 nm and an adjustable pulse energy of up to of 0.1 mJ/pulse. The system provides full control on laser parameters, such as spot size, energy density, pulse width, repetition rate (continuous from 1 to 1000 Hz) and beam shape. The spot size can be varied from 10 to 100 μm in diameter with energy densities on the sample between 0.1 and 50 J/cm^2.

The laser beam is delivered to the sample (thin sections or polished blocks contained in a He-flushed sample cell) through a fully automated and computer controlled microscope stage, modified with UV optical components to focus the laser beam and visualise the sample surface. Special emphasis in the construction was given to high quality optical imaging of the sample, while maintaining an optimum laser beam quality.

A custom-designed software allows integrated control on laser parameters, sample positioning and observation, as well as fully automated analyses through a synchronised operation with a *Thermo Neptune* MC-ICP-MS, equipped with a *Neptune Plus Jet Interface* for increased sensitivity.

We will present results on optimized analytical conditions for stable isotopes measurments of Fe, Si, and Mg at the micro scale in various matrices, such as minerals, glasses, and soils.

Climate change and the KISS principle

R.D. SCHUILING[1]*, O. TICKELL[2] AND S.A. WILSON[3]

[1]Institute of Geosciences, Utrecht University, the Netherlands (*correspondence: schuiling@geo.uu.nl)
[2]Oxford Climate Associates/Kyoto2 (oliver.tickell@kyoto2.org)
[3]Dept. Geological Sciences, Indiana University, Bloomington (siowilso@indiana.edu)

Mineral carbonation is the logical answer to rising CO_2 levels. The CO_2 is captured in a safe and sustainable way and returned to the rock record as solid carbonates. The recipe is simple and straightforward:

-select an abundant material that weathers easily (olivine or serpentine)

-mine and mill this material

-spread it in a favorable climate for weathering

Instead of leaving it at that, and follow the KISS principle (Keep It Simple, Stupid), most researchers try to develop techniques to speed up the carbonation. This costs extra energy and money. This is a major reason why the storage of CO_2 in abandoned oil and gas fields, or in saline aquifers is still the favored mitigation strategy. Mineral carbonation has been overlooked, mainly because researchers have made it too complicated in their attempts to speed up the reaction.

There is no need to speed up the reaction, as olivine grains of 100 μm weather and capture CO_2 in a few years in a suitable climate. Extrapolation of abiotic experiments suggests that weathering is not fast enough. Outside the laboratory the role of biotic factors like mycorrhizal fungi on land or lugworms on tidal flats has been demonstrated, which speed up the weathering reaction by factors of ten to almost one thousand. Crushed serpentinite mine tailings in British Columbia are known to weather fifty times faster than basaltic tuffs in even the most favorable climate for weathering.

For the global C-cycle it makes no difference where the CO_2 is captured, as the atmosphere is a well mixed reservoir on the timescale of a few months. Capturing and storing of CO_2 from flue gases is too expensive. The separation step alone costs already considerably more than straightforward enhanced weathering.

The strategy for enhanced weathering relies upon olivine mined in the wet tropics. This material is milled and the grains are spread over the surrounding area. The whole operation (mining, milling and transport) will cost around 10 Euro/ton of captured CO_2. Negative effects on the environment are unlikely.

Nanocalcite as a model for biogenic, geological calcite

L. SCHULTZ*, M.P. ANDERSSON, D. OKHRIMENKO, K.N. DALBY AND S.L.S STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*correspondence: lschultz@nano.ku.dk)

Many geological systems, including chalk, limestone, and calcareous sandstone, contain sub-µm (nano), biogenic calcite formed by organisms long ago. These systems are intimately linked to environmental and economic interests (e.g. aquifers and petroleum reservoirs). Many geochemical research studies seek to understand the transformation (e.g. growth/dissolution) and reactive influence of calcite on pore fluids. For model system calcite, studies typically use commercial samples or calcite synthesized from super-saturated solutions of Ca^{2+} and CO_3^{2-}. The particle size of these types is generally much larger than biogenic calcite, and industrial calcite often contains trace amounts of the chemicals used during the manufacturing process or for ensuring good storage properties.

We explored an alternative method for synthesizing nanocalcite by carbonating a Ca $(OH)_2$ slurry using gaseous CO_2. This method has been used for industrial product improvement, but the use of nanocalcite as a model research system with high purity and surface area has not been explored.

Surface- and bulk-sensitive techniques, including X-ray photoelectron spectroscopy (XPS), infrared spectroscopy (IR), and X-ray diffraction (XRD), indicate negligible contamination from unreacted hydroxyl or trace metals. Further, there was no evidence of other $CaCO_3$ polymorphs, vaterite or aragonite. SEM showed agglomerations of nanostructured particles and the BET method quantified specific surface area in the range from 13-16 m^2/g. IR spectra of industrial calcite, geological calcite (chalk) and nanocalcite displayed distinctly different peak widths, in the order of nanocalcite < chalk < industrial calcite. This indicates that nanocalcite has a relatively high degree of crystallinity and few defects.

This study shows that nanocalcite might improve research results in studies that seek to understand processes in ultrafine geological calcite. Ongoing work will use nanocalcite to more effectively analyze recrystallization rates and surface reaction/adsorption phenomena that are important to aquifer and oil reservoir applications.

Timing of early solar system homogenization from p-process ^{180}W heterogeneities

T. SCHULZ[1,2]* AND C. MÜNKER[1]

[1]Institut für Geologie und Mineralogie, Universität Köln, Germany

[2]Department of Geological Sciences, University of Vienna, Austria (*correspondence: toni.schulz@univie.ac.at)

Introduction

Collapse and subsequent formation of the solar system may have been triggered by a nearby supernova. This can explain the injection of freshly synthesized short-lived radionuclides into the young solar system and can also account for the presence of nucleosynthetic isotope anomalies in meteorites. In order to trace the mixing history of nuclides in the early solar system, we performed the first analyses of one of the rarest isotopes in the solar system, p-process ^{180}W (ca. 0.1 % relative abundance).

Methods and Results

Measurements were conducted using a Neptune ICP-MS, equipped with high sensitivity 10^{12} Ohm resistors. For most analyzed iron meteorites, clearly resolvable ^{180}W excesses (up to +7 $\varepsilon^{180}W$-units) were measured, whereas metals from chondrites and IAB iron meteorites overlap with the terrestrial value. There are distinct ^{180}W abundance variations between different groups of iron meteorites.

Discussion and Conclusion

Our first data provide clear evidence for an increasing homogenization of the early solar system by decreasing ^{180}W anomalies with decreasing age, suggesting mixing-timescales in the order of several million years. As most asteroidal parent bodies accreted and differentiated during this time span parent nuclides of short lived decay systems may not have been homogeneously distributed in the early solar system.

Because the production of ^{180}W requires distinct stellar environments, multiple supernovae explosions may have affected the early solar system, thus further weakening the astrophysical view that protostars have formed in relative isolation from their molecular cloud neighbours [1].

Could bacterial residues be an important source of SOM? – A case study from a glacier forefield

CHRISTIAN SCHURIG[1]*, RIENK SMITTENBERG[2], JÜRGEN BERGER[3], ERIKA KOTHE[4], ANJA MILTNER[1] AND MATTHIAS KÄSTNER[1]

[1]Helmholtz Centre for Environmental Research –UFZ, Environmental Biotechnology, Leipzig, Germany (*correspondence: christian.schurig@ufz.de)
[2]ETH Zürich, Geology Department, Zürich, Switzerland (smittenberg@erdw.ethz.ch)
[3]Max Planck Institute for Developmental Biology, Electron Microscopy Unit, Tübingen Germany
[4]Friedrich Schiller University of Jena, Microbial Phytopathology, Jena, Germany

Recently, stocks of soil organic matter (SOM) have been shown to decrease in European soils and also worldwide, which compromises soil fertility and enhances emissions of carbon dioxide to the atmosphere. However, the general structure of SOM, and thereby the mechanisms behind its genesis and loss, remain unclear.

In this framework, microbial biomass is generally regarded to be of low importance for SOM formation. In particular on freshly exposed surfaces, however, bacteria colonize barren mineral surfaces faster than fungi or higher plants. Moreover, recent results indicate that bacterial cell wall fragments frequently occur on soil mineral surfaces and also accompany the microbial colonization of previously clean and sterile activated carbon surfaces after incubation in groundwater. Hence, we hypothesized that, at least, in the initial stages of soil formation bacteria and their fragments may play an important role in particulate SOM formation bearing in mind that most dead organic matter entering the soil is processed by bacteria.

This hypothesis was proven by tracing the development of SOM in a chronosequence with samples from the forefield of a receding glacier (Damma-glacier, Canton Uri, Switzerland) by scanning electron microscopy and other methods. The initially barren mineral surfaces have been shown to be rapidely covered with microbial residues as soil age increases. Moreover, this data compares well to growing C/N-ratios, water contact angles and fatty acid contents in earlier deglaciated samples.

Iron isotope fractionation in soil solutions of a Gleysol

STEPHAN SCHUTH[1,2]* AND TIM MANSFELDT[1]

[1]Department of Geosciences, Soil Geography/Soil Science, University of Köln, Germany
[2]Institute for Mineralogy, Leibniz University Hannover, Germany (*correspondence: s.schuth@mineralogie.uni-hannover.de)

Analyses of Fe isotope compositions in a Gleysol with petrogleyic properties from NW Germany yielded bulk δ^{57}Fe values of +0.29‰ (Ah horizon, Fe_{total} ca. 50 g/kg) to –0.30‰ (Bg horizon, Fe_{total} ca. 320 g/kg). A special feature of this Gleysol is a local massive enrichment of Fe (hydr)oxides (comprising mostly goethite and ferrihydrite). In contrast to the overlying CrBg and Bg horizons, the 2Cr horizon which developed from glaciofluvial sands, is characterized by a relatively high δ^{57}Fe value of +0.22‰, but lowest total Fe amounts (ca. 7 g/kg).

To evaluate the relationship of Fe isotope composition of the four horizons and their soil solution, we sampled the soil solution at different depths during spring and autumn. Water of a nearby stream and Fe-rich precipitates in the stream sediments were additionally sampled.

The Fe isotope composition and Fe concentration of the soil solution strongly varied with both depth and abundance of Fe (hdr)oxides, but revealed little seasonal effects. We observed extremely low δ^{57}Fe values of –2.8‰ and Fe concentrations of ca. 3 mg/L in the soil solution of the CrBg horizon. In contrast, the soil solution obtained from the underlying sandy 2Cr horizon is characterized by δ^{57}Fe values of –1.5‰ and high Fe concentrations of up to 60 mg/L. The water of the adjacent stream showed δ^{57}Fe values of –0.03‰, whereas the Fe-rich precipitates in the stream bed are marked by a high δ^{57}Fe value of +0.55‰.

We conclude that the low δ^{57}Fe values in the soil solution are the result of preferential adsorption and precipitation of heavy Fe isotopes on abundant Fe (hydr)oxide phases in the CrBg horizon. The Fe-poor 2Cr horizon lacks this capability, therefore, higher δ^{57}Fe values and Fe concentrations are observed in its soil solution. For the Fe-rich precipitates of the stream, preferred removal of heavy Fe isotopes during precipitation entailed high δ^{57}Fe values.

Evaluation of lake biomarkers as indicator of environmental changes along a climatic gradient in Cameroon

VALÉRIE SCHWAB-LAVRIČ[1]*, YANNICK GARCIN[2], DIRK SACHSE[2], GILBERT TODOU[3], OLIVIER SÉNÉ[4], JEAN-MICHEL ONANA[4], GASTON ACHOUNDONG[4] AND GERD GLEIXNER[1]

[1]Max-Planck-Institut für Biogeochemie, Jena, Germany (*correspondence: vschwab@bgc-jena.mpg.de)
[2]DFG-Leibniz Center for Surface Process and Climate Studies, Institut für Erd- und Umweltwissenschaften, Universität Potsdam, Germany
[3]École Normale Supérieure, University of Maroua, Cameroon
[4]National Herbarium of Cameroon, IRAD, Yaoundé, Cameroon

Small crater lakes that have not been exposed to anthropogenic impacts are considered as sensitive recorders of environmental conditions. Here, we studied changes in lipid composition of sediments and water particles organic matter (POM) from lakes, and soils from lake catchments collected in Cameroon along a large environmental gradient (rainfall of ~ 4000 to 700 mm per year) to evaluate sedimentary lipids as indicators of local and regional environmental changes in the tropics.

Large abundances of an unresolved complex mixture and bacterial lipids in water POM, higher relative concentration of terrestrial refractory lipids in deeper water POM as well as differences in compound distributions and abundances between sedimentary and aquatic lipids indicate intense degradation of primary autochthonous organic matter throughout the water column. No characteristic changes in the distribution patterns of the major compounds, short- and long-chain *n*-alkanes, *n*-alkenes, alcohols and fatty acids, in the studied samples along the environmental gradient indicate that distribution of these source-specific biomarkers may not be appropriate to reconstruct ecosystem changes in tropical fossil records. In sediments, tetra- and penta-cyclic triterpenoids, principally consisting of brassicasterol and mainly terrestrial plants-derived stigmasterol and β-sitosterol, increase in abundance with rainfall. Campesterol is identified only in the drier zones. C_{32}-C_{34} botryococcenes usually associated with the freshwater *B. braunii* algae were found in soils and lake sediments of the rainiest site. A possible terrestrial contribution of these compounds to lake sediments in this environment will be discussed.

$PM_{2.5}$ chemical composition at rural background site in Central Europe

J. SCHWARZ[1]*, J. KARBAN[1], V. HAVRÁNEK[2], E. CHLUPNÍČKOVÁ[3] AND J. SMOLÍK[1]

[1]Institute of Chemical Process Fundamentals AS CR, Prague, Czech Republic (*correspondence: schwarz@icpf.cas.cz)
[2]Institute of Nuclear Physics AS CR, Řež at Prague, CR
[3]Czech Hydrometeorological Institute, Prague, CR

$PM_{2.5}$ mass and its chemical composition was studied from Feb 2009 to Mar 2010 at Czech rural backgroud site Košetice. The site is located about 80 km SE from Prague and it is part of EMEP, EUSAAR, and ACTRIS networks. Samples were taken 24 hours each 6th day, in total, 70 samples were analyzed. Besides gravimetry, water soluble ions (IC), elements (PIXE), OC/EC (TOT method) and levoglucosan (GC-MS) were analyzed.

The mass closure was calculated between $PM_{2.5}$ mass and analyzed species. The concentration of crustal elements (Al, Si, Ca, Ti, Fe, Mn were recalculated to their oxides, OC (corrected for positive sampling artifact) and EC were converted to OM resp. EC mass using factor 1.6 resp. 1.1. Using these factors the total analyzed mass was equal to 90% of $PM_{2.5}$ mass determined using gravimetry in average. A resulting average chemical composition of $PM_{2.5}$ mass at Košetice site is shown in the Fig. 1.

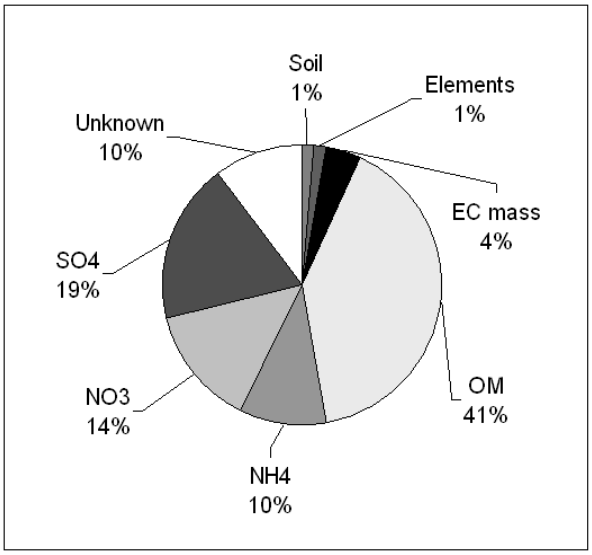

Figure 1: Average composition of PM2.5 at Košetice

$PM_{2.5}$ was dominated by OM and secondary inorganic ions. We thank for support to GA CR by grant No.205/09/2055.

The Ligurian ophiolite: An analogue to marine serpentinite-hosted hydrothermal systems

E.M. SCHWARZENBACH*, G.L. FRÜH-GREEN AND S.M. BERNASCONI

ETH Zurich, Department of Earth Sciences, Zurich Switzerland
(*correspondence: esther.schwarzenbach@erdw.ethz.ch)

Carbonate-veined mantle sequences in ophiolites exposed on continents show strong similarities to oceanic core complexes and to moderate temperature, peridotite-hosted hydrothermal systems found along slow-spreading ridges. Serpentinization processes associated with exposure of mantle rocks at the ocean floor thereby play a fundamental role in the global marine bio-geochemical cycles and in mass transfer between seawater and the oceanic lithosphere. Here we present a mineralogical and C and S geochemical study of serpentinites and ophicalcites from an ophiolitic sequence in the Northern Apennine (Italy) and compare this sequence to calcite-veined serpentinites from the Iberian Margin and serpentinites from the basement of the Lost City Hydrothermal Field. The comparison between ancient and modern peridotite-hosted hydrothermal systems provides constraints on fluid pathways, fluid fluxes, redox conditions and microbial activity and their time-integrated changes.

The Northern Apennine ophiolites include serpentinites and ophicalcites that are bounded by shear zones that form domal structures and are characterized by distinct talc-amphibole-chlorite alteration assemblages, which strongly resembles the damage zones associated with detachment faults along ocean ridges. The serpentinites and ophicalcites record multiple phases of seawater infiltration, with initiation of serpentinization above ~300°C and calcite precipitation at temperatures < ~150°C. The sulfide mineralogy is dominated by pentlandite, pyrrhotite, pyrite, millerite and siegenite, which reflects fairly oxidizing conditions and corresponds to redox-gradients typically found in oceanic serpentinites. The sulfur isotope signatures also indicate a multiphase history of fluid-rock interaction, but show a strong influence from microbial activity, similar to signatures in serpentinites from the Iberian Margin. Field and mineralogical observations show a strong relation of the Northern Apennine ophiolite to an oceanic setting near a mid-ocean ridge associtiated with detachment faults. In addition, the results of our study suggest that major fault zones strongly influence fluid circulation in these hydrothermal systems and control the incorporation of both carbon and sulfur from seawater.

Base metal ore deposits and marine mineral resources: Rare metal sources for sustainable energies?

U. SCHWARZ-SCHAMPERA

Federal Institute for Geosciences and Natural Resources, 30655 Hannover, Germany.

The progress in modern electronic technologies and the need for the use of renewable energies both increase the worldwide demand for metals and metalloids that are critical in high-technology products. There is significant and increasing demand for trace elements like indium, gallium, tellurium, selenium, molybdenum, cadmium, but also for major commodities like nickel, cobalt, copper. The group of so-called 'electronic metals' is already an integral part in most technical houseware and office products i.e., computers, notebooks, televisions, cell phones. New technologies and the need for renewable energy concepts in times of global climate changes lead to growing markets in photovoltaic industries. All major worldwide economies face a 20% - target of energy production from renewable energies until 2020. High-efficiency thin-film devices base on metals like indium, gallium, cadmium, tellurium, selenium, molybdenum; their substitution by keeping the high efficiency remains undeveloped. The market situation for these trace elements is tight and demand increases by an increasing number of industrial consumers. Production comes from known ore deposits on land and requires suitable and qualified technical facilities for the recovery of these trace components as by-products from conventional base metal concentrates. Few land-based ore deposits are known to host and produce these trace metals. Production increase, however, is limited due to restrictions on the production of the main commodities, metallurgical constraints, and limited refining capacities. A number of additional ore deposits, however, are capable to meet the demand if more scientific and technical effort is laid on the by-products. As a potential future source, marine mineral resources like manganese nodules, manganese crusts, and polymetallic massive sulfides are locally highly enriched in these trace metals and may define additional reserves. Enrichment factors, elevated concentrations, the mineralogical control, and ore characteristics in base metal deposits represent favourable conditions for the recovery of these metals. The actual production and demand situation is presented for the most important 'electronic metals' and the enhanced potential of ore deposits and marine resources in the future supply is discussed.

Revisiting the age of the Merensky Reef, Bushveld Complex

JAMES S. SCOATES[1], COREY J. WALL[1], RICHARD M. FRIEDMAN[1] AND KEVIN R. CHAMBERLAIN[2]

[1]Pacific Centre for Isotopic and Geochemical Research, University of British Columbia, Vancouver BC, V6T1Z4 (Canada, jscoates@eos.ubc.ca)

[2]Department of Geology and Geophysics, University of Wyoming, Laramie WY, 82071, USA

The giant Paleoproterozoic Bushveld Complex in the Kaapvaal craton of South Africa may have been emplaced and crystallized in a relatively short period of time [1], perhaps as little as a few million years, followed by rapid cooling [2]. Determination of the absolute duration of Bushveld-related magmatism requires careful application of the single-grain chemical abrasion ID-TIMS, or CA-TIMS, U-Pb zircon method. We recently reported a CA-TIMS zircon age for a sample of the PGE-rich Merensky Reef (West Mine, Rustenburg Section) in the Western Limb of the Bushveld Complex with a weighted mean $^{207}Pb/^{206}Pb$ age of 2054.4 ± 1.3 Ma (2σ, decay constant errors not included, n = 6) [3]. Use of the EARTHTIME ^{205}Pb-^{233}U-^{235}U tracer and synthetic U/Pb standard solutions now allow for assessing intra- and inter-laboratory reproducibility. We provide a new U-Pb age for zircon from a sample of the Merensky Reef in the Eastern Limb of the complex (Farm Driekop), 2055.30 ± 0.61 Ma (MSWD = 0.43, n= 10), and a revised age based on new analyses for our sample of the reef from the Western Limb, 2056.13 ± 0.70 Ma (MSWD = 0.44, n = 8). All ages were Th-corrected using Th/U = 3, characteristic of the B-1 and B-2 marginal rocks related to the Upper Critical Zone [4]. Compiled results for analyses of the 2000 Ma EarthTime standard solution are 1999.75 ± 0.47 Ma (MSWD = 0.42, n = 18). Analyses conducted at Wyoming by CA-TIMS, with EARTHTIME tracer and standard solutions, on zircon from the Western Limb sample yield a preliminary age of 2056.1 ± 1.1 Ma (MSWD = 0.096, n = 6). This interlaboratory comparison reveals that the crystallization age of the Rustenburg Merensky Reef sample is slightly older than the age reported in [3], although within analytical uncertainty. These results demonstrate the contemporaneity of these Merensky Reef samples, separated by ~300 km, and the potential for distinguishing magmatic events within the Bushveld Complex different in age by 1-2 million years.

[4]University of Manitoba, Winnipeg, MT R3T 2N2, Canada (bekker@cc.umanitoba.ca)

Seawater concentrations of biologically significant and redox-sensitive trace metals have varied through time, reflecting intimate coupling of geological and biological processes in the Earth System. Euxinic black shales, organic carbon-rich mud rocks deposited beneath sulfidic bottom waters, are commonly enriched in such trace metals. Recent work focusing on Mo enrichments have demonstrated the potential to use geochemical analyses of euxinic black shales to track temporal trends in the concentrations of other trace metals in seawater [1].

Multiple episodes of euxinic deposition have recently been identified in the Archean [2-4]. In this study we compare the enrichments of a suite of biologically relevant trace metals (Fe, Mo, Cu and Zn) from Archean euxinic black shales in order to identify temporal trends in their relative abundance in seawater. To strengthen our arguments for faithful preservation of seawater chemistry and to facilitate comparison between Archean shales, as well as comparisons to euxinic shales deposited throughout Earth history, we present our study in the context of additional redox proxies, including TOC, Fe speciation, multiple S isotope analyses and Re-Os systematics.

[2]Marum, Center for Marine Environmental Sciences and Department of Geosciences, Leobener Str., 28359 Bremen, University of Bremen, Germany
[3]Department of Earth, Atmospheric and Planetary Sciences, MIT, Cambridge, USA

Freshwater wetlands account for about 25% of the annual methane emissions to the atmosphere. A potential positive feedback exists between global warming and the production of this powerful greenhouse gas in sediments. This study explored seasonal variations in the dominant pathways (e.g. methanogenesis) of terminal metabolism in coastal, freshwater wetland sediments from three distinct biogeographic provinces. Through geochemical profiles, microbial rate assays, and lipid biomarker analyses, we assessed seasonal variability in the biogeochemical functioning in coastal Florida, Georgia, and Maine. We evaluated the role of temperature and other seasonal factors on rates and pathways of methane production and consumption, as well as sulphate reduction, acetogenesis, and acetate oxidation, through radiotracer rate assays. Intact polar membrane lipid analyses revealed distinct microbial communities at the three sites which varied with season and depth. The combination of microbial activities, sediment porewater geochemistry, and lipid biomarker analysis provides insight into seasonal fluctuations in microbial-mediated carbon mineralization in freshwater sediments.

Tracing sedimentary pyrite oxidation during managed aquifer recharge

S. SEIBERT[1,2]*, G. SKRZYPEK[2], C. DESCOURVIERES[1], C. HINZ[2] AND H. PROMMER[1,2]

[1]CSIRO Land and Water, Wembley, Australia (*correspondence: simone.seibert@csiro.au)
[2]The University of Western Australia, Crawley, Australia

Oxidation of sedimentary pyrite is often one of the main drivers affecting groundwater quality during managed aquifer recharge [1, 2]. In cases where this leads to the depletion of the sedimentary buffering capacity, groundwater acidification and particularly the associated mobilisation of heavy metals and metalloids (e.g. arsenic) can significantly deteriorate groundwater quality [3, 4]. Data and techniques that allow for a detailed identification and quantification of the mineral reactions are therefore crucial to assess and predict such adverse water quality changes.

The present study examines the feasibility of using stable sulphur isotope analysis as a supporting tool for tracking and characterising pyrite oxidation processes during an aquifer storage and recovery experiment in Perth, Western Australia. During the experiment pyrite oxidation was triggered by the injection of potable aerobic water into a well characterised heterogeneous, anaerobic aquifer. Stable sulphur isotope signals ($\delta^{34}S$) were analysed for sedimentary sulphur species and for aqueous sulphate concentrations in both the ground- and the injectant water in addition to extensive hydrochemical monitoring.

The collected data, including the $\delta^{34}S$ value was interpreted by geochemical and reactive transport modelling. The models were specifically adapted to incorporate all reactions and isotope fractionation processes that affect the evolution of $\delta^{34}S$ in the groundwater and the sediments.

The observed $\delta^{34}S$ data from the monitoring wells indicate that the released sulphate is characterised by a successively changing $\delta^{34}S$ signal during the injection phase. These observed $\delta^{34}S$ trends are thought to result from a highly variable $\delta^{34}S$ composition of the pyrite, which was most likely caused by isotopic fractionation associated with the sulphate reduction that occurred during and/or after the deposition of the sediments.

Mineralogy, geochemistry and age of greisen mineralization in the Li-Rb-Cs-Sn-W deposit Zinnwald, Erzgebirge, Germany

TH. SEIFERT[1]*, PETYA ATANASOVA[1], JENS GUTZMER[1] AND JÖRG PFÄNDER[2]

[1]TU Bergakademie Freiberg, Division of Economic Geology and Petrology, D-09596 Freiberg, Germany, (*correspondence: thomas.seifert@mineral.tu-freiberg.de)
[2]TU Bergakademie Freiberg, Division of Tectonophysics, Argon lab, D-09596 Freiberg, Germany

The Erzgebirge (Krušné hory) is a world class area for Li-Rb-Cs-F-Sn-W-Bi greisen mineralization, which is associated to late-Variscan, postcollisional 'small intrusion' Li-F granites in space and time [1]. A typical example is the Zinnwald/Cínovec Li-Rb-Cs-Sn-W deposit, which is hosted by the Cínovec-Zinnwald granite cupola and Teplice rhyolite. Sn-W(-Li) mining was active for about 700 years until 1990. The exposed intrusion (1.3 x 0.3 km) is composed of a Li-F-granite which in part is strongly greisenized by high-temperature fluids [1, 2]. The flat dipping quartz-zinnwaldite-topaz-fluorite cassiterite greisen ore bodies in the German part of the Zinnwald deposit have a thickness of up to 25 m and resources of about 50 kt Li, 19.5 kt Rb, 1 kt Cs, 6.7 kt Sn, and 2.7 kt W [3]. Three representative zinnwaldite-rich quartz-Li-mica-topaz-fluorite-cassiterite greisen samples with a total weight of 30 t were taken in two levels of the old mining area. The average bulk geochemistry and the range of 16 greisen subsamples indicate the high concentrations of rare elements and fluorine: Li (3290, 490-6990 ppm); Rb (2320, 440-4900 ppm); Cs (67, 13-160 ppm); Sn (1620, 50-13.900 ppm); W (140, 25-390 ppm); Nb (90, 52-153 ppm); F (2.7, 0.36-4.3 wt.%); Th (38, 22-85 ppm). The geochemical signature (e.g., relatively high Li, Rb, Cs, F, Nb, Sn) of the greisen and Li-F granite show similar trends [1, 3]. Seven Li-mica separates have been dated by Ar-Ar in Freiberg (ALF) using laser step heating techniques and an ARGUS multicollector noble gas mass spectrometer. Ages are interpreted as near-formation ages of Li-mica and range between 312.6 ± 2.1 Ma and 314.9 ± 2.3 Ma (2σ external).

Halogens are thought to be useful in the geochemical studies of rock and sediment formation. However, their analyses are difficult due to their low abundances, specifically Br and I. There are lack of reliable analytical results also for standard rocks. Therefore, we have examined separation procedures of Cl, Br and I from sediments and sedimentary rock samples by pyrohydrolysis. Halogens evaporated by pyrohydrolysis collected in trap solutions. The concentrations of Br and I were determined by ICP-MS and that of Cl was measured by ion-chromatograpy.

Using the developed methods, we have analysed Cl, Br and I in various standard rock samples. The analytical results agreed well with certified values. New data for standard rocks (e.g. JMS-1, JMS-2, JCp-1, JCt-1), in which the concentrations were not known, were also obtained.

We also analyzed sediments and carbonate nodules collected from methane hydrate areas in Japan Sea. In these areas, high iodine concentrations were observed in pore waters in the sediments. We also analysed Br and Cl for comparison.

Results obtained for these elements in solid phase of the sediments were in the ranges: Cl: 5000-10000 ppm, Br: 40-150 ppm, I: 10-200 ppm. High iodine concentrations are characterized by methane hydrate areas. Concentrations of Br and I showed the decreasing tendency with depth. Markedly high values of I in surface sediment was observed. This suggested that I was accumulated by the deposition of organic matters from seawater and also by the fixiation in oxic layer of the sediments from pore water. The concentrations of Cl, Br and I in carbonate nodules were about 100 ppm, 7 ppm, 4.6 ppm. I in carbonate nodules was found to be highly concentrated from pore water compared with Br. The I/Br ratios in carbonate nodules were much higher than those in pore water and solid phase of the sediments. Concentratian mechanisms of the iodine is being examined now.

Identifying the when and where of oil generation using platinum, palladium, osmium and rhenium geochemistry

D. SELBY[1], A.J. FINLAY[1] AND M.J. OSBORNE[2]

[1]Department of Earth Sciences, Durham University, Durham, DH1 3LE, UK (david.selby@durham.ac.uk, a.j.finlay@durham.ac.uk)

[2]BP International Centre for Business & Technology, Building H, Chertsey Rd., Sunbury-on-Thames, Middlesex, TW16 7LN, UK

Understanding the timing and source of petroleum generation permits more successful oil exploration and recovery. Traditionally, oil source rock identification uses organic chemical analysis of light oil fractions. However, common processes such as biodegradation preferentially removes light hydrocarbons from petroleum compromising traditional oil to source fingerprinting techniques. We therefore developed a new geochemical technique, which not only absolutely dates oil generation through Re–Os geochronology, but also enables the identification of source units through the comparison of ^{187}Osmium/^{188}Osmium at the time of generation (Os_g) and Platinum/Palladium (Pt/Pd) ratios in oils and their potential source units. We demonstrate the applicability of this method in the well understood United Kingdom Atlantic Margin (UKAM) petroleum system and then apply it to identify the source of the West Canadian Tar Sands (WCTS).

Our data yields a Re–Os age of 68±13 Ma (MSWD=20) for oils of the UKAM, indistinguishable from published basin models. Furthermore, the Os_g and Pt/Pd values of these oils are indistinguishable from those of the known source rock, demonstrating that Os_g and Pt/Pd values can be used to identify oil source. When applied to the WCTS, comparison of Pt/Pd and Os_g values with the three potential source units suggests that the dominant source unit is the late Jurassic Gordondale Fm. with only minor inputs from other sources (e.g. Devonian-Mississippian Exshaw Formation).

Unlike traditional organic geochemistry, Pt/Pd and Os_g fingerprinting is not rendered ineffective by biodegradation allowing oil source correlation in previously unsuitable petroleum systems and the deduction of migration pathways. Combining Re–Os geochronology with Pt and Pd geochemistry has identified the Gordondale Fm. as the source of the WCTS. This now permits both spatial and temporal constraints on petroleum systems to be established and therefore provide a significant tool for petroleum system exploration and development.

Bio-Au nanoparticles on archaeal and bacterial S-layers

S. SELENSKA-POBELL[1]*, T. REITZ[1], A.GEISSLER[1], M.L. MERROUN[2] AND T. HERRMANNSDÖRFER[3]

[1]Institute of Radiochemistry, HZDR, D-01328 Dresden, Germany (*correspondence: s.selenska-pobell@hzdr.de)

[2]Microbiology Dept., University of Granada, Granada, Spain

[3]Dresden High Magnetic Field Laboratory, HZDR, Dresden

Gold nanoparticles with substantially different properties were produced by using two alternative S-layer templates. The first one was a bacterial template, representing sheets of the S-layer of *Bacillus sphaericus*; the second one was in a form of empty cells (ghosts) consisting of the so-called SlaA-layer of the thermoacidophilic archaeon *Sulfolobus acidocaldarius*. The archaeal SlaA-layer is resistant not only to high temperatures and acidity but also to detergents, that allowed to purify the SlaA-layer-ghosts keeping the shape of the cells. The production of the Au nanoparticles was performed according to [1, 2] in a two-step procedure by using DMAB as a reducing agent.

We demonstrate that the SlaA-ghosts of *S. acidocaldarius* serve as a very efficient template for complete reduction of Au(III) to Au(0). In the case of using S-layer sheets of *B. sphaericus* only 40 % of the added Au(III) was reduced to Au (0) [2]. The size of the archaeal bio-Au nanoparticles was about 2.5 nm, while those of the bacterial ones was about 4 nm. The most striking property of the archaeal bio-Au nanoparticles is, however, that they are paramagnetic, in contrast to the bacterial ones and also to bulk gold, which are diamagnetic. As demonstrated by SQUID magnetometry, the archaeal bio-Au possesses an unusually large magnetic moment of about 0.1 μ_B/Au atom. HR-TEM combined with EDX analysis revealed that the archaeal Au nanoparticles are bound to sulfur atoms. The latter originate from the thiol groups of the cystein amino acid residues which are characteristic for the SlaA-layer of *S. acidocaldarius* but absent in the S-layer of *B. sphaericus*. Surprisingly, the magnetic moment of the archaeal bio-Au nanoparticles is substantially larger than the ones observed for thiol capped, chemically produced Au nanoclusters [3]. We suggest that the unusual shape and the biochemical characteristics of the SlaA-ghosts are responsible for the observed extraordinary properties of the archaeal bio-Au.

Combined U-Pb zircon dating and apatite trace element compositions applied to Paleozoic tephrochronology

BRYAN K. SELL[1]* AND SCOTT D. SAMSON[2]

[1]Sec. Earth & Envir. Sci., Univ. of Geneva, 1205, Geveva, Switzerland (*correspondence: Bryan.Sell@unige.ch)
[2]Dep. of Earth Sci., Syracuse Univ., Syracuse, NY 13244, USA, (sdsamson@syr.edu)

The global utility of a stratigraphic section that records important Earth history events requires a robust geological timescale. This could be accomplished either by establishing highly precise and accurate ages for the the section in question or by accurately correlating strata in the section of interest to those regions where a well-developed time scale has already been established. For pre-Cenozoic rocks the challenge of developing independent age constraints for any given section of rock increases with age.

An anomalously high abundance of tephra in the Late Ordovician of eastern North America and Scandinavia presents a unique opportunity to test aspects of the importance of high-precision U-Pb zircon geochronology combined with the utility of crystal-chemistry based tehprochronology. Specifically, high-precision ages combined with robust crystal chemical data can be assessed in view of its ability to help understand aspects of the Great Ordovician Biodiversification Event, end-Ordovician mass extinctions, various oceanic carbon isotope events, and the end-Ordovician glaciation. A few of the widespread tephra possibly derive from the largest known eruptions in the Phanerozoic, which may have triggered important biotic and climatic responses. Tephrostratigraphic correlation of these large eruptive units has been challenging beyond several 100's of square kilometers because the tephra are heavily altered and span different depositional and tectonic settings. Volcanogenic apatite trace element concentrations (Mg, Cl, Mn, Fe, Y, and Ce) have been successfully applied to these tephra correlation problems in the eastern U.S. and between North America and Europe. This apatite trace element tephrochronologic approach has been invaluable for investigating several chronostratigraphic schemes related to Ordovician biostratigraphy, chemostratigraphy, and sequence stratigraphy. Our new U-Pb zircon and apatite trace element data shows that there is some significant disparity in previously assumed temporal relationships, particularly between widely spaced locations.

Exoplanet atmospheres: From hot to habitable worlds

FRANCK SELSIS[12]

[1]Université de Bordeaux, Observatoire Aquitain des Sciences de l'Univers, BP 89, F-33271 Floirac cedex, France (selsis@obs.u-bordeaux1.fr)
[2]CNRS, UMR 5804, LAboratoire d'Astrophysique de Bordeaux, BP 89, F-33271 Floirac cedex, France

Current observational techniques allow us to detect a broad variety of extrasolar planets. In some cases we can measure properties such as the planetary radius, mass and temperature and constrain the structure, molecular composition and dynamics of their atmospheres. The diversity of observed exoplanets is extraordinary in terms of planetary system architectures, physical conditions and chemical compositions. I will present several striking cases that illustrate this diversity.

At two extremes of the known sample of exoplanets are hot gas giants, whose atmospheres constitute a puzzle for both physicists and chemists, and potentially "habitable" worlds which, despite very exotic properties, could host liquid water. I will focus on these two types of atmospheres and show that their modeling is a challenging but extremely rich subject. I will then discuss the prospects for the next step of exoplanet characterization.

A chlorine isotope view of mantle metasomatism via slab fluids/melts

J. SELVERSTONE* AND Z.D. SHARP

Dept of Earth & Planetary Sciences, University of New Mexico, Albuquerque, NM 97131 USA
(*correspondence: selver@unm.edu)

We use Cl, H and O stable isotope geochemistry to investigate fluid/melt infiltration of the Finero peridotite (Ivrea Zone) in a shallow mantle wedge setting (1.2-1.6 GPa, ~900°C, Perple_X modelling). Unaltered samples from the Balmuccia peridotite have typical mantle δ^{37}Cl values of -0.4±0.3‰ and provide a reference frame for the metasomatized rocks. Four lithologies from Finero (1: spinel harzburgites with minor amph ± phlog, 2: harzburgites with abundant phlog ± amph, 3: amph segregations, and 4: phlog segregations) have δ^{37}Cl values between –2.0 and +2.1‰ (Fig. 1). We also report preliminary chlorine isotope data from HP/UHP rocks (hydrothermally altered oceanic crust, serpentinites with rodingite dikes, and Mn-rich and calcmica schists) that represent likely subduction inputs (Fig. 1). The isotopic variability recorded at Finero cannot be reconciled with metasomatism by a single fluid. Three principal components describe the sample variability: (A) endmember peridotite, (B) a low δ^{37}Cl, high δD, and high δ^{18}O component (melt derived from subducted sediment), and (C) a high δ^{37}Cl, δD, [Cl], and [K] component (high-salinity fluid likely released from altered oceanic crust). Preserved cm-scale isotopic heterogeneities indicate channelized infiltration of fluid/melt at different times and from different slab source rocks. Small-scale fluid release events – not just large-scale serpentinite dehydration – are thus important in chemical transfer from subducted slabs to the mantle wedge.

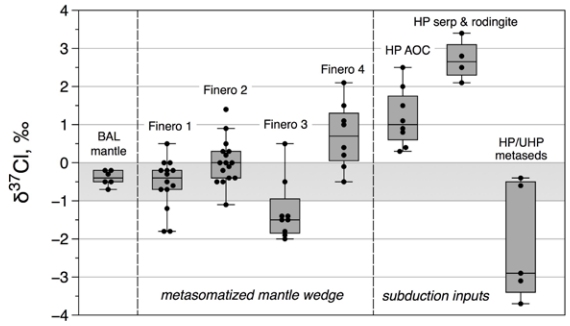

Figure 1: Box-and-whisker plot of δ^{37}Cl values from unaltered mantle peridotite (BAL), metasomatized Finero rocks, and various HP and UHP rocks from the western Alps.

Correlation of δ^{13}C and PGE contents in magmatic ores

D.V. SEMENOVA*, V.A. PONOMARCHUK AND V.V. RYABOV

Sobolev Institute of Geology and Mineralogy SB RAS, 630090 Novosibirsk, Acad. Koptyug av., 3, Russia
(*correspondence: semenovadina@gmail.com)

Typically, the spatial association of rare metals, including PGE, with the organic matter is regarded as an argument to the important role of organic matter in ore formation. As an example, ore deposit in black shales is given [1]. However, there are also many sedimentary basins with low metal concentrations. Thus, ore mineralization occurences in black shales are not a reliable criterion for genetic connection: mineralization – organic matter. Mineralized geological formations with low contents of reduced carbon are best suited to reveal such relations.

The example of correlation between the isotopic composition of carbon, it's content and PGE concentrations in the ores of one of the deposits of the northwestern Siberian platform is presented in this study. Carbon isotope composition were determined using Thermo Finnigan 253 mass spectrometer with specially-constructed line [2]. Special attention was paid for the signal from neutral C0 species (graphit, solid solution C) in the isotopic analysis. The contents of this carbon in the samples range from 15 to 80 ppm. δ13C values were mainly in the range of -21 to -26, 5 ‰. In rare cases, heavier isotope values were obtained for graphite: -12; -13, 5; -14, 5‰. Data have shown that there is no correlation between carbon contents and PGE concentrations (correlation coeffcient is 0.45). However, the comparison of PGE contents in ores and carbon isotope values (C0) has shown the complete linear dependence (the correlation coefficient is 0.94) between them: the weighting of carbon isotope composition was accompanied by the increasing of PGE contents in the same samples. Such a weighting of carbon isotope composition was noted earlier by Ryabov *et al*. [3]. The most possible explanations of the results is that platinum group elements are transfered by specific organometallic compounds rather than the whole organic matter.

Petrogenesis of mantle peridotites from the Kizildag ophiolite (SE Turkey): Implications from mineral composition

A.D. SEN[1], I. UYSAL[1], M. GODARD[2], U. BAGCI[3] AND M. KALIWODA[4]

[1]Karadeniz Technical University, Department of Geological Engineering, 61080-Trabzon, Turkey (*correspondence: ahmetds@gmail.com)
[2]Géosciences Montpellier, Universite Montpellier 2 - cc60Place Eugene Bataillon, 34095-Montpellier, France
[3]Mersin University, Department of Geological Engineering, 33342-Çiftlikköy/Mersin, Turkey
[4]Mineralogical State Collection Munich, LMU, D–80333, München, Germany

Kizildag (Hatay, SE Turkey) ophiolitic complex is one of the best maintained Tethyan lithospheric remnants of Turkey ophiolites. Mantle tectonites from the Kizildag ophiolite contains spinel with Cr# 0.47-0.61 which indicates that they are residue of ~23-30% of partial melting of primitive upper mantle, and are similar to the supra subduction zone peridotites. Pyroxenes have lower content of Al ($Al_2O_3^{Cpx}$=1.61-2.77 wt%) and Ti (TiO_2^{Cpx}<0.25), and also indicate the respectively high degree of depletion. Clinopyroxene from the twelve peridotite samples of Kizildag ophiolite complex analyzed by LA-ICP MS for their trace and REE contents. Clinopyroxenes from mantle tectonites show LREE enrichment (Sm_N/Lu_N=0.04-0.78) and nearly horizontal HREE (Er_N/Lu_N=0.49-1.32) patterns. There is a negative correlation between Sm/Yb vs. Yb contents of clinopyroxenes, which consistent with the hydrous partial melting and fluid-melt enrichment trend. There is also a negative correlation between Yb content in clinopyrexene and Cr# of spinel. The depleted composition of incompatible elements and LREE enriched pattern known as an evidence for mantle-melt interaction. There is a good correlation between Cr# of spinel and HREE concentration of clinopyroxenes. However, chondrite-normalized Ce concentrations $(Ce)_N$ of clinopyroxene in mantle tectonites of Kizildag ophiolite is higher (0.10-0.13ppm) than the abyssal peridotites. The mineral chemistry results indicate that the mantle tectonites shows higher degree of partial melting than abyssal peridotites. Subducting oceanic lithosphere produces LREE-enriched melt and/or fluids and this is resulted with the higher melting. These evidences indicate an arc magmatism i.e. a suprasubduction zone setting fort he genesis of Kizildag ophiolite.

Human impact on global element cycles

I.S. SEN* AND B. PEUCKER-EHRENBRINK

Woods Hole Oceanographic Institution, Woods Hole, MA 02540, USA (*correspondence: isen@whoi.edu)

Material flow caused by human actions has become a major component of the Earth's biogeochemical cycles. In order to constrain the effect of human activity on global elemental cycles, Klee and Graedel [1] quantified the magnitude of anthropogenic activities on 77 of the naturally occuring elements. Their study compiled estimates of natural (weathering of continental crust, net primary production, element mobilized through sea spray) and anthropogenic (mining, biomass burning, and fossil fuel combustion) element fluxes and determined the role of humans on global elemental cycles. While Klee and Graedel [1] assessed the role of a number of important natural and anthropogenic processes, their assessment was not comprehensive. For instance, global dust fluxes [2] and losses to and gains from the extraterrestrial environment were not considered.

Here we revisit the Klee and Graedel [1] study and add important sources (chemical flux contributions from volcanoes and aeolian dust, input of extraterrestial matter) that affect global elemental cycles. In addition, we updated chemical inventories and fluxes for a range of processes.

Our calculation shows a substantial change from the original Klee and Graedel [1] study. Geochemical cycle of 22 elements are dominated by human actions. Biogeochemical cycle of gold, platinum, palladium, rhenium and iridium are dominated by anthropogenic activities, followed by chromium, antimony, copper, mercury, rhodium, lead, bismuth, tin, tellurium, cesium, arsenic, tungsten, iron, silver, nickel, indium and uranium.

Assessments of the anthropogenic radiative forcing over the Amazon Basin: Aerosols and land-use change

E.T. SENA*, S.P. CAMARA, F.F. FRIGERI, A.L. CORREIA AND P. ARTAXO

Institute of Physics, University of São Paulo, R Matão, Trav R, 187, 05508-090, São Paulo/SP, Brazil (*correspondence: elisats@if.usp.br, spinc@if.usp.br, felipef@if.usp.br, acorreia@if.usp.br, artaxo@if.usp.br)

Man-made biomass burning activities that occur yearly in the Amazon send large amounts of smoke to the atmosphere, and alter the landscape by converting forested areas into pastures and cropland. This work addresses the radiative forcing (RF) of the smoke aerosol and of the land cover change in Amazonia, seeking to quantify their climatic impact over the Earth System.

The cloud-free direct RF due to biomass burning aerosols was derived from the CERES sensor (Clouds and the Earth's Radiant Energy System) [1] flux retrievals over the Amazon from 2000 to 2009, considering the peak of the burning season from August to September. The Amazon Basin was divided in 0.5° latitude-longitude grid cells according to [2], and the broadband shortwave (0.3 to 5.0 μm) radiation flux was regressed against the aerosol optical depth to determine the radiative flux under clean (no aerosol) conditions, F_{cl}. The direct RF was derived by subtracting from F_{cl} the flux under average aerosol conditions. The resulting aerosol RF shows large spatial and temporal variations, with an average of -10.4±4.4 W/m^2 in a basin-wide scale, during the biomass burning season from 2000 to 2009. In local spatial scales and across the solar spectrum this figure can vary significantly. For instance, over the city of Alta Floresta, Brazil (-9.9°N, -56.0°E) for the 2007 burning season the cloud-free spectral direct aerosol RF was estimated as -57 W/m^2 at 440 nm, -17 W/m^2 at 675 nm, +11 W/m^2 at 870 nm, and +6 W/m^2 at 1020 nm.

The RF due to land-use (albedo) change was estimated for clean (no aerosol) conditions over the state of Rondonia, Brazil, an area that has been heavily deforested since the 70's. Surface reflectance retrievals from MODIS (Moderate Resolution Imaging Spectroradiometer) were used to select study areas, and the RF was computed as the difference between the CERES radiative flux at the top of the atmosphere above forests and over nearly bare-ground deforested patches. The albedo land-use change RF was -22±3 W/m^2, a figure that can be compared to the direct aerosol RF, but in the Amazon these deforestation patches correspond to a nearly permanent modification of the surface albedo that also changes the local radiation budget.

Studies of the indirect (i.e. mediated by clouds) aerosol forcing over the Amazon Basin are currently under way and they will help throwing in one more puzzle piece to the set above, depicting key factors that define the human RF over the Amazon.

Osmium isotope signatures in peridotites from the ultra-slow spreading SWIR and RTJ

R. SENDA[1]*, H. SATO[2], K. NAKAMURA[1], H. KUMAGAI[1] AND K. SUZUKI[1]

[1]Japan Agency for Marine-Earth Science and Technology, Yokosuka, 237-0061 Japan (*correspondence: rsenda@jamstec.go.jp)

[2]School of Business Administration, Senshu University, Kawasaki, 214-8580 Japan

The ridge magmatic systems are the places where crust directly forms. They provide information on how different crust forms depending on variable spreading rates associated with amount of melt supply and the source of the supplied melts. The central part of the Southwest Indian Ridge (SWIR), known as an ultra-slow spreading system (14-16 mm/yr) was investigated. We had two cruises of R/V Hakuho-Maru in 2008 (KH07-4 Leg2) and 2010 (KH09-5 Leg4) R/V Hakuho-Maru and dredged aphyric to porphyritic basalts, peridotites, metamorphic and sedimentary rocks from 17 sites from 34E to 40E along SWIR. We also sampled peridotites from the Rodriguez Triple Junction (RTJ) where three ridge system, the Central Indian Ridge, the Southeast Indian Ridge and SWIR meet together (YK05-16 Leg1 at 2005 by R/V Yokosuka and Shinkai 6500).

The Re-Os isotope systematics were investigated to identify the source of basalts and peridotites. One of the major advantages using Re-Os system is that they are relatively robust to secondary effects, e.g. sea water alteration and mantle metasomatism. The Os isotope ratios of peridotites from SWIR and from RTJ are $^{187}Os/^{188}Os$ = 0.1239-0.1307, which are in the range of those reported as abyssal peridotites. The Os isotope ratios of spinels from SWIR, however, indicate more depleted signature; around $^{187}Os/^{188}Os$ = 0.121, compared to the primitive upper mantle ($^{187}Os/^{188}Os$ = 0.1296, [1]) and peridotites from SWIR of this study and [2]. Such mismatches of Os isotope ratios between the spinels and the peridotites have been also reported even within a hand specimen level [2]. The time of Rhenium depletion (T_{RD}) ages were estimated as around 1Ga for these spinels, which show that the host peridotites of spinels experienced melt extraction at least around 1Ga even they were recovered from the currently active ridge.

Molybdenite deposition in Bingham Canyon deposit: Role of sulfur, redox and pH chemistry in magmatic-hydrothermal fluids

JUNG HUN SEO, MARCEL GUILLONG AND CHRISTOPH A. HEINRICH

ETH Zurich, Institute of Geochemistry and Petrology, 8092 Zurich, Switzerland

The Bingham Canyon porphyry deposit shows a distinct metal zonation of 1) shallow Cu-Au mineralization (Cu-stage) and 2) deeper Mo mineralization (Mo-stage) occurring in a separate vein set that truncates earlier Cu-Au veins.

In deep low-grade Cu-stage quartz veins, we found high concentrations of Cu, S, and Mo in the fluids, whereas in low-grade Mo-stage veins, we found rather lower Cu, but similar concentrations of S and Mo, compared to the input fluids of the Cu-stage. Sulfur concentrations in intermediate density (ID) type inclusion in deep low-grade Cu-stage samples are similar to their Cu concentration, whereas ID-type inclusions in low-grade Mo-stage veins have S contents in excess over their Cu content. Compared to the P-T conditions of the Cu-precipitation stage (90-260 bars and 320-430 °C), the Mo-precipitating fluids extended to higher pressures and temperatures of 140-710 bars and 360-580 °C.

Mass-balance calculation and vapor/brine partitioning data indicate that the mass of vapor phase exceeded that of brine by about 9/1 and more than 70% of Mo, Cu, and S (by mass) were deposited by the vapor phase in both mineralization stages.

High Mo contents (max. 0.0054 Mo/Na in ID; 380 μg/g Mo in brine) in the hydrothermal fluids were maintained from the early Cu-stage to the late Mo-stage, suggesting that Mo concentration in the fluids may not be the decisive factor for the separate Cu & Mo precipitations in Bingham Canyon deposit. Instead, the metal separation may be explained by a reduction in redox and a pH increase in the fluids from evolving source region. This is indicated by 1) the stoichiometry of chalcopyrite and molybdenite precipitation reactions, 2) a difference in the Fe/Mn ratio in fluids of the two (Cu and Mo) veining stages, 3) incipient muscovite alteration along high-temperature molybdenite veins, and 4) an increasing vapor/brine partition for Mo.

We suggest that the early Cu-stage fluids were slightly oxidized, allowing efficient Cu-Fe sulfides precipitation and thereby consume much of the dissolved S. By contrast during the later Mo-stage, the fluids were more reduced and acidic, thereby allowing selective saturation of molybdenite as the first precipitating sulfide.

Uranium interactions with bacterial communities from contaminated soils in Chernobyl

Following the Chernobyl accident in 1986, vegetation, contaminated soil and other radioactive debris were shortly buried *in situ* in trenches. The present work describes the analysis of the structure of the bacterial communities that have been evolving in this environment for more than 20 years. Comparison of the diversities found in soil samples exhibiting contrasted radionuclides content is a prerequesite to point out the potential role of microorganisms in radionuclide migration in soils.

Bacterial communities were examined using a genetic fingerprinting method that allowed a comparative profiling of the samples (DGGE), with universal and group-specific PCR primers. Our results indicate that a long term exposure to radionuclides did not lead to extinction of bacterial diversity in Chernobyl soils.

A collection of aerobic and anaerobic culturable isolates was also assembled. A phylogenetic analysis of 250 heterotrophic aerobic isolates revealed that 5 phyla are represented: *Beta-, Gammaproteobacteria, Actinobacteria, Bacteroidetes* and spore-forming *Firmicutes*, the last being largely dominant [1].

Eleven representative fast-growing strains, related to diverse genera, were exposed to uranium. In each case, bacteria/uranium interactions exhibited different kinetics, suggesting that underlying mechanisms (biosorption, accumulation, precipitation) could be different.

Biomineralization of Fe^{II}-Fe^{III} green rust in γ-FeOOH coated sand column under saturated flow conditions

A.-S. SERGENT, K. HANNA, P.P. REMY AND F. JORAND*

LCPME UMR 7564 CNRS- Nancy-University, Jean Barriol Institute, 405 rue de Vandoeuvre, 54600 Villers-lès-Nancy, France
(*correspondence: jorand@pharma.uhp-nancy.fr)

The synthesis of Fe(II)–Fe(III) green rusts (GR) in environmental and engeneering systems is a challenging project due to the higher reactivity of GR towards a panel of organic or inorganic pollutants. While the biomineralization and stabilization of GR have been well described in batch reactor from ferric oxide respiration by *Shewanella putrefaciens* [1, 2] or mixed cultures of bacteria [3, 4], their formation routes as a main secondary iron mineral under flow-through conditions remain undescribed.

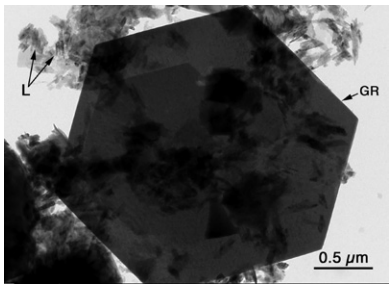

Figure 1: Picture of a green rust (GR) crystal obtained in a lepidocrocite (L) sand packed column incoculated with *S. putrefaciens* and fed with formate as electron donor.

Formation of both GR and magnetite was observed in a lepidocrocite-coated sand packed column at a flow rate of 0.1 mL/min. However, GR was the dominant secondary mineral when silicate was present in the injected feed solution (Fig.1). In this latter case, untransformed lepidocrocite was still present in the sand packed column. This behavior could be explained by the sorption of dissolved silicate on the lepidocrocite surface, which might hinder the reactive sites and so limit the bioreduction extent. On the other hand, the interactions of dissolved Si with the lateral faces of the GR crystals could stabilize the GR structure, thus preventing its transformation into magnetite.

Hg (II) sequestration by ettringite-type phases. A geochemical modeling and EXAFS study

S. SERRANO[1], D. VLASSOPOULOS[2], B. BESSINGER[3] AND P.A. O'DAY[1]

[1]University of California, Merced CA USA
[2]Anchor QEA, LLC., Portland OR USA
[3]S.S. Papadopulos & Associates, Inc., Portland OR USA

Sequestration of Hg by ettringite-type phases (Ca_6 [Al $(OH)_6]_2$ $(SO_4)_3 \cdot 26H_2O$), formed during hydration of Portland-type and super-sulfate cements, as a potential method for sediment remediation was investigated theoretically with a kinetic-equilibrium model and experimentally in co-precipitation (Hg+Al+SO_4+Ca and Hg+Fe+SO_4+Ca systems) and substrate-amended (quartz, clay, and/or sediment) batch experiments in aqueous NaCl solutions. Geochemical modeling predicted formation of ettringite and calcium-silicate-hydrate (C-S-H) gels as a function of reaction time, corroborating XRD results for amendment batch experiments. XRD patterns of the co-precipitation products showed Al-ettringite and gypsum as the main mineral phases in the Hg+Al+SO_4+Ca and Hg+Fe+SO_4 +Ca systems, respectively. Extraction results indicated that <20% of added Hg was associated with the exchangeable fraction in both co-precipitation and substrate-amended batch experiment. XAS and electron microprobe characterization of the Hg co-precipitation and cement hydration products suggests physical micro-encapsulation of Hg in ettringite as a polynuclear chloromercury calcium precipitate. Hg XAS analysis of the solid products in the Hg+Fe+SO_4+Ca system indicated Hg sorption on ferrihydrite as the main retention mechanism. These results revealed that, in the presence of Cl^-, Hg immobilization in cement systems is kinetically controlled by Hg-Cl complexation and precipitation of cement hydration products. However, in high Fe systems, Hg retention predominantly as the Hg $(OH)_2$ species, is controlled by fast sorption equilibrium on ferrihydrite.

Experimental study of mineral equilibria in the system Li_2O-K_2O-Al_2O_3-SiO_2-HF-H_2O (with topaz) at 400°C and 100 MPa

T.V. SETKOVA*, YU.B. SHAPOVALOV AND V.S. BALITSKY

Institute of Experimental Mineralogy, Academica Osipyana Street 4, Moscow distr. 142432, Chernogolovka, Russia (*correspondence: setkova@iem.ac.ru)

The experimental study of mineral equilibria in the system Li_2O-K_2O-Al_2O_3-SiO_2-HF-H_2O was carried out to determine influence of composition of solution (lithium content) on genesis of greisen deposits.

Topaz one of the major indicators of F-bearing minerals participating in most of the studied reactions. Experiments were performed in autoclaves in gold ampules with self-sealing shutter by a technique of monovariant reaction. This technique is based on change of topaz grain weight. All the mineral phases participating in the reaction were placed together into ampoules. The topaz was used as rounded grain whereas other components of reactions were added as powder. As a result influence of lithium on shift of topaz stability field on the diagram $\lg_{(mHF)}$ - $\lg_{(mKF)}$ established earlier [1] for modeling system K_2O-Al_2O_3-SiO_2-HF-H_2O has been estimated. At low concentration of LiF and high concentration of HF in the solution the line limiting the topaz field for monovariant equilibrium topaz-AlF_3 moves downwards to the axis $\lg_{(mHF)}$. Muscovite stability field is replaced by lepidolite field at relatively high concentration of LiF and low concentration HF in the solution. Absence of potassium in the solution leads to formation of the lithium-bearing alumina-fluoride phase.

Krypton and xenon in air bubbles from ice cores as tracers of past ocean temperature

JEFFREY P. SEVERINGHAUS[1] AND KENJI KAWAMURA[2]

[1]Scripps Institution of Oceanoggraphy, CA 92093-0244
[2]National Institute for Polar Research, Tokyo, Japan

The heavy noble gases krypton and xenon are quite soluble in liquid water, with a strong temperature-dependence of the solubility. Because the total inventory of these gases in the ocean-atmosphere system is constant, an increase in the oceanic inventory must be accompanied by a complementary decrease in the atmospheric inventory. Dinitrogen (N_2) gas is much less soluble and so its atmospheric inventory is little affected by ocean temperature change. Sources and sinks of N_2 may be neglected due to the great abundance of this gas in the atmosphere, and the fact that the entire denitrifiable inventory of N comprises less than 0.01% of the atmospheric pool. Thus the ratios Kr/N_2 and Xe/N_2 in the past atmosphere should predominantly reflect past ocean temperature change. These parameters may be estimated from measurements of trapped air composition in ice cores, making appropriate corrections for gravitational settling and thermal fractionation that occurred in the snow layer (firn) at the ice core site. Measurements are done by classical dual- dynamic-inlet electron impact mass spectrometry on air melt-extracted from 1 kg of ice, and encompass the krypton isotope pair $^{86}Kr/^{82}Kr$ and $^{15}N^{14}N$ for the purpose of making the gravity and thermal corrections.

This new proxy reflects mean ocean temperature change, albeit slightly weighted toward the cold end of the temperature distribution due to the greater solubility of these gases in cold water. Because the ocean's heat and gas burdens are set at the outcrop where air-sea equilibration last occurs, and they travel through the ocean interior nearly adiabatically and conservatively, there is no time lag between changes in ocean heat content and changes in atmospheric noble gas burden. Consideration of the solubilities and relative volumes of the reservoirs leads to the prediction that a 1˚C warming will produce a +0.5‰ increase in atmospheric Kr/N_2. Current measurement precision is around 0.2‰ for a 1-kg piece of ice, suggesting a precision of about 0.4˚C for this proxy. Reconstructions over the past glacial cycle suggest a glacial mean ocean temperature about 3˚C colder than present, with a rapid warming of about 2˚C between 18-15 ka. This was a time period of rapid atmospheric CO_2 increase, consistent with the hypothesis that atmospheric CO_2 lowering in the glacial episodes was caused by sequestration in a poorly ventilated, dense, cold deep water layer.

Enhanced *in situ* methanogenesis and microbial community analysis of coal beds

JOEL R. SEVINSKY AND WILLIAM R. MAHAFFEY*

Luca Technologies, Golden, CO 80129 USA
(*correspondence: bill.mahaffey@lucatechnologies.com)

Biogenic methane has enormous potential as a sustainable energy source and is found in a wide variety of subsurface, anaerobic, hydrocarbon bearing environments. The Powder River Basin in Wyoming, USA is an area previously shown to be an active 'geobioreactor', or an area where active *in situ* methanogenesis occurs as determined by coal conversion to methane in laboratory experiments, the presence of metabolic intermediates in coalbed methane formation waters, and the ability of the consortia present in these waters to convert the metabolites to methane. Understanding the composition and metabolism of the methanogenic consortia has been one of several key steps in commercializing the process of sustainable biogenic methane production.

In order to identify the microbes present in these methanogenic consortia, we performed microbial community analysis using error-correcting barcode pyrosequencing analyzed with the QIIME bioinformatic pipeline. This involved hundreds of samples collected from different locations within a set geographical area over several years. We used both bacterial and archaeal specific primers to amplify these distinct populations from our DNA samples. The QIIME pipeline was used for library demultiplexing, OTU picking, alignment, taxonomic identification, and statistical analysis of community structure using Unifrac. Spotfire was used for visualization of QIIME results with metadata from the formation.

Here we demonstrate the large scale areal and temporal sampling for community analysis of coalbed methane (CBM) wells within a discrete but large area of the Powder River Basin. Temporal consists of the baseline state, followed by a bio-stimulation phase (i.e. Restoration) and enhanced methane production phase. Under baseline conditions, we find distinct bacterial and archaeal populations that vary by coal, water chemistry, and time. Community profile signatures help determine the areas of greatest methanogenic potential and identify patterns of ground water recharge, water movement, and potential metabolic bottlenecks. Data will be presented showing increased gas production over pre-restoration decline curves, the period of enhanced methane production and the observed changes in the microbial community structure associated with enhanced gas generation.

An Exafs and *ab initio* study of aquated Cd^{2+} and chlorocadmium(II) complexes up to 300°C

T.M. SEWARD[1], K.H. LEMKE[2], C.M.B. HENDERSON[3], J.M. CHARNOCK[3] AND S.A. SADJADI[2]

[1]Victoria University of Wellington, New Zealand (terry.seward@vuw.ac.nz)
[2]University of Hong Kong, Hong Kong, kono@hku.hk
[3]University of Manchester, UK

The hydrothermal transport and deposition chemistry of cadmium in the Earth's crust is still poorly known. X-ray absorption spectroscopy and quantum chemical calculations can provide fundmental insight on a molecular level into the formation/stability and hydration of the geochemically relevant Cd(II) complexes.

We have measured the EXAFS of aqueous cadmium nitrate, perchorate and chloride solutions up to 300°C and at the equilibrium saturated vapour pressure using an X-ray optical cell employing silica glass windows. In dilute nitrate solutions ((0.01m Cd $(NO_3)_2$/0.01m HNO_3), Cd^{2+} is coordinated to 6 water molcules over the temperature range from 25 to 250°C. There is a small electrostrictive contraction of the Cd-water distance from 2.27 to 2.23Å with increasing temperature as the water solvent properties change at conditions along the two phase curve. In more concentrated nitrate and perchorate solutions (1.00m), the mono-, di- and trinitato- and monoperchoratocadmium (II) ion pairs were detected. The stepwise formation of chlorocadmium (II) complexes was also studied from 25 to 300°C in solutions having HCl concentrations from 0.001 to 3.00m. For example, in 3.00m HCl, the $CdCl_4^{2-}$ species predominated over the entire temperature range with the Cd-Cl distance remaining essentially constant at 2.46-2.45Å.

The computational part of the study was designed to provide further insight into the nature of Cd^{2+} hydration as well as to the coordination and hydration of the cadmium chloride complexes. We performed a systematic survey of the equilibrium geometries of $CdCl_m$ $(H_2O)_n$ for m=0-4 and n=0-11. We employed the cc-pVnZ (PP) (n=D, T) correlation consistent basis set for Cd, cc-pV (d+n)Z (n=D, T) for Cl and cc-pVnZ (n=D, T) for H and O (abbreviated as VnZ (PP) (n=D, T). Geometry optimisations for the various hydrated complexes were performed at the RHF and the results thereof then applied as starting geometries for subsequent MP2 level calculations. In the case of Cd $(H_2O)_6^{2+}$ for example, the optimal Cd-O distance is 2.28Å. If 7 waters are constrained to the first shell, then the distance extends to 2.35Å, however, this geometry with $7H_2O$ is unstable.

Composition modeling of pollution of groundwater by usage of geoelectrical and hydrogeochemical studies

MAHDI SHABANKAREH[1], A. GHASEMI[2] AND S. AFSHARI[3]

[1]ACECR, IUT branch, Isfahan University of thech, Isfahan, Iran (*correspondence: shabankareh@mi.iut.ac.ir)
[2,3]ACECR, IUT branch, Isfahan University of thech, Isfahan, Iran

Now a day, the use of indirect methods of measurement and detection of groundwater contamination due to high speed and lower cost is interested. Among the geophysical methods are very important. in this project was trying, with sampling of groundwater resources and their chemical analysis and Select the appropriate method, and the effect of trace pollutants using the results in comparison to groundwater modeling with integrated studies and hydrogeochemical and geoelectical was acting.

Thirteen profiles with the schlumberger array with south to north in the direction have been picked in study area. General review of the main geoelectrical sections are shown four layers and in some places raise up to six layers. To achieve good picture of the situation in depth, plans are extracted in different depths. These maps are identified manner and distribution of lateral variations of electrical resistance of geological formations.

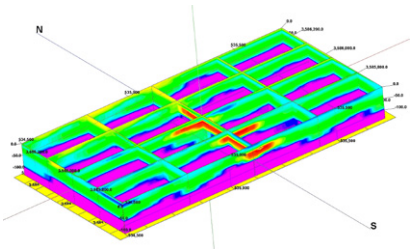

Figure 1: fence of 3d resistance modeling

10-meter depth Plan trend shows a noticeable decrease in the amount of resistivity is observed, especially in the south, it's the main zone of contamination, probably. These studies with samples from 69 water wells were investigated fully consolidated.

Discussion of Results

Results showed that the electrical resistance of contamination zone is lower than usual about the same sedimentary unit which is caused by the effect of pollutants. Based on field observations in the vicinity of this area there are water channel which converted this area to a washed zone that contaminations can penetrate into the soil with infiltrated water.

Geochemical zoning analysis based on 'Axes Level' innovative method

MAHDI SHABANKAREH[1], SEYED HASAN TABATABAEI[2] AND ZAHRA PIRMORADIAN[3]

[1]ACECR, IUT Branch, Isfahan University of Tech., Isfahan, Iran (shabankareh@mi.iut.ac.ir)

(*correspondence: syscadmi@sepahan.iut.ac.ir)

Primary Geochemical halo and alteration zones around ore deposits with the phenomenon formation of ore deposits in a relationship are genetic. So that the diagnosis clear boundary between alteration regions and geochemical alteration halo not be always possible. Observations have shown that spatial distribution (longitudinal, lateral and vertical) halo is complicated and controlled by several variables, such as differences in the mobility of elements which can be function of temperature, pressure, physicochemical specificities enclosing rock, etc.

These zonings can be classification of the use geochemical zoning, with the mineral solutions to flow instruments are matched. This can be useful as a guide in determining the direction and mineralization activity center used to be. Numerical methods in analyzing series of zoning are used in the primary halo, are:

1- Grigorian Method: Based on put data normalized data in a certain interval and compare their changes in shapes. [1]

2- Solovov method (gravity center): gravity center of halo for a two-element ratio is obtained. [1] This more comprehensive than the Gregorian method but has two problems: Effect of torque and weakness in analyzing horizons with different distances. 'Axis level' method was developed to correct these problems by using integral of the halo surface in Perpendicular direction of geochemical profiles. The aim of this method is effecting of halo shape to obtain the center of gravity.

This is similar to the mean value theorem in integral and led to obtain a gravity axe for vertical halo, this axe is called 'Axe Level'. Geochemical element zoning is the result of sorting axes levels.

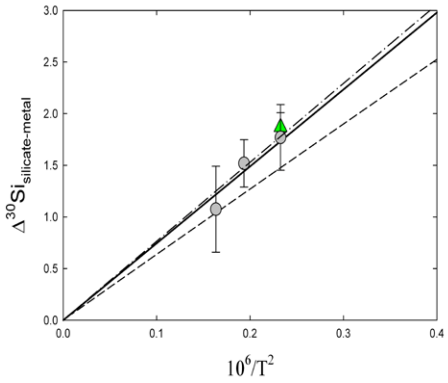
High pressure and temperature silicon isotope fractionation between metal and silicate

A. SHAHAR[1]*, V. HILLGREN[1], E. YOUNG[2], L. DENG[1], Y. FEI[1], C. MACRIS[2] AND R.B. GEORG[3]

[1]Geophysical Laboratory, Carnegie Institution of Washington, Washington D. C (*correspondence: ashahar@ciw.edu)
[2]Department of Earth and Space Sciences, UCLA, CA
[3]Water Quality Centre, Trent University, Peterborough, ON

The Si stable isotope fractionation between metal and silicate has been investigated experimentally in order to better constrain the amount of silicon present in the Earth's core. Experiments at 1800°C were conducted at 1 GPa, while those at 2000 and 2200°C were performed at 7 GPa. All experiments were in MgO capsules so that no silicon was lost during the run and the three-isotope technique was used to demonstrate equilibrium. The isotope analyses were measured by laser ablation MC-ICPMS as spatial resolution is a key parameter in analyzing experiments.



The temperature dependent silicon isotope fractionation is $\Delta^{30}Si_{silicate\text{-}metal} = 7.45\pm0.41*10^6/T^2$ shown in the figure above, experimental data points shown in circles along with best fit line (solid) and theoretical curve (dashed, [2]). The current experiments have: 1. duplicated our previous results [1] performed in a graphite capsule (triangle in figure above), demonstrating that several weight percent carbon in iron metal does not change the silicon isotope fractionation factor, as predicted; 2. shown that the silicon stable isotope fractionation between metal and silicate is insensitive to the structure and composition of the silicate as the fractionation between silicate melt and olivine is insignificant; and 3. shown that there is no pressure effect on isotope fractionation between 1 and 7 GPa (to within analytical uncertainty).

Nature and characteristics of metasedimentary rocks in Northern Sanandaj-Sirjan Zone

FATEMEH SHAJARI

School of Geology, College of Science, University of Tehran, Tehran, Iran (f.shajari@yahoo.com)

Upper Permian-Lower Trias sediments from the Sanandaj-Sirjan zone (SSZ) in western Iran record a cycle of Neotethyan oceanic basin opening and closure when the Central Iranian block separated from Gondwana and Arabia. Their studies could determine constraints of the geotectonic evolution of the area. The sediments were metamorphosed under mid-to-upper greenschist-facies conditions due to subsequent northeastward convergence of the oceanic domain below the Iran. Geochemical analysis implied that the studied metasedimentary rocks have relatively uniform chemical composition which may indicate differing from similar sedimentary rocks [1]. Davoudian *et al*. [2] however reported eclogite lenses from a locality near north of Shahrekord which indicate high pressure metamorphism in the SSZ and tectonic processes such as shearing leading to their exhumation during following continent–continent collision.

The granular and lepidoblastic to lepido-granoblastic textures are seen in the slates and phyllites, respectively. Andalusite and garnet are the major porphyroblasts in the schists. These rocks are composed of biotite, muscovite, quartz and feldspars. The schistosity of rocks is oriented in the NW-SE direction.

Major element data has a narrow range and enrichment in Al_2O_3, all of which can be interpreted as a reflection of a pelitic provenance. It is supported by low Cr and Ti concentrations that prevent a mafic source. In addition high aboundances of S-type granitoids that are penetrated into this metasedimentary country rocks reveal partial melting of metapelites to produce these felsic rocks.

Keep and touch – Dust and mineral iron utilization by the marine diazotroph *Trichodesmium*

Y. SHAKED[1,2]*, M. RUBIN[2,3] AND I. BERMAN-FRANK[3]

[1]Inst of Earth Sciences, Hebrew Univ., Jerusalem, Israel (*correspondence: yshaked@vms.huji.ac.il)
[2]Interuniversity Inst. for Marine Sciences, Eilat, Israel (formaxrubin@yahoo.com
[3]Faculty of Life Sciences, Bar Ilan Univ., Ramat Gan, Israel (irfrank@mail.biu.ac.il)

Oceanic blooms of *Trichodesmium*, a filamentous N_2 fixing cyanobacterium, provide ~50% of the new nitrogen sources to subtropical and tropical areas, fueling primary production and influencing nutrient flow and biogeochemical cycling of organic and inorganic matter. *Trichodesmium's* extensive surface blooms require large inputs of iron that are partly supplied by aeolian dust sources. Yet the processes and mechanisms associated with dust acquisition are currently poorly defined. Here we explore how natural populations and laboratory cultures of *Trichodesmium* collect, process, and utilize iron from synthetic iron oxides and desert dust. Using a combination of uptake and dissolution experiments with microscopic observations, we find that, similar to most phytoplankton, solid-phase iron has to dissolve prior to its acquisition by *Trichodesmium*. We show that, unlike other studied phytoplankton, *Trichodesmium* apply cell-surface processes that accelerate the rate of dissolution of iron from iron oxides and mineral dust particles, and thereby increase cellular iron uptake rates. Natural puff colonies are particularly effective in dissolving dust, probably due to efficient dust trapping by the intricate colony morphology, followed by active centering and packaging of the dust within the colony core (Fig. 1). Thus, colony formation in *Trichodesmium* provides an advantageous strategy for iron acquisition from particulate sources such as dust.

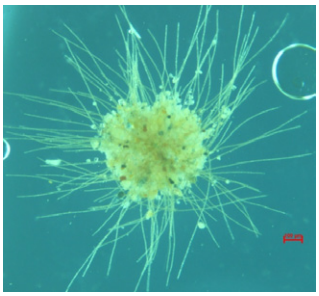

Figure 1: Active centering of dust by puff-shaped natural *Trichodesmium* colony, enabling it to dissolve and acquire iron from dust.

An experimental study on the effect of melt composition on partitioning behavior of copper in magmatic - hydrothermal systems

L.B. SHANG*, H. LI AND W.L. FAN

Institute of Geochemistry, CAS, 46 Guanshui Rd. Guiyang, 550002, China
(*correspondence: shanglinbo@vip.gyig.ac.cn)

Copper is one of the major ore metals in porphyry-type deposits. It has been proposed that metals in those deposits are magmatically derived. The essential feature of the magmatic-hydrothermal model is the separation of mental-rich aqueous fluid from silicate melt. Experimental studies on the partitioning of copper between granitic melt and aqueous fluids have demonstrated the importance of complexing agents, especially chloride, in the transport of copper. However, few experimental data are available concerning the role of melt composition in magmatic-hydrothermal process.

The present study was conducted to evaluate the effect of melt composition on the partitioning behavior of copper. We investigated experimentally the fluid/melt partitioning of copper in the systems synthetic haplogranite gel -H_2O-HCl at 1kbar, 850 °C with Ni-NiO buffer by using rapid-quench cold seal bombs. Experimental data show that the partition coefficient of copper $D_{Cu}^{fluid/melt}$ linearly increases with increasing HCl concentration. That agrees with results of other researchers, who interpreted this behavior as the result of the formation of CuCl complexes in the fluids. $D_{Cu}^{fluid/melt}$ show a strong melt compositon dependence, increasing from 1.28 to 10.09 with the molar $(Na_2O+K_2O)/Al_2O_3$ of melt varying from 1.56 to 0.83, and increasing from 1.35 to 22.18 with the molar Na/K of melt varying from 0.58 to 2.56. The data presented here suggest increasing partition of copper in peralkaline, especially K-rich, granitic melt phase. It implies that, like the fluids, the changes of melt composition also have great effects on the partitioning behavior of copper between aqueous fluids and silicate melt.

Nanoscale study of exopolymeric substance-mediated uranium biomineralization

PAUL P. SHAO[1]*, DANIEL S. ALESSI[1], MALGORZATA STYLO[1], JOHN R. BARGAR[2] AND RIZLAN BERNIER-LATMANI[1]

[1]Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland (*correspondence: paul.shao@epfl.ch)

[2]Stanford Synchrotron Radiation Lightsource (SSRL), Menlo Park, CA, USA

Bacterially-mediated biogenic reduction of soluble hexavalent uranium U(VI) into a less-soluble U(IV) product is among the planned bioremediation strategies at uranium-contaminated sites in the U.S. The primary product of this reduction is thought to be uraninite (UO_2), a highly insoluble crystalline nanoparticulate. While uraninite forms under certain conditions, recent research has shown formation of another U(IV) species under different conditions. *Shewanella oneidensis* MR-1, an intensely studied bacterium for its remediation properties, produces UO_2 under simple aqueous solutions (sodium bicarbonate). In the presence of moderate or high concentrations of alkaline earth cations such as Ca^{2+}, the same bacterium will form U(IV) diffusely distributed on cell biomass and biopolymers, termed monomeric U(IV) [1].

There is electron microscopy evidence that exopolymeric substances (EPS) play a role in the formation of UO_2 [2]. Moreover, EPS-deficient mutants appear to produce less UO_2 than the wild-type, confirming that prediction.

Here, we present a combined microscopic and spectroscopic approach to address the changes in U biomineralization as a function of medium. Using scanning transmission X-ray microscopy (STXM) coupled to near edge X-ray absorption fine structure (NEXAFS), we acquired carbon speciation and actinide elemental maps of *S. oneidensis* wild-type and mutant each generating either UO_2 or monomeric U(IV). In concert, we also provide cryo-preserved, low-dose transmission electron microscope (TEM) images of the reducing bacteria thin-sectioned to display ultrastructure features. The specificity of the association of UO_2 and monomeric U(IV) with biomolecules was demonstrated with these approaches suggesting the importance of individual biomolecules in controlling biomineralization products.

Modelling the free energy of adsorption of persistent organic pollutants at clay mineral-water interfaces

T.V. SHAPLEY* AND S.C. PARKER

Department of Chemistry, University of Bath, Bath, BA2 7AY, UK (*correspondence: t.v.shapley@bath.ac.uk)

Clay minerals represent a cheap alternative for the remediation of pollutants. The clay mineral bentonite has been shown experimentally to adsorb organic pollutants [1] and heavy metal ions [2]. Here we applied computational techniques to model the adsorption of a range of organic molecules, more specifically polyhalogenated compounds (PHCs), on the clay minerals montmorillonite and pyrophyllite. Montmorillonite, a dioctahedral smectite, is the principal constituent of bentonite, while pyrophyllite is the template for all dioctahedral smectites.

The CLAYFF [3] and GAFF [4] force fields were applied to the clay surface and organic molecules, respectively. The interatomic potentials were derived using simple mixing rules and TIP3P/FS [5] water was used in solvated systems. DFT-D2 calculations using the VASP code [6] were carried out to confirm the potential model. PMF free energy calculations were undertaken using the DL_POLY_2.0 code [7]. Further free energy calculations, steered molecular dynamics, umbrella sampling and metadynamics used the PLUMED software plug-in [8].

Our results show that the simple model for the interatomic potentials had good agreement with DFT-D2 calculations. Adsorption energies for montmorillonite were dependent on the counter ions. The free energy techniques all gave comparable results. However, metadynamics was both consistently accurate and less computationally demanding than the other methods. In general, for similarly structured PHCs the adsorption energy increased with the number of chlorine substituents. Even in simple systems the differences are significant, for example the free energies of adsorption for benzene and hexachlorobenzene on the surface of pyrophyllite were -9.6 and -38.6 $kJmol^{-1}$, respectively.

Relationship between incidence of esophageal cancer in Maravehtapeh region (Northeast of Iran - Golestan province) and concentration of trace elements in sediments

NEDA SHARIFI SOLTANI[1] AND FARID MOORE[2]

[1]Department of Geoscience, Shiraz University, Shiraz-Iran (*correspondence: N.sharifi09@gmail.com)
[2]Department of Geoscience, Shiraz University, Shiraz-Iran (*correspondence: Moore@susc.ac.ir)

Esophageal cancer is one of the ten most common cancer and the eighth cause of death in the world. In Iran annually about 51,000 new cases of cancer occur. Most organs of men and women involved in is gastrointestinal tract which about 6500 cases are esophageal cancer. Since the distribution of Esophageal squamous cell cancer (esophageal cancer belt) matches loess deposits of the world which is extended from north of China to north east of Iran, Therefore , likely there is a close relationship between loess deposits and this endemic disease.

Sediment samples of study area were taken from 50 stations in 'atrak' river basin. Trace elements results from ICP-MS analysis in the 'ACME' laboratory-Canada were studied.To obtain extent of external factors (Anthrapogenic impacts), 'Enrichment factor' and 'Muller's geoaccumulation index' was calculated which the amount of enrichment factor was mainly between 0.5-2.5 that shows concentration of elements not affected by anthrapogenic factors and the amount of geoacuumulation index was between -0.5-0.5 which also shows no significant pollution. Results of Analysis of varience 'Anova' test which is investigated the statistical relation of formation 'five formations in study area' with concentration of trace elements, shows concentration of Selenium is directly related with the type of formation since with 95 percent confidence level, there is a signicant difference in amount of Se in different formations especially loess deposits which have the least Se concentration. Considering that Se deficiency in body can enhance esophageal cancer risk, recommneded in future studies measuring of Se concentration in water samples and blood serum of residents of this area.

Mobilization of multi-walled carbon nanotubes in consecutive imbibition and drainage events

PRABHAKAR SHARMA[1] AND DENIS M. O'CARROLL[2]

[1]Department of Earth Science, Uppsala University, Villavägen 16, Uppsala, 75236 Sweden (prabhakar.sharma@geo.uu.se)
[2]Department of Civil and Environmental Engineering, The University of Western Ontario, London, ON, Canada (docarroll@eng.uwo.ca)

Carbon nanotubes (CNTs) are important engineered nanoparticles with unique and beneficial properties. As a result CNTs has been used in a wide range of commercial products including electronics, optical devices and drug delivery leading to their disposal in the natural environment. Literature studies have investigated the mobility of CNTs in saturated porous media under differing physical and chemical conditions. However CNT transport in temporally changing porous media water content has not been investigated thus far (a common scenario with rainfall/infiltration events in the vadose zone). This study investigated the mobilization of multi-walled CNTs (MCNTs) in repeated wetting and drying cycles with varying flow rates and ionic strength of the inflow solution. Imbibition-drainage-imbibition cycle experiments suggest that MCNTs mobilization increased with increase in flow rates. MCNTs mobilization occurred only with first imbibition events at low ionic strengths however less mobilization happened for higher ionic strength inflow solution in the first imbibition cycle and additional MCNTs were found in the outflow solution in second imbibition cycle, using low ionic strength solution. This observation was likely due to the attachment forces between MCNTs and sand surface. Most of the MCNT mobilization occurred during liquid-gas interface movement with less chance of MCNTs to jump the energy barrier at higher ionic strength solution experiments. As a result less detachment of MCNTs occurred from the sand surface.

The Cl isotope composition of the mantle revisited

Z.D. SHARP[1], J. SELVERSTONE[1] AND J.A. MERCER[1]

Dept. Earth & Planet. Sci. Univ. New Mexico, Albuquerque, NM 87131 (zsharp@unm.edu)

Published estimates for the δ^{37}Cl value of the mantle range from less than -3‰ to +5.7‰. We combine new data from mantle-derived materials with new chondritic and lunar data to refine the δ^{37}Cl value of the mantle to between -0.5 and 0.0‰ (SMOC). Samples include basalts from Hawaii, Iceland and New Mexico (δ^{37}Cl = -0.15±0.15‰, *n*=7), peridotites from Balmuccia, Italy (-0.25±0.16‰, *n*=5), and Cl-bearing diamonds from Canada (-0.05‰). The δ^{37}Cl values of our new and previously published data (Sharp *et al*. Nature, 2007; Science, 2010) average -0.15±0.35‰ (*n* = 26), indistinguishable from the lowest lunar sample (δ^{37}Cl = -0.7‰), the average of type 3 chondrites (δ^{37}Cl = -0.5‰; Mercer *et al*. LPSC 2011) and evaporites (~ 0‰).

Although Cl isotope variations do exist in contaminated mantle (John *et al*. EPSL, 2010), the large published range for the primitive mantle is explained by analytical artefacts. Published TIMS data are unreliable, yielding high δ^{37}Cl values (Nakamura *et al*. LPSC 2011). A published SIMS value for 'archived' MORB (< -3‰, Layne *et al*. Geol. 2009) has a Cl content an order of magnitude lower than corresponding standards, explaining the anomalously low value. Low mantle estimates from gas source mass spectrometry (Bonifacie *et al*. Science, 2008) are also likely artefacts of small sample size; their observed systematic decrease in δ^{37}Cl value with size is not seen in our work, presumably because we use a more sensitive continuous-flow method. We do see a sharp drop off to δ^{37}Cl values of < -3‰ for peak areas less than 200mV· sec, but larger replicates of the same mantle samples always give δ^{37}Cl values close to 0‰. The similarity of the crustal and mantle reservoirs explains the lack of secular variation in crustal samples, obviates the need for a fractionation mechanism between mantle and crust and defines a homogeneous inner solar system reservoir.

The Cl isotope composition of the Moon and Mars

Z.D. SHARP[1], C.K. SHEARER[2], F.M. MCCUBBIN[2] AND C.B. AGEE[1,2]

[1]Dept. Earth and Planet. Sci., U. New Mexico, Albuquerque, NM, USA 87131

[2]Institute of Meteoritics, U. New Mexico, Albuquerque, NM, 87131, USA

The bulk Earth and the least altered carbonaceous chondrites have Cl isotope compositions (δ^{37}Cl values) close to 0‰ (Sharp *et al*. Nature, 2007; Mercer et al, LPSC, 2011). In contrast, Cl isotope variations on Mars, and especially the Moon, are extreme – Apollo samples range from near 0‰ (the Earth value) up to 24‰ (Sharp *et al*. Science, 2010 and unpublished). We interpret the high δ^{37}Cl values as a result of degassing of metal chlorides. On Earth, Cl volatilizes from basaltic melts as HCl (g) with no apparent Cl isotope fractionation. In the absence of H_2O, Cl volatilizes as metal chlorides, which leads to the preferential loss of ^{35}Cl, and an ever-increasing δ^{37}Cl value of the residual Cl in the melt. The δ^{37}Cl value is a function of both the H/Cl ratio and total Cl content. The lowest and Earth-like δ^{37}Cl value is found as surface coatings of lunar glass beads which have the highest H- and lowest Cl-contents (Saal *et al*. Nature, 2007) of all measured samples. The highest δ^{37}Cl values are found in KREEP basalts (McCubbin *et al*. GCA in press), which formed in melts with high Cl contents. These results are consistent with a chemical divide between H and Cl. Cl is lost by HCl volatilization until either Cl or H is consumed, leaving the other element in excess. The low δ^{37}Cl samples (74002, 36) fall on the high H/Cl side of the chemical divide, the high δ^{37}Cl value samples lie on the low H/Cl side. If initial Cl contents are low, Cl vaporization will be minimal because Cl saturation of the melt may be only slightly overstepped. We conclude that the Moon was generally anhydrous (10s of ppb H), but anomalous eruptive samples (lunar glass beads) with high H- and low Cl-contents existed and are manifest as low δ^{37}Cl samples.

In contrast to the Moon, Martian meteorites range from -3‰ to +2‰ (*n*= 8). All shergottites have negative δ^{37}Cl value and all cumulates have positive δ^{37}Cl values. Only near-surface effects are known to fractionate Cl isotopes. The different Cl isotope compositions of Martian samples are explained by near-surface contamination or volatile loss.

Organic matter photochemistry: Singlet oxygen precursor lifetimes

CHARLES M. SHARPLESS

Department of Chemistry, University of Mary Washington, Fredericksburg, VA 22401 (csharple@umw.edu)

Background

Dissolved organic matter (DOM) photochemistry plays a key role in pollutant fate and carbon cycling [1, 2]. Central to this are various reactive intermediates whose production and reactions can alter the DOM. These include $^1O_2$, O_2^- and H_2O_2, e (aq)$^-$, •OH, and triplet DOM states (^{3}DOM*) [3]. Various evidence suggests that ^{3}DOM* is the $^1O_2$ precursor.

$$^1\text{DOM} + h\nu \rightarrow {}^1\text{DOM}^* \rightarrow {}^3\text{DOM}^* \quad (1)$$

$$^3\text{DOM}^* + {}^3O_2 \rightarrow {}^1\text{DOM} + {}^1O_2 \quad (2)$$

Intersystem crossing from the excited singlet forms ^{3}DOM* which then transfers energy to O_2. Despite many studies on $^1O_2$ production, the photophysical properties of ^{3}DOM* are not well known. This work uses the O_2 dependence of $^1O_2$ quantum yields (Φ_{1O2}) to estimate the yields and lifetimes of ^{3}DOM* as a function of wavelength. Experiments employed a Xe lamp, bandpass filters, and fufuryl alcohol as a $^1O_2$ probe. Buffered D_2O was used as a solvent to increase the $^1O_2$ lifetime, allowing for extensive experimentation.

Results and Discussion

Figure 1 displays data for Suwannee River OM at 370 nm. The asymptote above 0.5 mM O_2 shows that all ^{3}DOM* precursors to $^1O_2$ are being trapped and that their quantum yield is 0.025. The ratio of the intercept to slope of the inverse linear plot equals the lifetime of ^{3}DOM* multiplied by the total rate constant for its quenching by and energy transfer to O_2. Assuming a total value of 10^{10} M^{-1} s^{-1} for these processes yields a ^{3}DOM* lifetime of 6.5 µs, which is also found at 313 and 415 nm. Other samples have similar lifetimes that are also invariant with wavelength. However, the quantum yields vary by more than two-fold. This suggests that Φ_{1O2} is controlled by absolute yields of ^{3}DOM* rather than its decay kinetics.

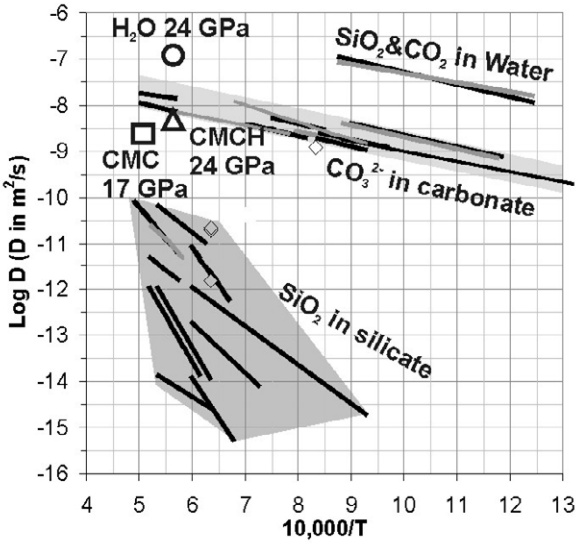
Dissolution-precipitation as a possible mechanism of C-O-H fluid/melt segregation in the deep mantle

A. SHATSKIY[1,2], K.D. LITASOV[1,2] AND E. OHTANI[1]

[1]Tohoku University, Sendai, Japan (shatskiy@m.tains.tohoku.ac.jp, klitasov@m.tains.tohoku.ac.jp, ohtani@m.tohoku.ac.jp)
[2]IGM SB RAS, Novosibirsk, Russia

Trace amounts of fluid dispersed in the mantle cannot be easily removed from the crystalline framework if that insoluble in the fluid. However, at the mantle conditions water and carbonates are excellent silicate solvents. Hence, the migration of a fluid droplet through a solid may proceed by a combination of dissolution and deposition of the solid at the forward and rear faces of the fluid/melt droplet respectively, and solute flow across the droplet. The driving force for this process is a concentration gradient of solid silicate in the fluid. This can be caused by temperature gradient, differences in stable and metastable phase solubilities, and stress.

In this study we measured MgO-SiO_2 diffusion in the $K_2Mg(CO_3)_2$ (KMC), $K_2Mg(CO_3)_2 2H_2O$ (KMCH), and H_2O at 17 and 24 GPa. The summary of obtained data is shown in the figure below along with available literature data on diffusion in the silicate and carbonate melts and water fluid.



Based on obtained results we estimate stress drived fluid migration rate. For example, at low mantle conditions (2000 K and 25 GPa) migration rate of 10-µm inclusion of hydrous fluid estimated to be 1-2 km/y at 10 MPa stress level.

Deep crust of the Siberian craton evidence from xenolith

V.S. SHATSKY[1]*, V.G. MALKOVETS[1], L. BUZLUKOVA[1], W.L. GRIFFIN[2], E.A. BELOUSOVA[2] AND S.Y. O'REILLY[2]

[1]V.S. Sobolev Institute of Geology and Mineralogy, Siberian Branch Russian Academy of Sciences, Novosibirsk, 630090, Russia (*correspondence: shatsky@igm.nsc.ru)
[2]GEMOC National Key Centre, Macquarie University, Sydney, 2109, Australia (wgriffin@els.mq.edu.au)

Deep-seated xenoliths hosted in kimberlite pipes (Udachnaya, Leningradskaya, Yubileynaya, Komsomolskaya, Botuobinskaya, Zapolyarnaya) from the Siberian craton include mafic and felsic garnet granulite, two-pyroxene granulites, gneisses, and amphibolite. Calculated equilibration temperatures range from 600 to 850 °C at pressures from 8 to 1.4 GPa. Garnet granulites give the highest temperatures (710-850 °C) and pressures (9-14 GPa) and amphibolites the lowest; felsic granulites fall between these two groups. The mafic xenoliths are picrobasaltic to basaltic in bulk chemical composition. The chondrite-normalised REE patterns for the mafic granulite xenoliths vary from flat to LREE-enriched (La_N/Yb_N=8.6-18.8); some have slight positive Eu-anomalies. Garnet granulite xenoliths with low REE contents and positive Eu-anomalies are interpreted as cumulates. The bulk compositions of felsic granulites and gneisses vary from andesite to rhyodacite. Zircon LAM-ICPMS dating shows several episodes in the formation of the deep crust of Siberian craton. Zircons from mafic granulites are metamorphic and have concordant ages from 1.78 to 1.97 Ga. Most zircon grains from felsic granulites show oscillatory zoning in BSE images; some show core-rim structure, in which the cores have oscillatory zoning. The age of 2.95 Ga obtained from zircon in felsic xenoliths of the Botuobonskay pipe is the oldest age recorded in the xenolith suite. Magmatic zircons from the Zapollyarnay pipe yielded NeoArchean ages of 2.71 Ga.

Primary biological organics in ambient PM in the Southeastern U.S.

S. SHAW[1], G. CASUCCIO[2], E. EDGERTON[3], T. LERSCH[4], A. ROHR[5] AND P. THORNE[6]

[1]Electric Power Research Institute, 3420 Hillview Avenue, Palo Alto, CA, 94306, USA (*correspondence: sshaw@epri.com)

[3]Atmospheric Research & Analysis, Inc., 410 Midenhall Way, Cary, NC, 15146, USA (eedgerton@atmospheric-research.com)
[4]R. J. Lee Group, 350 Hochberg Rd., Monroeville, PA, 15146, USA (tlersch@rjlg.com)
[5]Electric Power Research Institute, 3420 Hillview Avenue, Palo Alto, CA, 94306, USA (arohr@epri.com)
[6]University of Iowa, University Research Park, 126 IREH, Iowa City, IA 52242-5000, USA (peter-thorne@uiowa.edu)

Primary biological organic particles (or bioaerosols) are released by, or composed of, biological organisms. These can include fungal spores, microbes, pollen, or other materials. Little is known about the contributions of such biological materials to ambient particulate matter (PM), though indications are that in highly vegetated regions a substantial amount of organic PM mass could be due to such sources. Large areas of natural wilderness exist in the Southeastern U.S., and even the urban areas in the region are known to be heavily impacted by biological emissions.

Therefore a field campaign was launched at one urban (Atlanta, GA) and one rural site (Yorkville, GA) in fall 2009 and spring 2010 to quantify the amount of bioaerosols in both PM2.5 and PM10-2.5. Particle mass, elemental carbon (EC), organic carbon (OC), bioaerosol fragments, and several biochemical markers (endotoxin, protein, and β-D-glucans) were measured through established and modified sampling methods. The methods and method testing will be described, and preliminary results on the contributions of bioaerosol to particle organic carbon will be provided. For example, scanning electron microscopy demonstrated that bioaerosols accounted for 60-70% of the organic carbon mass in PM10-2.5.

This analysis will help to determine the amount and sources of organic PM mass (in particular the importance of primary biological particles to PM), and to investigate potential impacts of naturally emitted PM on human health.

Proxy validation from the culturing perspective: A top down approach

T.J. SHAW[1]*, M. MYRICK[1], T. RICHARDSON[2] AND L. HILL[1]

[1]Department of Chemistry and Biochemistry, University of South Carolina, Columbia SC 29208 (*correspondence: shaw@chem.sc.edu, myrick@chem.sc.edu, hill@chem.sc.edu)

[2]Department of Biological Sciences, and Marine Science Program, University of South Carolina, Columbia SC 29208 (richardson@biol.sc.edu)

Laboratory culture experiments offer promise for proxy validation under controlled environmental conditions. Long term culture experiments for benthic foraminifera have proved useful for validation of proxy metal uptake as distribution coefficients [1]. Culture experiments have also helped discern ontogenic variation and feeding effects from environmental variations [2]. However the time and culture reservoir size required for such experiments are daunting [3].

Cultures of planktonic species offer a much more practical approach to proxy identification and validation. Small cultures can be maintained under nearly constant environmental conditions. A new instrumental method allows for the analysis of plankton cultures on a cell by cell basis [4]. Measurable differences in cell physiology occur as a function of macro and micro nutrient concentrations. Results from *E. huxleyi* indicate evidence for variations in the Mg incorporation into pigment porphyrins. This technology is being developed to for field-based instruments and holds promise for tracking signals through the water column as material alters prior to burial.

Genesis of platinum mineralization in gabbro-dolerites of Pay-Khoy (Russia, Nenets autonomous district)

R.I. SHAYBEKOV

Institute of Geology Komi SC UB RAS, Syktyvkar, Russia, 54 Pervomayskaya st (*correspondence: shaybekov@geo.komisc.ru)

Platinum mineralization of dolerites of Pay-Khoy anticlinorium is superimposed on magmatic sulfide mineralization; therefore the formation record of PGE-mineralization has been reviewed by us within the framework of the genesis of sulfide mineralization at late magmatic and hydrothermal stages.

Based on the formation conditions, the PGE enrichment in Pay-Khoy gabbro-dolerites can be distinguished at: 1) isomorphic inclusions in magmatogene sulfides; 2) forming intrinsic minerals from residual fluid melt after crystallization of main sulfide minerals; 3) resedimented in the form of late chalcogenides during postmagmatic transformations. Our observations show that the highest thermal PGE form in the Pay-Khoy gabbro-dolerites represents microinclusions of platinum in sulfides. At decreasing temperature the intrinsic PGE minerals formed, predominantly palladium ones, and gradually the number of corresponding mineral phases increased.

Thus, the platinoids in Pay-Khoy gabbro-dolerites are nonuniformly distributed between three mineral associations: 1) early (magmatic) chalcopyrite-pentlandite-pyrrothine; 2) intermediate (magmatic) sulfide-telluride-sulfoarsenide; 3) late (hydrothermal) arsenide-telluride.

The work was made with the support of the program of the presidium RAS №09-П-5-1006 and SC-7198.2010.5.

Rates of oxidation in CSPV experiments involving H_2O-bearing mafic magmas

THOMAS SHEA* AND JULIA E. HAMMER

SOEST, Univ. Hawaii, 1680 East-west rd., Honolulu, HI, 96822, USA (*correspondence: tshea@hawaii.edu)

A difficulty in performing experiments on near-liquidus hydrous mafic melts in gas-medium cold-seal pressure vessels (CSPV) is the tendency for H_2O in the fluid phase to dissociate and H_2 to diffuse through capsule material, leading to progressive oxidation of sample material. Consequences include premature stabilization of Fe-Ti oxide phases and commensurate deviation of the liquid line of descent toward silica enrichment. Methodologies commonly employed to mitigate the oxidation problem, not without their own drawbacks, include incorporating CH_4 into the pressurizing gas, limiting run duration to 24 hours, enclosing samples in Au-alloy capsules, and incorporating solid buffering assemblages to serve as indicators of fO_2 excursion. Using the Co-Pd-O system as an fO_2 sensor [2], we examined the rate of oxidation of basaltic andesite at 1010 ºC and P_{H2O}=150 MPa pressurized with a mixture of Ar and CH_4. Our time-series reveals that oxidation occurs at very high rates of 3-4 log units within 48h. Both the variability of fO_2 and magnitude of dehydration-oxidation are considered unacceptable for phase equilibrium work. Incorporation of additional CH_4 serves only to offset the progressive oxidation trend toward a lower absolute range in fO_2. However, incorporation of a substantial mass of Ni metal powder as an O_2 getter to the outer capsule successfully (a) prevents oxidation within 48h, and (b) stabilizes fO_2 at the NNO buffer.

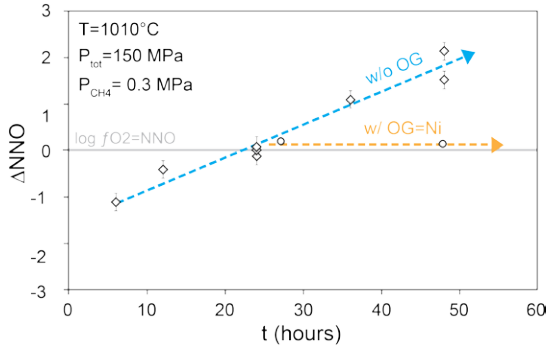

Figure 1: Rates of fO_2 variation in basaltic-andesite

The chemistry of some minerals from the Shir-Kuh granitoidic batholith, South-West of Yazd, Central Iran

M. SHEIBI[1]* AND A. NÉDÉLEC[2]

[1]Faculty of earth Science, Shahrood University of Technology, Shahrood, Iran (*correspondence: Sheibi58@gmail.com)
[2]University of Toulouse, LMTG/OMP, 14 Ave E. Belin, 31400 Toulouse, France (nedelec@lmtg.obs-mip.fr)

The S-type granitoidic batholith of Shir-Kuh (135 Ma) which is part of central Iran is located in SE of Yazd and consists of three main granodioritic, monzogranitic and leucogranitic units. The systematic changes in the composition of plagioclase reveal that the granodiorite is a calcic core plagioclase-rich, the monzogranite a differentiated melt, and the leucogranite a late residual melt. Totally, all biotites have high Al^{VI} (3.2 to 6.2 apfu) which is characteristic of peraluminous granites. The high almandine component of garnet is similar to those in other peraluminous plutons and, in particular, to the magmatic garnets. Muscovite appears as both primary and secondary-looking grains. Monazite occurs as two types of chemically crystals: monazite and brabantite [CaTh $(PO_4)_2$]. The observed homogeneous grains of Th and U poor monazite and tiny microcrystals of brabantite inside the apatite indicate dissolving apatite during anatexis. Little hematite (less than 10%) composition which included within restite biotite consists with the idea that the Shir-Kuh granite is generated from the sedimentary source materials contained graphite. Considering the mineral assemblages presented in the batholith, the fact that some biotite may represent restite and the mean temperature of 820°C in agreement with the zircon saturation thermometry, such liquids may have formed at a temperature 750 to 850°C by dehydration melting of biotite.

Paleosol constraints on atmospheric CO_2 levels in the Archaean and Proterozoic

N.D. SHELDON

Dept. of Geological Sciences, University of Michigan, 1100 N. University Avenue, Ann Arbor, MI 48109, USA

Precambrian atmospheric pCO_2 levels were previously estimated using simple thermodynamic models based upon the mineral assemblages in paleosols and BIFs [1–3]. However, thermodynamic approaches often require unreasonable or poorly constrained assumptions, and their results are highly dependent on the quality of the thermodynamic data available. In particular, re-evaluation of the paleosol thermodynamic model using more recent thermodynamic data [4] demonstrates that that approach [1] is unreliable and does not provide a significant contraint for atmospheric pCO_2 reconstruction.

As an alternative, a new model based upon paleosol mass-balance during weathering has been proposed [4]. The paleosol mass-balance model gives replicable results from multiple and widely distributed contemporaneous paleosols from the Paleoproterozoic (~2.2 Ga ago [4]) and Mesoproterozoic [4–5], and gives results that are consistent with independent proxies based on microfossils [6–7]. The pCO_2 curve generated by this method spans from 2.7–0.96 Ga ago [4, 5, 8] and indicates that: 1) late Archean and early Paleoproterozoic pCO_2 levels were similar, suggesting no significant change in response to the Great Oxidation Event; 2) from at least 2.7–1.8 Ga ago, pCO_2 levels were broadly consistent at 20–40 times pre-industrial levels; 3) between 1.8 and 1.1 Ga ago, there was a significant drop in pCO_2 to less than 10 times pre-industrial levels, coincident with a change in calcification and stromatolite abundance in the oceans. Climate model results using the paleosol-derived pCO_2 values indicate consistently equable conditions from 2.7–0.96 Ga ago and are also permissive of a Paleoproterozoic 'snowball' Earth event, which suggests that the paleosol mass-balance model provides a quantitatively valuable constraint on Archaean and Proterozoic pCO_2 levels.

Effect of helium on structure of SiO_2 glass probed by Raman spectroscopy

G. SHEN[1] AND P. LAZOR[2]*

[1]High Pressure Collaborative Access Team, Geophysical Laboratory, Carnegie Institution of Washington, Argonne, IL 60439, USA (gshen@ciw.edu)

[2]Department of Earth Sciences, Uppsala University, 75236 Uppsala, Sweden (*correspondence: peter.lazor@geo.uu.se)

SiO_2 glass represents a prototypical network-forming glass whose structure can be understood in terms of a continuous network of corner shared SiO_4 tetrahedra, with a high degree of intermediate range order. Numerous studies on structure and compressibility have been performed on SiO_2 glass under high pressure due to its importance as a model geological component, and an increased interest on polyamorphism of glasses and liquids.

In this work, SiO_2 glass was subjected to helium in diamond anvil cell at pressures up to 20 GPa. Micro-Raman measurements were performed in the back-scattering geometry utilizing argon-ion laser excitation. Single-stage, high throughput spectrometer equipped with an EM-CCD detector were used for data collection. Comparison of the evolution of Raman bands of SiO_2 glass upon compression with and without [1, 2] helium loading strongly supports incorporation of helium in the voids of SiO_2 glass structure. This is signified by a less profound narrowing of the inter-tetrahedral angle distribution, as revealed by the spectral widths of band corresponding to the symmetric bending motion of Si-O-Si linkage. Similar effect is seen in the Raman spectra of a recovered sample at ambient pressure. The shape of the corresponding Raman band is largely restored, although signs of local angular distortions remain.

The Raman results on the incorporation of helium are corroborated by a parallel x-ray diffraction study on the structure factor and compressibility [3]. Comparing these observations to the findings of other studies suggest that the effect of helium on the structure and compression of SiO_2 glass is unique. The strong effect of dissolved helium may have implications in Earth's evolution models and is also important in interpreting the high-pressure experiments in general because helium is widely used as a pressure medium.

Partial melting and element transfer during continental subduction-zone metamorphism: Geochemical insights from leucosome within UHP eclogite in the Dabie orogen

YING-MING SHENG* AND YONG-FEI ZHENG

School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (*correspondence: ymsaint@ustc.edu.cn)

Mineralgraphic observations, elemental and isotopic analyses of major and accessory minerals as well as simultaneous *in situ* LA-ICPMS analyses of zircon trace elements and U-Pb isotopes were carried out on a polymineralic leucosome (rutile + garnet + phengite + epidote + kyanite + quartz) and its host UHP eclogite from the Dabie orogen. The results are integrated to decipher the partial melting of UHP eclogite and its associated mass transfer during continental subduction-zone metamorphism. Multiphase inclusions mainly containing quartz + K-feldspar + K-rich melt ± plagioclase ± other silicate/carbonate minerals were found in garnet and epidote from both the leucosome and eclogite, indicating that the leucosome-forming fluid is a hydrous melt that is rich in K, Al and Si. Oxygen isotope analyses yield temperatures of 570-700ºC for quartz–garnet and quartz-kyanite pairs. The same minerals from the two rocks give nearly consitent $\delta^{18}O$ and δD values, suggesting that the hydrous melt was directly derived from *in situ* partial melting of the host eclogite. In comparison with the host eclogite, the leucosome is remarkably rich in phengite and epidote, indicating that the hydrous melt is associated with distinct LILE and LREE transport. Garnet and rutile in the leucosome show distinct higher contents of HREE (2.2-5.7 times) and Nb-Ta (1.8-2.0 times) than the host eclogite, indicating that these normally fluid-immobile elements are also active during partial melting of UHP eclogite. The LA-ICPMS analyses show that most zircons from the leucosome are metamorphic in origin, while the all zircons in the eclogite are residue of magmatic origin. This suggests that Zr as an incompatible element is preferrentially partitioned into the partial melt. Zircon U-Pb dating gives protolith ages of 774±45 Ma for the eclogite, and metamorphic ages of 217±2 Ma and 210±2 Ma for the leucosome. Thus, the leucosome is interprated to have formed via the partial melting of UHP eclogite during exhumation of the deeply subducted continental crust. In this regard, fluid flow and element transfer in the continental subduction zone occurred in the stage of exhumation rather than subduction.

The effects of silver nanoparticles on wastewater biofilms

Z. SHENG AND Y. LIU*

Department of Civil and Environmental Engineering, University of Alberta, Edmonton, AB, T6G 2W2, Canada (*correspondence: yang.liu@ualberta.ca)

The goal of research

The objective of this research is to understand the potential effects of silver nanoparticles (Ag-NPs) on biological wastewater treatment processes.

Methods adopted

Molecular biology techniques (polymerase chain reaction — denaturing gradient gel electrophoresis, PCR-DGGE) were used to analyze the effects of Ag-NPs on wastewater biofilms, which reveals the response of various genera in the complex biofilm microbial community. Electron microscopy was also used to examnie the uptake of Ag-NPs into the biofilms.

Results and discussion

It was found that intact wastewater biofilms were highly tolerant to Ag-NPs. With an application of 200 mg Ag/L Ag-NPs for 24 h, no significant reduction of bacteria in the biofilms was detected. PCR-DGGE studies showed that microbial susceptibility to Ag-NPs is different for each genus. For instance, sulfur oxidizing bacteria *Thiothrix* sp. are more sensitive to Ag-NPs than other bacteria in the biofilms. Ag-NPs are quickly sorbed to the biofilms during incubation and trapped in extracellular polymeric substances (EPS) in the biofilms. This can be an important reason for the high tolenrance of wastewater biofilms to Ag-NPs. After the removal of loosely bound EPS, the viability of wastewater biofilms was reduced when treated under the same conditions (200 mg Ag/L Ag-NPs, 24 h).

Metal complexation in hydrothermal fluids: Insights from *ab initio* molecular dynamics

DAVID M. SHERMAN[1]* AND YUAN MEI[1,2]

[1]School of Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK (*correspondence: dave.sherman@bris.ac.uk)
[2]School of Earth and Environmental Sciences, University of Adelaide, Adelaide SA 5000, Australia

Complexation of metals by Cl^- and HS^- ligands in hydrothermal fluids is a fundamental process in the evolution of the Earth's crust and the formation of ore deposits. Current thermodynamic models of complexation equilibria under hydrothermal conditions depend on extrapolations of experimental data using equations of state based on the Born model of solvation. Thermodynamic parameters for aqueous species are often provisional estimates based on systematic correlations between fundamental properties such as entropy, volume, ionic radius etc. Computational molecular simulations, however, can be used to test current thermodynamic models, predict metal speciation, and even estimate thermodynamic properties. For a condensed fluid, molecular dynamics simulations can be used to sample the configurational degrees of freedom in order to predict properties as a function of pressure and temperature. Simulations of dilute solutions, however, require very large systems (1000's of atoms) and very long (> 1 ns) simulation times; such calculations are only practical by treating the atomic interactions using classical two- or three-body interatomic potentials. However, classical potentials seem to be unreliable for describing metal-ligand interactions, especially for transition metals and metalloids such as Sn^{+2}, Au^{+3}, Cu^{+2} and Cu^+. 'Ab initio molecular dynamics' treats the molecular motions classically but the atomic interactions quantum mechanically. Although these simulations are only practical for systems with 100's of atoms over short times (< 100 ps), they are giving fundamental new insights on metal speciation in hydrothermal fluids. Here, we describe simulations of Cu, Zn, Sn, Au, and Ni in NaCl- and HS-bearing aqueous fluids up to 350 °C. We show that predicted structures and speciation are in close agreement with experiment. Based on our simulations, we propose that the major driving force for metal complexation in hydrothermal fluids is the change in translational entropy between reactants and products. Entropies and free energies of complex formation can be estimated using thermodynamic integration and metadynamics. Applications of these techniques to Zn-Cl and Cu-Cl-HS stability constants will be presented.

Collection and determination of suspended particulate trace metals: The US GEOTRACES Intercalibration cruises

R.M. SHERRELL[1]*, H. PLANQUETTE[2], M. PAUL FIELD[1], J.K.B. BISHOP[3], T. WOOD[3], P. LAM[4], B. TWINING[5] AND P. MORTON[6]

[6]Department of Oceanography, Florida State Univ., Tallahassee, FL 32306-4320 USA (pmorton@fsu.edu)

As part of the GEOTRACES Intercalibration and Methods Development effort, we have been working to optimize techniques for the accurate and precise determination of suspended particulate trace metals (TMs) from full water column profiles in various oceanic regimes. The goal has been to determine the best particle collection and analysis methods for future GEOTRACES ocean basin sections and to carry out laboratory intercalibration to arrive at community consensus on analytical methods and results. We will present results from the Atlantic and Pacific Intercalibration cruises (IC1 and IC2; 2008-09), with a focus on the feasibility of accurate and precise determination key Geotraces TMs as well as other TMs on small volume (~10L) samples collected from rosette-mounted Go-Flo bottles. We will summarize our findings with respect to filter type, practical performance, blanks and potential artifacts such as dissolved metal adsorption. Details of the filtration methodology will be described, with an important emphasis on minimizing element-dependent particle settling artifacts and determining appropriate procedural blanks. Digestion methods for particulate samples will be evaluated and results from an interlaboratory intercalibration exercise will be presented, with a summary of ICP-MS analytical approaches. Results for samples collected using 5-10L Go-Flo bottle samples will be compared with parallel samples collected with large-volume *in situ* pumps.

Manganese precipitation and the removal of zinc from No Cash Creek, Keno Hills, Yukon, Canada

B.L. SHERRIFF[1], B. JOHNSON[2] AND S. DAVIDSON[3]

[1]Department of Geological Sciences, University of Manitoba, Winnipeg, MB, Canada, R3T 2N2 (*correspondence: BL_Sherriff@umanitoba.ca)

[2]InTerraLogic Inc.4715 Innovation Dr, Suite 110, Fort Collins, CO 80525, U.S.A

[3]Access Consulting Group, #3 Calcite Business Centre151 Industrial Road, Whitehorse, Yukon Y1A 2V3Canada

No Cash Creek is a natural stream that receives water from the 500-level adit of the historic No Cash Mine (1948 to 1988). The adit discharge water and stream sediments contain elevated concentrations of Mn, Fe and Zn which decrease rapidly downstream in cascading (aerated) and additionally in a quiescent peat bog environment.

Optical microscopy showed that there were coatings around lithic grains and plant fragments in stream sediments within 600 m of the adit. EMP BSE images and element mapping of the lithic coatings show concentric bands rich in Mn and Zn (Fig. 1).

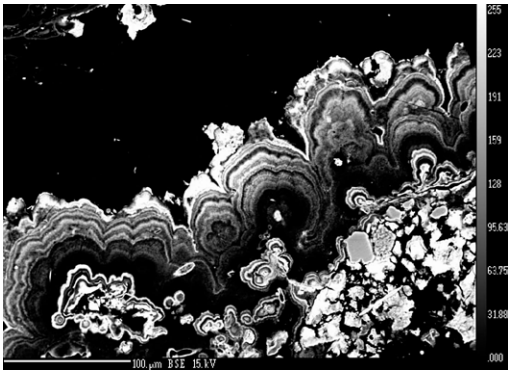

Figure 1: Mn-rich coating on a lithic grain

Initial data show that the average concentration of Mn and Zn varies within one sample with type of mineral substrate from 23 wt. % Mn and 6 wt. % Zn around pyrite to 9 wt. % Mn and 4 wt. % Zn around sphalerite. Mafic lithic fragments also have higher Mn and Zn than silicic grains. There is also considerable variation across one coating (Fig.1) from 30 to 12 wt. % Mn and 8 to 4 wt. % Zn although the Mn:Zn ratio remained constant at 3.1 (st. dev. 0.5).

Coatings around wood contain predominantly Fe with <30 wt. % Fe and <3 wt. % Zn. There is no apparent relationship between the concentration of Fe and Zn.

In conclusion, the major process removing Zn from the water of No Cash Creek is coprecipitation with or absorption on Mn-rich coatings around lithic grains.

Hotspot: The Snake River geothermal drilling project

JOHN W. SHERVAIS

Dept Geology Utah State University, Logan Utah 84322-4505 (john.shervais@usu.edu)

The Snake River Plain (Idaho, USA) represents the track of deep-seated mantle hotspot that has thinned the lithosphere and fueled the intrusion of up to 10 km of hot basaltic magma into the lower and middle crust. The heat from these intrusions, and from rhyolites formed by the basalt, drives the high heat flow and high geothermal gradients observed in deep drill holes from throughout the Snake River Plain [1-3]. Heat flow in the SRP tends to be high along the margins of the plain (80-100 mW/m^2-s) and low in shallow drill holes along the axis of the plain (20-30 mW/m^2-s). However, deep drill holes (>1 km) along the axias of the plain are characterized by high heat flows and high geothermal gradients below about 500 m depth [2]. This discrepancy is caused by the Snake River aquifer – a massive aquifer system that extends under the plain. Thermal gradients through the aquifer are static until the base of the aquifer is reached, then rise quickly at deeper levels in the crust. Below the aquifer along the axis of the plain, heat flow values are comparable to heat flow values along the margins of the plain or higher (75-110 mW/m^2-s [2]). Bottom hole temperatures for wells along the margins of the plain near Twin Falls are typically around 30-60°C at 400-600 m depth [4] and as high as 120°C at 2800 m depth in the axial region of the plain [2].

The Snake River Geothermal Drilling Project is jointly funded by the US Department of Energy (DOE) and by International Continental Drilling Program (ICDP). Our goal is to evaluate geothermal potential in three settings: (1) the high sub-aquifer geothermal gradient associated with the intrusion of mafic magmas and the release of crustal fluids from the associated wall rocks, (2) the valley-margin settings where surface heat flow may be driven by the up-flow of hot fluids along buried caldera ring-fault complexes, and (3) in the western SRP graben. Drilling is currently in progress.

Geological characteristics of the Hukeng tungsten deposit, Jiangxi Province, South China

GUODONG SHI, MAOYAN MA, JUN LIU, HAIJIAO YOU, YOUFEI GUAN AND YONG ZHAN

The Civil Engineering School, Anhui University of Architecture, P.R. China (gdshi@aiai.edu.cn)

Hukeng tungsten deposit, located in Wugongshan metallogenic belt in central part of Jiangxi Province, South China, is one large scale quartz vein type wolframite deposit, which is in the south margin of Hukeng granite intrusion, covering the area of 6 km^2.

The strata exposed in the Hukeng ore district belong to the Sinian Laohutang formation and Likeng formation, and are composed of slightly metamorphic sericite phyllite, phyllitic siltstone and phyllitic sandstone. Two groups of faults are well developed in the Hukeng ore district, NE and NW faults separately, which are all composed of silicated breccia and mylonite and control the formation of the Hukeng tungsten deposit. There developed the Hukeng muscovite granite stock ($\gamma^{52\ (2)c}$) with age of 151.6±2.6 [1], where developed the wolframite-bearing quartz veins. The muscovite granites are with high content of garnet, developing silicification and greisenization generally and associated with W, Zn Bi and S mineralization. Wall rock alteration in the Hukeng deposit includes silicification, potassic feldsparization, fluoritization and hornfelsic alteration.

In this deposit, more than 310 ore veins with WO_3 grades from 0.1% to 2.5% have been recognized. These ore veins distribute in Xinsheng'ao sector, Hukeng sector and Xijialong sector. Ore types are mainly wolframite quartz ores, wolframite-fluorite quartz ores and wolframite-sulfide quartz ores. Ore minerals in this deposit are mainly wolframite and pyrite, secondly sphalerite and chalcopyrite, with minor amounts of molybdenite, chalcocite, cubanite, bismuthinite and native bismuth. The ore textures mainly include idiomorphic texture, hypautomorphic texture and poikilitic texture, and the ore structures include massive structure, banding structure and compound structure of massive and banding. Based on cross-cutting relationships of the ore veins, mineral assemblages, paragenetic sequence and ore fabrics, the ore-forming process can be divided into three mineralization stages: quartz-wolframite stage, quartz-fluorite-wolframite stage and quartz-pyrite-sphalerite-wolframite stage.

This research was financially supported by the Doctoral Fund of Anhui University of Architecture of China (No.K02415).

Experimental test of the CO self-shielding model for the early Solar System's oxygen isotope evolution

X.-Y. SHI[1], Q.-Z. YIN[2], Z. LUO[1], H. HUANG[1] AND C.-Y. NG[1]

[1]Dept. Chemistry, Univ. California, Davis, CA, USA
[2]Dept. Geology, Univ. California, Davis, CA, USA

We designed a laboratory experiment to test the carbon monoxide self-shielding (COSS) model advanced to explain the oxygen isotope distribution in the early Solar System materials [1-3]. Our unique 'windowless' vacuum ultra-violet (VUV) ultra high resolution laser photodissociation and photoionization mass spectrometry is designed to mimic the solar nebular photochemistry environment and experimentally verify if the CO photodissociation at VUV wavelengths (90-110 nm) would produce the expected mass independent oxygen isotope fractionation as predicted in the recently revived self-shelding model [1-3]. This model has been invoked to explain the peculiar oxygen isotope distribution observed in early solar system materials and has a specific prediction for the Sun's oxygen isotope composition [4], a top science priority of NASA's GENESIS mission.

However, the first experimental test of COSS model by [5] using the Advanced Light Source (ALS) at Lawrence Berkeley National Laboratory (LBNL), poses a serious question on the COSS model, although the validity of [5] were immediately challenged by [6-8]. The significance of COSS model for the early solar system warrants a second opinion with closer experimental scrutiny. If the COSS model stands the test of experimental verification, it has major implications for the origin and transport of water in the Solar System that governs the ultimate habitablility of planets.

Our VUV laser system can generate 4-5 orders of magnutide higher optical resolution, with brightness more than 6 orders of magnitude greater than the broadband synchrontron light source at ALS at LBNL. This will ensure higher signal-to-noise ratios when studying weak transitions or transitions of less abundant isotopologues, such as $^{13}C^{17}O$. Our initial finding supports a 'slope-1' ^{16}O depletion line as the COSS model postulates and observed in the early solar system material and now observed in the Sun [9].

Evolution mechanism of groundwater environmental factors under artificial recharge

SHI XU-FEI[1,2] AND ZHANG WEN-JING[1,2]

[1]College of Environment and Resources, Jilin University, Changchun 130026, China
[2]Institute of Water Resources and Environment, Jilin University, Changchun 130026, China

Research Content

In order to study the effect of artificial recharge on the groundwater quality, the mixed effect of artificial recharge water and groundwater was studied by use of mathematical simulation. The evolution of the groundwater environment and characteristics of elements was studied by analysising the correlation of different amount of recharge water, temperature, redox conditions and pH, which provided basis for environmental control in indoor simulated experiment.

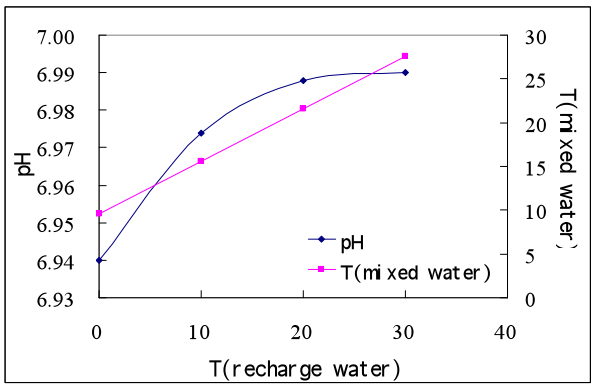

Figure 1: Curve of T of recharge water vs pH and T of mixed water (Recharge water:Groundwater=6:4)

Results

The artificial recharge water will not lead to catastrophe or decrease of water quality in aquifer, and it will improve water quality in aquifer to some extent. The influence sphere of temperature, redox conditions and pH in different artificial recharge conditions was determined.

Discussion on radioactively environmental problems during phosphorite mining and processing in Longmenshan area

SHI ZE-MING, NI SHI-JUN AND ZHANG CHENG-JIANG

Department of Geochemistry, Chengdu University of Technology, China (shizm@cdut.edu.cn, nsj@cdut.edu.cn, zcj@cdut.edu.cn)

Longmenshan area is the main phosphorite producing zone in Sichuan province, with abundant phosphorite resources which are mostly reservoired in strata of upper Sinian, lower Cambrian and upper Devonian. The phosphorites are neritic sedimentary deposits characterized by containing less high-grade ore, more lean ore and harmful impurities unevenly distributed. There are two major phosphorite mines in studied area: Qingping and Jinhekou mines. And the phosphorus chemical enterprises in Sichuan province are mainly located in the Tuojiang basin.

Phosphorites, especially the marine facies phosphorites are widely distributed and strongly accumulated in uranium. Most of phosphorites have high radioactive uranium contents. Owing to phosphorite mining and processing in Longmenshan area, the Chengdu plain, especially in Tuojiang basin, has higher level in radioactive element content. The primary source tracing results show that average content of uranium in phosphorites is 31.0mg/kg, much higher than the background value, and nearly 10 times of uranium content in wall rock. And the average content of uranium in phosphate fertilizer is 20.9 mg/kg, about 7 times of that in wall rock. Phosphorite mining and processing are main causes for the high radioactive elements contents in this region.

The uranium content analysis on the main river water of Tuojiang basin, Mianyuan River and Shitingjiang River, shows that the average uranium content in water is up to 1.90 ng/ml of Mianyuan River, and 0.79 ng/ml of Shiting River. Both of the values are much higher than the average level (0.309 ng/ml) of rivers all over the world.

The uranium content study on the horizontal and vertical profile of soil in the vicinity of phosphogypsum dumps in phosphate fertilizer plant shows that phosphogypsum dumping has great impact on the soil radioactive level with uranium diffusion more than 2km width in horizontal and 50cm depth in vertical.

Pb sources of bivalves from Western Canada, Mexico and Hawaii

A.E. SHIEL, A.C. BYRNE AND D. WEIS

PCIGR, EOS, Univ. of British Columbia, Vancouver, BC V6T 1Z4, Canada (ashiel@eos.ubc.ca)

Bivalves from British Columbia (Canada), Hawaii (US) and Baja California (Mexico) show human-related trace metal input that we track with Pb isotope 'fingerprinting'.

Oysters from both Desolation Sound (BC mainland) and Barkley Sound (west coast of Vancouver Island) have relatively low Pb contents (0.05–0.22 μg g^{-1} dry weight) with Pb isotopic signatures (^{206}Pb/^{207}Pb = 1.1483–1.1744) indicating large contributions from anthropogenic sources. The Pb isotopic ratios can be explained by mixing of modern anthropogenic Pb emissions with natural Pb end-members (e.g. Coast Plutonic Complex [1]). The Pb isotopic signatures of the BC oysters are also consistent with those of BC atmospheric aerosols (recorded by lichens [2]) and road dust collected from highways in the lower BC mainland [3]. More specifically, Desolation Sound oysters have higher Pb contents and lower ^{206}Pb/^{207}Pb values than those from Barkley Sound. The lower ^{206}Pb/^{207}Pb ratio exhibited by the BC mainland oysters is attributed to contributions of anthropogenic Pb emissions from a source that is characteristically unradiogenic (low ^{206}Pb/^{207}Pb), potentially emissions from ore smelting in a nearby facility [4].

The Pb isotopic signature (1.1652 for ^{206}Pb/^{207}Pb) of Hawaiian oysters (Honolulu Harbor) is comparable to that exhibited by BC oysters, despite significantly higher Pb concentration (5.7 μg g^{-1} dry weight). Lead contents (0.07–0.42 μg g^{-1} dry weight) of Mexican bivalves (Baja California) are within the range of those of BC bivalves with Pb signatures (^{206}Pb/^{207}Pb = 1.1788–1.2088) closer to natural values.

The similarity between the Pb isotopic compositions of bivalves from BC, Hawaii and Mexico suggests comparable anthropogenic Pb sources across the NE Pacific, e.g. from unleaded motor gasoline and diesel fuel. Even with the low Pb levels found in some bivalves (e.g. BC oysters), Pb isotopes can be used to identify emissions from industrial processes and consumption of fossil fuels as important Pb sources.

Structure and petrology of the mantle beneath Hawaii constrained by seismic discontinuity imaging and mineral phase relations

S.-H. SHIM[1], Q. CAO[1], R.D. VAN DER HILST[1] AND M.V. DE HOOP[2]

[1]Massachusetts Institute of Technology
[2]Purdue University

Hawaiian volcanoes has been regarded as the archetype of the surface representation of deep mantle plume. Yet, the structure and chemisty of the plume remain uncertain. Our GRT imaging of velocity discontinuities combined with phase relations studied in mineral physics provides new constraints on the structure and petrology of the mantle between 200 and 1000 km depths.

While only small topographic changes were found directly beneath Hawaii, large depth variations of the *410*, *520*, and *660* discontinuities were found up to 2,000 km west of Hawaii. The deepening of the *410* and *520* discontinuities are consistent with high-temperature response of the α-to-β and β-to-γ transformations due to their positive Claepyron slopes. Westward from Hawaii the *660* discontinuity changes from anomalously shallow to anomalously deep, suggesting a lateral transition from the post-spinel to a post-garnet transformation (in pyrolitic mantle) across a high temperature anomaly near the base of the transition zone. The large spatial scale of *660* topography (compared to *410*) is consistent with a regional-scale boundary layer and ponding of hot material at 660-km depth.

Our images also reveal reflectors at 300 and 800 km depths and splitting of the *520* discontinuity. Splitting of the *520* discontinuity can occur if the host rock is significantly enriched with Ca and Si. The *300* discontinuity can be related to a silica transition, requiring Si-enrichment. The *800* discontinuity can be related to either the post-stishovite transformation or post-garnet transformation in an Al, Si-rich rock. Therefore, these structures indicate significant presence of non-pyrolitic components in the top 1000 km of the mantle beneath Hawaii, and the composition that is responsible for these structures is likely basaltic. Our study provides first seismic evidence for the significant existence of recycled components in the mantle beneath Hawaii.

Nature of mantle heterogeneities

S.-H. SHIM, R.D. VAN DER HILST, B. GROCHOLSKI, K. CATALLI, Q. CAO AND X. SHANG

Massachusetts Institute of Technology

Seismic studies have revealed discontinuous changes and lateral variations in velocities at different depths in the mantle. While temperature variation is an important factor, the interpretation of some large-scale mantle structures requires compositional variation. However, the composition of the heterogeneities remains unclear (e.g. primordial or recycled).

Our high-resolution seismic GRT imaging revealed discontinuities at 300, 540, 800 km depths beneath Hawaii [1]. The silica phase transitions can explain the shallower discontinuities. The post-stishovite transition in an Al-rich rock or the post-garnet transition in a Si-rich rock can explain the deeper discontinuity. We also found splitting of the *520* discontinuity (to 520 and 540), which can be related to the exsolution of $CaSiO_3$ perovskite in a Ca-rich rock. These suggest a significant amount of recycled materials (e.g. basalt) in the upper mantle beneath Hawaii.

In the mid-mantle, Fe^{3+} in perovskite [2] and Fe^{2+} in ferropericlase [3] undergo high spin to low spin transitions. Although these transitions are unlikely to cause seismic discontinuities, the spin transition of Fe^{3+} in perovskite may change the bulk sound speed of Al-rich heterogeneities (such as basalt) at 1700-2000 km depth, where lateral variations in bulk sound speed have been documented seismically [4].

The effects of Al in the lowermost mantle would make the perovskite-to-postperovskite boundary seismologically undetectable in pyrolite [5, 6]. Our new experiments reveal that the boundary is seismically detectable in harzburgite and basalt due to element partitioning with ferropericlase and silica, implying that the observation of the D″ discontinuity is related to a significant presence of recycled materials in the lowermost mantle [6].

This series of studies implies that differentiated rocks (e.g. basalt) injected into the mantle by subducting slabs may exist over the entire depth range of the mantle and survive over geologic time scales.

Electrolyte ion adsorption at the hematite/water interface: A cryogenic X-ray photoelectron spectroscopy study

KENICHI SHIMIZU*, ANDREI SHCHUKAREV, PHILIPP KOZIN AND JEAN-FRANÇOIS BOILY

Department of Chemistry, Umeå University, Sweden
(*correspondence: kenichi.shimizu@chem.umu.se)

Cryogenic X-ray photoelectron spectroscopy was used to probe monovalent ions (Na^+, K^+, Rb^+, Cs^+, NH_4^+, F^-, Cl^-, Br^-, I^-) associated to the hematite/water interface. Our findings revealed coexisting cations and anions both below and above the isoelectric point of hematite. Surface loadings tend to follow the trend in the ionic radii of both alkali metal and halide ions. Chloride loadings are largely unaffected by the identity of the associated alkali metal ion. Sodium loadings are, on the other hand, considerably affected along the halide series (Fig. 1). Sorption of ammonium ion occurs by hydrogen bonding to surface hydroxyl groups, a mechanism shifting the pK_a of NH_4^+ from 9.3 in water to 8.4 at the interface.

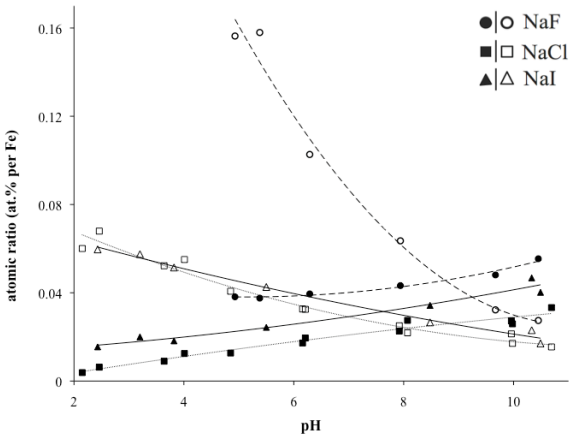

Figure 1: Surface loadings of electrolytes sodium (closed symbols) and halide (open symbols) ions (I=50 mM).

Geochemical study of fresh volcanic glasses from ~145Ma Shatsky Rise

K. SHIMIZU[1]*, J-I. KIMURA[1], Q. CHANG[1] AND T. SANO[2]

[1]IFREE, JAMSTEC, Yokosuka, Kanagawa, 237-0061, Japan (*correspondence: shimmy@jamstec.go.jp)

[2]National Museum of Nature and Science, Tokyo 169-0073, Japan

Shatsky Rise is a Late Jurassic-Early Cretaceous large oceanic plateau located in the northwestern Pacific. It consists of three major massifs: Tamu, Ori and Shirshov Massifs from southwest (older) to northeast (younger), forming along the trace of a triple junction at a mid oceanic ridge. The Rise is 1000km × 200km in size. During the IODP Exp. 324 (Sept.-Nov., 2009) five sites were drilled on Shatsky Rise, two on Tamu Massif (Sites U1347 and U1348; east flank and north flank), two on Ori Massif (Sites U1349 and U1350; summit and east flank) and one on Shirshov Massif (Site U1346; summit). Unaltered fresh volcanic glasses were sampled from all sites except for Site U1349. Glass is preserved as thin rims of lava flow margins or fragments in volcanic breccias. All glasses (115 samples) are sub-alkalic (tholeiitic) basalts, with MgO and SiO_2 contents ranging from 8.5 to 5 wt% and from 48.5 to 52 wt%, respectively. Three types of magmas (normal-Ti, low-Ti and high-Nb) are identified in this study. Assuming that source of these magmas was depleted MORB source mantle [1], the trace element patterns of the normal-Ti magmas suggest that they formed at deeper depths within the garnet stability field (~3GPa), whereas the low-Ti and high-Nb magmas may have formed at shallower depths, where spinel was stable (~1 GPa). Glasses with high Nb/U from Site U1348 and high-Nb type from Site U1350 indicate that the magmas of Shatsky Rise require more than one mantle source. Deep mantle melting and multiple sources for these magmas are different from N-MORB and are important factors to constrain for genesis of Shatsky Rise.

Large regional variations in F/Cl ratios for the MORB source mantle

N. SHIMIZU

Woods Hole Oceanographic Institution (nshimizu@whoi.edu)

Fluorine (F) and Chlorine (Cl) are highly incompatible in mantle-basalt systems (Dalou *et al*. 2011) and their abundances in basaltic melts are generally unaffected by solubility limits (e.g. Carroll and Webster, 1994). These features could make their abundance ratio (F/Cl) in mid-ocean ridge basalts (MORBs) a good additional tracer for elucidating how heterogeneity of the MORB source mantle has evolved. Using analytical procedures developed with a Cameca IMS 1280 at Woods Hole Oceanographic Institution, F and Cl concentrations in glasses of basaltic compositions are determined routinely with precisions of ±10% (2σ) for F and ±5% (2σ) for Cl. Based only on melt inclusion data obtained here and in literature (~220) from EPR (Siqueiros FZ, Saal *et al*. 2002; JdF Axial, Helo *et al*. 2011), MAR (17°N, FAMOUS, 23-27°N, 33°S), and Gakkel Ridge (Shaw *et al*. 2010), it is found that F/Cl ratios display non-overlapping clusters for regions, and subgroups of a region: F/Cl = 10±1 for MAR (17°N, 23-27°N, a subgroup of FAMOUS), consistent with the north Atlantic average value of Schilling *et al*. (1980). F/Cl = 5±1 for Gakkel and a subgroup of JdF, and samples from 33°S MAR and a subgroup of JdF and FAMOUA possess F/Cl=2.5±0.5. In contrast, the Siqueiros dataset display distinctly high and variable F/Cl (14 – 80). It is evident that the observed variations are not produced directly by seawater-related mechanisms, and that no single F and Cl composition can be assigned to the MORB source mantle, suggesting local as well as regional heterogeneity due to incorporation of lithologies with diverse F/Cl fractionation prehistories. It is also noticeable that the range of F/Cl in MORBs is significantly different from that for arc magmas (< 0.5, e.g. Le Voyer *et al*. 2010).

Effect of thickness of oceanic lithosphere on chemical composition of OIBs: Implication for origin of the South Pacific magmatism

G. SHIMODA

Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, Tsukuba 305-8567, Japan (h-shimoda@aist.go.jp)

The northwest Pacific Ocean is known to contain a large number of Cretaceous seamounts and several oceanic plateaus and rises. These seamounts, plateaus and rises may have formed during the large-scale magmatic event in the South Pacific that is still active in the present-day French Polynesia region. Although it is unclear whether the Cretaceous seamounts and plateaus were produced by the same process that is now operate in the South Pacific, distinct isotopic signatures of the Cretaceous seamounts can be traced back to the magmas of the South Pacific, suggesting that single process has been active since the Cretaceous [1].

In order to examine the geochemical connection between the Cretaceous seamounts and present-day ocean islands, elemental ratios are determined for fluid-immobile incompatible elements (La/Yb, Nb/Zr, Ta/Zr, Th/Nb and Th/Ta). A notable geochemical feature of these ratios is a correlation between the elemental ratios and 'relative age' that can be an index of the thickness of lithosphere beneath hot spots. In addition, there are no systematic difference in the elemental ratios between the Cretaceous seamounts and present-day ocean islands. As the thickness of oceanic lithosphere is a function of square root of its age, these correlations suggest importance of tectonic environment to determine the chemical composition of the magmas. Other important geochemical feature is that the elemental ratios of mid-ocean ridge basalts (MORBs) from the East Pacific Rise (EPR) may not be on these trends. This observation could imply that source material of the EPR MORBs is different from that of the seamounts and islands. Since the source material of EPR MORBs can have a representative composition of upper mantle beneath the South Pacific, this difference could imply the material flow from the deep mantle. Therefore melting of mantle plume from the lower mantle, which melting condition depends on thickness of lithosphere, can be a plausible origin of the magmatism in the South Pacific.

Geochemical characteristics of black slate-hosted uranium deposits in the Okcheon Metamorphic Belt, Korea

DONGBOK SHIN*, SUJEONG KIM AND MINA CHOI

Kongju Nat'l Univ. 314-701, Korea (*correspondence: shin@kongju.ac.kr)

Carboneceous black slates in the Okcheon Metamorphic Belt of South Korea are thin beds known for their low grade U mineralization accompanying rare elements such as Ba, V, and Mo. U mineralization is distinctly concentrated in coalish slates which are imbedded in the black slates. Coalish slates show highly disturbed pattern in their texture unlike black slates, and contain quartz vein and sulfide minerals such as pyrite and pyrrhotite. Chondrite-normalized REE patterns of 36 samples for both of the rock types show that coalish slates are more enriched in HREE compared to black slate, and the total REE contents are higher in coalish slate (231 ppm) than in black slate (159 ppm). These petrographical as well as geochemical features strongly suggest that U mineralization in the black slate was related with post depositional hydrothermal activity. U also shows strongly positive correlation with V, Cu, and Mo, indicating that they were precipiated together during the hydrothermal process. Sulfur isotope compositions of black slate are low in values from -19.5 to 1.5‰, implying organic sulfur from sedimentary process, and those of coalish slate range from 7.3 to 9.0‰, possibly by metamorphism or hydrothermal process. As for carbon isotope, black slate ranges from -16.8 to -3.8‰ and coalish slate from -15.8 to -4.6‰. The wide range of carbon isotope reflects the mixture of organic carbon with calcite carbon from seawater origin. On the contrary, oxygen isotope compositons of the two rock types are narrow in range and similar to each other (14.6 to 15.5‰ for black slate and 14.9 to 18.5‰ for coalish slate), implying that oxygens are from calcite of seawater origin. Thus it seems like that the rare elements listed above would have been remobilized to participate in the formation of coalish slate after they were originally introduced to black shale under reduced condition.

Introduction of three granitoid types with different origins from ophiolitic mélange of Nain (Central Iran)

N. SHIRDASHTZADEH[1]*, R. SAMADI[2] AND G. TORABI[3]

[1]Department of Geology, Faculty of Science, University of Isfahan, Iran (*correspondence: nshirdasht@sci.ui.ac.ir)
[2]Department of Geology, Science and Research Branch of Isalamic Azad University, Tehran, Iran
[3]Department of Geology, Faculty of Science, University of Isfahan, Iran

Introduction

Mesozoic ophiolte melange of Nain is located in Central East Iranian microcontinent. Field studies and petrography indicate presence of three types of granitoids (plagiogranites, high-K granites, and tonalites) with different origins in ophiolitic mélange of Nain. Three granitoid types are different in mineralogy and are including of: (1) Plagiogranites (containing Qtz+Pl+Amp±Prh±Chl) (Mineral abbrevations from [1]); (2) high-K granites (including of Qtz+Pl+Or+Ms+small magmatic Grt (Alm) grains); (3) tonalites that are seen as intruded dikes in the amphibolitic rocks, containing Qtz+Pl+Amp+ small metamorphic Grt (Alm-Sps) grains ±Prh.

Discussion

Plagiogranites are indicated by [2] to be originated of differentiation of primary basalt. Mineral chemistry of garnets in high-K granitoids (almandine) show they have an igneous origin formed through melting of high Ca-Al sedimentary rocks. Garnets in tonalites (almandine-spessartine) have formed by regional metamorphic processes occurred after formation of tonalites (based on Fig. 11 in [3] and Table 1). In Breif, (1) plagiogranites are the final products of primary basalt differentiation, (2) high-K granites have formed through melting of sediments and (3) tonalites have been resulted by some degrees of partial melting and anatexis of their host amphibolite.

Rock Type	High K-granite		Tonalite	
Pyrope	5.63	5.94	13.66	13.71
Almandine	76.07	75.82	45.35	45.76
Grossular	2.28	2.11	4.54	5.20
Spessartine	16.02	16.09	36.40	35.25

Table 1: End members percent of garnets.

3 Ga onset of the supercontinent cycle: SCLM and crustal evidence

STEVEN B. SHIREY[1], STEPHEN H. RICHARDSON[2] AND MARTIN J. VAN KRANENDONK[3]

[1]DTM-Carnegie Institution of Washington, 5241 Broad Branch Rd, NW, Washington, DC 20015 USA
[2]Department of Geological Science, University of Cape Town, Rondebosch, 7700, South Africa
[3]Geological Survey of Western Australia, 100 Plain St, East Perth, WA 6004, Australia

A full understanding of the formation and evolution of the continents requires the use of constraints from both the subcontinental lithospheric mantle (SCLM) and crust. Significant differences exist globally between >3.2 Ga versus <3.0 Ga crust and SCLM. We propose that this time is a boundary between different geodynamic regimes on Earth and the start of the supercontinent (Wilson) cycle [1, 2].

To characterize the SCLM through time, we use geochronological studies of sulfide and silicate inclusions in diamonds from more than 20 kimberlites on 4 cratons [3]. Diamonds >3.2 Ga contain exclusively peridotitic (harzburgitic) silicate and sulfide inclusions whereas diamonds <3.0 Ga contain predominantly eclogitic silicate and sulfide inclusions. Similarly, >3.0 Ga kimberlite-borne eclogite xenoliths are largely absent in the SCLM rock record, whereas they are common thereafter.

Archean crust also records major differences across the 3.0–3.2 Ga interval. Prior to 3.2 Ga, crust grew by vertical accretion over upwelling mantle in long-lived plateaux floored by extremely depleted residual harzburgitic SCLM or via slab melting and crustal imbrication over shallow subduction zones (e. g West Greenland) [4], whereas lateral accretion, allochthonous greenstone belt growth and calcalkaline magmatic products of mantle wedge melting emerge only after 3.2 Ga [5].

This temporal and geochemical change can perhaps best be explained as the result of a step-wise change in the tectonic style of the planet from rapid mantle convection, small plates, shallow subduction, and localized recycling >3.2 Ga, followed by large plates, steep subduction, and full upper mantle recycling <3.0 Ga. These geodynamic changes would have had profound effects on mantle depletion, crustal growth, and geochemical cycles.

Magma storage conditions of Mutnovsky volcano, Kamchatka

T.A. SHISHKINA[1]*, R.R. ALMEEV[1], R.E. BOTCHARNIKOV[1], F. HOLTZ[1] AND M. PORTNYAGIN[2]

[1]Institute of Mineralogy, Leibniz University of Hannover, Callinstrasse 3, 30167, Hannover, Germany (*correspondence: t.shishkina@mineralogie.uni-hannover.de)
[2]IFM-GEOMAR, Kiel, Germany

Mutnovsky is a typical island-arc tholeiitic volcano, located in the southern part of the Eastern Volcanic Front of Kamchatka (Russia). This active volcano hosts a hydrothermal field, one of the largest in Kamchatka, providing an excellent example of modern interaction of magmatic and hydrothermal systems. Investigations of the magma storage conditions such as depth, temperature, volatile budget and redox state beneath Mutnovsky volcano are crucial to understand the input and the role of magmatic component in the course of magma-hydrothermal interactions. We investigated these conditions experimentally and with the help of melt inclusion study.

To evaluate the magma storage conditions, two sets of crystallizaton experiments at 100 and 300 MPa have been performed using the most magnesian basalt of Mutnovsky as a starting composition [1]. The mineral phenocryst assemblage of Mutnovsky basalts (Ol, Pl, CPx, and Mt) was succesfully reproduced at 100 MPa (1025-1100°C, 0.5–3.5 wt.% H_2O) and at 300 MPa (1000-1075°C, 1.5–5.0 wt.% H_2O). The mineral phenocryts compositions in the experimental runs and in Mutnovsky basalts were similar. Compositions of experimental residual glasses saturated with Ol+Pl+CPx+Mt assemblage reproduce well the natural liquid line of descend and confirm a genetic link between primitive and more evolved eruptive products of Mutnovsky volcano.

Olivine-hosted melt inclusions from basaltic tephra (50-55 wt.% SiO_2; 4-6.5 wt.% MgO) contain 1.7-2.7 wt.% H_2O and 0-180 ppm CO_2. According to our experimental data on H_2O-CO_2 solubility in Mutnovsky basalt [1], these volatile abundances correspond to shallow depths (pressures below 110 MPa). The values of S^{+6}/S^{-2} in melt inclusion obtained by XANES correpond to the range of logfO_2 between QFM+0.9 and QFM+1.7 (QFM is quartz-faylite-magnetite buffer).

Our study confirms the presence of a shallow magma reservoir beneath Mutnovsky volcano at about 3 km depth. The phenocrysts in lavas could, however, crytallize at different depths in magmatic conduit during a polybaric crystallization (starting at least from 300 MPa).

The generation of geochemical asymmetry in MORB around Iceland by radially symmetric plume flow under an asymmetric ridge system

O. SHORTTLE AND J. MACLENNAN*

Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, UK (*correspondence: jcm1004@cam.ac.uk)

Geochemical asymmetry in Mid-Ocean Ridge Basalt (MORB) around Iceland was first recognised almost forty years ago and similar spatial patterns of MORB compositions been reported from a number of other plume-influenced ridges. Basalts from the Kolbeinsey Ridge to the north of Iceland are depleted in incompatible trace elements and have low $^{87}Sr/^{86}Sr$ and high $^{143}Nd/^{144}Nd$ when compared with basalts from the Reykjanes Ridge to the south. Previous models that have attempted to account for this asymmetry have typically been based upon the presence of asymmetry in the compositional field, temperature field or flow field in the Icelandic plume. Here we instead propose that the geochemical asymmetry around Iceland is controlled by asymmetry in the geometry of the ridge system. The presence of such geochemical asymmetry does not require radial asymmetry in the plume composition, temperature or flow field other than that imposed by the plate spreading.

Geophysical observations indicate that the plume conduit is centred under south-eastern Iceland. If mantle flows radially in the plume head from this position, then it will arrive at the Reykjanes Ridge without passing under a fully developed spreading system and will therefore have barely been melted before it rises and melts in the corner flow under the Reykjanes Ridge. In contrast, radial plume head flow dictates that the mantle that rises and melts under the Kolbeinsey ridge has travelled through the deep parts of the melting region under the Northern Volcanic Zone of Iceland. While only modest extents of melting may occur in the deep part of the melting region, it is likely that this melting preferentially extracts magma from enriched, fusible heterogeneities in the mantle. Therefore, the mantle rising under the Kolbeinsey Ridge may already have been stripped of an enriched geochemical signature by small extents of melting during transit under the Northern Volcanic Zone. Simple quantitative models of this depletion of mantle flowing radially in the deepest parts of the melting region are able to match the first order observations from Iceland and other plume-influenced ridges such as the Galápagos.

Analysis of thermal phases in Canaanite ceramic 'Metallic Ware' using FT-IR spectroscopy

SHLOMO SHOVAL[1] AND YITZHAK PAZ[2]

[1]Geology Group, Department of Natural Sciences, The Open University of Israel, The Dorothy de Rothschild Campus, 1 University Road, POB 808, Raanana, Israel (shovals@openu.ac.il)

[2]Institute of Archaeology, Tel-Aviv University, Tel-Aviv, Israel

Early Bronze Age (EBA) ceramic 'Metallic Ware' from the North Canaan was analyzed using FT-IR spectroscopy and applying of curve fitting and second derivative techniques. The Metallic Ware is hard, highly fired pottery which resounds with a distinctive metallic ring when struck. The spectroscopic analysis is advantageous in analysis of amorphous and short-range ordered thermal phases lacking of XRD peaks. The applying the spectral analysis improves the identification of the individual phases in the composition of the pottery. The results demonstrate that the ceramic 'Metallic Ware's are composed of non-calcareous or poorly-calcareous ceramics. The spectra demonstrate that the vessels are composed mainly of meta-clay. The type of the meta-clay in the composition of the pottery is identified by the location of the main SiO stretching band using curve fitting and second derivative techniques. Most of the ceramic 'Metallic Ware's contain mixtures of metakaolinite and meta-smectite. The appearance of both phases, indicates that calcareous raw materials contained smectite and kaolinite, were used for manufacture of the 'Metallic Ware'. It seems that the presence of smectite in the raw material enable sintering at lower firing temperature.

Study of geochemistry, geochronology and petrogenesis of the Early Paleozoic granites in South China

L.S. SHU* AND Y. ZHANG

State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing, China (lsshu2003@yahoo.com.cn)

This paper shows results of petrology, geochemistry, zircons U-Pb dating and *in situ* Hf isotope. Geochemically, the A/CNK values have an average of 1.16; the REE compositions show higher ΣREE contents, enrichment in LREEs, depletion in Eu and REE patterns; the trace element spider diagrams are enrichment in Rb, Th, U and depletion in Ba, Sr, Nb, Ti. Zircons mostly exhibit euhedral and high Th/U values, an average of 1.08. The zircons from thirty plutons yielded rather similar U-Pb concordia ages from 436±6 Ma to 441±4 Ma, corresponding to Llandovery Epoch of Silurian. Several xenocrysts yielded the U-Pb ages around 700 Ma, implying that a breakup event took place during Neoproterozoic. *In situ* Lu–Hf isotopic analysis shows that all the εHf (t) value of zircons are negative, and their model ages (TDM2) values indicate that the Silurian granitic magma came from the recycle of Meso-Paleoproterozoic basement. Researches suggest that an intracontinental tectono-magmatic event took place during the Early Paleozoic, which is characterized by folding and thrusting, leading to crustal shortening and thickening. The high geothermal temperature from thickening crust and accumulation of producing high-heat radioactive elements will gradually soften crustal rocks and cause a partial melting, forming peraluminous granitic magma. Under the post-orogenic extensional and de-pressure condition, these granitic magma rose and emplaced in the upper crust, leading to development of S-type plutons.

Compositions of phyllosilicates from the TAG hydrothermal system at 26°N on the Mid-Atlantic Ridge as guide to subseafloor entrainment of seawater: Results from ODP Leg 158

L. SHU, W. BACH, A. KLÜGEL AND N. JÖNS

Fachbereich Geowissenschaften, Universität Bremen, Klagenfurter Straße, 28359 Bremen (liping@uni-bremen.de, wbach@uni-bremen.de, akluegel@uni-bremen.de, njoens@uni-bremen.de)

The TransAtlantic Geotraverse (TAG) hydrothermal system east of Mid-Adlantic Ridge at 26°N in a water depth of 3670 m is one of the largest known massive sulfide accumulations on the seafloor (2.7 million tonnes of sulfide; [1]). Anhydrite is an ideal tracer in active hydrothermal systems, but (unlike phyllosilicates) it dissolves after hydrothermal activity has ceased. Phyllosilicate compositions can provide useful constraints on sub-seafloor seawater entrainment, which supplement and extend the record in gangue. Calibrating the phyllosilicate record of fluid evolution against that of anhydrite in the TAG subseafloor may hence provide us with a useful tool in studying fluid mixing in hydrothermal stockwork zones underlying ancient volcanigenic massive sulfide deposits.

Results from trace element concentrations indicate that the paragonite patterns are fairly uniform and – compared to N-MORB – show positive Ba, U, Pb, Sr anomalies. In contrast, chlorite patterns are variable and can be divided into 3 different types: chlorite type A occurs in a breccia from the peripheral part of the upflow zone and in the deepest part of Holes 957E and 957C. Type A shows negative Sr and Ba anomalies and positive U and Pb anomalies. Chlorite type B occurs throughout Holes 957E and 957C in the central part of the mound, but is lacking in samples from the periphery of the upflow zone. Type B shows no or small Sr anomalies but positive U, Ba, and Pb anomalies. Chlorite type C occurs in alteration halos of basalt from underneath the mound. It shows no significant U anomalies, but negative Ba anomalies and large positive Pb anomalies.

The results suggest that the different chlorite pattern types relate to sub-seafloor fluid flow dynamics, which are variably dominated by (i) seawater entrainment and heating, (ii) mixing of seawater and hydrothermal fluid, and (iii) pooling and conductive cooling of hydrothermal fluids.

Ultra-depleted eclogites: Residues of TTG melting

Q.SHU[1,2]* AND G.P. BREY[1]

[1]Univ. Frankfurt, Germany
[2] China University, Beijing
(*correspondence: shu@em.uni-frankfurt.de)

Eclogites from the Bellsbank diamond mines (SA) fall into categories A and B of Coleman [1]. We collected eclogites from a coarse concentrate dump from the present day production. These fall into three groups, one in A (Mg-rich) and two groups B1 (Fe-rich) and B2 (Ca-rich). They are derived from a temperature range between 850 to 1050°C (A and B1) and 1050 to 1150°C (B2). All xenoliths have exceptionally fresh and clear clinopyroxenes. REE patterns from A and B1 show the ultra-depleted character in their REE patterns which were LREE depleted in both cpx and grt. However, the LREE up to Sm were reenriched in most cases disturbing the Sm-Nd system. Both phases have extremely high εH with one sample giving the highest εHf ever measured with 13753 in garnet and 6518 in cpx. Such values require a long time integrated history with very high Lu/Hf in the bulk rock. We suggest that the eclogites are derived in the early Archean from picritic to basaltic protoliths of low pressure origin, which were subsequently subducted and partially molten with not much time delay. The products of the partial melting process should be TTG melts according to experimental work (e.g. [2]). The partial melting generated the high Lu/Hf ratios in the residue which are necessary to reach such extreme high εHf values as found in our rocks. The higher temperature Group B2 eclogites have positive Eu anomalies which indicate a low pressure origin as plagioclase cumulates. These eclogites still have higher εHf as most known eclogites and may also have been involved in the partial melting process. Lu-Hf grt-cpx two-point isochrones give eruption ages around 120 Ma for samples with T > 950°C; lower-T samples give increasing ages with decreasing temperature. The Sm-Nd isotope system does not give any consistent information on the origin of the rocks because of subrecent addition of LREE to the rocks.

Active methanogenesis in the subsurface during development process

Y.H. SHUAI*, S.C. ZHANG, J.K. MI AND M. LIU

PetroChina Research Institute of Petroleum Exploration & Development, Beijing, China
(*correspondence: yhshuai@petrochina.com.cn)

Methanogenic biodegradation of organic matter provides us prospects of methane resource artificially generated continuously in the subsurface anaerobic condition. Unfortunately, this process is such a long period in the geological condition that human being can not wait for. However, several cases in China demostrate methanogenesis process could be very quick.

Examples presented in this article are related to the biodegradation of heavy oil components and the significant change of the associated gas characteristics. The first example is from Liaohe depression, Bohaiwan basin. Biodegradated gases were produced widely in the west of the depression, from 1300~1600 m, with temprature ranging from 45 °C to 60 °C. Accompanied crude oil had been biodegraded heavily above 4 degree biodegradation. During producing stage less than a decade, the dryness (C_1/C_{1+}) of gas became higher and higher from 0.92 to 0.97. Based on meterial balance method, about 80 percent of producing gas should be neogenicly generated. The second example is from Songliao Basin, Northeastern China. The dry coefficient of associated natural gas increased from the beginning 85% (40 years ago) to present 95%. And content of non-hydrocarbon components, such as H_2S and CO_2, slightly increases, too. The similar trend happened in the another field, Liuzhuang field of Jinhu depression in the Subei basin, Eastern China. Differently, the dryness of associated gas has been stable at 98 %, but the stable carbon isotope ratio of CH_4 varied from -51.2 ‰ to -53.6 ‰.

All those cases demonstrate that biogenic methane could be generated in amazing rates. Once appropriate conditions provided, the interesting geomicrobes can give us whatever we want.

Mineral chemistry of the skarn type ores from Furong Tin deposit in Hunan Province, P.R.China

Y. SHUANG[1,2]*, J. CHEN[1,2] AND H. LI[1,2]

[1]Chongqing Key Laboratory of Exogenic Minerallization and Mine Environment, Chongqing Institute of Geology and Mineral Resources, Chongqing 400042, China
(*correspondence: shy0124@yahoo.com.cn)
[2]Chongqing Research Center of State Key Laboratory of Coal Resources and Safe Mining 400042, China

Tin in skarns forms a significant part of the total Sn resource of South China. The Furong tin polymetallic deposit in the central Nanling region, South China is dominantly composed of skarn type ores hosted in Carboniferous and Permian strata and Mesozoic A-type granitic intrusions. In this study, mineral chemistry research has been carried out on skarn ores from No. 19 ore lode using microscope and EPMA analysis, in order to constrain the tin mineralization condition of skarn in Furong deposit.

Primary skarns in Furong deposit are mainly consisting of grossular-andradite, baicalite, ferro-edenite, malayaite, and minus idocrase, wollastonite, cassiterite formed under oxidizing conditions. The garnet and ferro-edenite are characterized with high Sn concentration (0.22~0.73%), distinctly higer than those formed under reducing conditions [1]. Accordingly, the primary skarn formed under oxidizing conditions. In this case, tin dominantly occurs as Sn^{4+} and entered the crystal lattices of skarn minerals.

Under the alteration of the F-, Cl- and Sn-riched ore-forming solution exsolved from biotite granite magma, the primary skarn was regressive metamorphosed to form hydrothermal minerals and ores. Along the endo-contact zones of the granite and the carbonate wallrock, the primary skarns were altered to type Ⅰ ores with the association of cassiterites + phlogopite + fluorite + magnetite, which mainly related to the hydrothermal fluids exsolved from biotite granite. The association of tremolite, diopside, chlorite, sulphide, i.e. Type II ores was formed along the exo-contact zones of the biotite granite, which was significantly influenced by the fluid from wallrock.

This research project was financially supported by the National Natural Science Foundation of China (41003024).

The impact of heavy metals concentration on soil biological properties in Kintyre Pb mining area, Jamaica

N. SHUKUROV[1], CLAION ROBINSON[2], PAUL WRIGHT[2] AND G. LALOR[2]*

[1]Institute of Geology & Geophysics, Academy of Sciences of Uzbekistan, 49, N.Khodjibaev Str., Tashkent-100041, Uzbekistan (nosirsh@yahoo.com)

[2]International Centre for Environmental and Nuclear Sciences, University of the West Indies, Mona, Kingston 7, Jamaica, West Indies (*correspondence: glalor@uwimona.edu.jm)

Soil contamination with heavy metals occurs as a result of both anthropogenic and natural activities. Heavy metals could have long-term hazardous impacts on the health of soil ecosystems and adverse influences on soil biological processes. Soil microorganisms are recognized as sensors towards any natural and anthropogenic disturbance occurring in the soil ecosystem. Similarly, soil nematodes are also considered as one of the important soil biota and frequently influenced by HM contamination. The total number of nematode individuals has recently been used to investigate changes in soil biota composition in response to environmental stresses. This study was conducted within the Kintyre Pb mining area. Soil sampling plots are located in the Hope River valley, in the foothills of the Port Royal Mountains near to the Kingston. Mining was discontinued in the late 19th century, leaving a legacy of superficial tailings and crushed ore. These materials have been dispersed into the surrounding areas. HM concentrations, soil pH, soil moisture content (SM), total number of nematode individuals (TotalNem) and nematode community structure were studied. 18 soil samples (0-10 and 10-20 cm) from 3 sampling plots with different pollution levels (low (<100 mg/kg), moderate (300-700 mg/kg) and very high (>1000 mg/kg) concentration) were sampled in triplicate. Airdrieyed soils samples were sieved trough 2mm mesh and HM, TotalNem, SM, pH were determined in subsamples. TotalNem was significantly lower ($p<0.05$) in soil samples with high concentration of HM from the soil sampling plot C than in soils with low and moderate HM content from the soil sampling plots A and B. No significant differences were observed SM and pH between soil layers and sampling plots. TotalNem patterns confirmed that the concentration of heavy metals had a significant impact on nematodes. The soil nematodes were sensitive to Pb, Cd and Zn as an indicator of soil pollution with HM and can be used within the Environmental assessment projects.

A Chinese antimony smelting site and possibility for its phytoremediation

SHURKHUU TSERENPIL* AND LIU CONG-QIANG

State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, 550002 Guiyang, PR China (*correspondence: tserenpil.sh@gmail.com)

Anthropogenic sources such as mining operations and smelting plants are great contributors to antimony (Sb) accumulation in the environment. Sb is considered a non-essential element and is toxic to most living organisms at elevated concentrations. Chinese Sb vein-type ore deposits account for 55% of the world's resources of Sb [1], and the country has been the global dominant in its production for over 10 decades. As a consequence, water and soil as well as fauna and flora within Sb mining and smelting areas are significantly contaminated by this metalloid and co-occurring elements [2-5]. Its anthropogenic release is mainly to the land; therefore, it is crucial to investigate the fate of Sb within the soil system in the smelting areas where its release is often very high and land needs to be cleaned up.

Discussion of results

Soils were sampled at uncultivated, cultivated and fallow farmland in the vicinity of a Sb smelter in Guangxi Zhuang, China. Topsoils at all the sites were heavily polluted by metals including Sb, Pb and As; and their concentrations were measured at 410-3330 $mg \cdot kg^{-1}$, 410-3690 $mg \cdot kg^{-1}$ and 200-460 $mg \cdot kg^{-1}$, respectively. However, the elevated concentrations of Hg (0.11-0.30 $mg \cdot kg^{-1}$) may be occurred both naturally and anthropogenically at the sites studied. This study showed that aerosol particles from Sb smelter can result in severe pollution of the local environment by toxic metals and pose a high risk via agricultural plants. Dissoluble proportion of Sb was insignificant (0.70-1.63%) compared to its deposition in the surface soils; however, water extractable amounts produced a slightly reduced germination rate on wheat seed with a lighter weight. Sb(III) adsorption on the smelting site soil was studied in order to examine its mobilization in pH changes; furthermore, to determine an optimal pH for higher Sb mobility that could facilitate plant uptake. The adsorption maximum (56 $ml \cdot g^{-1}$) appeared at pH of 3, while it was 10-17 $ml \cdot g^{-1}$ at pH of 6-7 which showed anion sorption may be dominant in Sb sorption onto bulk soil. It is therefore suggested that to maintain soil pH near neutral will increase Sb concentration in the soil water solution and it will enhance the feasibility of the phytoremediation.

The effect of iron-oxidizing bacteria on the stability of the gold-thiosulfate complex

J. SHUSTER[1]*, A. SMITH[1], T. BOLIN[2] AND G. SOUTHAM[1]

[1]Department of Earth Sciences, The University of Western Ontario, London, ON CANADA N6A 5B7 (*correspondence: jshuster@uwo.ca)
[2]CMC-XOR-Sector 9, Advanced Photon Source, Argonne Laboratory, Argonne, IL USA 60439

Acidophilic iron oxidising bacteria, enriched from a Rio Tinto river sample collected approximately 7 km SW of Nerva, Spain, precipitated colloidal gold when exposed to 2 μM to 20 mM Au $(S_2O_3)_2^{3-}$. Growth of the consortium produced soluble ferric iron and colloidal, ferric iron-oxide mineral precipitates. A range of gold (I) thiosulfate solutions reacted with the whole cultured system and with each component system separately (i.e. bacteria, spent media, mineral precipitates) immobilized gold from solution within several hours. Transmission electron microscopy and scanning electron microscopy demonstrated that the immobilization of gold occurred differently by the three components in the microbial system. When each separate constituent was exposed to 20 mM gold: bacteria precipitated 30.78% gold in the form of 5 nm colloids concentrated along the cell envelope; the colloidal, iron-oxide minerals precipitated 26.26% gold as 5 nm colloids that reduced and replaced the acicular iron-oxide filaments extending outward from the particles; and spent media, devoid of residual organics and solid iron oxides precipitated 99.51% gold as 200 nm to 2 μm gold sulfide colloids and aggregates. In a chemical control experiment, gold did not react with soluble ferrous iron under the same experimental conditions. This suggests that stripping electrons from organic material and a role for ferric iron in destabilising the gold thiosulfate complex were critical to colloidal gold formation. Analysis of whole culture systems exposed to 2 mM gold using XANES/EXAFS demonstrated that gold (I) was immobilized and reduced to a gold sulfide and elemental gold, respectively. The direct immobilisation of gold by these iron oxidising bacteria and the indirect immobilization of gold by biologically-mediated, iron oxide precipitates suggests an active and passive role the biosphere has in influencing the mobility of gold as soluble complexes or as colloids. Understanding the biogeochemistry of gold interception and accumulation within a geologic temporal setting would provide insight into dispersal of gold in natural weathering systems where weathering of gold bearing metal sulfides occurs.

Mercury stratigraphy: A proxy for volcanogenic CO_2 buildup in Neoproterozoic snowball Earth and volcanism in the K-T transition

A.N. SIAL[1], L.D. LACERDA[2], C. GAUCHER[3]; V.P. FERREIRA[1], L. CHIGLINO[1], M.S. CAMPOS[1]; M.V. NASCIMENTO-SILVA[1] AND W.S. CEZARIO[1]

[2]LABOMAR, UFC, Fortaleza, Ceará, Brazil
[3]Fac. Ciencias, Univ. Republica, Montevideo, Uruguay

Mercury tends to concentrate in sediments deposited right after major glacial events [1] as a result from leaching of volcanogenic Hg from land surface and accumulation along argillaceous sediments. Wherever geological background of Hg is negligible, its concentration in sediments may be useful for investigation of climatic changes.

Volcanism is assumed to be responsible for CO_2 build up in the atmosphere during Snownall Earth event with subsequent greenhouse effect, ice melting and cap carbonate deposition [2]. Intense volcanism witnessed the Cretaceous-Tertiary transition [3] and was, perhaps, responsible for dramatic climatic change.

We have used Hg as a proxy of volcanism intensity and CO_2 buildup during snowball events in Neoproterozoic cap carbonates in NE Brazil. Localities where carbonates are in sharp – but not erosional – contact with basal diamictites (earliest stages of aftermath of glacial events) and show $\delta^{13}C$ values ~ –5‰ were analyzed. Hg contents are usually over 10 times higher than background values (<1 ngg^{-1}), occasionally reaching values > 200 ng g^{-1}. Hg contents in cap carbonates of the Sergipano Belt and Ubajara Basin are similar to those in carbonates deposited coevally to volcanic activity elsewhere. This study supports mantle-origin for the CO_2 in cap carbonates, transferred to the atmosphere by volcanism.

In three drill-hole cores in carbonate rocks that register the K-T transition (KTB) in the Paraiba Basin, NE Brazil, Hg increases (4 ngg^{-1}) in the early Danian right after the KTB. Hg spikes predating the KTB register volcanism before this transition. Hg shows stratigraphic variation synpathetic with $\delta^{13}C$ and $\delta^{18}O$ stratigraphies.

This study supports Hg stratigraphy as possible tracer of dramatic climatic changes as those in Neoproterozoic snowball Earth events and in the KTB.

The effects of road salt influx on the geochemical cycling of Woods Lake, Kalamazoo, MI

R.J. SIBERT, C.M. KORETSKY*, C. SNYDER, A. MACLEOD AND S. BARONE

Dept of Geosciences, Western Michigan University, Kalamazoo, MI 49008
(*correspondence: carla.koretsky@wmich.edu)

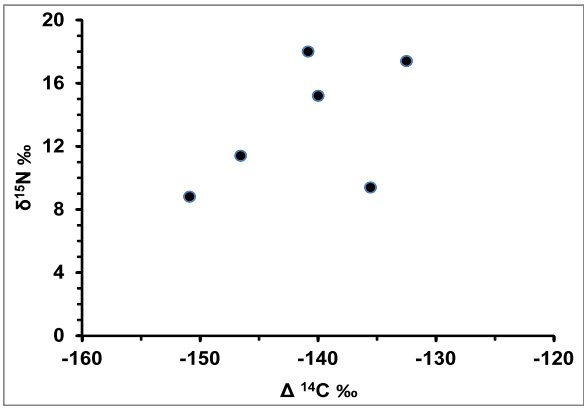
The seasonal application of road deicing salts in densely populated areas can exacerbate eutrophication, and change the seasonal geochemical/mixing cycles of urban lakes through the gradual elevation of chloride concentrations. Elevated chloride levels in hypolimnetic waters may lead to persistent density and redox stratification (i.e. meromixis), stable anoxia in bottom waters, and a decrease in biological diversity. Therefore, the goal of this study is to examine the influence of road salt influx on the geochemical and physical mixing cycles of Woods Lake, a small, kettle lake in urban Kalamazoo, MI (Z_{max} ~13 m). Water samples were collected monthly between May and July 2010, and approximately twice a month between August 2010 and March 2011 at 1 m intervals using a van Dorn sampler. Temperature, pH, conductivity, and dissolved oxygen (DO) values were obtained *in situ* using a YSI 650MDS/600QS multiparameter sonde. Laboratory samples were analyzed colorimetrically for Fe^{2+}, total alkalinity, ΣNH_4^+, ΣPO_4^{3-}, ΣH_2S, and Mn^{2+}, by IC for Cl^- and SO_4^{2-}, and by ICP-OES for major ions and trace metals (Mg, Ca, K, Na, Zn, Ni, Co, Cu, and Pb). The data indicate that temperature varies seasonally in a predictable manner; typical summer and fall thermal stratification is antecedent to inverse wintertime stratification, punctuated by a transition period of thermal homogeneity (November) within the water column. However, analyses of redox sensitive species (i.e. Fe^{2+}, Mn^{2+}, ΣPO_4^{3-}, ΣH_2S, etc) show that Woods Lake displays persistent redox stratification and hypolimnetic anoxia throughout the entire sampling period. For example, maximum Fe^{2+} concentrations are >290 μM in fall and >250 μM in winter below 9 m, indicative of the relative persistence and magnitude of hypolimnetic anoxia. Conductivity profiles indicate the presence of a chemocline that varies from ~8 m in the spring, summer, and fall, to ~10 m in the winter. Conductivity and Cl^- data correlate strongly throughout the sampling period, typically with an $R^2 > 0.95$. Concentrations are more than one hundred times higher than those found in rural lakes of the same region. These data imply persistent hypolimnetic anoxia and redox stratification, presumably due to nutrient and road salt inputs, and that both fall and spring turnover events never fully reach completion.

Radiocarbon depression in aquatic foodwebs of the Colorado River, USA: Coupling between carbonate weathering and the biosphere

J.O. SICKMAN*, M.A. ANDERSON, D.M. LUCERO, J. MCCULLOUGH AND W. HUANG

Department of Environmental Sciences, University of California, Riverside CA 92521
(*correspondence: jsickman@ucr.edu)

The ^{14}C content of living organisms is generally considered to in isotopic equilibrium with the atmosphere. We measured substantial radiocarbon depression of organisms within planktonic and benthic foodwebs of Copper Basin Reservoir, a short residence-time lake at the intake to the Colorado River Aqueduct in California, USA. All levels of the foodweb, had depressed radiocarbon content with inferred 'age' of ca. 1100 to 1200 radiocarbon years ($\Delta^{14}C$ range: -137 to -151‰, Figure 1).



We presume that 'dead' carbon from carbonate weathering entered into the foodweb via photosynthesis, depressing the ^{14}C content of organisms below that of the atmosphere. A two-component mixing model incorporating carbonate weathering and atmospheric CO_2, shows that 15-17% of the carbon in the aquatic foodwebs of Copper Basin is derived from weathering of carbonate minerals in the Colorado River basin. Worldwide, only a few cases of radiocarbon depression have been reported for aquatic ecosystems and the degree of ^{14}C depression in the Colorado River is much larger than that observed in the Arctic or deep ocean environments.

Geochemistry of Paleocene volcanism and oceanic island arc affinities of the Chagai Arc, Balochistan, Pakistan

REHANUL HAQ SIDDIQUI[1], MUHAMMAD ASIF[2] KHAN AND MUHAMMAD QASIM JAN[3]

[1]GeoscienceAdvance Research Laboratories, Geological Survey of Pakistan, Shahzad Town, Islamabad Pakistan
[2]National Centre of Excellence in Geology University of Peshawar, Pakistan
[3]National Centre of Excellence in Geology University of Peshawar, Pakistan

The main exposures of the Paleocene lava flows occur in an east-west trending subduction related magmatic belt known as Chagai arc in the western part of Pakistan.

The Paleocene lava flows are mainly represented by basalts (49.22-52.46 wt. % SiO_2) and basaltic-andesite (52.75-53.90 wt. % SiO_2. The petrochemical studies show that these are mainly medium to low -K oceanic island arc tholeiites. The trace element patterns show enrichment in LILE and depletion in HFSE relative to N-MORB. The primordial mantle-normalized trace element patterns show marked negative Nb anomalies with positive spikes on Ba and Sr which strongly confirm their island arc signatures, which is further supported by flate-slightly LREE enriched chondrite-normalized REE patterns. These volcanics have lower average $^{87}Sr/^{86}Sr$ ratio (0.70446), which is more consistent with a depleted mantle source and closely correlate with oceanic island arcs rather than continental margin type arcs. The average trace element ratios including Zr/Y (2.25), Ti/V (15.47), La/Yb_N (1.62), Ta/Yb (0.03) and Th/Yb (0.24) of these volcanics are more consistent with oceanic island arc tholeiite rather than analogous rocks of the continental margins type arcs.

Eruptive history and chemical evolution of the Acigöl volcanic field, central Anatolia, Turkey, based on geochemical and isotopic (Sr-Nd-Pb, $\delta^{18}O$) constraints and ion microprobe zircon analysis

W. SIEBEL[1], A.K. SCHMITT[2], M. DANIŠÍK, [3] F. AYDIN[4] AND E. KIEMELE[1]

[1]University of Tübingen, Germany
[2]UCLA, USA
[3]University of Waikato, New Zealand
[4]University of Nigde, Turkey

The Acigöl volcanic field has been interpreted as a thermally growing system, where smaller magma pulses coalesced into a large, interconnected silicic magma reservoir [1]. We established a high temporal resolution chrono-stratigraphic framework for rhyolitic volcanism at Acigöl from zircon U-Th disequilibrium and (U-Th)/He dating combined with thermometry and O-Sr-Nd-Pb isotopic data. In contrast to previous dating [2], we found that zircon crystallized in only two pulses corresponding to separate eruptions in the eastern and western Acigöl field during Mid- (~150–200 ka, group I) and Late Pleistocene (~20–25 ka, group II) times, respectively. For group II zircons, resolvable differences exist between interior (average: 30.7±0.9 ka; 1σ error) and rim (21.9±1.3 ka) crystallization ages. These translate into radial crystal growth rates of ~10^{-13} – 10^{-14} cm/s. Rim crystallization ages and (U-Th)/He eruption ages (24.2±0.4 ka) overlap within age uncertainty. Compositionally, group I lavas are less evolved (SiO_2 = 71–73 wt.%), than group II lavas (SiO_2 = 74–75 wt.%). Within each group, compositional variability is small, and Nd-Pb isotope ratios are fairly homogeneous. Group II rhyolites have $\delta^{18}O$(zircon) overlapping mantle values (5.56 ± 0.16 ‰), whereas group I rhyolites are slightly more enriched in ^{18}O, consistent with some crustal material input. By contrast, group II rhyolites have markedly more radiogenic $^{87}Sr/^{86}Sr$ ratios (0.7065–0.7091) compared to those of group I (0.7059–0.7065). The correlation between hydration (loss on ignition data) and $^{87}Sr/^{86}Sr$ in the group II lavas indicates that Sr was added during post-eruption alteration by wind-blown material. Isotope constraints preclude the possibility that the rhyolite magmas formed by partial melting of any known regional crystalline basement rocks. Despite the longevity of rhyolite volcanism at Acigöl, and trends from group I to group II rhyolites of progressive depletion in compatible trace elements and decreasing zircon saturation temperatures, evidence for brief zircon residence is consistent with autochthonous crystallization in small discrete magma batches rather than in a fully interconnected magma reservoir.

Molybdenum isotope fractionation during soil formation: A new proxy?

C. SIEBERT[1], J. PETT-RIDGE[2], S. OPFERGELT[1,3], K. BURTON[1] AND A.N. HALLIDAY[1]

[1]Dept. Earth Sciences, Univ. of Oxford, Oxford, UK (*correspondence: christopher.siebert@earth.ox.ac.uk)
[2]Dept. Crop and Soil Science, Oregon State University, OR 97331, USA (julie.pett.ridge@gmail.com)
[3]Earth and Life Inst., Univ. catholique de Louvain, Louvain-la-Neuve, Belgium (sophie.opfergelt@uclouvain.be)

Over the last decade molybdenum has become one of the most investigated tracers for redox conditions in the oceans. However, little is known about the processes controlling the isotope composition of the riverine inputs to the oceans. Several recent studies [1, 2] have shown that many river waters have a heavy Mo isotopic composition. However, crustal rocks are in general close to zero and therefore fractionation of Mo isotopes must occur during weathering or transport. This study has investigated the behavior of Mo isotopes under different weathering conditions. Results from a soil climate gradient from Hawaii show that redox conditions during soil formation can control Mo isotope compositions in soils. Reducing soil profiles have light isotope compositions whereas oxidizing profiles are heavy. This general isotope behavior is confirmed by results from soil profiles from Iceland. Here reducing layers within the profiles show marked negative isotope excursions. In general oxic profiles show positive isotope compositions increasing with depth and organic C content. In addition these profiles show that fractionation relative to the source rock is dependent on the degree of weathering, i.e. relatively un-weathered profiles do not show isotope fractionation. Sequential extractions confirm that organic matter plays a crucial role in fractionating molybdenum isotopes in soils. These observations together with the generally heavy isotope composition of rivers indicate that the current mass balance of molybdenum in Earth surface processes might not be in steady-state. In addition, our data open interesting possibilities for the use of molybdenum isotopes as a paleo-proxy for soil processes. Finally, our data show that interpretations of the marine sedimentary record are difficult as long as we do not understand changes in the molybdenum input over time.

Diamond anvil cell applied to the geochemistry of Earth's core formation

JULIEN SIEBERT[1,2], JAMES BADRO[2], DANIELE ANTONANGELI[1,2] AND FREDERICK J. RYERSON[2]

[1]IMPMC, Université Pierre et Marie Curie, UMR CNRS 7590, 4 place jussieu, 75005 Paris, France
[2]IPGP, 1 rue jussieu, UMR CNRS 7154, 75005, Paris, France
[3]Lawrence Livermore National Laboratory, 7000 East Avenue, Livermore, California, 94550, USA

The abundances of siderophile elements in the Earth's mantle bear the imprint of the core formation in the early Earth. Thermodynamic expressions used to constrain the metal-silicate partitioning behavior of siderophile elements are mainly established from large volume press experiments that do not cover the full range of potential P-T conditions for core-mantle equilibrium. The diamond anvil cell is the only static technique capable of achieving required P-T conditions but until now its capabilities to perform quantitative metal-silicate partitioning experiments at extreme conditions has been untapped. We use protocols that effectively link high P-T diamond anvil cell with analytical techniques such as focused ion beam device (FIB); NanoSIMS; electron microprobe; transmission electron microscopes; and *in situ* synchrotron X-ray diffraction measurements allow us to obtain quantitative data on element partitioning at superliquidus conditions above 30 GPa and 3000 K. Here we present our advances in both experimental and analytical methods. We look at the partitioning of 6 siderophile elements (Ni, Co, Cr, V, Mn, and Nb) that have been extensively studied at lower P-T conditions and constrain the solubility of light elements (Si and O) at these extreme conditions. Experiments were conducted between 35-75 GPa and 3100-4400 K. We then update expressions that describe the partitioning behavior of these elements to address the validity of proposed core formation models (i.e. single-stage core formation model and continuous core formation model).

Ore processing and metallurgy technologies applied to soil washing: Feasibility studies in the Linares area (Andalucía, Spain)

C. SIERRA[1], D. JIMÉNEZ-GÁMEZ[1], J. MENÉNDEZ-AGUADO[1], E. AFIF[1], J. MARTÍNEZ[2], J. REY[2] AND J.R. GALLEGO[1]*

[1]Environmental Biotechnology and Geochemistry Group. University of Oviedo. C/Gonzalo Gut. S/N, 33600-Mieres (Asturias), Spain (*correspondence: jgallego@uniovi.es)

[2]Escuela Politécnica Superior de Linares, Universidad de Jaén, 23700 Linares (Jaén, Spain)

For centuries, an important mining industry was developed in the area of Linares (Andalucía, Spain). This activity produced a large quantity of waste materials, which were accumulated in the surrounding of the exploitation and ore processing sites, affecting the qulity of several Ha. of soil [1]. In this work, we have assessed the viability of physical separation of toxic elements, given that soil washing is a suitable remediation technique to reduce the volume of contaminated soil [2, 3]. On this purpose, we have conducted a feasibility study by means of chemical analyses, and a detailed edaphic and mineralogic characterization of the soils, followed by grain-size, gravimetric, and magnetic separation pilot-scale tests.

Chemical analyses revealed anomalous concentrations of Sb, Cu, Ag, Cd, Mn, Pb and Zn, exceeding both natural backgrounds and the maximum levels permitted by Spanish environmental laws. In this context, we propose an approach based on similar ore processing and metallurgy strategies to those used in the past to recover Pb and other metals in the study area [4]. Thus, wherever geochemical data indicated that the contaminants are predominantly present as free minerals (areas mainly related with mining waste), a treatment by means of grain-size classification methods is feasible. On the other hand, in soils with ancient metallurgy affection, the contaminants are more uniformly distributed in all size fractions; therefore the complexity is higher, and as a consequence, other treatments such as hydrodynamic separation (hydrocycloning), or magnetic separation (HGMS) are needed to complement grain-size classification.

Thermal stability of soils and the detection of use-induced changes

CHRISTIAN SIEWERT

University of Applied Sciences Dresden, Pillnitzer Platz 2, D-01326 Dresden, Germany (cs@csiewert.de)

Several investigations on soils are currently focused on sustainable land use. However, there are still no common laboratory method to distinguish soils from carbon containing substrates (CCS). This makes the detection and evaluation of use-induced soil changes not easy.

We tried to fingerprint natural soils using thermogravimetry. The goal was to create a reference base for easier detection of use-induced soil changes with a simple detection method. For this purpose, over 150 samples under natural vegetation were collected and analysed from natural parks, biosphere reserves and other protected regions in US, Europe, South America and Russia.

Using different statistical approaches, it was not possible to directly derive common characteristics of natural soils from peaks or curves from thermogravimetric data.

But, the thermal mass loss allows a reliable detection of organic carbon, nitrogen, clay and carbonates in soils with high accuracy [1]. Further, typical relationships were found to exist between mass losses in distinct temperature areas in soils under natural vegetation.

For example, nearly all natural soils characterised by a correlations between mass losses around 125 °C and 525 °C with high coefficient of determination (0.7 – 0.9). This correlation can easily be explained by the long term influence of clay minerals on water sorption (mass losses around 125 °C) and on accumulated of humic substances [2] (mass losses around 525 °C). In contrast, CSS are ususally a result of shorter time periods or prevalence of non biotic processes. Additional water binding by plant residues can modify mass losses aroun 125 °C and disturb the correlation. At 525 °C the decay of black carbon has a similar effect.

Further investigations should clarify to what extend the correlations found in natural soils can be used to distinguish soils from carbon containing substrates and to detect influences of cultivation, fertilization and other land use technologies.

[5]University of Sydney, Sydney, Australia

Organic biomarkers are valuable sources of information on the biodiversity and environment of early Earth. However, with organic biomarkers, especially in old samples, there are often problems of syngeneity and many of the most ancient biomarkers are suspected of being younger contamination.

A type of sample where biomarkers are better constrained in the rock is oil-bearing fluid inclusions, especially if single inclusions can be analysed. However, most inclusions, including Precambrian oil-bearing fluid inclusions are so small (less than 10 μm) that analyzing single ones with conventional techniques is not possible. Therefore, we have developed an approach employing time-of-flight secondary ion mass spectrometry (ToF-SIMS) to selectively open individual oil-bearing inclusions by C_{60}^+ ion etching, and to subsequently analyse their content. Using this approach steranes and hopanes could be detected in single Ordovician oil-bearing inclusions (15-30 μm) from the Siljan impact structure in Sweden.

Now the developed approach has been applied on Precambrian samples. Four different oil-bearing fluid inclusions trapped in a 1.43 Ga sandstone from the Roper Superbasin in Australia were opened and analysed with ToF-SIMS. The ToF-SIMS spectra of the oil in the different inclusions were similar to each other indicating that the same oil was trapped in all inclusions. In addition, the ToF-SIMS spectra contained peaks that could be assigned to alkanes, cycloalkanes, aromatic moities, steranes and hopanes.

With further development and if applied on other Precambrain samples this approach could help answering questions regarding early evolution of life on Earth.

The impact associated to wastewaters treatment plant discharges into a fluvial system (Central Portugal)

A. SILVA, N. CARVALHO, P. ALMEIDA, N. OLIVEIRA, I.M.H.R. ANTUNES, A. FERREIRA AND T. ALBUQUERQUE

Polytechnic Institute of Castelo Branco, 6000-243 Castelo Branco, Portugal (teresal@ipcb.pt)

The Ocreza River is an important fluvial system in inner central Portugal, which originates in the Gardunha Chain at 1160 meters high and stretching for about 80 km before flowing into the Tagus river. It has several creeks and tributaries along which there are several communities dedicated mostly to agriculture and livestock activities. The impact of several wastewaters treatment plants discharges on water quality must be characterized, monitored and, mostly controlled as it has a crucial role on local communities' welfare.

This paper focuses on the Alcains and Castelo Branco wastewaters treatment plants which discharges into the Líria River, an Ocreza's tributary. Twenty georeferenced water samples were collected between the wastewaters treatment plants discharges and the Ocreza river confluence. Secondary inflows were identified and sampling performed at approximately equal distances and, were conducted during three different hydrological periods in 2010: rainy winter (January), intermediate conditions (March) and dry season (June). The following chemical parameters were analyzed: biochemical oxygen demand (BOD), dissolved oxygen concentration (DO), dry residue, P_{total}, N_{total}; pH, temperature and microbiological parameters. The dissolved oxygen concentration (DO), biochemical oxygen demand (BOD) and microbiological parameters were used as indicators to the presence of organic matter in the body of water, and consequentlty as parameters for evaluating the environmental pollution.

The QUAL2kw software was used to construct a water quality model performing a coupled hydrodynamic and water dispersion model to simulate the pollution in the Ocreza River due to sewage effluent. The model's fair calibration is demonstrated by the simulation consistent results with field observations and demonstrate that the model has been correctly calibrated. The model is suitable for evaluating the environmental impact of sewage effluent on Ocreza River from the wastewaters treatment plant inflows, allowing feasibility studies of different treatment schemes and the development of specific monitoring activities.

Recognition of mucilage and microbial events on the Early–Late Pliensbachian (Lusitanian Basin, Portugal)

R.L. SILVA[1]*, L.V. DUARTE[1], J.G. MENDONÇA FILHO[2], F.S. DA SILVA[2], T.F. SILVA[2] AND M.J. COMAS-RENGIFO[3]

[1]IMAR-CMA and DCT, UC, 3000, Coimbra, Portugal (*correspondence: ricardo.silva@student.dct.uc.pt)
[2]LAFO, UFRJ, 21949-900, Rio de Janeiro, Brazil
[3]UCM-CSIC, 28040, Madrid, Spain

In the Lusitanian Basin (Portugal), the Early–Late Pliensbachian interval (c. a. 186 Ma, Early Jurassic) is characterized by the deposition of organic-rich marl–limestone hemipelagic alternations on a north-westerly dipping low-energy carbonate ramp [1]. The aim of this work is to present the characterization of these organic-rich facies at a basinal scale, supported by the combination of Sedimentology, Stratigraphy and Paleontology with Geochemistry, Organic Petrography, Palynofacies and Biochemistry.

Several well defined black shales (*s. l.*) are observed throughout the studied sections, where TOC values reach up to 26.3 wt.%. From the integration of the available data, we suggest that these black shales correspond to mucilageneous agreggates and/or microbial biofilm events, whose origin is related with palaeoceanographic and palaeoclimatic changes. Modern and fossil examples show that massive mucilage and microbial outbreaks can have severe effects on the biota [e.g. 2, 3] and that their preservation can be an important factor in influencing several elemental cycles and their major disturbances [e.g. 4].

It has been evoked that the Late Pliensbachian corresponds to a widespread organic matter preservation interval (Late Pliensbachian OMPI), linked to the complex chain of events that ultimately led to the Toarcian Oceanic Anoxic Event [5]. Our data highlights the relationship between microbial development and contemporaneous palaeoenvironmental changes and adds valuable information to understand their role in the modern world.

This work is a contribution to project PTDC/CTE-GIX/098968/2008 (FCT-Portugal, COMPETE/FEDER).

[5]Stable Isotope Laboratory, LABISE

The interaction between Central America and South America has been extensively studied due to important implications that the separation of the Caribbean and Pacific oceans may have in terms of oceanography, ecology (i.e. connectivity) and global climate. Timing the exact closure of the Panama Isthmus has remained difficult due to the lack of a well-constrained chronostratigraphic framework for the Panamanian-Colombian area. The Panama Basin is the main tectonic feature separating the Chorotega and Choco-Darien Blocks [1]. Previous investigations have suggested a connection between western Panama and North America at ca 19 Ma; implying disconnection between the Chorotega and Choco-Darien during that time [2]. However, recent geochronologic investigations along eastern and western Panama have suggested a tectonic interaction between Central America – South America at ca 23 Ma [3, 4].

The Darien Formation in the Choco-Darien Block consists of Eocene-Oligocene collisional arc-related volcanics. Exquisitely well-preserved coral reef patchy carbonate successions nonconformably overlay the Darien Formation. Sr-isotope chemostraigraphic data and calcareous nanoplankton suggests a depositional age between 23.3 and 13.65 Ma. The depositional age of such carbonate successions that cover the latest arc record in eastern Panama provides a unique temporal framework for the beginning of Panama-Northern South America tectonic interaction and the resulting Cenozoic paleoceanographic, paleoclimatic and paleobiologic changes in the neotropics.

Novel denitrifier method for measuring ^{15}N and ^{18}O of nitrate

H. SILVENNOINEN[1], J. ZHU[1]*, PT. MØRKVED[2], L. BAKKEN[1], J. MULDER[1] AND P. DÖRSCH[1]

[1]Norwegian University of Life Sciences, 1432 Ås, Norway (*correspondence: jing.zhu@umb.no)
[2]Institute for Energy Technology, 2007 Kjeller, Norway

The 'Denitrifier Method' using *Pseudomonas aureofaciens* to convert NO_2^- and NO_3^- quantitatively to N_2O, first devised by Sigman & Casciotti *et al*. [1, 2] has become a state-of-the-art method for nitrate preparation prior to IRMS analysis of ^{15}N & ^{18}O. This method is, however, relatively laborious and requires numerous successive steps of culturing, purging and concentration, all of which increase the risk of contamination by non-sample NO_3^- or N_2O. Moreover, the viability of the used *P. aureofaciens* cultures typically remains unreported, making it difficult to assess fractionation biases through incomplete NO_2^- and NO_3^- conversion. Here we present a novel denitrifier method that uses *Paracoccus denitrificans* (a complete denitrifier) to remove any NO_3^- and N_2O background from the growth medium before culturing *P. aureofaciens*. We found that *P. aureofaciens* cultures growing oxically in sterilized *P. denitrificans* treated medium can be switched successfully to anoxic respiration in the presence of 20 mM NH_4^+ with the sample NO_2^- and NO_3^- as the sole electron acceptor. This significantly shortens preparation times and reduces the risk of contamination (Tab. 1). We successfully tested the method for water samples with pH as low as 4 and for soil extracts containing 0.5 M KCl. First results applying the novel method to pore water samples from an N-saturated subtropical forest in southwest China will be presented.

Large sulfur isotope fractionation does not require disproportionation

MIN SUB SIM*, SHUHEI ONO AND TANJA BOSAK

Department of Earth, Atmospheric, and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139, United States (*correspondence: mssim@mit.edu, sono@mit.edu, tbosak@mit.edu)

Microbial sulfate reduction (MSR) controls the partitioning of sulfur isotopes among various sulfur reservoirs, leaving a sedimentary sulfur isotope record that is used to track the oceanic budgets of oxidants, the progressive oxygenation of Earth's surface, and the evolution of microbial metabolisms through geologic history. Although previous environmental studies and models suspected that MSR alone could produce sulfur isotope offset between sedimentary sulfides and sulfates as large as ~ 75‰, all culture studies to date reported enrichment factors for MSR ($^{34}\varepsilon$) smaller than 47‰. ^{34}S fractionation larger than 47‰ and its relationship to ^{33}S fractionation ($^{33}\lambda$) were thus thought to indicate active microbial disproportionation and oxidative recycling of sulfur.

A pure, actively growing culture of the recently isolated marine sulfate reducing bacterium (DMSS-1) produces sulfide depleted in ^{34}S by 6 to 66‰. The largest isotope effects occur during the very slow growth of cultures grown on glucose, a recalcitrant organic substrate. The large isotope effects and the associated $^{33}\lambda$ values produced by DMSS-1 during sulfate reduction approach the equilibrium value between sulfate and sulfide at low temperatures (<40 °C). These findings bridge the long-standing discrepancy between the upper limit for $^{34}\varepsilon$ in laboratory cultures and the corresponding observations in nature and indicate that near-equilibrium $^{34}\varepsilon$ and $^{33}\lambda$ do not unambiguously record the stepwise oxygenation of Earth's surface environment. Instead, the strong dependence of $^{34}\varepsilon$ on the availability and quality of natural organic matter suggests that temporal or regional changes in the sulfur isotope systematics may reflect the changing nature of organic material that fueled sulfate reduction during the Proterozoic and the Phanerozoic.

Iron distribution in the clay of weathering crust of Katalambinskoe ore field

Y.S. SIMAKOVA*, V.P. LIUTOEV AND A.Y. LYSIUK

Institute of Geology of RAS , Syktyvkar. 167982, Russia
(*correspondence: yssimakova@rambler.ru)

Samples of the so-called structureless clays from mature weathering crust of Katalambinskoe ore field have been studied. Kaolinizated white clay and ocher brown clay characterized using infrared (IR), EPR and Mössbauer spectroscopy. X-ray diffraction (XRD) study indicates that raw materials consists of low-ordered kaolinite (up to 70%), well-ordered muskovite and minor relics of initial chlorite. Major impurities in ocher clay are goethite, lepidocrocite, magnetite and uncrystallized iron oxide.

Kaolinite substituted muscovite and paragonite in the initial rocks. IR spectra in the region of stretching vibrations of OH groups are also indicated presence of structurally imperfect kaolinite. Chemical analysis of the kaolinizated sample show content Fe_2O_3 = 3, 10%, FeO = 0, 35%, in ocher sample - Fe_2O_3 = 20, 64% and FeO = 0, 44%, respectively.

Mossbauer spectrum of white kaolinizated clay can be described by a superposition of two doublet of three-and ferrous iron. According to [1], the doublet can be attributed to the octahedral position of ferric iron in the kaolinite structure. High linewidth of the doublet of ferric iron indicates a low ordering kaolinite. Ferrous doublet has parameters typical of octahedral cis-positions in muscovite present in the samples according to the x-ray analysis. It accounts for about 15% of the total iron content in the sample.

Sextet structure shows the presence in the brown clay of the two magnetically ordered phases, characterized by the values of magnetic hyperfine fields 500 and 470 kOe. It should be noted that the doublet spectrum can be observed in goethite, if present by nanoscale particles. According to X-ray analysis is goethite is the dominant Fe-containing phase.

Thus, in the process of weathering crust Katalambinskoe ore field iron can form oxide-hydroxide secondary phases and enter the structure of usually iron-free phyllosilicates (ex. kaolinite).

Biogeochemical footprint of the Ta-, and Nb-bearing carbonatite, Blue River Area, British Columbia, Canada

GEORGE J. SIMANDL[1,2], ROBERT FAJBER[1] AND COLIN E. DUNN[3]

[1]British Columbia Geological Survey, Victoria, BC, Canada
[2]University of Victoria, School of Earth and Ocean Sciences, Victoria, BC, Canada
[3]Consulting Geologist/Geochemist, Sidney, BC, Canada

This orientation survey demonstrates that coniferous trees are suitable sampling media in the exploration for carbonatites and related rare earth elements (REE), Ta, Nb, and phosphate deposits.

Twenty four samples of twigs with needles from Subalpine Fir (Fir) and White Spruce (Spruce) were collected over the Upper Fir carbonatite and surrounding amphibolites and paragneisses. Twigs and needles were analyzed separately. Twigs were milled using a Wiley mill. The resulting pulps were digested in HNO_3, then Aqua Regia and then analyzed by ICP-MS/ICP-ES. Needles were ashed, digested in Aqua Regia and then submitted for ICP-MS/ICP-ES analysis.

Light rare earth elements (LREE), Y, Zr and P in both twigs and needles are good exploration vectors for carbonatite-related REE and apatite mineralization. The highest concentrations of LREE are detected directly over carbonatites or fenites. Concentrations of heavy rare earth elements (HREE) are near or below the detection limit. Tantalum is found in detectable concentrations only in spruce twig samples spatially related to carbonatite. Detectable Ta concentrations range from 0.001 to 0.003 ppm. Niobium concentrations range from 0.02 to 0.24 ppm in Spruce twigs, 0.005 to 0.071 ppm in Spruce needles (dry weight normalized), and 0.012 ppm to 0.030 ppm in Fir needles (dry weight normalized).

Spruce twig data show a positive correlation between Fe, REE and Zr; Nb correlates positively with Fe, Ti, Ce, and Nd. Fir twigs were not analysed. Spruce needle data suggest strong positive correlations between P, Mg and Ti, as well as Nb and REE, and Zr and Fe, and a moderate positive correlation exists between P and Ca. There are not enough Fir needle samples for formal statistical analysis, however, strong positive correlations are suspected between Fe and REE, Fe and Ti, and P and Zr.

Rare Earth Elements (REE) recovery as a by-product of fertilizer production from sedimentary Phosphate deposits – Conceptual evaluation

LAURA SIMANDL[1]*, GEORGE J. SIMANDL[2,3] AND ROBERT FAJBER[2]

[1]St-Michaels University School, 3400 Richmond, Victoria, British Columbia, Canada, V8P 4P5 (*correspondence: laura.simandl@smus.bc.ca)
[2]British Columbia Ministry of Energy and Mines, Victoria, British Columbia
[3]University of Victoria, School of Earth and Ocean Sciences, Victoria, BC, Canada

Worldwide, phosphate deposits are classified into three main categories: a) phosphorites (sedimentary phosphate deposits), b) apatite-rich igneous rocks and related residual deposits, and c) modern and ancient guano accumulations. Marine phosphorites are the most significant in terms of global phosphate production, reserves and resources. Phosphorites average approximatley 460 ppm total rare earth elements (∑REE), are enriched in REE relative to typical shale (207 ppm ∑REE), and can contain more than 1600 ppm of ∑REE. Total concentration and proportions of individual REEs within phosphorites vary substantially.

Currently, China produces the vast majority of the world's REE supply. Rapid increases in internal demand for REE have motivated the Chinese government to introduce limits and taxes on REE exports. The resulting insecuirty regarding global REE supply created a rise in REE prices. The world's REE demand for 2010 was estimated at 125 000 tonnes. Assuming average REE content of 460 ppm ∑REE in phosphorite, the world's phosphate production of 170 million tonnes represents over 70 000 tonnes of contained REE.

Considering the phosphorites of the Fernie Formation in British Columbia (Canada), at current REE prices, a tonne of phosphate rock has an 'in the ground value' of more than US$ 160. This is more than the current market value of high-quality commercial phosphorite concentrate (approximately US$ 130-150). The above rudimentary considerations indicate that at current REE prices, the economic viability of REE recovery as a by-product of phosphate mining should be re-evaluated.

In situ SXRF determination of trace element abundances in aqueous fluid at 1 - 3 GPa and 300 – 500°C: Applications to subduction zone element cycling

A. SIMON[1], L. TANIS[1], O. TSCHAUNER[1], M. FRANK[2], P. CHOW[3], Y. XIAO[3], G. SHEN[3] AND J. HANCHAR[4]

[1]Department of Geoscience, High Pressure Science and Engineering Center, University of Nevada Las Vegas, Las Vegas, USA

[4]Department of Earth Sciences, Memorial University of Newfoundland, Canada

Interpreting trace-element variability in arc magmas that are hypothesized to have an aqueous fluid signature is predicated on having a quantitative understanding of the aqueous fluid-mediated trace-element transfer at PT conditions attending slab-sediment devolatilization. Experimental efforts to quantify the element-scavenging potential of aqueous fluid (s) were historically performed ex situ by recovery-type experiments. Here, we report further development of a synchrotron-based hydrothermal diamond anvil cell technique that allows *in situ* quantitative determination of trace element abundances in aqueous fluid at PT conditions appropriate for slab devolatilization. Notably, *in situ* reversals can be performed. The technique was developed by measuring the dissolution of YPO_4 (xenotime), a proxy for the behavior of heavy rare earth elements (HREE), in aqueous fluid at 1 to 3 GPa and 300 to 500°C. Yttrium concentrations and pressure were measured *in situ* by using synchrotron X-ray fluorescence (SXRF) and X-ray diffraction (XRD) of gold, respectively. Yttrium standards were measured in the same sample chamber as xenotime experiments, and a multi-point standard calibration curve was used to calculate Y abundances in the fluid in the xenotime dissolution experiments. This ensures a constant fluorescence excitation volume for the standards and the unknowns. The new data indicate that Y (HREE) concentrations in aqueous fluid are relatively constant at 300 to 500°C and 1 to 3 GPa, suggesting that increasing temperature, at a given pressure, does not increase the HREE-scavenging ability of aqueous fluid. These data have important implications for HREE recycling in subduction zone environments.

Balancing of geological acidity and buffering potentials of Mid German lignite open casts by long-term experiments

A. SIMON[1], N. HOTH[1], J. RASCHER[2] AND P. JOLAS[3]

[1]TU Bergakademie Freiberg Akademiestraße 6, 09596 Freiberg (andre.simon@ tu-freiberg.de)
[2]GEOmontan, Am St. Niclas Schacht 13, 09599 Freiberg
[3]MIBRAG mbH, Glück-Auf-Straße 1, 06727 Theißen

Problem and Solution

Open cast lignite mining induces sulphide weathering associated with Acid Mine Drainage - phenomena (mobilisation of acidity, sulphate, heavy metals). This partial weathering of sulphides is embedded in hydro-geochemical buffering reactions. Essential buffers are carbonates, aluminium/ iron hydroxides and aluminium silicates. Especially the carbonate buffering is important [1].

For sustainable strategic activities to reduce the acidification of ground waters by the lignite dump sites Peres and Schleenhain (Germany, South of Leipzig/Saxony), it is essential to evaluate the acidification and buffer potentials of the overburden units. These investigations need to consider the applied mining technology [2].

In long-term experiments (>500d), wet samples of forefield drillings of the five aquifers and some aquiclude units were exposed to weathering (T = 10 °C).

These tests shows clearly that the Oligocene aquifers (Aquifer 2 and 3) are the main problem sediments. The low pH values are coupled to a high acidity, iron and sulphate release. In contrast the glacial marly till contributes by buffering carbonates.

The subsequent buffering tests with aquifer 2 and 3 material in combination with the glacial till sediments, shows a clear effective buffering with increasing addition of glacial till. A release of iron and heavy metals can be completely prevented for longer times. The detailed investigation of the already existing water phase of the dump site Peres confirms the buffering effect by these carbonates.

Therefore the overburden dumping technology will be even more directed to the effective buffering by mixing the problematic materials with the buffering tills.

Ca isotopes of Central American arc basalts lack carbonate component

J.I. SIMON[1], S.T. BROWN[2] AND D.J. DEPAOLO[2]

[1]KR, NASA Johnson Space Center, Houston, TX 77058, USA (Justin.I.Simon @NASA.gov)
[2]Center for Isotope Geochemistry, Unversity of California and Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA

Subduction of sediment fundamentally represents a loss of continental crust and a gain of relatively enriched components to the mantle. Provided that possible mixing end members can be defined, stable Ca isotope signatures provide a powerful probe for identifying various sources in volcanic arc magmas. For example, marine carbonates are enriched in light Ca isotopes by about -0.2 to > -1.0‰ [1], relative to igneous rocks and should clearly implicate subducted sediment. Here we present Ca isotopic compositions for basalts from along the active Central American volcanic arc front that represent the range of trace element signatures indicative of various amounts of sediment recycling through the subduction zone (e.g. based on Ba/La values).

In an attempt to balance sedimentary input and arc volcanic output across the Nicaraguan margin [2] compared sediment input (i.e. high Ba/La) in arc magmas to offshore sedimentary drill cores, concluding that over the last ~20 Ma as much as 75% of the modern sedimentary column has been subducted. Despite measuring samples with trace element signatures that imply large amounts of subducted carbonate, we find no resolveable evidence for a low $^{44}Ca/^{40}Ca$ component. In detail, arc basalts from Guatemala, Honduras, and Nicaragua range from 0.04 to -0.18‰ in $^{44}Ca/^{40}Ca$ (mantle=0 scale). These nearly indistiguishable results are somewhat surprising given the fact that $CaCO_3$ has ≥4 times more Ca than the basalts. Mass balance shows that ~2-10% carbonate should produce resolvable effects.

Several potential reasons for the missing Ca isotopic signal are considered, including that: (1) subducted carbonate has an isotopic composition similar to mantle Ca, cf. [1], (2) subducted carbonate is largely dolomite, and/or (3) the record found in the drill cores is not representative of subducted sediment in the modern arc. Our new Ca isotope data imply that, at least for the Nicaraguan volcanic arc, trace element geochemistry may be less well understood than we believe. This is supported by the fact that the highest $\delta^{18}O$ values are associated with low Ba/La [3], and not the high Ba/La values typically correlated with increasing fluids from the slab.

The influence of melt structure on the partitioning of trace elements

S. SIMON[1] *, M. WILKE[1], S. KLEMME[2], W.A. CALIEBE[3] AND K.O. KVASHNINA[4]

[1]GFZ, German Research Centre For Geosciences, Potsdam, Germany (*correspondence: ssimon@gfz-potsdam.de)
[2]Westfälische Wilhelms-Universität, Münster, Germany
[3]Deutsches Elektronen-Synchrotron, Hamburg, Germany
[4]European Synchrotron Radiation Facility, Grenoble, France

Partitioning of trace elements between melt and crystal is a versatile tool to reconstruct the origin of igneous rocks, thus it is essential to understand the controlling parameters. It is generally accepted that the partitioning of trace elements (TE) is controlled by T, p, fO_2 and crystal chemistry (e.g. [1]). Several studies have also proposed a significant influence of the melt composition and thus melt structure on TE partitioning [2 – 4]. Particularly, Prowatke & Klemme's results [4] on TE partitioning between melt and titanite, which varied over several orders of magnitude, suggest a strong control of the melt composition and thus melt structure. To date there is no clear understanding of the relationship between melt structure and element partitioning. Ponader & Brown [5] report already that coordination of some rare earth elements (REE) in quenched melts changes with the degree of polymerization of the melts, this was used to explain differences in chemical partitioning. However they did not provide a direct correlation between the analysis of the element coordination and partitioning data.

In this study, different melt compositions were taken from Prowatke & Klemme [4], doped with selected REE (0.5 wt%, 2 wt%) and synthesized as glasses. EXAFS was used to get information about coordination and radial distances to the neighboring atoms of the REE in the glasses. Resonant Inelastic X-ray Scattering (RIXS) provides information about the electronic structure and was used to derive further constraints on the coordination. The measured EXAFS spectra show small variation in the distance to the first oxygen neighbours to the different glasses. The RIXS and high resolution XANES indicate only slight differences in site symmetries. Although only preliminary, our results show that the strong difference in element partitioning correlates only with rather small changes in the TE coordination.

Formation of carbonate minerals during magmatic/hydrothermal alteration of volcanic rocks at Unzen volcano, Japan

A. SIMONYAN[1]*, S. DULTZ[1,2], H. BEHRENS[1], J. FIEBIG[3] AND K. VOGES[1]

[1]Institute for Mineralogy, Leibniz University of Hannover, Callinstr. 3, 30167 Hannover (*correspondence: simonian@mineralogie.uni-hannover.de)
[2]Institute of Soil Science, Leibniz University of Hannover, Herrenhäuser Str. 2, D-30419 Hannover
[3]Institute for Geosciences, J.W. Goethe University of Frankfurt, Altenhöferallee 1, D-60438 Frankfurt am Main

The alteration processes of dacitic and andesitic rocks of Unzen volcano are characterized by almost complete substitution of amphibole phenocrysts with two types of carbonates (up to 20 wt.%), quartz, muscovite and chlorite. In this study we investigate the main factors responsible for the alteration of porous volcanic rocks at Unzen.

It is determined that unaltered dacite has pores in the range from 100 nm to 10 μm, whereas the most frequent pore sizes for coherent altered dacites are observed in the range between 30 and 400 nm. All samples are characterized by interconnected porosity.

The unaltered amphiboles exhibit a homogeneous oxygen isotopic composition, with $\delta^{18}O$ vs VSMOW varying between 6.6 and 7.0‰, pointing to their primary magmatic origin. The oxygen isotopic composition of carbonates substituted amphiboles ranges from 6.0 to 9.1‰ vs VSMOW and their carbon isotopic composition varies between –4.7 and –6.4‰ vs VPDB. It implies that magmatic CO_2 and primary silicates provide the main sources for the carbonate carbon and carbonate oxygen, respectively. Hydrogen isotope composition of unaltered amphiboles shows typical magmatic signatures (δD=-48‰) without any evidence for late- or post-magmatic contamination by meteoric waters.

A series of hydrothermal fluid/rock interaction experiments in different systems, i.e. dacite or pure amphibole + H_2O, $H_2C_2O_4 \cdot 2H_2O$, $Ag_2C_2O_4$, Pl, $CaCO_3$ in different proportions were conducted at temperatures from 300 to 700°C and at pressures from 100 to 300 MPa, respectively. The first analyses of the experimental products show that amphiboles participate in exchange reactions with fluid with the formation of new mineral phases, e.g. $CaSiO_3$, however the size of produced phases was too small for proper identification. Raman spectra confirm that carbonates are indeed present as secondary phases in altered amphiboles (<5μm), providing constraints on the carbonation reactions.

Further experiments are required to reproduce natural mineral assemblages and to determine typical conditions for carbonate formation in Unzen conduit.

Do ^{226}Ra-^{230}Th isochrons provide realistic crystallization ages?

KENNETH W.W. SIMS[1]*, SYLVAIN PICHAT[2], MARK REAGAN[3], PHILLIP KYLE[4], NELIA DUNBAR[4], JANNE BLICHERT-TOFT[2,]

[1]Dept of Geology and Geophysics, University of Wyoming, Laramie,, WY, USA (ksims7@uwyo.edu)

[3]Department of Geoscience, University of Iowa Iowa City, IA, USA (mark-reagan@uiowa.edu)
[4]N.M.B.G/E&ES Department, New Mexico Tech, Socorro, NM, 87801, USA (kyle@nmt.edu, nelia@nmt.edu)

In this contribution we investigate the timescales of magma genesis, melt evolution, crystal growth rates and magma degassing in the Mt Erebus magmatic system using measurements of ^{238}U-^{230}Th-^{226}Ra-^{210}Pb-^{210}Po; ^{232}Th-^{228}Ra-^{228}Th and ^{235}U-^{231}Pa-^{227}Ac. These are the first measurements of ^{231}Pa-^{227}Ac in volcanic samples and thus this is the first data set to present the entire suite of relevant ^{238}U, ^{235}U and ^{232}Th decay series nuclides in a volcanic system. Our sample suite consists of 22 historic bombs, ranging from 1972-2005; and 5 anorthoclase megacrysts separated from historic bombs for the years 1984, 1989, 1993, 2004, 2005. These samples ^{238}U-^{230}Th and ^{230}Th-^{226}Ra are significant and uniform over the 36 year historical record. The anorthoclase megacrysts and phonolite glass show complimentary ^{226}Ra/^{230}Th disequilibria. In all samples, ^{210}Pb/^{226}Ra are in secular equilibrium for both phases. For phonolite glass separates ^{227}Ac/^{231}Pa is also unity. For the phonolite glass ^{228}Ra/^{232}Th is in equilibrium, whereas in the anorthoclase megacrysts ^{228}Ra/^{232}Th is significantly greater than unity..

Instantaneous crystal fractionation, with long magma residence time (> 100 years, < 3 kyrs, depending on D_{Ba}/D_{Ra}), can account for the ^{238}U-^{230}Th-^{226}Ra-^{210}Pb and ^{235}U-^{231}Pa-^{227}Ac systematics. However, the significant ^{228}Ra/^{232}Th disequilibria in the anorthoclase megacrysts preclude this simple interpretation. To account for this apparent discrepancy we have developed an open-system, continuous crystallization model, which incorporates both nuclide in-growth and decay during crystallization and recharge. Our model can successfully reproduce all of the measured ^{238}U- ^{235}U- and ^{232}Th- decay series disequilibria. More importantly, this model shows that when the timescale of crystallization is comparable to the half-life of ^{226}Ra, the simple ^{230}Th-^{226}Ra isochron techniques typically used in most U-series studies likely provide erroneous ages.

Dissolved ^{230}Th-^{232}Th dynamics in the Eastern Tropical Pacific Ocean

AJAY K. SINGH[1], FRANCO MARCANTONIO[1] AND MITCHELL LYLE[2]

[1]Department of Geology & Geophysics, Texas A& University, College Station, TX 77843, USA (*correspondence: asingh1@neo.tamu.edu)
[2]Department of Oceanography, Texas A&M University, College Station, TX 77843, USA

We present data for dissolved ^{230}Th and ^{232}Th concentrations in seawater from nine depth profiles along a transect (~85°W) from about 7°N to 8°S in the eastern tropical Pacific Ocean. Our sampling sites cover the highly productive regions of the Pacific cold tongue close to the equator, and less productive regions of the Panama and Peru Basins. Dissolved ^{230}Th is thought to be scavenged onto sinking particles, and reversible exchange between dissolved and particulate phases takes place throughout the water column. As a result vertical dissolved ^{230}Th profiles should show a linear increase in ^{230}Th concentration with increasing water column depth.

Filtered (dissolved fraction of ^{230}Th-^{232}Th) and unfiltered (dissolved and particulate fraction of ^{230}Th-^{232}Th) seawater samples have been processed following established protocols developed by GEOTRACES. Our data thus far show little evidence for a linear increase in the concentration of dissolved ^{230}Th with depth, and the observed vertical structure may be related to either water mass or particle flux effects. Dissolved ^{230}Th concentrations range from 0.25 to 1.46 dpm/1000L for filtered samples. Dissolved ^{232}Th concentrations are low and range from 0.002 to 0.007 dpm/1000 L for filtered samples. While concentrations of ^{230}Th are slightly higher in the unfiltered samples, ^{232}Th concentrations are ususally much higher in the unfiltered samples (up to 170% higher), compared to those concentrations in the filtered samples. The greatest differences between filtered and unfiltered Th concentrations occur in the bottommost samples. Our preliminary results also indicate that that there is a concentration gradient along the transect—higher concentrations of ^{230}Th are found in the low-particle-flux Peru Basin while very low concentrations of ^{230}Th have been determined in profiles closer to the Panama Basin. Like the ^{230}Th data, the ^{232}Th concentrations are highest the further south in the transect. However, in contrast to the ^{230}Th concentrations, there is little structure in the ^{232}Th concentrations, which vary little with depth.

Grain size analysis of sediments of Thar Dessert, India to infer sedimentary environment

CHANDER KUMAR SINGH, RINA KUMARI AND SAUMITRA MUKHERJEE

School of Environmental Sciences, Jawaharlal Nehru University, New Delhi-110067

Grain size is a fundamental descriptive measure of sediment and sedimentary rock. Grain size parameters are useful for recognizing sedimentary environments as dune, river, beach marine and others of continental shelf through graphical, moment and statistical methods. Bivariate plots between various statistical grain size parameters can be successfully used for distinction of such environments. The statistical grain size parameters were treated using different statistical tools such as factor and discriminatory analysis to decipher the depositional history of the sediments of the study region. The analysis suggests that the deposits are not unequivocally aeolian, but contain sediments contributed by marine, shallow marine, fluvial, aeolian and lacustrine processes. Fluvial and fluvio-lacustrine deposits formed the base for the aeolian deposition in the region. SEM analysis of grains are a type of caliche formation in which fine grained calcareous sediments has reached near surface by capillary action and deposited. Angular outlines and features such as high relief, sharp edges and articulate steps were observed in the grains. The results of bivariate plots of mean (phi), moment mean and discriminant analysis does not show any specific trend of grain size for different geomorphic environments however these functions states that the sedimentary depositional environment in the study area has been mainly controlled by fluvial and marine activities but the importance of aeolian action also can not be ignored.

Geochemistry and mineralogy of Tertiary sedimentary rocks from Kerala, South India – Implications to REE behaviour under intense chemical weathering

PRAMOD SINGH* AND C.G. LAKSHMIDEVI

Department of Earth Sciences, Pondicherry University, Pondicherry 605014, India
(*correspondence: pramods@yahoo.com)

The Tertiary sedimentary rocks of Kerala along the south-west coast of India are mainly divided into three formations, Vaikom, Warkala and Quilon. This research evaluates the clay mineral and geochemical compositions including the rare earth elements (REE) of the mudstones and sandstones from two sedimentary sections of Warkala formation from the Karuchal and the Warkala region. The high CIA values ranging between 97 and 99 for Karuchal area and between 85 and 98 for Warkala area suggests that these sediments are extremely weathered. Further Kaolinite as the dominant clay in rocks from Karuchal section and Kaolinite / Gibbsite as the dominant clay in rocks from Warkala section also corroborate higher degree of weathering. All elements except Al, Ti and Ni exhibit depletion in comparison to UCC. The chondrite normalised REE pattern exhibit high degree of fractionation, ((Ce/Yb)n ranging between 30 and 67 for sediments of Karuchal section; (Ce/Yb)n ranging between 14 and 50 for sediments of Warkala section. On normalizing with all the probable source rocks exposed in the area, the REE plot of the sediments exhibit LREE enrichment and HREE depletion. This indicates that the higher (Ce/Yb)n ratios are not because of source, but due to the loss of HREE and residual enrichment of LREE bearing phases. This suggests mobilisation and removal of HREE from the system under extreme chemical weathering. Our finding has important implications as REE is commonly accepted to reflect the nature of exposed continental crust [1].

Sustainable water resource management in Eastern Punjab using remote sensing and GIS to demarcate water potential zones

RAVI PRAKASH SINGH[1], C.K. SINGH[2] AND S. MUKHERJEE[3]

[1](singhravi004@gmail.com)
[2](chanderkumarsingh@gmail.com)
[3](saumitramukherjee3@gmail.com)

Water is a fluctuating resource making it difficult to measure in time and in space. To demonstrate the efficiency of the geographic information system (GIS) for groundwater management, information on the parameters controlling groundwater such as lithology, geomorphology, soil type, land use and land cover and lineament analysis were analyzed. IRS LISS-III and Landsat satellite data of the area was used to infer information on the geologic lineaments and geomorphology. To identify linear features i. e lineament enhancement and directional filtering was performed on single bands of Landsat images. Thematic maps for geology, slope, soil, geomorphology and lineament were prepared and integrated in GIS by assigning the weights and ranking to various parameters controlling the occurrence of groundwater to generate the groundwater potential map for the study area. The results indicate that the floodplain of river and its adjoining areas have very good groundwater potential, whereas the steeply sloping area in the northern part having high relief and slope possesses poor groundwater potential. The groundwater potential zones were obtained by weighted overlay method using the spatial analysis module in ArcGIS 9.0. The southern part of the study area showed highest decline in water level in last 3 decades. Thus a holistic water resource management strategy needs to be developed for this part of the district. The floodplain of the river in the area holds potential for further groundwater development as these areas belong to good class in GPI map.

Toward a self-consistent pressure scale: Elastic moduli and equation of state of MgO and Ringwoodite by simultaneous X-ray density and Brillouin sound velocity measurements at high-P and high-T

STANISLAV SINOGEIKIN[1,2]*, DMITRY LAKSHTANOV[2,3], VITALI PRAKAPENKA[4], CARMEN SANCHEZ-VALLE[2,5], JINGUING WANG[2,5], GUOYIN SHEN[1,4] AND JAY BASS[2]

[5]Institute for Mineralogy and Petrology, ETH Zurich, CH

Accurate phase diagrams and PVT equations of state (EOS) of materials strongly depend on the PVT calibrations of standard materials (e.g. MgO, NaCl, Au, Pt), which currently do not predict identical pressures at the same experimental conditions. MgO is one of the simplest and most studied materials and is a common pressure standard, although its accurate high-PT EOS is still uncertain. The direct way of obtaining a self consistent pressure scale is by measuring acoustic velocities (Vp and Vs) and density simultaneously. Such P-V-T-Vp-Vs measurements allow one to determine the pressure directly, without resort to a separate calibration standard.

Recently, as part of a major COMPRES initiative, we have constructed a Brillouin spectrometer at GSECARS, APS, which allows accurate simultaneous sound velocity and lattice parameter measurements at high P and high T. Such measurements were performed on single crystal MgO in diamond cells. At each PT we measured the unit cell parameters and the acoustic velocities in several crystallographic directions, and directly obtained all three single crystal, and isotropic adiabatic bulk (Ks) and shear (μ) elastic moduli.

In addition we demonstrate that successful P-V-T-Vp-Vs measurements can be performed on certain polycrystalline materials, e.g. Ringwoodite (gamma-Mg_2SiO_4). The results of these experiments and implications for a self consistent P-V-T (-Vp-Vs) pressure scale will be presented and discussed.

In situ Fe-Mg isotopic analysis of zoned olivines

C.K. SIO[1], N. DAUPHAS[1], F.-Z. TENG[2], R.T. HELZ[3] AND M. CHAUSSIDON[4]

[1]Origins Laboratory, Dept. of the Geophysical Sciences, The University of Chicago (ksio@uchicago.edu)
[2]Dept. of Geosciences and Arkansas Center for Space and Planetary Sciences, The University of Arkansas
[3]Uinted States Geological Survey, Reston, VA
[4]CRPG, Vandoeuvre lès Nancy, France

Chemical diffusion profiles in zoned olivines may be used to infer the thermal history of the system surrounding them. However, diffusive transport is not the only way to produce a chemical gradient. An olivine that crystallized rapidly may produce a similar zoning pattern.

Fe and Mg isotopic analyses of bulk olivines reveal that isotopes can be used to recognize chemical diffusion in olivines [1-3]. Chemical diffusion can induce large isotopic fractionations because light isotopes always diffuse faster than their heavier counterparts [4-5]. At equilibrium, little isotopic fractionation is expected given the high temperatures of magmatic systems.

Olivines in Kilauea Iki lave lake have large chemical zoning profiles and lighter iron isotopic compositions than the bulk basalts [1]. Teng *et al*. [1] showed that in these olivines, the isotopic compositions are correlated by a slope of -3.3 in a plot of $\delta^{56/54}$Fe vs. $\delta^{26/24}$Mg, in close agreement to the predicted slope of -2.7 for binary diffusion [2]. Here we provide definite evidence that diffusive transport is responsible for the light Fe isotopic compositions measured in olivines in Kilauea Iki lava lake.

A zoned olivine ~4 mm in size was microdrilled in two orthogonal traverses for Fe and Mg isotopic measurements. Isotopic compositions were measured by MC-ICPMS. Profiles are observed with iron isotopic compositions ranging from -1.2 ‰ in the core to to -0.2 ‰ in the rim ($\delta^{56/54}$Fe deviations from IRMM-014). The variations can be explained by diffusion of Fe into olivine following magmatic evolution towards more Fe-rich and Mg-poor compositions.

In situ Fe and Mg isotopic measurements in olivines can help identify grains that are affected by chemical diffusion. These olivines may be used as tools for diffusion-based geothermometry.

Potentially toxic metal bearing mineral phases in total suspended particles from Budapest, Hungary

P. SIPOS[1], E. MÁRTON[2], T. NÉMETH[1], V. KOVÁCS KIS[3], Z. MAY[4] AND Z. SZALAI[5]

[1]HAS Institute for Geochemical Research, Budapest, Hungary (sipos@geochem.hu)
[2]Paleomagnetic Laboratory, Eötvös Loránd Geophysical Institute, Budapest, Hungary
[3]HAS Research Institute for Technical Physics and Materials Science, Budapest, Hungary
[4]HAS Institute of Materials and Environmental Chemistry, Budapest, Hungary
[5]HAS Geographical Research Institute, Budapest, Hungary

Total suspended particles (TSP) in the urban air can be both inhaled and ingested so causing health damage due to their size, shape or toxic components. In this study mineralogical (XRD, AEM), geochemical (XRF) and magnetic (MS) analyses were performed to characterize the mineral phases containing potentially toxic metals in TSP from three sampling sites in Budapest. The samples represent wide range of physico-chemical properties. Their particles are generally below 50 μm with a maximum frequency at around 10-12 μm. Between 45 and 80% of their particles belong to the PM10 fraction. They show significant enrichment in several potentially toxic metals with concentrations 1342-19 046 mg/kg for Zn, 434-3597 mg/kg for Pb, 394-699 mg/kg for Zn and 38-144 mg/kg for As. Their main mineral components reflects the geological characteristics of the sampling areas. Additionally, large amount of magentite (up to 15%) and amorphous organic matter, as well as gypsum and halite was also found in the samples.

The most important toxic metal bearing mineral phases are spherular or xenomorphic magnetite particles containing 2-3 wt% Pb and Zn. These magentite particles often form aggregates and are closely associated with soot and/or clay minerals. In samples with high magnetite content toxic metal-free magnetite spherules up to a few micrometer size also appear. The magnetic analyses showed that the sizes of the magnetite particles is rarely below 30 nm. Clay minerals and mica particles may also contain significant amount of Zn (up to 5wt%). Additionally, ZnO and $ZnCO_3$ particles were also found in the sample with highest Zn content. Magnetite particles are resistant to weathering releasing its toxic components slowly to the environment, while layer silicates may be the source of mobile toxic metals in these samples. The study was financially supported by the OTKA (K 76317 and K 75395).

Pyroxene and olivine exsolution textures in majoritic garnets from the Mir kimberlitic pipe (Yakutia)

E.A. SIROTKINA*, A.V. BOBROV, V.K. GARANIN, A.V. BOVKUN, B.B. SHKURSKII AND D.V. KOROST

Geological Faculty, Moscow State University, Moscow, Russia (*correspondence: katty.ea@mail.ru, archi3@yandex.ru)

Majoritic garnets are widely abundant as inclusions in diamonds worldwide [1]. Pyroxene exsolution textures were registered in garnets from mantle xenoliths in kimberlites [2, 3], as well as in rocks of ultrahigh-pressure metamorphic complexes [4], which provides evidence for their crystallization at pressures >7–8 GPa. We studied three large (>5 mm) garnet xenocrysts (Samples 317, 559 and 563) from the Mir pipe (Yakutia) containing regularly oriented pyroxene and olivine lamellae with angles of 71–72° between them. Garnets of all samples are pyrope-rich (75.1–78.6 mol %), with medium CaO (4.5–5.8 wt %) and low Cr_2O_3 (up to 0.59 wt %) concentrations. Clinopyroxene lamellae are enriched in diopside component (89.9–94.4 mol %). Olivines are characterized by the high Mg# (up to 0.96) and extremely high NiO concentration (1.6 wt % in Sample 559; 2.79 wt % in Sample 317). According to the data of 3D X-ray tomography using a scanner SkyScan1172 and 3D analysis (CT-An software), garnet (Sample 317) contains 9 vol % pyroxene and 0.5 vol % olivine lamellae. Calculation of the compositions of primary garnets demonstrated that Si content in them exceeded 3 f. u. (3.084 in Sample 317; 3.088 in Sample 559; 3.094 in Sample 563) providing evidence for incorporation of majoritic component. The formation of such garnets occurred at pressures >7.5 GPa and high temperatures (Ni in majoritic garnet and olivine). Subsequent decrease of *PT* parameters to 3.0–3.1 GPa and 950–1000°C [5] resulted in pyroxene and Ni-olivine exsolution in former majoritic garnet.

The slow dissolution kinetics of Mg-rich silicates has become a critical issue for the geologic CO_2 sequestration in basic rocks. Previous batch carbonation studies on San Carlos olivine performed in CO_2 saturated water (at 90°C and PCO_2= 280 bar) have focused on the role that secondary phases, such as amorphous silica layers (SiO_2 (am)), have on the transport of reactants from and to the reactive surfaces. The fluid composition remained roughly constant over the duration of the experiment, close to saturation with respect to amorphous silica and with a $[Mg^{2+}]/[SiO_2$ (aq)] ratio close to stoechiometric release, suggesting a passivation of the olivine surface by the silica layer.

In order to accelerate the dissolution process, organic ligands such as citrate and acetate were added to the solutions and tested at 1M and 0.1M concentrations in similar batch experiments. An intrinsic increase of the dissolution rate of olivine was expected prior to the formation of a passivating silica layer.

Preliminary results confirm this idea since Mg was released in non-stoechimoetric proportions with respect to SiO_2 (aq) (found to be in equilibrium with SiO_2 (am)).

Similarly, a slight increase of temperature (from 90°C to 120°C) accelerated the reaction kinetics as well, possibly impacting the textural properties of SiO_2 (am). Current TEM investigations are directed to confirming a possible link between the observed increase of the rate and textural properties of secondary phases. In addition, because carbonate minerals have a retrograde solubility, thermodynamical modelling suggests that this temperature increase should allow the fluid to reach saturation with respect to carbonates before reaching saturation with respect to SiO_2 (am). Enough Mg can therefore be released to initiate the formation of carbonates before the silica precipitates and passivates the olivine surface.

[3]Dept. Chemistry, University of Reading, RG6 6AB, UK (g.d.brown@reading.ac.uk)

Earthworms can be found living in arsenic contaminated soil. Generally earthworm activity increases the mobility and bioavailability of contaminants [1]. Using soil collected from Devon Great Consols containing 1150 mg As kg^{-1} we have investigated how the secretion of earthworm mucus and the passage of soil through the earthworm gut impacts mobility and speciation of As.

Lumbricus terrestris were cultivated in the As-contaminated soil and the casts collected. Water soluble As increased from 1.6 mg kg^{-1} in the bulk soil to 18 mg kg^{-1} in the casts. Casts were then aged and this effect was still present 56 days after soil excretion. Analysis indicated that these changes were due to release of As(V) from soil particles during the digestion process as a result of increases in pH and increased concentrations of disolved organic carbon. No reduction of As(V) to As(III) was detected despite passage of the As through the anoxic rear-gut of the earthworm.

Solutions of earthworm mucus were produced by washing earthworms with deionised water. These solutions were then used as an extractant for the As-contaminated soil. At low mucus concentrations As extraction was reduced relative to deionised water due to formation of ternary complexes between the amino acids present in the mucus, As and surfaces of Fe oxyhydroxides. However, at higher mucus concentrations increased pH and dissolved organic carbon effects dominated resulting in increased extraction of As.

The mobilisation of As (and other elements) from contaminated soils in the environment by cast production and mucus secretion may allow for accelerated leaching or uptake into biota which is under-estimated in current risk assessments based on analysis using soils in the absence of soil biota.

Continental subduction, slab breakoff and eduction: End-member processes for UHP rock histories

ELENA SIZOVA, TIBAULT DURETZ AND TARAS GERYA

Institute of Geophysics, Swiss Federal Institute of Technology, Sonneggstrasse 5, 8092 Zurich, Switzerland (taras.gerya@erdw.ethz.ch)

We conducted a set of numerical experiments to study the evolution of a subduction–collision system subject to spontaneous slab breakoff. The study takes into account complex rheological behaviour including plasticity, viscous creep and Peierls creep and mineralogical phase transformations including UHP melting. A limited number of contrasting geodynamic scenarios were observed that combine several previously suggested end-member tectonic processes such as continental subduction, multiple crustal stacking, oceanic slab delamination and breakoff, plate eduction, ductile crustal extrusions and buoyant partially molten trans-lithospheric plumes. In the explored parameter space, breakoff depth can range from 40 to 400 km with Peierls creep in the cold subducted mantle been a key mechanism for slab necking. We also found that melting of crustal materials at ultrahigh pressure metamorphic (UHPM) conditions can trigger the exhumation of high temperature-ultrahigh pressure metamorphic (HT-UHPM) rocks. In the model, the generation of temperatures high enough for anatexis during subduction is due to the continental crust and associated sediments coming into contact with hot asthenospheric mantle of the wedge at ultrahigh pressure conditions. The consequent enhanced buoyancy of the melt-bearing crustal and associated sedimentary materials drives the subsequent exhumation of the HT-UHPM rocks from mantle depths to mid-to-lower crustal levels. Exhumation occurs by a thermally induced slab-parallel ductile extrusion of melt-bearing crustal materials along the interface between the stagnant subducted slab and the mantle wedge. The up to 1000 C peak temperatures achieved in the experiments at UHPM conditions are the highest obtained so far in experiments using numerical models; they are similar to many natural HT-UHPM rocks. The sensitivity studies suggest that some other mechanisms proposed previously for the exhumation of UHPM rocks including multiple crustal stacking, plate eduction, trans-lithospheric crustal plumes and channel flow are mainly controlled by the oceanic slab age and length and by the incoming passive margin geometry. Indeed, all these exhumation processes typically result in colder P-T paths with the coldest (<500 C) peak temperatures been produced by the eduction-driven exhumation.

Trace elements and lead isotopes in moldavites: Source material fractionation or variable parent lithologies mixing?

ROMAN SKÁLA[1]* AND LADISLAV STRNAD[2]

[1]Institute of Geology ASCR, v.v.i., Rozvojová 269, 16500 Praha 6, Czech Republic (*correspondence: skala@gli.cas.cz)

[2]Faculty of Science, Charles University, Alberov 6, CZ12800 Praha 2, Czech Republic (lada@natur.cuni.cz)

Samples and data collection

Contents of selected minor and trace elements and lead isotope composition have been determined for 16 moldavites from South Bohemian (4), West Moravian (5) and Cheb Basin (7) partial strewn fields. Data were measured using ICP-MS technique from solution following the protocol of Strnad *et al*. [1].

Results

After normalizing the measured values to average element contents for moldavites from the South Bohemian partial field it appeared that the moldavites from Cheb Basin differ from those from South Bohemia and Moravia. They are highly enriched in Zn, Ba, Pb, and U while they display significant depletion in Cr and Ni. Moravian moldavites display either no or significantly less differences when compared to South Bohemian moldavites.

Chondrite-normalized REE contents overlap existing literature data. HREE tend to be enriched in Moravian samples whereas the samples from the Cheb Basin appear to be depleted in HREE compared to the moldavites from the South Bohemian field. Concentrations of LREE remain more or less invariant among all regions.

In the plot $^{208}Pb/^{206}Pb$ *vs*. $^{206}Pb/^{207}Pb$ the moldavites from the Cheb Basin are clearly separated from the rest of the samples analyzed; samples from South Bohemia and Moravia do not differ.

Conclusions

The data collected do not corroborate idea of selective source material fractional vaporization, or that of selective condensation neither the hypothesis of Engelhardt *et al*. [2] explaining the formation of moldavites by preferential trapping of large ions into early condensates. We assume that measured composition reflects the lithological variability of the target area instead.

Primary aromatic amino groups are often the position of initial attack during the mineral-catalyzed oxidative transformation processes of soil and groundwater contaminants. Here, we explored the N isotope fractionation associated with the oxidation of substituted anilines as a diagnostic tool for identifying the initial oxidation steps of such degradation processes. Apparent ^{15}N-kinetic isotope effects, $AKIE_N$, were determined for oxidation of various substituted anilines in suspension of manganese oxide (MnO_2) and compared to reference oxidation experiments in homogeneous solution and at electrode surfaces, as well as to density functional theory calculations of intrinsic KIE_N for electron and hydrogen atom transfer reactions.

Spectroscopic characterization of MnO_2-particles as well as the investigation of co-solute effects on mineral reactivity showed that despite complex reaction kinetics of contaminant disappearance, substituted aniline oxidation occurred in one elmentary, isotope-sensitive reaction step. Owing to the partial aromatic imine formation after one- electron oxidation and corresponding increase in C–N bond strength, $AKIE_N$ -values were *inverse*, substituent-dependent, and confined to the range between 0.992 and 0.999 in agreement with theory. However, $AKIE_N$-values became *normal* once the fraction of cationic species prevailed owing to ^{15}N-equilibrium isotope effects, EIE_N, of 1.02 associated with N atom deprotonation. The observable $AKIE_N$-values are substantially modulated by the acid/base pre-equilibria of the substituted anilines and isotope fractionation may even vanish under conditions where normal EIE_N and inverse $AKIE_N$ cancel each other out. Our work suggests that the observed pH- and substituent-dependent trends of N isotope fractionation provide a new line of evidence for the identification of oxidative degradation processes of substituted primary aromatic amines.

Solubility and toxicity of hydroxylapatite (hap) nanoparticles (nps): Implications for nanobiomaterial safety

KYRIAKI SKARTSILA, SUPERB MISRA AND EVA VALSAMI-JONES

Natural History Museum, London UK (kyrs@nhm.ac.uk)

Nanotechnology has the potential to solve many of modern society's problems, notably in medicine and the environment. Although an increase in interest in regulating risks from nanotechnologies is evident in recent years, research and regulation of risks lag behind the driving forces of intellectual curiosity and commercial potential. The aim of this work is to contribute to a better understanding of the risks of nanotechnology and ultimately to their control. We specifically focus on the reactivity and the potential toxicity of HAP NPs, which are used in many medical innovations.

A variety of HAP NPs were synthesised selected on the basis of their biocompatibility and particle size. Full detailed physicochemical characterisation was carried out in parallel. The synthesis method was then optimised to provide control over crystal growth, agglomeration, particle size and shape mainly by investigating the effect of synthesis parameters such as: synthesis temperature, pH, maturation time, concentration of the capping agent, drying and calcination temperature.

The reactivity/chemical stability of the nanoHAPs was assessed by solubility experiments, which showed that solubility exponentially increases as the grain size decreases. This is in agreement with the modified version of the Kelvin equation, which describes the prediction that solubility is dependent on the particle size and is expected to increase exponentially as particles get smaller. Furthermore, these experiments showed that solubility correlates well with the crystallinity of nanoHAPs.

Protein adsorption studies were carried out as a proxy for toxicity; high proportion of protein adsorbed indicates better biocompatibility, and therefore less likelihood for toxicity. These experiments showed that more protein was absorbed by the smallest, least crystallised and non-functionalised HAP NPs, suggesting that these are the most biocompatible nanoHAPs.

Flux rates for water and carbon during greenschist facies metamorphism

ALASDAIR SKELTON

Department of Geological Sciences, Stockholm University, 106 91 Stockholm, Sweden (alasdair.skelton@geo.su.se)

The time-averaged flux rate for a CO_2-bearing hydrous fluid during greenschist facies regional metamorphism was estimated to $10^{-10.2 \pm 0.4}$ $m^3 . m^{-2} . s^{-1}$. This was evaluated by combining 1) Peclet numbers obtained by chromatographic analysis of the propagation of reaction fronts in 33 metamorphosed basaltic sills in the SW Scottish Highlands (Fig. 1), 2) empirical diffusion rates for CO_2 in water obtained by Wark & Watson (2003), and 3) calculated time-averaged metamorphic porosities. The latter were calculated using an expression obtained by combining estimated Peclet numbers with the empirical porosity – permeability relationships obtained by Wark and Watson (1998) and Price *et al*. (2006) and Darcy's law. This approach yielded a time-averaged metamorphic porosity of $10^{-2.6 \pm 0.2}$ for greenschist facies conditions. The corresponding timescale for metamorphic fluid flow was $10^{3.6 \pm 0.1}$ years. By using mineral assemblages to constrain fluid compositions, I further obtained a time-averaged annual flux rate for carbon of 0.5-7 mol-C. $m^{-2} . yr^{-1}$. This matches measured emission rates for metamorphic CO_2 from orogenic hot springs. These fluxes significantly exceed estimated rates of CO_2 drawdown by orogenic silicate weathering and therefore indicate that orogenesis is a source rather than a sink of atmospheric CO_2.

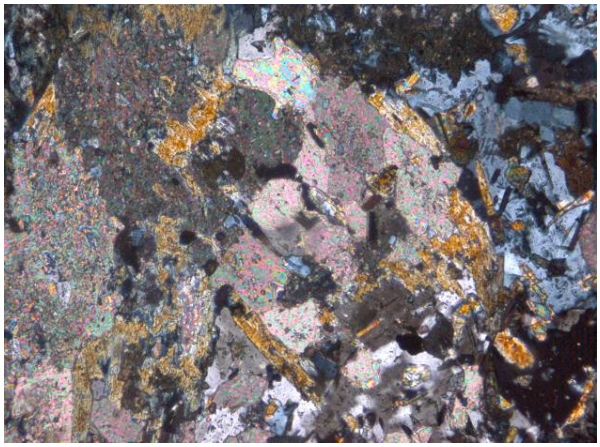

Figure 1: Photomicrograph (in XPL) showing replacement of amphibole by calcite: evidence of carbon transfer, preserved in a metabasaltic sill from the SW Scottish Highlands.

Tracing episodic magma accretion by zircon $^{18}O/^{16}O$ isotopes and U-Pb dating in the Adamello batholith, Italy

A. SKOPELITIS[1]*, I. BINDEMAN[2], A. ULIANOV[3], P. BRACK[4] AND U. SCHALTEGGER[1]

[1]University of Geneva, 1205 Geneva, Switzerland (*correspondence: Alexandra.Nowak@unige.ch)
[2]University of Oregon, OR 97403, USA
[3]University of Lausanne, 1015 Lausanne, Switzerland
[4]ETH, 8092 Zürich, Switzerland

Styles and timescales of batholith formation still remain a matter of debate. There is growing evidence that batholiths are not formed by a single ascent of magma but by accretion of multiple batches. In the latter case, are they derived from the same source or different ones, and do they suffer similar degrees of contamination?

In order to answer these questions, we study tonalites from the Adamello batholith (33-43 Ma) localized in the northern Italian Alps. Previous studies mainly based on cooling ages highlighted a younging of magmatic activity towards the north [1, 2, 3], which is confirmed by our new U-Pb zircon LA-ICP-MS dating. Isotopic compositions of both Sr and O indicated increased contribution from higher $\delta^{18}O$, more radiogenic supracrustal sources in the same direction [4]. We present new data from a $^{18}O/^{16}O$ isotope study on small quantities of freshest and refractory separates of quartz, amphibole, titanite and zircon, and best estimate $\delta^{18}O$ magma values [5]. The data confirm increasing crustal contamination towards the north indicated by elevated $\delta^{18}O$ values up to 7‰ in zircon. H isotope ratio is strongly negative (-97‰) for the amphibole in the most northerly sample suggesting an assimilation of hydrothermally-altered rocks or an assimilation of marine sediment. We will quantify the contamination by AFC modelling using geochemistry, whole rock and mineral isotopes. As a preliminary conclusion, the Adamello batholith was formed by different pulses over ca 10 m. y. coming from different in $\delta^{18}O$ magma reservoirs with contrasting oxygen isotope compositions, due to their different depth in a $^{18}O/^{16}O$ zoned crust.

Melting of carbonaceous sediments in subduction zones

S. SKORA* AND J. BLUNDY

Dept of Earth Sciences, University of Bristol, BS8 1RJ, UK (*correspondence: Susanne.Skora@bristol.ac.uk, Jon.Blundy@bristol.ac.uk)

The terrestrial carbon cycle is of immense interest to geoscientists as it has important consequences for, inter alia, Earth's climate, diamond formation, carbonatite volcanism and mantle metasomatism. Subduction zones provide the major geotectonic settings where surficial carbon can enter the Earth, and potentially return via arc volcanism. To date, experimental phase equilibria studies as well as thermodynamic calculations suggest that carbonates behave in a refractory manner under most subduction zone conditions in the slab. This stands in contrast to observations from nature, namely that CO_2 is released in arc volcanoes. Stable isotopic characteristics further suggest that most arc carbon is sediment-derived.

The suggested limited release of CO_2 at sub-arc depths, either by melting or by decarbonation, poses a great challenge to explain the high arc-flux of CO_2. This study aims to test the hypothesis that calcareous lithologies melt more readily at sub-arc conditions in the presence of external water, similarly to the melting behaviour of non-calcareous lithologies.

Two different calcareous lithologies were picked from the southern Lesser Antilles arc – one containing approx. 5% and one with approx. 35% carbonate. Initial experiments at 900°C, 3 GPa, 10% added water have yielded very high degrees of silicate melts, despite the fact that previous experimental studies have placed the solidus at temperatures >900°C at 3 GPa (fluid-absent conditions). This suggests that the fluid-saturated solidus in carbonaceous sediments has not been adequately constrained by the available fluid-absent experiments. In addition to glass, experimental run products contain either garnet + phengite + rutile + carbonate (5% carbonate lithology) or zoisite + quartz + rutile + carbonate (35% carbonate lithology). We will further investigate under which conditions CO_2 can be transported into the overlying mantle wedge.

The 1.86-1.84 Ga magmatism in the Western East European Craton (Lithuania): Implications for a convergent continental margin

G. SKRIDLAITE[1]*, M. WHITEHOUSE[2], S. BOGDANOVA[3] AND L. TARAN[4]

[1]Nature Research Centre, Vilnius, Lithuania (*correspondence: skridlaite@geo.lt)
[2]Swedish Museum of Natural History, Stockholm, Sweden
[3]Department of Geology, Lund University, Sweden
[4]Belarussian Research and Geological Exploration Institute

The East European Craton in western Fennoscandia was mostly formed by the accretion of distinct terranes at c. 1.8 Ga. TTG magmatic rocks in the age range 1.86-1.84 Ga are abundant in the crystalline crust of S, central and NW Lithuania. In the south, TTG rocks compose the large Randamonys massif. A Zm347 tonalite yielded an 1859±5Ma concordia age, while a Vr268 diorite was dated at 1848±6 Ma. A strongly deformed 7Gr granitic rock in adjacent NW Belarus gave a similar 1844±8 Ma igneous age. In central Lithuania, the Glv99 igneous mafic granulites display magmatic 1839±15 Ma and metamorphic 1809±9 Ma ages. The nearby Grz105 gneissic granite was intruded at c. 1837±6 Ma, while the Kz65 granite further north was emplaced at 1844±5 Ma [1]. The area to the south and west of the above described rocks in Lithuania and in N Poland is dominated by younger c. 1.83-1.79 Ga magmatic rocks. The fragments of a c. 1.83-1.82 Ga volcanic island arc in Sweden [2], N Poland and Lithuania [3] compose a considerable part of this younger domain.

The distribution of 1.86-1.84 Ga magmatic arc-related rocks in Lithuania likely delineates fragments of a convergent continental margin. It continues northwestwards across the Baltic Sea into south-central Sweden, and southwards to N Poland and NW Belarus.

Abnormal (Y+REE)-enriched zircon from the pegmatite dike (Gridino, the Belomorian province, Fennoscandian shield)

S.G. SKUBLOV[1]*, O.L. GALANKINA[1] AND S.G. SIMAKIN[2]

[1]Institute of Precambrian Geology and Geochronology, Russian Academy of Sciences, St. Petersburg 199034, Russia (*correspondence: skublov@gmail.com)
[2]Jaroslavl Branch of Institute of Physics and Technology, Russian Academy of Sciences, Jaroslavl 150055, Russia (simser@mail.ru)

Zircon can contain naturally U and Th up to 10 wt% and several thousands of ppm of REE. The maximum known contents of REE (up to 98, 154 ppm) was found in zircons from Bidoudouma stream close to Oklo, Gabon [1].

We found abnormal (Y+REE)-enriched zircon in the thin pegmatite dike cutting precambrian eclogites (village Gridino, the Belomorian province, Fennoscandian shield, see outcrop photo in [2]). Zircon core ($^{207}Pb/^{206}Pb$-age 2685 Ma) is captured eclogite protolith with regular REE distribution. Rim is characterized by high contents of REE (61, 280–96, 760 ppm), Y (55, 360–84, 800 ppm) and distinctly positive Ce anomaly. U and Th contents are not so high – maximum 2230 and 90 ppm, respectively.

Age of rim crystallization is svecofennian (1875 Ma) following high-pressure metamorphism event

Nanoparticle bioremediation: Application of solid phase capture

R.L. SKUCE*, D.J. TOBLER, M.R. LEE AND V.R. PHOENIX

Department of Geographical and Earth Sciences, University of Glasgow, UK
(*correspondence: rebecca.skuce@ges.gla.ac.uk)

The use of engineered nanoparticles continues to expand rapidly. As this intensifies, so does the environmental risk posed if they are released into the environment. This is of particular concern due to the potential toxicity of some nanoparticles. As it stands, we are poorly prepared to deal with nanoparticle pollution and thus remediation strategies must be developed. Here ureolysis-driven calcium carbonate precipitation by the urease positive bacterium *Sporosarcina pasteurii* is investigated as a means of removing nanoparticles from aquatic systems. This technology has been investigated for the solid phase capture of radionuclide and trace element contaminants in groundwater systems [1]. However its potential to capture nanoparticles has yet to be examined.

Batch experiments showed the successful removal of highly stable organo-metallic nanoparticles at concentrations up to 10mg/l (the highest concentration tested thus far). Over 90% of nanoparticles were captured within 24 hours and capture efficiency appeared to be inversely proportional to calcite precipitation rate. As calcite precipitated, the nanoparticles became trapped within the growing calcite crystal. As the calcite-nanoparticle composite continued to grow, it adhered to surfaces (such as the edge of the reaction flask, or the edge of a pore space), immobilizing the nanoparticles from solution. Nanoparticles are believed to act as nucleation sites for the precipitating calcite. First order reaction kinetics were calculated to determine reaction rate constants, and in particular, S_{crit}, the critical saturation required for nucleation. This technology has the potential for application in contaminated groundwaters and soils as an *in situ* remediation technique for nanoparticle pollutants.

Testing a geochemical tracer tool in New Zealand water

ANGELA T. SLADE[1]*, N.R. WARNER[2], A. VENGOSH[2] AND BRANDON WHITEHEAD[1]

[1]School of Environment, The University of Auckland, 23 Symonds Street, Auckland 1142, New Zealand, (*correspondence: a.slade@auckland.ac.nz)
[2]Division of Earth and Ocean Sciences Nicholas School of the Environment, Duke University, Durham, NC 27708,

Deteriorating water quality along the Tarawera River, in Kawerau (New Zealand), is thought to be correlated to the solid and liquid waste disposal practices of the local pulp and paper mill in conjunction with naturally occurring geothermal discharge in the area. Due to high concentrations of boron in the liquid from both of these sources this study investigates the use of this element as a tool to assist in improving the management of the waterways and water quality in the region.

Comprehensive scientific studies that have been conducted for over 20 years have identified boron as a successful natural tracer for use in water bodies in different parts of the world. [1-3] Drawing on this information we executed a temporal water quality survey to assess the consistency of boron isotope composition values at a localised scale. This survey included monthly sampling over a six-month period spanning the wet and dry seasons. The water samples were a selection of pond, river, ground (shallow and deep zones), and geothermal, coupled with leachate and aeration pond water from a pulp and paper solid waste site. The boron concentration data and isotope ratios were established using ICP-MS and negative TIMS, respectively.

This paper discusses: 1) the effectiveness of boron isotope composition values as signatures for water; 2) the reliability of these signatures as a tool for water quality and management purposes; 3) the level to which sampling, analytical and environmental anomalies have influenced the results.

Factors affecting detrital zircon age distribution – Natural samples and experimental approach

J. SLAMA* AND J. KOSLER

Centre for Geobiology and Department of Earth Science, University of Bergen, Allegaten 41, N-5007 Bergen, Norway (*correspondence: jiri.slama@geo.uib.no)

We have investigated some of the factors that affect the accuracy of detrital zircon age provenance studies. The main goal was to quantify the effects of individual factors in the deviation of the measured detrital age spectra from the real zircon age distribution in the sediment and in the sediment source. The analysis has been carried out in a natural catchment in the Scottish Highlands representing simple two-component source system and on samples of synthetic sediment prepared on purpose for this study using zircon-free quartz sand and known number of zircon grains of known age distribution. Our results suggest that the zircon fertility of the source rocks and physical parameters of zircon grains represent the most important factors affecting the distribution of zircon age populations in the stream sediments. It can account for a several-fold difference between the ratio of the rocks in the source area and abundance of zircon in the sediment. Additional age biases can be introduced during sample preparation and data processing. The sample preparation and selection of zircons from the mineral concentrate may result in preferential loss of small grains and enhancement of the age component represented by larger grains. This can, together with the preference for larger grains during handpicking, cause several-fold difference compared to the real age distribution in the sediment sample. These factors appear to be more important for the reproducibility of zircon age spectra than is the number of zircon grains analyzed per sample. Even the most abundant age population in the sample may deviate by tens of percent from its real content in the sediment after hundred or more analyses have been done. The complex relations between proportion of zircon age populations in the source, sediment and analyzed sample make it difficult to relate the peak intensity in the age spectra to the sediment quantity contributed from different sources. At all times, the analytical limits of the dating techniques must be considered when evaluating potential overlap of zircon populations that are closely spaced in time. Although the visualization of U-Pb data in probability density plots is commonly used for comparison between samples, the detrital zircon age spectra must always be interpreted relative to the volume of individual age populations, not to the intensities of the age peaks.

Fluoride removal by calcite – Stirring rate/temperature effects

S.B. SLEAP, B.D. TURNER*, K. KRABBENHOFT AND S.W. SLOAN

Centre for Geotechnical and Materials Modelling, The University of Newcastle, N.S.W., 2308, Australia (*correspondence: Brett.Turner@newcastle.edu.au, Scott.Sleap@newcastle.edu.au, Kristian.Krabbenhoft@newcastle.edu.au Scott.Sloan@newcastle.edu.au)

Fluoride contamination of groundwater due to anthropogenic activities remains a major concern for many industries worldwide. The effects of stirring rate and temperature on the removal of fluoride by calcite have been studied in order to determine the most efficient and cost effective method of remediating such contamination.

The kinetics of calcite dissolution and precipitation in aqueous solution has been the subject of numerous investigations. However, little study has been undertaken on heterogeneous systems where mass transport processes and surface reactions determine rates. Aleksey, *et al*. [1] have noted that traditional thermodynamic approaches to determine equilibrium are problematic and there is a need for a kinetic approach to solving these problems. The effects of stirring and temperature on the heterogeneous calcite/F systems are the focus of this study.

A series of free drift experiments were conducted in a controlled temperature (CT) room at 20°C, 30°C and 40°C, with P_{CO2} in equilibrium with the atmosphere ($P_{CO2} \approx 10^{-3.5}$). Calcite was added to potassium fluoride solutions and stirred at 0, 200 and 300rpm using an overhead stirrer. The results in Table 1 have been determined by fitting the experimental data to the non-linear Hill 1 function ($r^2 > 0.98$).

RPM	Temp	Minutes	RPM	Temp	Minutes
300	40°C	5,143	0	40°C	13,224
300	30°C	9,196	0	30°C	24,250
200	40°C	11,287	0	20°C	138,169
200	30°C	22,330			

Table 1: Time (min) to reach equilibrium F removal

The results clearly demonstrate that a greater rate (dF/dt) of fluoride removal is possible with increased stirring rate and temperature. Early in the reaction <200 minutes dissolution is largely a function of a surface reaction as mixing has little effect on the rate [2]. In the latter part of the reaction, stirring rate has a significant effect, consequently hydrodynamic transport effects dominate [2].

Minerals of Pt_3Sn-Pd_3Sn-Pd_3Pb-Pd_3As-Pd_3Sb system in PGE-Cu-Ni and PGE ores of the Norilsk region

S.F. SLUZHENIKIN AND A.V. MOKHOV

IGEM RAS, Staromonetny 35, Moscow 119017 Russia (*correspondence: nlo_s@mail.ru)

All minerals of the system – rustenburgite Pt_3Sn, atokite Pd_3Sn, zvyagintsevite Pd_3Pb, guanglinite Pt_3As and unnamed mineral with Pd_3Sb composition were found in Norilsk ores. A wide isomorphizm between Pt and Pd is established in the system, in particular within Pt_3Sn-Pd_3Sn series. The minerals very often contain Au as an admixture up to 6 wt.% (Fig. 1). An almost complete isomorphism between Sn, Pb, As и Sb is found. Chemical isomorphism is expressed in terms of zonal occurrences of the minerals during successive growth and replacement.

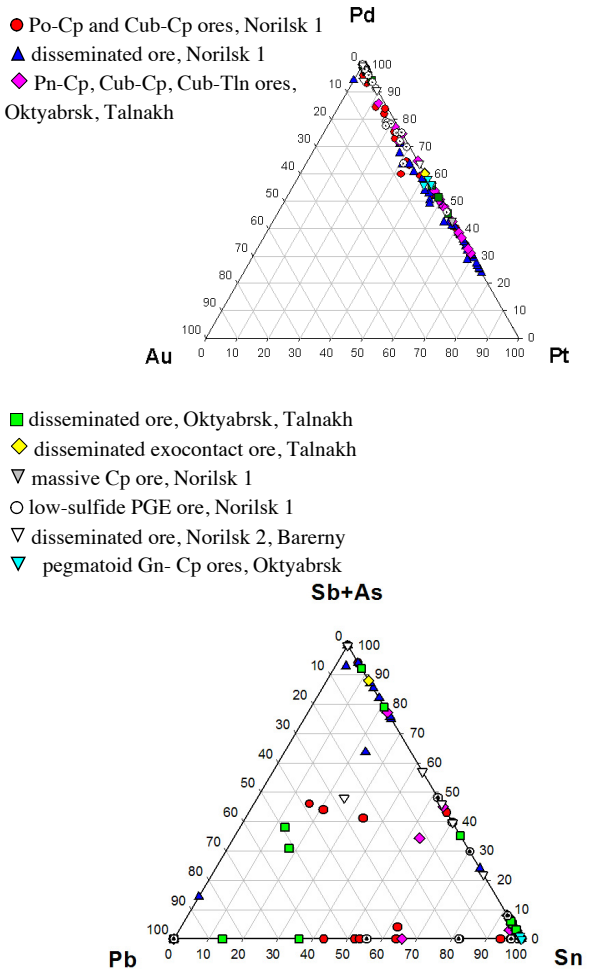

Figure 1: Chemical composition of Pt_3Sn-Pd_3Sn-Pd_3Pb-Pd_3Sb-Pd_3As minerals from Norilsk ore.

Does aerosol alter entrainment mixing in warm cumulus?

J.D. SMALL[1,2], H.H. JONSSON[3] AND P.Y. CHUANG[1]

[1]Earth and Planetary Sciences, University of California Santa Cruz, Santa Cruz, CA, 95064, USA (*correspondence: pchuang@ucsc.edu)

[2]NASA/JPL, Pasadena, CA, 91109, USA (Jennifer.Small@jpl.nasa.gov)

[3]Center for Interdisciplinary Remotely Piloted Studies (CIRPAS), Naval Postgraduate School, Marina, CA, 93933, USA (hjonsson@nps.edu)

We analyze the cloud microphysical response to entrainment mixing in warm cumulus clouds observed from the CIRPAS Twin Otter during the GoMACCS field campaign near Houston, TX in summer 2006. Cloud drop size distributions and cloud liquid water contents from the Artium Flight phase-Doppler interferometer in conjunction with meteorological observations are used to investigate the degree to which inhomogeneous versus homogeneous mixing is preferred as a function of height above cloud base, distance from cloud edge, and aerosol concentration. Using four complete days of data during which 101 non-precipitating cloud penetrations (minimum 300 m in length), we find that inhomogeneous mixing primarily explains liquid water variability in these clouds.

While theory predicts the potential for aerosol to affect mixing type via changes in drop size, over the range of aerosol concentrations experienced (moderately polluted rural sites to highly polluted urban sites), the observations, while consistent with this hypothesis, do not show a statistically significant effect of aerosol on mixing type. Instead we find two non-aerosol effects primarily control the microphysical response to entrainment mixing. First, we show that there is a tendency for mixing to be more homogeneous towards cloud top, which we attribute to the combination of increased turbulent kinetic energy and cloud drop size (due to condensational growth) with altitude which together cause the Damköhler number to increase by a factor of between 10 and 30 from cloud base to cloud top. Second, we find that cloud edges appear to be air from cloud centers which have been diluted solely through inhomogeneous mixing. We give plausible explanations for this second effect, but none thus far has been demonstrated using the observations.

Lastly, we discuss the possible ramifications of these observations on other key cloud properties, in particular warm rain formation and cloud albedo.

(*correspondence: kasmart@ualberta.ca)

Diamonds are key to understanding the sources, speciation and cycling of carbon in the mantle, and together this information is crucial for the study of mantle redox processes. The carbon isotope composition of diamond provides essential information on both the source and redox-state dependent speciation of C reservoirs involved in diamond growth. Growth models are commonly based on xenocrystic diamonds sampled from kimberlites and usually represent mixed populations and multiple growth events. In contrast, *in situ* studies of single growth zones in individual diamonds are better suited for building diamond growth models. Here we present the results of a coupled CL-imaging and SIMS δ^{13}C-N study of a single, 0.5cm diamond from an eclogite xenolith from the Jericho kimberlite, Canada.

CL images of the diamond show a relatively homogeneous core mantled by oscillatory dark and light growth layers towards the rim. SIMS analyses of carbon isotope composition and nitrogen content in the core show systematic and coupled variations: N decreases rimwards from ~5000 to 1000 ppm and δ^{13}C increases from -4.1 to -2.7‰ in the same direction. We interpret these systematic co-variations to reflect fractional crystallization of diamond from a single melt/fluid pulse. Moreover, the coupled rimward enrichment in ^{13}C and depletion in N indicate diamond formation from an oxidized growth medium where N behaved compatibly in diamond relative to the medium. Modelling the core zone growth shows that the initial δ^{13}C value of the diamond-forming fluid/melt was between -2.3 and 0‰ (depending on temperature and C speciation, e.g. CO_3^{2-} or CO_2). The carbon source therefore was either subducted carbonates (δ^{13}C~0‰) that had undergone partial decarbonation causing ^{13}C depletion or primary mantle fluids/melts (-5‰) that had undergone extensive C fractionation prior to precipitation of the diamond investigated here. We favor a model where the carbon was sourced from a carbonatite-like medium, potentially derived from subducted sediments, as the host eclogites themselves have evidence for crustal protoliths and interaction with carbonatite-like metasomatic agents[1].

Biotic dissolution of Tl(I)jarosite by *Shewanella putrefaciens* CN32

C.M. SMEATON*, B.J. FRYER AND C.G. WEISENER

Great Lakes Institute for Environmental Research, University of Windsor, ON, Canada
(*correspondence: smeato3@uwindsor.ca)

Jarosites (MFe$_3$ (SO$_4$)$_2$ (OH)$_6$) are precipitated in the Zn industry to scavenge iron, alkali metals and sulfate ions during base metal processing and often contain toxic metals such as Pb, Ag and Tl. During this process, large volumes of jarositic wastes are produced and often confined to large repositories. Despite the toxicity of Tl, few studies exist on the abiotic and biotic dissolution of thallium mineral phases. In this study we examined the dissolution of synthetic Tl (I)-jarosite (TlFe$_3$ (SO$_4$)$_2$ (OH)$_6$) by *Shewanella putrefaciens* CN32 using batch experiments under anaerobic circumneutral conditions.

ATP, Fe and Tl concentrations were measured over time and showed increased Fe(II) and Tl in inoculated versus control samples (Fig 1). Tl concentrations in inoculated samples increased by a factor of 2 compared to control samples (Fig 1). In contrast to previous studies with Pb and Ag-jarosite, SEM images of *S. putrefaciens* CN32 did not show precipitation of Tl nanoparticles associated with the cell surface thus suggesting an alternative mechanism for Tl detoxification [1, 2].

Volcanism on Methana (W Aegean arc): Magma mixing, crustal contamination & mantle sources

I. SMET[1]*, E. DE PELSMAEKER[1], M. ELBURG[1], F. VANHAECKE[2] AND T. ANDERSEN[3]

[1]Department of Geology and Soil Science, Ghent University, 9000, Belgium (*correspondence: ingrid.smet@ugent.be)
[2]Department of Analytical Chemistry, Ghent University, 9000, Belgium
[3]Department of Geosciences, University of Oslo, Norway

The peninsula of Methana represents the westernmost active centre of the (continental) South Aegean arc. Volcanism started about 1.1 Ma ago and the last eruptive phase is as young as 2200 years. Volcanic deposits are mostly andesitic to dacitic lava domes and flows with abundant mafic enclaves, but two volcanic centres also show volumetrically important pyroclastic deposits [1].

The many mafic enclaves in the lavas suggest that magma mingling has been important. Evidence for magma mixing includes a poor correlation between modal mineralogy and silica content, and the common occurrence of disequilibrium assemblages (such as biotite, zircon, quartz + olivine). Major and trace element concentrations of different lava flows and domes show a large variability, seemingly unrelated to silica content. $^{87}Sr/^{86}Sr$ ratios are variable (0.705-0.708), and the correlation with silica content is poor.

Enclosed xenoliths are mostly carbonates (and a few silicates) and are restricted to the two volcanic centres that also show pyroclastic activity. $^{87}Sr/^{86}Sr$ isotope ratios of these volcanics increase with increasing Sr concentration, suggesting carbonate assimilation. Interestingly, carbonate contamination is only observed in the pyroclast-bearing centres, and could therefore be responsible for their more explosive behaviour, as already suggested for Merapi volcano in Indonesia [2].

One lava flow displays a combination of the highest Sr concentrations (530 ppm, versus 200-350 ppm for the other volcanic deposits) and the lowest $^{87}Sr/^{86}Sr$ ratios (0.705). Similar volcanics have been found on the islands of Aegina and Nisyros, and point towards variations in mantle sources.

Uranium (U) is a natural chemo- and radiotoxic heavy metal. The exposure of humans to U is mainly determined through uptake by drinking water. This paper reports on the U content in 4251 tap waters and 350 groundwaters from Germany collected by several research groups over the last 5 years and discusses the possible origin of U. This database is by far the largest available in the country and it represents data of drinking water to which 76% of the entire German population has access. The mean U concentration was 1.61 μg/L U, the median 0.50 μg/L U. 25.2% of all samples had U concentrations below the detection limits, which accounts for water to which 41.0% of the entire population has access. 24% of samples were above 2 μg/L U, 4.4 above 10 μg/L U, representing a population of 10.2 and 0.28%, respectively. The regional distribution of U concentrations follows the geological structures reported for mineral waters, however in contrasts to this clear evidences for anthropogenic influence through agricultural activities were found in drinking and groundwaters of areas with intense cropping productions in southern and northern Germany. Soil analyses show the high mobilisation capacity of fertilizer-derived U from arable soils in comparison to unfertilized control sites.

Processes of heavy metals immobilization in mires

BEATA SMIEJA-KRÓL[1]*, BARBARA FIAŁKIEWICZ-KOZIEŁ[2] AND JERZY WIEDERMANN[3]

[1]University of Silesia, 60 Będzińska, 41-200 Sosnowiec, Poland (*correspondence: beata.smieja-krol@us.edu.pl)
[2]Mickiewicz Univ., Dzięgielowa 27, 61-680 Poznań, Poland (basiafk@amu.edu.pl)
[3]Institute for Ferrous Metallurgy, 12 Miarki, 44-100 Gliwice, Poland (J.Wiedermann@imz.pl)

Long time mining and smelting activities have produced a widespread regional anomaly in Pb, Zn and Cd concentration in soils of Silesia region, southern Poland. Two mires: Bagno Bruch (BB) and Bagno Mikołeska (BM), located within the anomaly, were chosen to study processes of heavy metals immobilization in acid, water-logged and peat accumulating ecosystems.

The chemical analyses of peat were conducted using ICP-MS method. The solid samples (inorganic particles and peat) were investigated using FESEM.

A narrow peat layer, highly enriched in Pb, Zn and Cd, were detected at depth between 9 and 27 cm below the mires surface. The contaminated layer contained 460-1190 mg/kg of Pb, 1037-2371 mg/kg of Zn and 11.92 - 62.6 mg/kg of Cd. Above and below the layer, metal concentrations were several times lower, reaching values of 0.3-8.0 mg/kg Pb, 22-73 mg/kg Zn and 0.1-0.5 mg/kg of Cd in the deeper (below 50 cm), pre-industrial peat layer.

The study shows that an important part of the contaminants are immobilized in inorganic particles. In the contaminated layer, the fly-ash particles, originated from dust deposition, comprise up to 1.7% by volume of dry peat. The formation of authigenic (Zn, Cd)S (up to 1.1% by vol.), barite (~0.5% by vol. in BB, not found in BM), and traces of PbS, indicates the importance of secondary processes, like microbial activity, in metals distribution and immobilization.

The research was funded by the grant N N304 319136 from the Polish Ministry of Science and Higher Education.

Deformation of garnet in eclogite: Dominant mechanisms and the active role of fluids

M.A. SMIT[1], E.E. SCHERER[1], T. JOHN[1] AND A. JANSSEN[1,2]

[1]Institut für Mineralogie, Westfälische Wilhelms-Universität, Corrensstrasse 24, D-48149, Münster, Germany (m.a.smit@uni-muenster.de)
[2]Institute for Transuranium Elements, European Commision Joint Research Center, Hermann-von-Helmholtz-Platz 1, D-76344, Eggenstein-Leopoldshafen, Germany

The response of subducting rocks to stress under different physicochemical conditions is crucial to predicting the evolution of slab strength and the generation of earthquakes. Experiments on mafic rock rheology [1, 2] suggest that prograde metamorphism to eclogite should not significantly change bulk-rock viscosity. Yet, field evidence demonstrates a dramatic, but temporary competence loss as a result of such reaction [3]. This discrepancy underscores the need for further study into the relationship between fluid-flow, mineral reactions, and rheological properties of eclogite.

Garnet fabrics are particularly enigmatic features that sometimes indicate very efficient deformation of this mineral under conditions where it is expected to remain rigid. To investigate this, we compared the textural and microstructural characteristcs of garnet in an eclogite mylonite (Caledonian eclogites, Norway) to those of garnet that crystallized statically in a high-pressure seismic melt (Zambian eclogites).

In contrast to the static garnet crystals, mylonite garnet is flattened parallel to the main foliation. The grains exhibit foliation-perpendicular fractures, random crystallographic orientations, and abundant dissolution features, indicating mass transfer away from the grain boundaries. The grains accomodated large strains by intergranular pressure solution in the presence of fluid at high pressure.

This study shows that fluid-wetted grain boundaries occur in eclogite at depth and that these play a crucial role in the rheological weakening of such rock. Seismic imaging monitors the slab depth at which such weakening occurs as a distinct perturbation, beyond which slab coherrence is strongly reduced [4]. Even though fluid invasion may be only short-lived [5] and eclogites should rigidify when fluids exit the system, the temporary competence loss of these rocks could have a great impact on slab dyanmics.

Fractionation of a hydrous arc magma: The origin of adakitic and alkaline signatures at Savo volcano, Solomon Islands

D.J. SMITH[1]*, M.G. PETTERSON[1], A.D. SAUNDERS[1], G.R.T. JENKIN[1] AND J. NADEN[2]

[1]Geology Dept., University of Leicester, Leicester, LE1 7RH, UK (*correspondence: djs40@le.ac.uk)

Savo, Solomon Islands, is a historically active volcano dominated by sodic, alkaline lavas and pyroclastic rocks with up to 7.5 wt % Na_2O, and high Sr arc-like trace element chemistry. The petrogenetic history of the erupted suite suggests high water contents in the parental melts, favouring: a) the early fractionation of oxides; b) early, abundant crystallisation and differentiation of hornblende; and c) limited extraction of feldspar. Instead, it shows pseudo-closed system crystallisation; plagioclase forms but does not fractionate, so although crystals record formation in a melt of decreasing Sr, whole rock Sr increases with magmatic evolution [1].

Early amphibole fractionation and limited plagioclase fractionation contribute to an adakite-like geochemical signature of the Savo suite. Previous authors have noted this [2], but in the case of Savo, the adakite signature is a consequence of the fractionation history. The sodic, alkaline nature can also be attributed to feldspar; whole rock Na increases with SiO_2 as albite is retained. Na/K increases by biotite fractionation.

Much of the magma's water load appears to be released prior to eruption; Savo's eruptive style is that of dome formation, and pyroclastic rocks are all crystalline and non-vesicular. Fluids are released to a hydrothermal system [3] with the potential to form economic mineralisation. The oft-made linkage between 'adakitic' magmatism and economic copper and gold mineralisation (see [4] for review and criticism) may instead be an association between mineralisation and hydrous parental magmas.

Understanding bioavailability of iodine in soils of Northern Ireland

H.E. SMITH[1,2]*, E.L. ANDER[2], E.H. BAILEY[1], N.M.J. CROUT[1], M.J. WATTS[2] AND S.D.YOUNG[1]

[1]School of Biosciences, Biology Building, University of Nottingham, University Park, Nottingham NG7 2RD
[2]British Geological Survey, Kingsley Dunham Centre, Keyworth, Nottingham NG12 5GG
(*correspondence: plxhes@nottingham.ac.uk)

The impact of soil-iodine dynamics on the availability of iodine to plants has been investigated, with a focus on uptake to grass as pasture from a range of soil types in Northern Ireland. The aim of the work was to determine how the availability of iodine to plants is dependent on soil properties. A predictive model of iodine behaviour based on the findings will take into account location, soil type and seasonal changes within Northern Ireland as a case study. The model may ultimately be useful in predicting human and animal populations at risk of iodine deficiency diseases.

The transformations and dynamics of ^{129}I added as either $^{129}I^-$ or $^{129}IO_3^-$ to soils have been followed. Results indicate rapid transformation of inorganic iodine into organic forms, with ultimate incorporation into soil organic matter via formation of intermediates e.g. HOI or I_2. Rates of incorporation are highly dependent on physico-chemical parameters including soil pH, organic matter content and major oxide composition. Rate of transformation to organic forms depends upon initial iodine speciation. Iodide is lost more rapidly (minutes-hours) than iodate (hours-days), especially in soils with high organic matter. In all cases initial incorporation has been demonstrated by size exclusion chromatography to be in the low molecular mass humic substances.

The ultimate speciation and location of iodine in soil will affect the amount potentially available to plants, which therefore depends strongly on both the speciation of iodine and soil properties.

Monogenetic basaltic volcanoes represent extraction rather than melting events

I.E.M. SMITH[1]*, L.E. MCGEE[1], S.J. CRONIN[2], M. BEBBINGTON[2] AND J.M. LINDSAY[1]

[1]School of Environment, University of Auckland, PB92019, Auckland, New Zealand (*correspondence: ie.smith@auckland.ac.nz)

[2]Institute of Natural Resources, Massey University, Palmerston North, NZ (S.J.Cronin@massey.ac.nz, m.bebbington@massey.ac.nz)

Magmas from very small basaltic systems (volumes <0.1 km3) leak from the mantle on time scales of 10^4- 10^6 years to form fields of small volcanoes each resulting from a single short-lived eruption sequence. Because magma volumes are small and rise quickly they do not fractionate within the crust or assimilate components from it. Hence, their chemical compositions and variability reflect the interplay of processes deep in the system. The range of chemical compositions displayed by individual eruptions shows the diversity of these processes. Do these small magma batches represent discrete melting events or instead extraction episodes tapping long-lived (10^4 year) zones of partial melting? In the Auckland Volcanic Field N.Z. paleo-magnetic measurements [1] correlated with the ~ 31 ka Mono Lake magnetic excursion identify five eruptions of alkali basalt magmas from depths of ~80km within a time interval of a few hundred years. The chemical composition erupted in each event cannot be related to the others by fractionation processes. Heat flux constraints suggest that these discrete magma batches cannot represent distinct melting events. Rather they represent separate extraction events from a continuous but heterogeneous melt zone. Their near simultaneous eruption along with the overall pattern of volcanic activity at Auckland indicates that such extraction events may be driven by plate boundary related tectonic processes occurring over 600 km away.

Australasian sea surface temperatures over the past millennium

MARITA SMITH[1]*, JOCHEN BROCKS[1], PATRICK DE DECKKER[1], RAQUEL LOPES DOS SANTOS[2] AND STEFAN SCHOUTEN[2]

[1]Research School of Earth Sciences, The Australian National University, Canberra, ACT 0200, Australia (*correspondence: marita.smith@anu.edu.au)

[2]Department of Marine Biogeochemistry and Toxicology, Royal Netherlands Institute for Sea Research, P.O Box 59, 1790 AB Den Burg, Texel, The Netherlands.

The 'hockey-stick' temperature increase of the 20th century has instigated concern for a global warming trend. In order to investigate this temperature increase, it is necessary to derive high-resolution temperature records that span the last millennium. Currently, data from this period is sourced almost exclusively from the Northern Hemisphere, predominantly from terrestrial records. There is a considerable lack of temperature records for the Southern Hemisphere, making analysis of hemispheric and global trends in temperature changes difficult.

Marine sediments can often represent a continous geological record of climate through the gradual deposition of organic matter on the sea floor over time. Biomarkers are organic compounds produced by living organisms that have extraordinary preservation potential in sediments. The most useful biomarkers are resistant to diagenesis and can be readily linked to a characteristic group of producing organisms [1]. The lipids of some haptophyte marine algae (alkenones) and marine Crenarchaeota (glycerol dialkyl glycerol tetraethers) in the sedimentary record are biomarkers that may be converted to sea-surface temperature via the $U^{K'}_{37}$ [2] and TEX_{86} [3] proxies, respectively.

Here, we present a record of sea-surface temperature using multicores sourced from near the Australian east coast (at ~1, 000 m depth) utilising the combined capacities of these biomarker proxies. This is the first temperature record to span the past millennium in the Southern Hemisphere and provides an important means of palaeoenvironmental inference for hemispheric and global climatic trends during this period.

Mercury isotope fractionation in layered roasted ore waste

ROBIN S. SMITH[1,2]*, JAN G. WIEDERHOLD[1,2], ADAM D. JEW[3], GORDON E. BROWN JR.[3], BERNARD BOURDON[4] AND RUBEN KRETZSCHMAR[1]

[1]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland (*correspondence: robin.smith@env.ethz.ch)
[2]Isotope Geochemistry, ETH Zurich, Switzerland
[3]Department of Geological & Environmental Sciences, Stanford University, Stanford, CA 94305, USA
[4]ENS Lyon and CNRS, France

High concentrations of mercury (Hg) can often be found in the environment around inactive Hg mines. During mine operation, rock containing the primary ore mineral HgS was crushed and heated in furnaces to temperatures of ~ 700 °C (calcination). Most of the resulting elemental Hg vapor was condensed and collected and the remaining mine tailings (calcines) were piled on site. This removal process was not complete and significant amounts of Hg remained in the calcines. Large pieces of calcine often exhibit a characteristic internal layering, with dark-grey cores, light-grey outer rims, and red outer surface layers. The speciation of the Hg-bearing compounds in these wastes determines the solubility, volatility, and thus mobility of the remaining Hg [1, 2].

Various environmental processes fractionate the stable Hg isotopes via mass-dependent (MDF) and/or mass-independent fractionation (MIF); however, the controlling mechanisms are not fully understood. These isotopic signatures provide a promising new tool for further understanding Hg transformations and emissions from highly contaminated mining sites. Here we report stable Hg isotope results for different layers in calcine cobbles collected at the inoperative New Idria Hg mine, San Benito County, CA, USA.

Differently colored layers in the calcines were carefully separated, powdered, and digested following either total or sequential procedures [3]. Isotopic analyses were performed on a Nu Plasma MC-ICP-MS with cold vapor introduction.

Our analyses revealed significant concentration gradients across the different layers, with higher Hg concentrations in outer rims and lower concentrations in inner regions. In all sequential extractions, the 12M HNO_3 soluble fraction displayed the highest Hg concentration. In general, bulk calcine samples were isotopically heavier than ore and unroasted ore wastes, and significant MDF δ^{202}Hg gradients existed from isotopically heavy centers to lighter rims. These findings suggest that incomplete roasting of ore rocks led to pronounced Hg isotope gradients which were presumably caused by kinetic effects during diffusive processes.

[8]Beppu Geothermal Laboratory, Kyoto University, Japan
[9]Kyoto Fission-track Co., Ohmiya, Kita-ku, Kyoto, Japan

To further understand abrupt climate changes, and any geographical leads and lags, it is important to precisely correlate high-resolution terrestrial, marine and ice core archives from around the globe. This requires improved dating techniques and methods for correlating these sedimentary archives. Volcanic ash (tephra) layers provide ideal markers to synchronise records over regional areas, and $^{40}Ar/^{39}Ar$ eruption ages can provide direct temporal constraints. Here we discuss the methodology used to obtain high-precision $^{40}Ar/^{39}Ar$ age of a tephra within the SG06 Suigetsu archive.

The 73 m-long SG06 core from Lake Suigetsu, Japan provides continuous record of sedimentation spanning the last ~150 kyrs [1] and represents one of the most important Late Pleistocene palaeoclimatic records. SG06 is annually layered (varved) down to ~65 kyrs and contains numerous terrestrial plant macrofossils, from which a varve chronology and radiocarbon analyses are currently being paired to generate a wholly terrestrial radiocarbon calibration dataset that extends to the older limit of the radiocarbon analytical method (see [1]). We present our $^{40}Ar/^{39}Ar$ ages along with the varve and ^{14}C chronology to show that it is possible to get accurate and precise ages of eruption units that are near the young limit of the $^{40}Ar/^{39}Ar$ method.

The scale factor in the ectomycorrhizal fungal weathering debate

M.M. SMITS[1], Z. BALOGH-BRUNSTAD[2], L. SACCONE[3], H. WALLANDER[4] AND J.V. COLPAERT[1]

[1]Centre of Environmental Science, Hasselt University, Belgium (mark.smits@uhasselt.be)
[2]Hartwick College, Oneonta, NY, 13820 USA
[3]H.H. Wills Physics Laboratory, University of Bristol, UK
[4]Microbial Ecology, Lund University, Sweden

Ectomycorrhizal fungal weathering research has a long history, but with the launch of the term 'Rock-eating Fungi' this research topic attracted increased attention. There is growing evidence that ectomycorrhizal fungi do interact with soil minerals. Carefully designed laboratory experiments show increased mineral dissolution rates in the presence of ectomycorrhizal fungi. Even at the scale of the individual hyphae we gain more insight in the mechanisms of fungal-mineral interactions via sophisticated (ultra)-microscopic and spectroscopic techniques. But the basic question whether ectomycorrhizal fungi have a significant contribution to soil mineral weathering, remains unanswered.

Over the past decades several reviews have been published, some advocating and others opposing the role and significance of ectomycorrhizal fungi in soil mineral weathering. Most of the arguments used in this debate are scale-dependent. The ignorance of the importance of scale has hindered communication and better insight into each other arguments. Key points in the arguments opposing ectomycorrhizal weathering are that mineral dissolution is expected to be mainly driven by water or proton-metal exchange reactions and not through the formation of organic-metal complexes due to extremely low concentrations of organic chelators in soil solutions. Key points in the arguments in favour of ectomycorhizal weathering are that fungi act at the scale of individual hyphae, creating isolated water pockets with probably very dinstict chemistry and showing hyphal-mineral contact interactions.

It is important to realize that in ectomycorrhizal plants, the fungal partner is the main interface between plant and soil. Recent studies show that fungal hyphae preferentially colonize some minerals over others, implicating that plant/fungal interactions with minerals take place in a nonrandom fashion. But fungal hyphae only cover <5% of the mineral surfaces. The scale and heterogeneity of weathering actions should be acknowledged before drawing conclusions in relation to the relevance for the actual soil mineral weathering process.

Excess argon systematics under HP-LT conditions: A tracer for metamorphic fluid connectivity?

UV laserprobe single-grain fusion apparent $^{40}Ar/^{39}Ar$ ages of phengite from a gl + jd bearing blueschist of the Tauern Window, Eastern Alps range between 35.35 ± 0.37 Ma and 43.67 ± 0.50 Ma (1σ). These ages are between 2—11 Ma older than the age of blueschist-facies metamorphism determined by U—Pb allanite [1] and Rb—Sr [2] multi—mineral geochronlogy. Pseudosection calculations show that the phengite grew close to peak pressure conditions of ~10 kbar at 450° C, before Barrovian metamorphism (~7 kbar, 550°C) at ca. 30 Ma [3]. The anomalously old $^{40}Ar/^{39}Ar$ phengite ages show that the sample contains excess ^{40}Ar, i.e. ^{40}Ar decoupled from parent ^{40}K. Concentrations of excess ^{40}Ar vary on the mm—cm lengthscale.

The incompatible nature of Ar means that high concentrations of fluid—borne Ar are required to facilitate partitioning of Ar into mica. Numerical modelling of Ar diffusion in phengite provides an estimate of the expected $^{40}Ar/^{39}Ar$ age for a mica following the Tauern PTt path. We show that the measured 'older' apparent ages may be reproduced by: 1. an open rock volume, where Ar is fluid—borne within an interconnected grain boundary reservoir, 2. a closed system in which the Ar concentration of the grain boundary reservoir is controlled by metamorphic porosity and whole—rock K_2O content, or 3. a temporal variation between these two end-member scenarios. Collectively, these calculations show that, provided an independent constraint on the timing of mica growth exists, excess ^{40}Ar contamination can be used to investigate degrees of fluid flow and fluid pathway connectivity during a metamorphic cycle.

Hydrous phases in the lower mantle

JOSEPH R. SMYTH AND DAVID A. BROWN

Department of Geological Sciences, University of Colorado, Boulder CO 80309 USA (smyth@colorado.edu, davanbro@colorado.edu)

Dehydration of subducting lithospheric slabs to less than 200 ppmw H_2O in the upper mantle is virtually impossible given the stability of nominally hydrous phases such as serpentine, 10Å phase, phase A, chondrodite, and clinohumite. Velocity models of the transition zone are consistent with significant hydration (> 1000 ppmw H_2O), but not with a dry pyrolite composition. It seems likely then that transition zone is relatively hydrous and that slabs penetrating the TZ are also hydrous. Where slabs push through 660 km into the lower mantle the fate of the water depends on the H solubility in $MgSiO_3$-perovskite, periclase, akimotoite, and majoritic garnet as well as the nominally hydrous phase D.

FTIR studies indicate relatively low solubility of H in perovskite and periclase [1]. However, we have synthesized $MgSiO_3$-perovskite with up to 2000 ppmw H_2O as measured by SIMS. It is, however, as yet unclear if the H is in the structure or as inclusions. We have measured up to 3000 ppmw H_2O in majoritic garnet where hydration may be associated with Mg octahedral vacancies. Phase D ($MgSi_2H_2O_6$) is a nominally hydrous phase stable to depths up to 1500km. We have synthesized Phase D in silica-excess and Mg-excess compositions as well as aluminous compositions. Phase D has a high bulk modulus but a relatively low density so that hydrous slabs penetrating 660 km may be buoyant [2]. Further experimental work is required for a meaningful constraint on possible H contents of the lower mantle.

Hot summers in the Western United States during the Late Cretaceous and Early Cenozoic

[4]University of California Santa Cruz, Santa Cruz, CA

Understanding how seasonal temperatures on land respond to global greenhouse climate conditions is important for predicting effects of climate change on ecosystem structure, agriculture and distributions of natural resources. Fossil floral and faunal assemblages suggest winter temperatures in middle and high latitude continental interiors during the Cretaceous and early Cenozoic were at or above freezing, whereas terrestrial summer temperature estimates are uncertain. Carbonate clumped isotope (Δ_{47}) temperature estimates from lacustrine and paleosol carbonates appear to be generally biased toward summer temperatures in middle and high latitudes. Though problematic for reconstructing mean annual temperature (MAT), this bias presents an opportunity to reconstruct terrestrial summer temperatures and, through comparison with paleobotanical data, estimate past terrestrial seasonality.

Here, we compile MAT estimates from paleoclimate and paleoelevation studies in the western United States. We then compare these data with existing [1, 2] and new Δ_{47} temperature estimates from Late Cretaceous – Present lacustrine and paleosol carbonates from the western United States. In this compilation, land temperatures are warm during the Late Cretaceous, reach an apex during the early-middle Eocene and then cool to the present (sharply from the late Miocene to Pleistocene). Both MAT and summer temperature estimates are warmer than modern MAT and summer temperature estimates at the study sites throughout the Cenozoic and Late Mesozoic. Summer temperatures from low paleoelevation sites during the Late Cretaceous to the Early Eocene are relatively warm (~30 – 40°C), though these values may include a few degrees of radiant solar heating of the surface. Regardless, these data suggest that at middle latitudes, both winters and summers in continental interiors may warm substantially under greenhouse climate conditions.

Anthropogenic contributions of ^{129}I and ^{85}Kr to global reservoirs: Current distribution patterns and projected increases

G.T. SNYDER[1]*, J.E. MORAN[2] AND A. ALDAHAN[3,4]

[1]Rice Universtiy, Houston, TX, 77003, USA
(*correspondence: gsnyder@rice.edu)

(*correspondence: ala.aldahan@uaeu.ac.ae)
[4]United Arab Emirates Univ., Al Ain, United Arab Emirates

^{129}I and ^{85}Kr are two isotopes whose presence in global surface reservoirs is due primarily to nuclear reprocessing activities. A knowledge of the partitioning of these isotopes in surface reservoirs is critical to our understanding of how release and storage of these isotopes should be handled presently and in the future.

Long-lived ^{129}I (half-life=15.6 Myr) partitions primarily into shallow soil and seawater. While its residence time in the atmosphere is short, repeated cycling of iodine between surface waters and the atmosphere has resulted in its distribution far from point sources. Downwelling of surface waters in the North Atlantic presently transports ^{129}I to deep waters which provide a temporary sink for anthropogenic iodine. In contrast, the relatively short-lived ^{85}Kr (half-life=10.76 yr) partitions primarily into the atmosphere and its dispersal is a result of wind patterns in the troposphere. We compare the present distribution of these two isotopes and model their increase into the future when the bulk of nuclear reprocessing is projected to move from Western Europe to Asia. We also discuss the effect of speciation of ^{129}I and stable ^{127}I in the environment, and disequilibrium between these two isotopes.

Combined use of Raman, ToF-SIMS and AFM imaging for characterizing the surface reactivity of sea salts

S. SOBANSKA*, M. CHOËL, M. MOREAU AND J. BARBILLAT

LASIR/CNRS University of Lille 1, Bât C5, 59655 Villeneuve d'Ascq Cedex, France
(*correspondence: sophie.sobanska@univ-lille1.fr)

Sea salt particles are typically emitted in the atmosphere through by breaking waves and bursting bubbles at the ocean surface where Cl^-, Na^+, Mg^{2+}, K^+ and SO_4^{2-} are the most abundant ions. It is well established that sea salts can react with gaseous species to form complex aerosols [1, 2]. Such reactive uptakes on the surface of particles during their atmospheric residence time can significantly alter their optical properties and affect their ability to act as cloud condensation nuclei. In addition, some products may be photochemically active at solar wavelengths and may affect the oxidative properties of the atmosphere [3]. Finally, in the marine atmosphere fatty acids (FA) are known to be present as particles and/or as a coating on sea salt particles which could influence sea salt reactivity [4]. *In situ* observation of the atmospheric processing of the surface of particles can be performed in laboratory by Raman microspectrometry (RMS) and Atomic Force Microscopy. The combined use of both techniques is a powerful tool to determine the morphology and the distribution of molecular species within individual micrometer-size particles [5]. Moreover, the first layers at the surface of particles (few nm) can be analyzed using Time-of-Flight Secondary Ion Mass Spectroscopy (Tof-SIMS) [6]. In this study, laboratory experiments were conducted to simulate heterogeneous reaction at the surface of sea salt particle (NaCl) coated with FA and exposed to gaseous pollutants (NO_2). As expected, formation of nitrate salts on the surface of NaCl was evidenced and influence of FA demonstrated at the surface scale. Finally, by using RMS imaging in the UV range (266 nm and 325 nm), the photochemistry of formed nitrates and influence of FA on their photo-reactivity was also studied. This work demonstrated the the potential of the combination of RMS, AFM and ToF-SIMS imaging for studying the heterogeneous chemistry of the particle surfaces.

Mineral composition of sediments of the Southern Baltic Sea and their heavy metals content

K. SOBCZAK[1]*, J. BEŁDOWSKI[2] AND M. MICHALIK[1]

[1]Institute of Geological Sciences, Jagiellonian University, ul. Oleandry 2a, 30-063 Kraków, Poland (*correspondence: katarzyna.sobczak@uj.edu.pl, marek.michalik@uj.edu.pl)

[2]Marine Chemistry and Biochemistry Department Institute of Oceanology, Polish Academy of Sciences, Powstańców Warszawy 55, 81–712 Sopot, Poland (hyron@iopan.gda.pl)

Samples of sediments were collected from eight cores in three areas of the southern Baltic Sea (the Gulf of Gdańsk, Bornholm Deep and the Odra Bank) from three different depths (0-3cm, 25-28cm and 35-38cm).

Mineral and chemical composition of sediments was studied using XRD, SEM-EDS, ICP-MS, and ICP-AES methods. Chemical composition of leachates from sequential extraction was also determined.

Samples from the Gulf of Gdańsk are dominated by silty fraction, samples from the Odra Bank represent fine to medium sands with abundant shell fragments, sediments from Bornholm Deep are mainly clay. Quartz predominates in all samples. In silty samples framboidal piryte is present; halite and gypsum occurs only in few of them. Clay minerals occur in low amount in silty samples. Ilmenite, zircon and Fe compound are common in sand, but appear sporadically in silt samples.

Geoaccumulation index (Igeo = ln (Cn/1.5×Bn); Cn-measured concentration, μg/g, Bn - geochemical background value, μg/g) indicates strong to very strong Cd pollution in three surface samples. Other factors revealed pollution by As, Cd, Mo and Hg. Variation of concentration of heavy metals occurs in profiles, e.g. Hg and Cd are concentrated in uppermost samples but As and Mo concentration increase downward. Results of sequential extraction suggest significant diversity of metals speciation in sediments.

Crustal recycling: New findings and challenges

A.V. SOBOLEV[1,2,3]

[1]ISTerre, University J. Fourier BP 53, 38041 Grenoble Cedex 9, France (alexander.sobolev@ujf-grenoble.fr)

[2]Max Planck Institute for Chemistry, Postfach 3060, 55020 Mainz, Germany

[3]Vernadsky Institute of Geochemistry, RAS, 119991 Moscow, Russia

Since Hofmann and White's paper [1] crustal recycling via subduction and convection is a widely accepted explanation for the heterogeneity of OIB sources. Recycled crust has been recognized even in the sources of MORB (e. g [2, 3]). However, there are still no common view on the amount, composition and ages of recycled materials in both parts of the mantle.

In this paper I review recent approaches for estimating the contents and ages of recycled crust in the sources of OIB, LIP and MORB. In particular, I discuss the ability of olivine phenocrysts to record the magma source mineralogy in their concentrations of Ni, Mn, Fe, Zn, Co, Sc and Ca. I show that adiabatic decompression of deep-sourced mantle magmas and the presence of garnet in their sources do not compromise the ability of olivine to register olivine-free source lithologies.

Large datasets of new olivine compositions and published high-precision analyses [3, 4] suggest the common presence of olivine-free pyroxenite produced by melting and reaction of oceanic crust in the sources of OIB, LIP and MORB. The proportions of pyroxenite-derived melt commonly correlate with trace element and isotope data from bulk rocks [5, 6] indicating binary mixing of melts from peridotitic and pyroxenitic sources. High amounts of recycled oceanic crust are associated with high excess mantle temperatures and high depths of melt generation, in agreement with the high density and melt productivity of a garnet-rich source [3].

The ages of recycled oceanic crust estimated from correlation of bulk-rock $^{187}Os/^{188}Os$ ratios and the proportions of pyroxenite-derived melt [5] or from the $^{86}Sr/^{87}Sr$ of ancient recycled seawater [7] are in the range of 1.0-0.2 Ga. This implies a time-scale of general mantle circulation of a few centimetres per year.

Heterogeneities in the mantle plume: Spatial scales and ages

A.V. SOBOLEV[1,2,3], A.W. HOFMANN[2], K.P. JOCHUM[2], D.V. KUZMIN[2] AND B. STOLL[2]

[1]ISTerre, University J. Fourier BP 53, 38041 Grenoble Cedex 9, France (alexander.sobolev@ujf-grenoble.fr)
[2]Max Planck Institute for Chemistry, Postfach 3060, 55020 Mainz, Germany
[3]Vernadsky Institute of Geochemistry, RAS, 119991 Moscow, Russia

Recycling of oceanic crust through subduction, mantle upwelling, and remelting in mantle plumes is a widely accepted mechanism to explain ocean island volcanism. However, neither time scales of this process nor spatial scales of the resulting mantle heterogeneities are well understood.

We report data on trace elements, $^{87}Sr/^{86}Sr$, $^{207}Pb/^{206}Pb$, and $^{208}Pb/^{206}Pb$ ratios for 138 melt inclusions in olivine phenocrysts from single lava of Mauna Loa shield volcano, Hawaii, indicating enormous mantle source heterogeneity. The variations in isotopic compositions and trace element ratios far exceed all known ranges for Hawaiian shield stage volcanoes. The variation range is highest for melt inclusions trapped in the most magnesian olivines. This is consistent with the interpretation that melt inclusions in early olivine phenocrysts yield information on the compositions of unmixed parental melts, while lavas and inclusions in more evolved olivine are mixtures of these melts.

We show that highly radiogenic strontium ($^{87}Sr/^{86}Sr$=0.7081± 0.0006, 2σ) in severely Rb-depleted melt inclusions matches the isotopic composition of 200-650 Ma old seawater. We infer that such seawater must have contaminated the Mauna Loa source rock, prior to subduction, imparting a unique 'time stamp' on this source. Small amounts of seawater-derived strontium in plume sources may be common but can be identified clearly only in ultra-depleted melts originating from generally highly (incompatible-element) depleted source components.

We also show that the Sr-rich component of Mauna Loa lavas is particularly unradiogenic ($^{87}Sr/^{86}Sr$ < 0.7030), supporting the suggestion that it corresponds to plagioclase cumulate gabbros from recycled oceanic crust (Sobolev et al, Nature, 2000).

Enormous isotope heterogeneity of melts mixed in a single plumbing system favours small-scale mantle source heterogeneity preserved in the mantle plume. The presence of 200-650 Ma old oceanic crust in the source of Hawaiian lavas implies a time-scale of general mantle circulation with an average rate of about 2 (± 1) cm/a, a much faster rate than previously thought.

Modeling relationships between a mantle plume, a large igneous province and a mass extinction

S.V. SOBOLEV[1], A.V. SOBOLEV[2,3], D.V. KUZMIN[3], N.A. KRIVOLUTSKAYA[3], A.G. PETRUNIN[1], N.T. ARNDT[2], V.A. RADKO[3] AND YU.R. VASILIEV[3]

[1]GFZ, German Research Centre for Geosciences, 14473 Potsdam, Germany (*correspondence: stephan@gfz-potsdam.de)
[2]ISTerre, University J. Fourier BP 53, 38041 Grenoble Cedex 9, France (alexander.sobolev@ugf-grenoble.fr)
[3]Vernadsky Institute of Geochemsitry, RAS, 119991 Moscow, Russia

Large Igneous Provinces (LIPs) are known for their rapid production of enormous volumes of magma, for dramatic thinning of the lithosphere and for their links to global environmental catastrophes. Controversy surrounds even the basic idea that LIPs form through melting in the heads of thermal mantle plumes. The Permo-Triassic Siberian Traps – the type example and the largest continental LIP, is located on thick cratonic lithosphere and was synchronous with the largest known mass-extinction event. However, there is no evidence of pre-magmatic uplift nor of a large lithospheric stretching of the basaltic sequence, predicted above a plume head. Moreover, estimates of magmatic CO_2 degassing from the Siberian Traps are considered insufficient to trigger climatic crises leading to the hypothesis that the release of thermogenic gases from the sediment pile caused the mass extinction.

Here we present petrological evidence for a large amount (15 wt%) of dense recycled oceanic crust in the head of the plume and developed a thermomechanical model that predicts no pre-magmatic uplift and requires no lithospheric extension. The model employs source-composition and temperature [1, 2] petrological constraints, non-linear elasto-visco-plastic rheology [3] and pressure- and temperature-dependent melting of a heterogeneous mantle. The model implies extensive plume melting and heterogeneous delamination of the thick cratonic lithosphere during a few hundred thousand years. The model also suggests that massive CO_2 and HCl degassing from the plume could *alone* trigger the Permian-Triassic mass extinction and predicts it happening *before* the main volcanic phase.

The effect of pressure on tetrahdral tilting in feldspars

L.M. SOCHALSKI-KOLBUS* AND R.J ANGEL

Dept. Of Geosciences, Virginia Tech, Blacksburg, VA 24060, USA (*correspondence: lsochals@vt.edu, rangel@vt.edu)

Feldspars are framework aluminosilicates that comprise approximately 60 percent of the Earth's crust. The defining features of the feldspar framework are corner-sharing TO_4 tetrahedra connected into chains of 4-rings that run parallel to a-axis and b-axis. These 4-rings are connected by their corners and form a 'double-crankshaft' chain parallel to the d (100).

The response of the feldspar structure to pressure is very anisotropic with approximately 60-70% of the volume compression attributed to the length of the crystallographic direction d (100) [1]. It is of interest to undermine the details of this anisotropy and to predict thermodynamic properties and phenomena such as elastic softening for petrologic and geophysical investigations. Previous attempts to predict structural behavior of feldspars have been focused on individual T-O-T angles [2, 3], but this has been unsuccessful in describing structural reasons for either changes or the thermodynamic properties. Megaw (1974) [4] proposed a model that considers four independent tilt systems derived and 2 of the four tilt systems effect the length of the d (100).

Single crystal X-ray diffraction was performed on an ordered plasioclase crystal of 20% anorthite content and structures were determined from 0 – 9.221 GPa. The effect of high pressure on these four different tilt systems have been studied on Na-rich plagioclase from this study and previously measured samples from 0 - 37 % anorthite. I found that 3 of the 4 tilt systems change similarly until 5-6 GPa. After this pressure range, these three tilt systems change behavior. Interestingly, these are the approximate pressures that there is elastic softening seen in the volumes for Na-rich feldspars. The systematics found from this current study are being investigated to see if tetrahedral tilting is a useful tool for predicting the thermodynamic properties and behavior of feldspars at high pressure.

A new statistical method for modeling mixing of mantle end-members for global MORB and OIB isotopic data

R. A. SOHN [1]* AND K.W.W. SIMS[2]

[1]Woods Hole Oceanographic Institution, 360 Woods Hole Rd., MS #24, Woods Hole, MA, 02543 (*correspondence: rsohn@whoi.edu)

[2]Dept of Geology and Geophysics, University of Wyoming Laramie, Wy, 82070 (ksims7@uwyo.edu)

Long-lived isotopic ratios have been used to identify reservoirs of chemically distinct material in the Earth's interior, typically labeled DMM, EM1, EM2 and HIMU [1, 2]. We have developed a new statistical method that allows us to find best-fitting mixing curves and surfaces for binary and ternary systems, respectively, and we apply this method to global compilations of isotopic ratios ($^{87}Sr/^{86}Sr$, $^{143}Nd/^{144}Nd$, $^{206}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$, $^{208}Pb/^{204}Pb$) for MORB and OIB samples in order to rigorously test various mixing hypotheses. The method also allows us to refine isotopic ratio estimates for the putative mantle end-member components, and quantify the misfit between a given dataset and an arbitrary mixing model.

We find that the global suite of MORB data requires at least three end-member components, one of which is DMM, a second that is similar to EM1 but with distinct Pb isotopes defined by samples from the South Atlantic, and a third that is similar to, but nevertheless distinct from, HIMU, defined by samples from the equatorial Atlantic. The global suite of OIB data, on the other hand, requires at least five end-member components, four of which appear to mix with the common component FOZO [3, and references therin]. Some OIB sample sets (e.g. Hawaii, Iceland), however, are difficult to distinguish statistically from the MORB field.

Our mixing analysis focuses on finding the simplest model that fits the MORB and OIB isotopic data and is consistent with the wider body of geochemical evidence. This type of rigorous statistical method is indispensable for analyzing large amounts of complex geochemical data, and it provides an objective means for discriminating between competing models of mantle mixing through formal hypothesis testing.

Protracted history of continental subduction at the southern edge of the Maya Block, central Guatemala: Petrological and geochronological evidences

L.A. SOLARI[1]*, A. GARCÍA CASCO[2], J.K.W. LEE[3] AND A. ORTEGA-RIVERA[4]

[1]Centro de Geociencias, UNAM, Juriquilla, 76001 Querétaro, Mexico (*correspondence: solari@servidor.unam.mx)
[2]Departamento de Mineralogía y Petrología, Universidad de Granada, 18002 Granada, Spain (agcasco@ugr.es)
[3]Department of Geology, Queen's University, Kingston, Ontario, K7L 3N6, Canada (lee@geol.queensu.ca)
[4]ERNO, Instituto de Geología, UNAM, 83000 Hermosillo, Son., México (amabel@servidor.unam.mx)

The Rabinal Granite Suite is an anatectic S-type composite pluton which fringes the southernmost North America Plate margin in Central Guatemala. It is a Kfs-Pl-Ms-Qtz granite-granodiorite, showing increasing deformation along its southern margin where it is crosscut by the dextral, Late Cretaceous, top-to-NE Baja Verapaz Shear Zone. Previously considered as Devonian-Mississippian in age, it has been recently dated at 562-453 Ma. LA-ICPMS U-Pb and Ar-Ar geochronology, combined with microprobe mineral chemistry, allow precising its P-T-time history. U-Pb zircon ages indicate a crystallization age of 471 +3/-5 Ma (Middle Ordovician), as well as abundant cores inherited from the metapelitic source with main density peak distributions at 700, 806, 900, 996, 1376 Ma. Laser total fusion Ar-Ar analyses of magmatic muscovite (Si= 6.2-6.4 atoms per 20 O and 4 OH) indicate cooling at various times during the mid-late Paleozoic. The petrologic conditions of the Ordovician metamorphism, partial melting of a metapelitic protolith and seggregation-ascent-crystallization of the granitic melt occurred along a clockwise P-T-t path at intermediate P, with maximum P of 8 kbar (ca. 25 km) during prograde metamorphims and peak T of 750 °C (at mid-crustal levels, 5-7 kbar). This evolution is interpreted as the result of a tectonic cycle related to the initial opening of the Rheic Ocean. A second clockwise path at high-P is indicated by high silica muscovite (Si= up to 7.0 atoms pfu), with peak P of ca 10 kbar at ca. 330 °C. This second event did not recrystallize the U-Pb clock in zircons, but it is clearly recorded by a main peak of laser total fusion Ar-Ar analyses on high Si muscovite grains yielding an average of 70.09 ± 0.5 Ma. This latest Cretaceous stage is related to subduction of the North America plate margin (cover and pre-Mesozoic basement) below the Caribbean Plate and ensuing collision with the Caribbean volcanic arc.

Evolution of magma oceans

V.S. SOLOMATOV

Washington Univ., St. Louis, MO, 63130, USA (slava@wustl.edu)

Lord Kelvin's vision of the early molten Earth has been reincarnated after the samples returned by the Apollo missions presented evidence that the Moon might once have been molten. This evidence led to a hypothesis of a lunar magma ocean. The idea of an early molten Earth - the terrestrial magma ocean hypothesis - was developed not long after and rapidly gained a broad acceptance [1]. Magma oceans or magmaspheres of various types on Earth as well as on other terrestrial planets have been proposed [2-8]. The growing list of extrasolar planets now includes planets which currently are likely to be at least partially molten [9]. The hypothesis of magma oceans is undoubtedly among the most important building blocks in the modern narrative of planetary formation and evolution. The major challenge in describing the evolution of magma oceans is that we have to deal with the extreme conditions of planetary interiors where the material properties and global dynamics are poorly understood [10, 11]. Answers to even basic questions concerning whether solid phases sink or float in magma oceans, how long it takes magma oceans to crystallize and where chemical equilibriation occurs have been eluding researchers for decades. Yet, these questions are critical for the interpretation of geochemical data, for the understanding of how magma oceans lead to the current planetary structures and to the current dynamic regimes of planetary interiors including the existence of plate tectonics on Earth [12].

Mobility of elements from cesium formate residue emplaced on pegmatite tailings

P. SOLYLO* AND B. L. SHERRIFF

[1]Department of Geological Sciences, University of Manitoba, Winnipeg, MB, Canada, R3T 2N2 (*correspondence: patrick_solylo@hotmail.com)

A unique Cesium Products Facility (CPF) manufactures a cesium-formate drilling mud from pollucite ore at a pegmatite mine in SE Manitoba, Canada. The CPF is a closed system, with the waste slurry discharged to containment cells. When a cell is full, the Cs-rich slurry is dewatered, and the residue is dry-stacked on neutral tailings in a hydrogeologically closed tailings management area. This study concentrated on the geochemical and mineralogical reactions occurring within the residue pile and the underlying tailings to determine the mobility of Cs and other residue-related elements including Rb, Sr, Ba and Li.

Drill cores were extracted from the residue and tailings. The mobility of residue-related elements was examined through mineralogical observations, sequential extraction and porewater analysis.

The residue contains an order of magnitude more Cs (up to 2 wt. %) than the tailings (up to 0.3 wt. %). Sequential extraction results showed that 47% of the total Cs in the residue is mobile under natural conditions, compared with only 24% in the tailings. The stable forms of Cs in the residue are pollucite, feldspar and formate with sulphate and carbonate being the mobile forms. The Cs being released into the tailings does not appear to be re-precipitating in secondary phases. Cesium is predominantly in pollucite in the tailings. Rb, Sr, Ba and Li are all immobile in both the residue and the tailings in feldspar, lepidolite and barite.

Earth's early atmospheric density revealed from Archaean raindrop imprints

SANJOY M. SOM[1]*, DAVID C. CATLING[2] AND ROGER BUICK[2]

[1]NASA Ames Research Center, Moffett Field, CA 94035, USA (*correspondence: sanjoy.m.som@nasa.gov)
[2]University of Washington, Seattle, WA 98195, USA (dcatling@u.washington.edu)
[3]University of Washington, Seattle, WA 98195, USA (buick@ess.washington.edu)

The Archaean atmosphere has been investigated dominantly by numerical models that typically assume a total atmospheric pressure of ~1 atm [1-3]. However, barometric pressure may have been different, owing to the negligible presence of oxygen in the atmosphere [4], and the resulting difference in the redox-sensitive cycling of the other major gas, nitrogen.

We have developed a new method that uses lithified raindrop imprints as a proxy for atmospheric density. We consider the physics that determine the morphology of raindrop imprints preserved in tuff of the ~2.7 billion year old Ventersdorp Supergroup of South Africa [5]. Volume and surface area of raindrop imprints are a function of raindrop size and terminal velocity, the latter being dependent upon air density, whereas maximum raindrop size is not.

We experimentally determine the relationship between imprint volume and surface area as a function of raindrop size in wet ash (10% moisture by weight) from the 2010 Eyjafjallajokull event (Iceland) and Pahala (Hawaii), as modern analogs to the Ventersdorp tuff. We are then able to place an upper bound on the late Archaean atmospheric density, which has previously had no such observational constraint.

'WEERTMAN' cracks: A possible mechanism for near sonic speed diamond extraction from the Earth´s mantle

H. SOMMER[1]*, K. REGENAUER-LIEB[2,3], O. GAEDE[3], H. JUNG[1] AND B. GASHAROVA[4]

[1]School of Earth and Environmental Sciences, Seoul National University, Seoul, 151-747 Korea (*correspondence: info@holgersommer.de)
[2]School of Earth & Geographical Sciences, The University of Western Australia, Perth, Western Australia 6009, Australia
[3]CSIRO Exploration & Mining, PO Box 1130, Bentley, WA 6102, Australia
[4]ANKA/Inst.Synchotron Radiation, Forschungszentrum Karlsruhe GmbH, Hermann-von-Helmholtz-Platz 1, Eggenstein-Leopoldshafen, D-76344 Germany

'Weertman' cracks are two-dimensional liquid-filled cracks, which can move with a velocity close to Rayleigh-wave speed driven by the buoyancy or gravitational potential energy of the fluid and external stress fields. Therefore 'Weertman' cracks would be a potential transport mechanism for the diamond bearing kimberlitic-melt from the Earth's mantle to the Earth's surface. Arguments for the formation of 'Weertman' cracks are threefold: i) The geometry of kimberlite pipes resembles the shape predicted by 'Weertman' cracks; ii) Like Weertman cracks kimberlites themselves never develop an explosive stage besides the phreatomagmatic eruption due to contact with groundwater close to the Earth's surface; the melt often gets trapped near the Earth's surface; iii) The speed for the uplift of the diamonds from >150 km depth must be larger than 800 km/h to explain preservation of diamonds. The question to be answered is: What method can be used to confirm the formation of 'Weertman' cracks? Here we show that OH-diffusion profiles in nominally water free minerals, recorded from quenched diamondiferous host rock, are indicative for near sonic speed diamond extraction from the Earth´s mantle. This unforeseen discovery shows that 'Weertman' cracks are the only possible transport mechanism for diamonds from the Earth's mantle to the surface. Further, our findings show that the observed breadths of kimberlite pipes are surprisingly short, given the fact that the magma ascends from depths is in order of up to ~330 m/s. The ascent rates of kimberlites are of high economic interest, because if the diamonds are to long in contact with the kimberlitic melt they start to dissolve within a few minutes.

Provenance discrimination of plants from three bedrock types using strontium isotopes and chemical analysis

B.Y. SONG[1], G. MUKESH[2], W.J. SHIN[2], M. CHOI[2] AND K.S. LEE[2]*

[1]Graduate School of Analytical Science and Technology, Chungnam National Univ (songby10@kbsi.re.kr)
[2]Korea Basic Science Institute, Ochang Center, Chungbuk 363-883, Korea (*correspondence: kslee@kbsi.re.kr)

This study is to assess the inter–lithological variations in the stable Sr isotopes that define an ecosystem/ habitat nutrient cycle and their signature in the aboveground vegetation. Five plant species, *Acacia sp*., *Zelkova serrata*, *Prunus serrulata*, *Capsicum annuum*, *Zea mays* and *Allium fistulosum* commonly found growing on granite, limestone and basalt formations were selected. Our hypothesis is based on the two facts-one the $^{87}Sr/^{86}Sr$ ratios depends on geological regime and this ratio varies significantly from one geological formation to another [1]. Second plants display particularly strong isotopic signals because they construct their tissues from such small molecules [2]. Based on these premise this natural phenomenon can be put into use to explain inter–lithological differences and effects of these inter–lithological variations on plant nutrient physiology.

Preliminary analsysis shows that $^{87}Sr/^{86}Sr$ ratios of tree leaves and fruit vegetables varied according to bedrock types in which they grow. $^{87}Sr/^{86}Sr$ ratios of plant leaves and vegetables well reflected the geological characteristics of three regions where they were grown.

Integrated model to simulate and predict fate and transport process of contaminant in vadose zone

LINRUI SONG[1], JING ZHANG[2]* AND HUILI GONG[3]

[1]The Key Laboratory of Resource Environment and GIS of Beijing, Capital Normal University, Beijing 100048, P.R. China

[2]The Key Laboratory of Resource Environment and GIS of Beijing, Capital Normal University, Beijing 100048, P.R. China (*correspondence: maggie2008zj@yahoo.com)

[3]College of Resource Environment and Tourism, Capital Normal University, Beijing 100048, P.R. China

Interaction between surface water and groundwater is always a hot research topic in geochemistry, ecohydrology and interdisciplinary sciences. It's better to reveal the law of contaminant behavior in the regional water cycle process coupling of surface water and groundwater simulation, and also provide a good basis for the comprehensive consideration in environment changes effected by nature and anthropogenic. Vadose zone is the bond linking of surface water and groundwater, therefore, the physical mechanism of integrated model will be greatly enhanced considering the dynamics of vadose zone water movement. In this research, the rural plain area in the Capital City of China, Beijing with water eco-system protection function has been selected as the study location which experiences period of drought and wetness annually. Based on the use of traditional field survey techniques combined with remote sensing technology to access to the model parameters, this research will discuss the comparison between two surface - groundwater integrated models (MIKESHE and IHM) to simulate and predict the fate and transport process of nitrogen loading in the study area.

The molybdenum isotopic indication of low-medium temperature hydrothermal ore-forming systems: A case study on the Dajiangping pyrite deposit, Western of Guangdong Province, China

SONG SM[1], HU K[1], WEN HJ[2] AND ZHANG YX[2]

[1]State Key Laboratory for Mineral Deposits Research, School of Earth and Engineering, Nanjing University, Nanjing 210093, China

[2]Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China

We present molybdenum isotope data from 12 hydrothermal syndepositional silicalite and carbonaceous slate samples from the Dajiangping pyrite deposit in western Guangdong Province, South China. The $\delta^{97/95}$Mo values from Orebody III range from -0.02‰ to 0.29‰, with an average of 0.18‰. In contrast, the composition values from Orebody IV display a larger variation from -0.70‰ to 0.62‰, especially the five samples from the main ore bed all show strong negative values. Orebody III is likely to have been deposited from submarine exhalative hydrothermal fluids under a relatively strong reducing environment and Orebody IV may have also been influenced by hydrothermal superimposition in a more oxidized disequilibrium condition. The $\delta^{97/95}$Mo values of Orebody IV are clearly negative, together with the values increasing stratigraphically upward in the ore beds, suggesting that the metallogenic environment of Orebody IV could be present dynamic fractionation in this restricted environment. Microorganisms including organic matter and replacement and/or adsorption of Fe-Mn oxides might influence the Mo isotopic fractionation in the ore-forming fluids.

Structural controls on surface hydroxyl reactivity in iron hydroxides

XIAOWEI SONG* AND JEAN-FRANÇOIS BOILY

Department of Chemistry, Umeå University, Sweden (*correspondence: xiaowei.song@chem.umu.se)

Mineral surfaces are populated with distinct types of hydroxyl groups displaying various catalytic roles with respect to gases, solvents and solutes. Knowledge of the types and distributions of hydroxyl groups on minerals with different surface structures is essential for gaining molecular-scale resolution of these processes.

This work provides Fourier transform infrared (FTIR) spectroscopic signatures of hydroxyl groups present on surfaces of FeOOH minerals, including lath- and rod-shaped lepidocrocite (γ), (nano) goethite (α) and akaganéite (β).

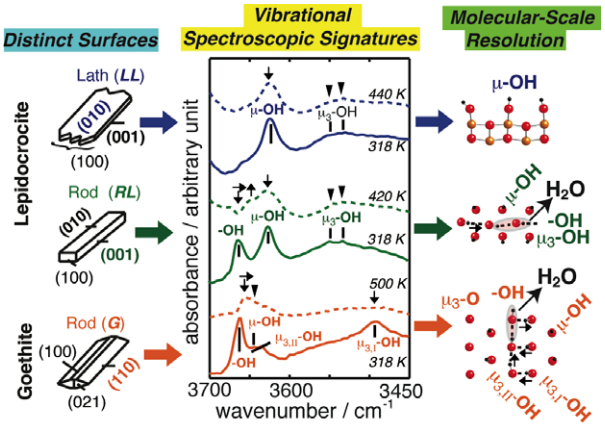

Figure 1: Synopsis of FTIR work, assisted by MD simulations, used to identify surface species and reactivity.

Our combined FTIR and molecular dynamics studies of these FeOOH surfaces enabled the extraction of unique spectroscopic signatures for distinct hydroxyl groups. Individual responses of these groups to variations in proton loadings and temperature provide experimental validation to previous theoretical accounts on their reactivity. These efforts now provide new possibilities for probing important gas-phase adsorption processes. They should moreover lay foundations for interfacial studies involving water.

La-Ce and Sm-Nd isotope geochemistry of felsic granulite in the Jirisan complex, Yeongnam Massif, Korea

YONG-SUN SONG[1], SEUNG-GU LEE[2]*, YOSHIHIRO ASAHARA[3] AND TSUYOSHI TANAKA[3]

[1]Department of Earth Environmental Sciences, Pukyong National University, Pusan 608-737, Korea (yssong@pknu.ac.kr)

[2]Geological Research Division, Korea Institute of Geoscience and Mineral Resources, Daejeon 305-350, Korea (sgl@kigam.re.kr)

[3]Department of Earth and Environmental Sciences, Nagoya University, Nagoya 464-8601, Japan (asahara@eps.nagoya-u.ac.jp, tanaka@eps.nagoya-u.ac.jp)

REEs contain two long-lived decay systems, the ^{147}Sm-^{143}Nd and ^{138}La-^{138}Ce decay systems, which provide us with the information on ages and initial ratios that helps us understand their origin and history. Hence, the application of the La-Ce and Sm-Nd isotope systematics in petrogenetic studies has enabled an estimation of the light rare earth element (LREE) patterns in source materials of the rocks.

We report La-Ce and Sm-Nd isotopic data of highly evolved granites with the composition of major and rare earth element from the felsic granulite, which occurs at the Jirisan Complex in the Yeongnam Massif, Korea. Based on the Ce and Nd isotopic data, we also discuss the REE geochemistry of source material of the Jirisan felsic granulite. The felsic granulite shows three different types of chondrite-normalized REE pattern: one is a tetrad REE pattern of M-type with a large negative Eu anomaly, another is a W-type tetrad REE pattern, and the third is an REE pattern of crustal type showing an LREE-enriched and HREE-depleted pattern. U-Pb zircon and Rb-Sr whole rock ages are 1874 Ma and 1831±36 Ma (2σ) with initial 0.7028±0.0097, respectively. However, Sm-Nd isotopic system from these rocks shows error-chron ages from 1235 Ma to 1570 Ma suggesting that Sm-Nd isotopic system might have been disturbed by specific geochemical processes related to the formation of the tetrad REE patterns. Nevertheless, initial Ce-Nd isotopic values show that all three types were derived from the isotopically similar source materials. Our data also indicate that La-Ce and Sm-Nd isotopic system may be useful in understanding REE fractionation between rock and its source material.

Direct observation of chemical modification of Asian Dust particles during long-range transport

YOUNG-CHUL SONG, HAE-JIN JUNG, HYEKYEONG KIM AND CHUL-UN RO*

Department of Chemistry, Inha University
(*correspondence: curo@inha.ac.kr)

In our previous works [1-3], it was clearly demonstrated that the combined use of quantitative energy-dispersive electron probe X-ray microanalysis (ED-EPMA), known as low-*Z* particle EPMA, and attenuated total reflectance FT-IR (ATR-FT-IR) imaging technique had the great potential for detailed characterization of individual aerosol particles. In this work, individual Asian Dust particles collected during an Asian dust storm event occurred on Nov. 11, 2002 in Korea were characterized by the combined use of low-*Z* particle EPMA and ATR-FT-IR imaging technique. By the combined use of the two single-particle analytical techniques on the same individual particles, it was observed that Asian Dust particles had experienced extensive chemical modification during long-range transport, through heterogeneous reactions with nitrogen or sulfur oxide species resulting in nitrate and/or sulfate formations, respectively. On the basis of information on their morphology, elemental concentrations, and functional groups of individual particles available from the two analytical techniques, overall 109 individual particles were classified into four particle types: Ca-containing (38%); $NaNO_3$-containing (30%); silicate (23%); and miscellaneous particles (9%). Among overall 41 Ca-containing particles, the numbers of particles containing nitrate, sulfate, and both are 14, 8, and 17, respectively, whereas the number of unreacted $CaCO_3$ particles is just 2, clearly demonstrating that the Asian Dust particles had extensively experienced heterogeneous reactions during long-range transport. The combined use of the two single particle analytical techniques could provide detailed information on their physicochemical characteristics of individual Asian Dust particles, and thus the identification of airborne amorphous phase calcium carbonate particles and nitrite species in aerosol phase, and mineralogy of silicate particles on a single particle basis could be performed.

The gully nitrogen migration and flux at northern China city

YUJIA SONG AND HUIQING LIU*

School of Urban and Environment Science, Northeast Normal University, 130024, Changchun, China
(ccssf0431@163.com,
*correspondence: jlsongyujia@126.com)

Research Object and Results

Yitong River at a representative northern China city, Changchun, was selected as research object. We quantitatively investigated the migration path and flux of nitrogen at gully region in the city under rapid urbanization process.

The results showed that at Yitong River basin, the total nitrogen input flux was 188 kg/hm^2, following the sequence of fertilizer input> biological immobilization> feed> atmospheric deposition. the total nitrogen output flux was 102.5kg/hm^2, following the sequence of products> waste output> denitrification> surface runoff. the net nitrogen storage was 85.5kg/hm^2. The migration path and flux of nitrogen were obviously by human activities, showing an imbalance of input and output and a tendency of nitrogen accumulation and pollution.

Discussion of Results

Nitrogen migration is a combined effect from meteorology, hydrology, topography and agricultural practices, among which rainfall is the key driving force [1]. The material input and migration directly impact nutrient loss [2].

Under the background of globalization, the nitrogen migration and the biogeochemical processes become extremely complex due to the coupling effects from interfering and natural factors [3], the knowledge about nitrogen source and destination is still very limited, China is localized at monsoon area, where the highest rate of environmental change occurs. Thus, long-term monitoring and modeling regarding entire watershed ecosystem as a whole and quantitative analysis of the coupling mechanism of human activity and natural processes are required. This will provide theoretical support for the healthy evolution and development of cities.

Mechanisms of Cd sorption to montmorillonite (Na-SWy-2) clay affected by ionic strength and microbial ligand

Z. SONG[1], B.A. BUNKER[1] AND P.A. MAURICE[2]

[1]Department of Physics, University of Notre Dame, Notre Dame, IN 46556, USA (*correspondence: zsong@nd.edu)
[2]Department of Civil Engineering and Geological Sciences, University of Notre Dame, Notre Dame, IN 46556, USA

Many microorganisms exude low molecular weight organic ligands known as siderophores to acquire nutrient Fe; these ligands may also affect the fate and transport of other metals. In this study, we investigated the effects of pH, ionic strength, and the siderophore desferrioxamine B (DFOB) on Cd sorption to montmorillonite using batch experiments, Extended X-ray Absorption Fine Structure (EXAFS) analysis, and X-ray Diffraction (XRD) measurements to monitor changes in montmorillonite 001 d-spacing upon sorption.

The extent of Cd sorption to montmorillonite increased with increasing pH and decreasing ionic strength. The presence of DFOB inhibited Cd sorption at pH < ~7 and enhanced Cd sorption at pH > ~7. Sorption densities ranged from 1.1 (11% sorption) to 10.0 (100% sorption) μmol sorbed/gram of clay. EXAFS analysis showed that the detailed sorption mechanism varied as a function of pH, ionic strength and DFOB concentration (0 or 1.0 mM). In the absence of DFOB, at low pH (~5.0 for samples in 0.1M $NaNO_3$ and ~5.0 and ~7.5 for samples in 0.01M $NaNO_3$), EXAFS showed that Cd sorbed outer-spherically; at higher pH (~7.5 and ~8.5 for samples in 0.1M $NaNO_3$ and 8.5 for samples in 0.01M $NaNO_3$), Cd sorbed as a mixture of inner-sphere and outer-sphere complexes. In the presence of DFOB, at pH ~5.0, Cd sorbed outer-spherically; at pH ~7.5 and 8.5, Cd sorbed as a mixture of inner-sphere and outer-sphere Cd-DFOB complexes. Furthermore, the ratio between inner-sphere and outer-sphere sorption increased with both pH and ionic strength. XRD measurements indicate that layer spacing did not vary substantially as a function of Cd concentration, ionic strength, or pH. However, in the presence of DFOB, the d-spacing expanded by ~ 2Å, which is consistent DFOB absorption. This study demonstrates that Cd sorption to swelling clay can involve a complex interplay of mechanisms depending upon environmental conditions.

Experimental fluid-rock interaction simulating brine reinjection in greywacke-hosted reservoirs of the Taupo Volcanic Zone, New Zealand

R. SONNEY AND B.W. MOUNTAIN*

GNS Science, Wairakei Research Centre, 114 Karetoto Rd, Taupo 3377, New Zealand (*correspondence: b.mountain@gns.cri.nz)

A high temperature-pressure fluid-rock interaction apparatus has been used to simulate greywacke - brine interaction at 154ºC and 27 bars using a continuously-flowing fluid. The experiment was designed to reproduce the scenario where reinjection brine is disposed in a fractured greywacke aquifer; a typical lithology at New Zealand geothermal power plants. The fluid used was an actual reinjection brine from an operating plant, containing ~3400 mg/kg of total dissolved solids including SiO_2 (960 mg/kg), Na (799 mg/kg), K (131 mg/kg), Cl (1027 mg/kg) and SO_4 (423 mg/kg). In order to remove atmospheric oxygen contamination, the fluid was degassed first with ultrapure N_2 followed by a H_2S:N_2 mixture (1:100) for 20 minutes. The final pH of the fluid was 6.8 at room temperature. For the simulation, 24 g of crushed, seived and ultrasonically-cleaned greywacke (1-2 mm) was placed in the core holder of the flow-through apparatus. At room temperature and 1 ml/hr of brine flow (one week duration), the reacted fluid attained a pH of 7.8 and contained elevated concentrations of Ca and Mg (77 and 6 mg/kg, respectively). This is attributed to calcite dissolution. After a temperature increase to 154ºC, the reacted fluid remained oversaturated with respect to amorphous silica but a loss of 240 mg/kg of SiO_2 was observed. Of the other dissolved species: Mg, Ca, Sr, Al, Mn, and Fe showed a significant decrease; while Li, Na, K, As, and the anions showed no measurable change. Variation of flow rate (0.5 ml/hr) showed little change in effluent chemistry suggesting partial equilibrium with some mineral phases. SEM examination of the run products at the entry point of the brine showed a complete overgrowth of amorphous silica on all mineral surfaces. Reacted material at the exit point of the fluid did not show extensive silica overgrowths indicating removal of polymerised silica nanospherules early during water-rock interaction. Partial equilibrium with a secondary phase containing Ca-Mg-Fe suggests a possible control on fluid composition by calcite and/or clay minerals. This was observed in previous experiments using distilled water. These results show that the silica phase precipitating at these conditions in the geothermal aquifer is amorphous silica.

Geochemical fingerprint of an Oligocene to Miocene arc segment in Eastern Mindanao (Philippines)

IRIS SONNTAG[1,3]*, ROBERT KERRICH[2] AND STEFFEN HAGEMANN[3]

[1]CSIRO, ARRC, Kensington, WA 6151, Australia (*corrospondence: Iris.Sontnag@csiro.au)
[2]University of Saskatchewan, Saskatoon, Canada S7N 5E2
[3]CET, University of Western Australia, Nedlands, WA 6009, Australia

The Oligocene to Miocene arc segment in central Eastern Mindanao (Philippines) is part of the Philippine Mobile Belt (PMB) and is related to the low sulfidation epithermal Co-O mine. The PMB constits of the Paleogene volcanic Philippine arc and accreted crustal framgents from the Eurasian plate [1]. This sudy of the Co-O magma suite addresses the geochemical fingerprint of this arc segment, inlcuding the nature of the mantle wedge, involement of subducted material such as sediment or crustal fragments (form the Eurasian plate) and relationships between geotectonic setting and ore forming processes.

The Co-O magma series displays typical island arc geochemical patterns highlighted by the conjunction of LREE-enrichment with depletion of Nb, Ta and Ti. The igneous rocks are dominantly calc-alkaline magma series (andesites and dacites), with some tholeiitic trends for basaltic rocks. There are no significant enrichment of LILE or LREE when compared to younger Pliocene magmas of the Philippines. Nb contents and Zr/Nb ratios (x-y) of the basalts are comparable to other primitive arc magmas in the Pacific (e.g. Marianas) signifying a MORB-like mantle wedge. Th/Ce values below 0.1, and Th/La ratios similar to the Marianas (that are close to mantle values), rule out sediment melting or seamounts on the slab. This magma series involved thin arc crust in an intraocenaic arc setting related to a potentially intermediate to steep dipping subduction zone in an extensional to neutral geochtectenic remige, without addition of rifted fragments or continental crust. The Co-O gold mine has relatively high base metal contents and is comparable to other low sulfidation deposits genereated in a neutral geochtectonic arc regime and is potentially in transition to a porphyry deposits, in contrast to bimodal volcanism in back-arc regimes [cf. 2]. However, the low to medium K Co-O magma series varies partly from other arc magma series related to low sulfidation epithermal systems due to its lack of ‘crustal contamination’.

Origin of nepheline-normative primitive magmas in island arcs

F. SORBADERE[1]*, P. SCHIANO[1], N. METRICH[2]

[1]Clermont Université, Université Blaise Pascal, Laboratoire Magmas et Volcans, Clermont-Ferrand, France (*correspondence: F.Sorbadere@opgc.univ-bpclermont.fr)
[2]Institut de Physique du Globe, Sorbonne, Paris-Cité, Univ. Paris Diderot, Paris, France

Here we address the question of the origin of Si-undersaturated arc magmas, although they are rarely emitted on Earth surface, through a systematic on major and trace elements in primitive olivine-hosted melt inclusions. Samples are Mg-rich basalt to ankaramite lavas and lapilli scoriae from different volcanic arcs (Vanuatu, Lesser Antilles, Indonesian, Luzon and Aeolian arcs).

Melt inclusions display trace element patterns typical of arc-related calk-alkaline basalts, with variable enrichments in LILE, Sc (20 to 90 ppm), and La/Yb or Nb/Y ratios ranging from 1 to 18, and from 0.1 to 0.3, respectively. In CMAS projections, the melt inclusions delineate a trend linking two well-defined end-members strongly or poorly enriched in diopside component.

As a whole, the melt inclusions provide snapshots of instantaneous melts recording a compositional diversity of primitive magma batches, which requires the multi-stage mixing between melts generated by partial melting of peridotite and amphibole-bearing clinopyroxene-rich lithologies. This hypothesis is also supported by trace element models including Sc and incompatible element ratios, where melt inclusions form mixing trend between the two lithologies. We conclude that amphibole-bearing clinopyroxenite, occuring as metasomatic segments in the upper mantle of island arcs [1, 2], could be a suitable source for Ne-normative, Di-rich melt inclusions found in arc environments [3-7]. The progressive melting of these lithologies and surrounding peridotite could account for the geochemical characteristics of the studied melt inclusions.

Ni speciation and isotope fractionation in marine ferromangenese deposits

JEFFRY V. SORENSEN[1], BRANDY M. TONER[1], BLEUENN GUEGUEN[2,3] AND OLIVIER ROUXEL[2,3]

[1]University of Minnesota, St Paul, MN, USA (toner@umn.edu, sore0317@umn.edu)
[2]Université de Brest, IUEM, Plouzané, France (bleuenn.gueguen@univ-brest.fr, orouxel@univ-brest.fr)
[3]IFREMER, Département Géosciences Marines, Plouzané, France

Marine ferromanganese deposits have slow deposition rates and laminar growth habits. Variations in major and trace element speciation and isotopic composition of successive layers within the crusts have the potential to retain information regarding ocean chemical conditions. It is thought that Ni can incorporated into the structure of marine ferromanganese deposits such that the Ni is retained over time [1],[2]. The goal of this study is to explore Ni isotope systematics in marine ferromanganese deposits as a tracer for metal sources and chemical conditions at the time of Ni sorption.

Our study pairs stable isotopic fractionation measurements (via MC-ICP-MS [3]) with synchrotron X-ray spectroscopy techniques to identify the local coordination environment of sorbed Ni. This is accomplished by using laboratory generated 2-line ferrihydrite, goethite, and hexagonal-birnessite that have had Ni sorbed under a suite of pH values and Ni concentrations. We're also investigating a range of natural marine deposits such as ferromanganese nodules and crusts from different oceanic basins.

Preliminary findings show that: (1) initial aqueous Ni concentration can affect the fractionation of sorbed isotopes, and (2) pH can influence both the structural location of Ni sorption as well as the fractionation of Ni isotopes. Mineral surface charge and structural properties likely control the extent of Ni isotope fractionation. We hypothesize that in a natural deposits, mineralogy together with Ni sources and enrichment conditions are important parameters controlling Ni isotope signatures.

Early Paleozoic granites in the Jiamusi terrane of the Central Asian fold belt

A.A. SOROKIN[1]*, A.B. KOTOV[2], Y.B. SAL'NIKOVA[2] AND N.M. KUDRYASHOV[3]

[1]Institute of Geology and Nature Management, Blagoveshchensk, Relochny, 1, Russia (*correspondence: sorokin@ascnet.ru)
[2]Institute of Precambrian Geology and Geochronology, St.Petersburg, Russia
[3]Geological Institute of the Kola Sc., Apatity, Russia

In the structure of the eastern part of the Central-Asian fold belt a series of continental blocks (terranes) is distinguished. These are: the Argun, Mamyn, Bureya, Jiamusi blocks (terranes) composed of granitoids of different ages but their age has being remained disputable for quite a long time. At present a series of age datings are obtained (U-Pb method). Basing on that datings we can say with certainty that the Early Paleozoic granitoids are widely developed in this terrane.

In the northeastern part of the Jiamusi terrane we obtained the age of 480±4 Ma granites of Sutara massif, the age of 471±10 Ma of leucogranites of the Kabala massif and the age of 461±5 Ma of quartz syenites of the Durilovsky massif.

Similar age values are also given for granites in the south Jiamusi terrane [1] and for granites in the Argun, Mamyn, Bureya terranes [2-5]. In this connection it cannot be excluded that all above mentioned Early Paleozoic granitiods belong to a single orogenic belt.

Thise study was supported by RFBR (Gr.No 10-05-00172), FEB RAS (Gr.No 09-I-ONZ-09, 09-II-SB-08-007).

Geochemical features of the Amur River sediments in its middle reaches

O.A. SOROKINA

Institute of Geology and Nature Management FEB RAS, Russia, Relochniy 1, Blagoveshchensk, Amur Region, Russia (library@ascnet.ru)

The Amur River is one of the largest rivers of the East Asia. The main channel and tributaries of the Amur River cross the geological units of different ages.

A distribution of rare earth elements in the studied samples of the bottom sediments of the Amur River is moderately differentiated ([La/Yb] n=9.6-14.9). A characteristic feature of their distribution is also an enrichment in LREE relatively to MREE and comparatively gentle graph in the in the field of MREE and heavy HREE which is supported by the ratios of [La/Sm]n=3.3.-4.1 and [Gd/Yb]=1.1-2.2. All spectra of rare earth elements have moderately expressed negative Eu anomaly (Eu/Eu*=0.7-0.9) (Fig.1).

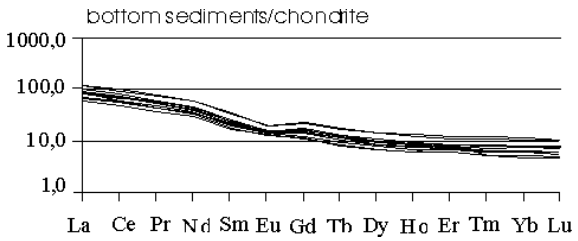

Figure 1: The rare earth elements' distribution in the bottom sediments of the Amur river. The composition of chondrite is used according to [1].

In comparison with the composition of the upper continental crust the bottom sediments under study are at a definite degree depleted in such elements as Sc (3.7 – 9.0 ppm), Cu (8-22ppm), Nb (9-13 ppm), Ta (0.21-0.37 ppm), Y (9-17 ppm). The concentration of Zn (50-75 ppm), Rb (82-109 ppm), Sr (290-350 ppm), Pb (15-24 ppm), W (1.1-2.2 ppm), Th (5.2-11.9 ppm), U (1.0-5.4 ppm), REE correspond to the level of those in the upper continental crust while the concentrations of Ba (550-840 ppm), V (63 – 81 ppm), Cr (63-80 ppm), Co (12-14 ppm), Ni (31-43 ppm), Zr (190-309 ppm) a bit higher than their crust values.

It was established that the most probable sources of the bottom sediments in the studied section of the Amur River were siliceous acid magmatic or metasedimentary rocks.

Systematic underestimation of the oxidation state of MORB glasses

PAOLO A. SOSSI[1,2]* AND HUGH ST.C. O'NEILL[2]

[1]Department of Geology and Geophysics, University of Adelaide, Adelaide, SA 5000, Australia

[2]Research School of Earth Sciences, Australian National University, Canberra, ACT 0200, Australia (*correspondence: paolo.sossi@anu.edu.au)

The $Fe^{3+}/\Sigma Fe$ of a magma and its fO_2 are related by:

$$Fe^{2+}O + 0.25\ O_2 = Fe^{3+}O_{1.5}$$

This dependence has been calibrated using a wide range of silicate melt compositions equilibrated at known fO_2 and analysed by wet chemistry ([1], [2]) and Mössbauer. Analyses of large sets of natural MORB glasses by wet chemistry (e.g. [3], [4]) report tight distributions around $Fe^{3+}/\Sigma Fe \approx 0.1$, corresponding to the relative oxidation state $\Delta QFM \approx -0.5$. However, recent determinations of $Fe^{3+}/\Sigma Fe$ on MORB glasses by XANES ([5], [6]) consistently return more oxidised values, about 0.16, correponding to $\Delta QFM \approx +0.5$.

The wet chemistry method [7] relies on the complete oxidation of Fe^{2+} to Fe^{3+} by reduction of V^{5+} to V^{4+}. However, it does not discriminate between Fe^{2+} and other reduced species. One such species, S^{2-}, is present in MORB glasses at $\sim 10^3$ ppm, but not in the glasses used to establish the $Fe^{3+}/\Sigma Fe$- fo_2 relationship.

To test the effect of S^{2-} during wet chemistry, a series of Fe-free glasses with the An-Di eutectic composition were prepared using CO_2-CO-SO_2 gas mixtures to produce S^{2-} ranging from 0 to 4500 ppm [8]. These glasses were subjected to the procedure of ref. [7]. The results establish that S^{2-} is fully oxidised during dissolution to S^{6+} (i.e. sulfate) according to the reaction:

$$S^{2-} + 8V^{5+} = 8V^{4+} + S^{6+}$$

From the reaction stoichiometry, 1000 ppm S^{2-} is equal to 2 wt% Fe_2O_3, which is more than enough to account for the discrepancy in the $Fe^{3+}/\Sigma Fe$ of MORB between wet chemistry and XANES. Determination of S and its speciation in basalts is essential to understanding their redox state, since degassing of S as SO_2 will tend to further reduce basalts with S^{2-} but oxidise basalts with S^{6+} [9].

Searching for ancient crusts: Integrating Pb isotopes in plagioclase with Hf isotopes in zircon

A.K. SOUDERS[1]*, P.J. SYLVESTER[1] AND J.S. MYERS[2]

[1]Department of Earth Sciences, Memorial University, St. John's, NL A1B 3X5, Canada (*correspondence: kate.souders@mun.ca)

[2]Department of Applied Geology, Curtin University, Perth, WA 6845, Australia

The composition of the Earth's early crust is a topic of much interest in geology today. We present *in situ* analyses by LA-MC-ICPMS for the Pb isotope compositions of preserved igneous plagioclase (An 75-89) megacrysts and the Hf isotope compositions of BSE-imaged domains of zircon grains from 21 samples from two anorthosite complexes in southwestern Greenland, Fiskenæsset and Nunataarsuk, which represent two of the best-preserved Archean anorthosites in the world. *In situ* LA-ICPMS U-Pb geochronology of the zircon grains suggests that the crystallization age of the Fiskenæsset complex is 2936 ± 13 Ma (2σ, MSWD = 1.5) and the Nunataarsuk complex is 2914 ± 6.9 Ma (2σ, MSWD = 2.0). Initial Hf isotope compositions of zircon grains from both anorthosite complexes fall between depleted mantle and a less radiogenic crustal source with a total range up to 5 ε_{Hf} units. In terms of Pb isotope compositions of plagioclase, both anorthosite complexes share a depleted mantle end member yet their Pb isotope compositions diverge in opposite directions from this point: Fiskenæsset toward a high-μ, more radiogenic Pb crustal composition and Nunataarsuk toward low-μ, less radiogenic Pb, crustal composition. By using Hf isotopes in zircon in conjunction with Pb isotopes in plagioclase we are able to constrain both the timing of mantle extraction of the crustal end member and its composition. At Fiskenæsset, the depleted mantle melt interacted with an Eoarchean (~ 3600 – 3800 Ma) mafic crust with $^{176}Lu/^{177}Hf$ ~ 0.026. At Nunataarsuk, the depleted mantle melt interacted with a Hadean (~ 4200 Ma) mafic crust with $^{176}Lu/^{177}Hf$ ~ 0.032. Using our new *in situ* approach, contamination of mantle derived magma by ancient mafic crust has been discovered in both the Fiskenæsset and Nunataarsuk anorthosite complexes of Greenland. The isotope data presented here suggest the survival of Hadean and Eoarchean crust until ~ 2900 Ma. There is potential that this old mafic crustal could be preserved at the surface within the Nunataarsuk and Fiskenæsset regions today.

REE and isotope (Sr, S, Pb) geochemistries to constrain the genesis of the F-(Ba-Pb-Zn) ores of the Zaghouan District (NE Tunisia)

F. SOUISSI[1]*, N. JEMMALI[1], R. SOUISSI[1] AND J-L. DANDURAND[2]

[1]Institut national de recherche et d'analyse physico-chimique. 2026 Sidi Thabet, Tunisia (*correspondence: souissi_foued@yahoo.fr)

[2]Université de Toulouse, UPS (OMP), LMTG, 14 Avenue E. Belin, 31400 Toulouse Cedex, France

The F-(Ba-Pb-Zn) ore deposits of the Zaghouan District, which are located in NE Tunisia, occur as open space fillings or stratabound orebodies, hosted in Jurassic, Cretaceous and Tertiary layers. Ore fluids are hydrothermal (80 to 200°C) brines (10 to 30 wt % NaCl equiv.). The chondrite-normalized REE patterns may be split into three groups: (i) 'Normal marine' patterns characterizing the wallrock carbonates; (ii) REE patterns sloping to the right-hand side, with small negative Ce and Eu anomalies, characteristic of the early ore stages; (iii) Bell-shaped REE patterns displaying LREE depletion, as well as weak negative Ce and Eu anomalies, characterizing fluids of subsequent stages. The $^{87}Sr/^{86}Sr$ ratios, show that the Sr of the epigenetic carbonates (dolomite, calcite) and ore minerals (fluorite, celestite) is more radiogenic than that of the country rocks. The uniformity of this ratio throughout the District, provides evidence for the isotopic homogeneity and, consequently, the identity of the source of the mineralizing fluids. The $\delta^{34}S$ values of barite associated to mineralizations, are close to the $\delta^{34}S$ of Triassic sea water (17%). The $\delta^{34}S$ values of sulphide minerals show a wide range for galena (-13.6 to +11.4%), but restricted for sphalerite (-2.6 to +2.1%). However, considered individually, each deposit is characterized by a restricted range of $\delta^{34}S$ values for both sulphides, which requires that reduction took place in closed systems. The more negative $\delta^{34}S$ values are assigned to bacterial reduction, while the more positive are assigned to thermo-chemical reduction of Triassic sulphates. Taking account of the homogeneity in the Pb-isotope composition of galenas, a single upper crustal source for base-metals is accepted. The Late Paleozoic basement seems to be the more plausible source for F-Pb-Zn concentrated in the deposits. The formation of the Zaghouan District ore deposits is considered as the result of the Zaghouan Fault reactivation during the Upper Miocene period.

Binge/purge oscillations of the thawing Fennoscandian Ice Sheet revealed by ε_{Nd} and biomarkers

G. SOULET[1,2]*, G. MENOT[1], G. BAYON[2], F. ROSTEK[1], E. PONZEVERA[2], G. LERICOLAIS[2] AND E. BARD[1]

[1]CEREGE, Univ. Aix-Marseille, CNRS, IRD & Collège de France, Technopole de l'Arbois BP80, 13545 Aix en Provence cedex 4, France (*correspondence: soulet@cerege.fr)

[2]Ifremer, centre de Brest, Géosciences Marines, 29280 Plouzané cedex, France

At its maximum extent, the FIS advanced into the watershed of the Dnepr River, one of the main rivers feeding the former Black Sea 'Lake'. As a consequence, the Black Sea basin potentially represents a suitable location to investigate the dynamics of the FIS retreat and its impacts on global/regional climate and European hydrographical reorganizations in the context of the Last Deglaciation.

Here, we report high-resolution geochemical data from a core retrieved in the Black Sea. We combine the use of Nd isotopes in clay fraction (ε_{Nd}) and bulk XRF-Ti/Ca as tracers for sediment provenance, together with biomarkers as tracers for river runoff (BIT-index) and boreal soil leaching (C_{25}-alkanes). During Heinrich Event 1 (HE1), four drastic periods of Deglacial Water Pulses (DWPs) occurred as unequivocally revealed by the biomarkers. Concomitantly, ε_{Nd} signatures clearly demonstrated that the DWPs were generated by the thawing FIS. Each period of DWPs (~200 yr in duration) occurred repeatedly every 200 yr, displaying a peculiar cyclic-like pattern. By analogy with MacAyeal [1]'s model, we propose a binge-purge model to explain the observed cyclicity: the binging period requiring a continuous FIS retreat, the purging period involving regional interactions between the formed proglacial lakes and the atmosphere.

Impact of aerosols on the equilibrium response of the climate system

GABRIELA SOUSA SANTOS* AND ISABELLE BEY

Institute for Atmospheric and Climate Science & Center for Climate Systems Modeling, ETH Zurich (*correspondence: gabriela.sousa-santos@env.ethz.ch)

Aerosols have both a direct and indirect effect on climate. The first effect arises from the aerosol scattering and absorption of radiation in the atmosphere. The indirect effect relates to their influence on cloud properties.

In the present study, we investigate the equilibrium response of the climate system to two scenarios of primary emissions of black carbon, organic carbon, sulfur dioxide, benzene, toluene, and xylene correspondent to 1850s and today conditions. We use the fully-unified aerosol-climate model ECHAM5-HAM coupled to a mixed layer ocean (MLO)[1, 2, 3]. Using a MLO coupled to the climate-aerosol model allows us to diagnose the aerosol impact in a comprehensive manner. The emissions were taken from the ACCMIP (Atmospheric Chemistry & Climate Intercomparison Project) [4], an inventory developed for the next IPCC assessment.

We will show results of several equilibrium simulations with a focus on the response of the hydrological cycle to aerosol effects, like impacts on water vapour, sensible heat fluxes, precipitation minus evaporation patterns, convective mass fluxes, etc. Preliminary results indicate that the aerosol forcing of black carbon, organic carbon, and sulfur dioxide from 1850s to present day resulted in a global mean surface cooling of 0.9K, a reduction in global mean precipitation of 0.11mm/d (3.41%), and an increase in cloud cover of 1.1%.

A 50-year record of PGEs in Antarctic snow

TSEREN-OCHIR SOYOL-ERDENE[1], YOUNGSOOK HUH[1]*, SUNGMIN HONG[2] AND SOON DO HUR[3]

[1]School of Earth and Environmental Sciences, Seoul National University, Seoul, Korea (soyoloo@snu.ac.kr, *correspondence: yhuh@snu.ac.kr)

[2]Department of Oceanography, Inha University, Incheon, Korea

[3]Korea Polar Research Institute, Incheon, Korea

Antarctic snow preserves an atmospheric archive that enables the study of global atmospheric changes and anthropogenic disturbances from the past. We report atmospheric deposition rates of platinum group elements (PGEs) in Antarctica during the last ~50 years based on determinations of Pt, Ir and Rh in snow samples collected from Queen Maud Land, East Antarctica to evaluate changes in the global atmospheric budget of these noble metals. The 50-year average PGE concentrations in Antarctic snow were 17 fg g^{-1} (4.7–76 fg g^{-1}) for Pt, 0.12 fg g^{-1} (<0.05–0.34 fg g^{-1}) for Ir and 0.71 fg g^{-1} (0.12–8.8 fg g^{-1}) for Rh. The concentration peaks for Pt, Ir and Rh were observed at depths corresponding to volcanic eruption periods, indicating that PGEs can be used as a good tracer of volcanic activity in the past. A significant increase in concentrations and crustal enrichment factors for Pt and a slight enhancement in enrichment factors for Rh were observed after the 1980s. This suggests that there has been large-scale atmospheric pollution for Pt and probably Rh since the 1980s, which may be attributed to the increasing emissions of these metals from anthropogenic sources such as automobile catalysts and metal production processes.

Geochemistry and distribution of total heavy mineral concentrations of beach sediments of the Sakarya Delta (SW-Black Sea)

K. SÖZERI*, M. ERGIN, Z. KARAKAŞ AND B.D. ESER

Ankara University, Faculty of Engineering, Department of Geological Engineering/Affiliated with Geological Research Center for Fluvial, Lacustrine and Marine Studies (AGDEJAM), Tandoğan, Ankara, Turkey 06100 (*correspondence sozeri@eng.ankara.edu.tr, ergin@eng.ankara.edu.tr, karakas @eng.ankara.edu.tr, Basak.Eser.Dogdu@eng.ankara.edu.tr)

This study aims to investigate geochemistry and total heavy mineral distributions of marine beach sediments of the Sakarya Delta (SW-Black Sea, Turkey) where some higher metal contents were reported in sediments and related to possible occurrences of beach placers. With support of TÜBİTAK (Project No: 108Y333) and Ankara University-Sci. Res. Pro. Of. (Project 20070745007HPD), 48 surficial sediment samples were collected from the coastal beaches of Sakarya Delta representing modern shoreline and backshore sub-environments. In addition to geomorphological field observations, multielement and grain size analysis as well as total heavy mineral determinations are performed. Multielement geochemistry was carried out using ICP-MS method. Preliminary results showed that beach bulk sediments of the Sakarya Delta generally contained similar amounts of Ti, Pb, U, Mg and Sn compared with average rock composition of Earth's crust. The concentrations of As (6-24 ppm), Sb (0, 3-2, 1ppm), Ca (2-9 ppm), Cr (17-3999 ppm) were comparatively higher whereas Cu (6-27 ppm), Mo (0, 1-0, 7 ppm), Sn (0, 4-5, 2 ppm), Y (5-27 ppm), Nb (4-36 ppm) and Ta (0, 3-2, 5 ppm) contents are lower. Elements Cr, Fe, Mn, Co, Ni, Nb, Y and Ce reached their highest concentrations in sediments collected close to the Sakarya River mouth. The total heavy mineral concentrations of the bulk sediments are generally low, with except of 3 samples which contained highest total heavy mineral concentrations (70-95 %). The locations of these 3 samples were also aligned to or towards the river mouths.

Recycling elements from the slab to arc crust: Insights from element mass balance of the Izu arc system

CARL SPANDLER

School of Earth & Environ Sci, James Cook University, Townsville, Australia (Carl.Spandler@jcu.edu.au)

One of the most important processes leading to formation of continental crust is element transfer from subducting lithosphere to newly-formed arc crust. Despite extensive study of HP/UHP metamorphic rocks that represent paleo subducted slabs and experiments to replicate subduction zone conditions, little consensus has been reached on the nature of the mass transfer agents (e.g. aqueous fluid or hydrous melt), or the efficiency of the recycling process. Here, I use a mass balance of K and Ce in the Izu arc system as an alternative approach to resolving recycling processes in subduction zones. Potassium and Ce are enriched in arc lavas and are controlled by phengite and allanite/monazite in subducted crustal rocks. The extensive stability of these phases in the slab means K and Ce in slab fluids should be buffered to beyond sub-arc depths [1, 2].

The Izu arc was chosen for this study as the subducting Pacific slab is relatively cold and has been well characterised for chemical composition [3]. The ~50 Ma tectonic and magmatic history of the arc is well constrained, and the volume and composition of the arc crust can be accurately determined thanks to an excellent ash record, numerous seismic profiles of the arc and exposure of mid/lower arc crustal sections in the Tanzawa plutonic complex, Honshu.

Rates of arc crustal growth are calculated to be 130 - 200 km^3 km^{-1} strike length m. $y.^{-1}$. Comparing the composition of this crust (corrected for mantle input and subduction erosion) to subduction inputs reveals that 50 to 90% of the K and 10 to 15% of the Ce is recycled from the subducting plate back to the arc crust. Using experimentally-determined solubility relations [1, 2], these fluxes would require all of the available water in the sub-arc crust plus a 0.1 - 0.7 km column of slab serpentinite if the mass transfer agent is a hydrous slab melt. By contrast, excessive volumes of slab serpentinite (6 - 60 km thick column!) are required to provide the water needed if the transport agent is an aqueous fluid. These results confirm slab melts to be the dominant mass transfer agent in the Izu subduction zone and highlights the importance of subducted serpentinite as a water source for arc magmatism.

How to safely store water samples prior to stable hydrogen and oxygen isotope analyses?

JORGE E. SPANGENBERG

Institute of Mineralogy and Geochemistry, University of Lausanne, CH-1050 Lausanne, Switzerland (Jorge.Spangenberg@unil.ch)

Safe storage of water samples between sampling and their stable hydrogen and oxygen isotope analyses (determination of δ^2H and $\delta^{18}O$ values) is still a topic of concern in hydrological studies. Water sorption and the diffusive transfer of water molecules through organic polymeric material may entail an isotopic fractionation [1]. A methodological study of variation of δ^2H and $\delta^{18}O$ values of waters stored in different type of bottles was performed.

A set of sixteen botlles of eleven different organic polymers (plastics), including low and high density polyethylene (LDPE and HDPE), polypropylene (PP), polycarbonate (PC, polyethylene terephthalate (PET), and high resistance Teflon® (PFA) from different size (10 to 500 mL) and wall thickness (0.20 to 1.50 mm) were completely filled (no headspace) with the same bottled water coming from a single natural spring (Evian® water, Evia-les-Bains, France) and were properly closed. Additionaly, 16 narrow neck bottles of amber glass were filled with the same water for comparison. All the water-filled bottles (n = 16 x 12 = 192) were stored at room temperature, and were opened one after the other over a period of time ranging from 0 to 659 days between 17 November 2008 and 7 September 2010. Immediately after the bottles have been opened, two 10 mL glass vials were filled, and stored at +4°C prior to analysis. The δ^2H and $\delta^{18}O$ values of all the water samples were determined using Cr-reduction in a Thermo Fisher Scientific H-Device and CO_2–equilibration in a Gas Bench II, respectively. Changes of up to +5‰ for δ^2H and +1.5‰ for $\delta^{18}O$ values were measured, depending on the type of plastic bottle. The carbon and hidrogen isotope compositions of the different plastic materials range from –33.3 to –27.5‰ and –108.1 to –71.7‰, respectively. The PET and PC plastics have $\delta^{18}O$ values ~22.5‰.

Particulate Organic Carbon deposition offshore Taiwan following typhoon Morakot

ROBERT SPARKES[1,2]*, NIELS HOVIUS[2], ALBERT GALY[2], VASANT KUMAR[1] AND JAMES LIU[3]

[1]Department of Materials Science and Metalluryy, University of Cambridge, UK (*correspondence: rbs26@cam.ac.uk)
[2]Department of Earth Sciences, University of Cambridge, UK
[3]Institute of Marine Geology and Chemistry, NSYSU, Taiwan

Woody debris and petrogenic carbon can be exported by hyperpycnal discharge from the fluvial and shallow-marine system, and stored on geological timescales in basins, but offshore storage of fresh Particulate Organic Carbon (POC) and the efficiency of burial of petrogenic carbon are poorly constrained. We present a case from Taiwan, where riverine fluxes are known [1].

Following Typhoon Morakot (2009, up to 3m rainfall), eight sediment cores totalling 191 cm were collected from turbidites in the Kaoping submarine canyon at depths up to 976 m, and from the neighbouring slope. Coarse, modern woody debris was present in 32% of core samples, exclusively within the sandy parts of turbidites. Total Organic Carbon concentrations were highest in slope deposits, averaging 0.59%, and in sandy canyon deposits. Canyon and floodplain samples had similar distributions of isotopic values, suggesting mixing of two endmembers. One is a combination of fresh woody debris and recycled coal-grade material from sedimentary rocks in the hinterland. The other is higher-grade carbonaceous material including graphite, likely from the central mountain belt. The river signal was fully preserved in the canyon. Slope deposits had a lighter ^{13}C signature indicating marine organic carbon input.

Raman spectroscopy suggests that high-grade graphite and low-grade material were sourced from Plio-Pleistocene deposits in the western foreland, whilst intermediate-grade graphitic material was sourced from the central mountain belt. High-grade graphite metamorphic conditions are not exposed in Taiwan: this material must have survived at least two cycles of erosion and deposition.

Time-resolved metal(loid) reactivity at biogeochemical interfaces

DONALD L. SPARKS[1]*, MATTHEW GINDER-VOGEL[2] AND GAUTIER LANDROT[3]

[1]Delaware Environmental Institute, University of Delaware, Newark, DE 19716, USA (*correspondence: dlsparks@udel.edu)
[2]University of Delaware, and Calera Corporation, Los Gatos CA 95032 USA (mginder-vogel@calera.com)
[3]University of Delaware, and Lawrence Berkeley National Lab, Berkeley, CA 94720 USA (GJLandrot@lbl.gov)

The rates of important chemical processes at biogeochemical interfaces including ion exchange, sorption, and redox can occur over wide time scales. Ex- situ batch and flow techniques offer high elemental sensitivity, but their time resolution is not adequate to capture rapid reaction rates that often comprise a significant portion of many processes such as sorption and oxidation-reduction. Measurement of rapid, initial rates of environmentally important reactions at the mineral/water interface is critical in determining reaction mechanisms. Until recently, experimental techniques with sufficient time resolution and elemental sensitivity to measure initial rates were very limited. Some techniques such as pressure-jump methods can capture rapid reactions on millisecond time scales, but the rate parameters are indirectly measured and reaction mechanisms can only be inferred. Ideally, one would prefer to follow reaction rates in real-time, in situ, and at the molecular scale to definitively determine reaction mechanisms. In this presentation the use of *in situ* synchrotron-based, quick scanning X-ray absorption spectroscopy (Q-XAS), at sub-second time scales, is applied to measure the initial oxidation of As(III) and Cr(III) by hydrous manganese oxide [1], [2]. Results indicate that with these techniques, chemical kinetics are being measured. The rapid kinetic techniques are coupled with synchrotron-based XAS and XRD, and a stirred-flow technique, to provide a comprehensive assessment of As(III) and Cr(III) oxidation kinetics and mechanisms on hydrous manganese oxide over a range of temporal scales [3], [4].

Rapid age determination of oysters using shell Mg/Ca ratios

BILL SPENCE[1], DAVID P. GILLIKIN[2], DAVID H. GOODWIN[3], DAMON BYRNE[2], PETER ROOPNARINE[4] AND LAURIE ANDERSON[5]

[1]CETAC Technologies, Manchester, UK (bspence@cetac.com)
[2]Union College, Dept of Geology, Schenectady, NY (gillikid@union.edu, byrned@garnet.union.edu)
[3]Denison University, Dept of Geosciences, Granville, OH (goodwind@denison.edu)

[5]Louisiana State University, Geology and Geophysics, Baton Roughe, LA (glande@lsu.edu)

Magnesium to calcium (Mg/Ca) ratios exhibit a strong temperature dependence in foraminifera and corals, but not in bivalve mollusks. Various studies have reported Mg/Ca-temperature relationships with R2 values ranging from 0.8 to 0.3, and significantly different relationships for bivalves growing at different salinities was reported. However, this poor temperature correlation does not render Mg/Ca data useless. A weak temperature dependence would allow time (seasons and years) to be determined along the growth axis of shells. This would provide information about age, growth rate and also allow other proxies to be aligned with time. Previous studies have shown that Mg/Ca ratios can indeed by used for this purpose in a gastropod and pen shell (Pinna); these studies hand drilled powders from the shells and analyzed them using wet chemistry, which is relatively time consuming. Line scans using laser ablation systems can cover several centimeters of shell in a few minutes. If line scans could be used to put calendar dates on shell material it would allow very rapid assessment of the aforementioned variables. We test this method on the resilifer of two oyster species (Crassostrea gigas and C. virginica) using a CETAC LSX-213 laser ablation system coupled to a PE Elan 6000 DRC ICP-MS. Shells of both species exhibit annual cyclicity in Mg/Ca ratios using spot and line scan laser sampling, which matches the seasonal cyclicity determined using stable oxygen isotopes. Elemental maps will be generated to determine the distribution of Mg over the resilifer. Our preliminary results suggest that line scans offer a rapid technique for determining age, growth rate and timing of shell growth in oyster reslifers.

Super-Si garnet breakdown kinetics and implications for craton evolution

D. SPENGLER*, Y. NISHIHARA AND K. FUJINO

Ehime University, Matsuyama 790-8577, Japan (*correspondence: spengler@geo.uni-potsdam.de, yunishi@sci.ehime-u.ac.jp, fujino@sci.ehime-u.ac.jp)

Decompression experiments have shown that super-Si garnet (Grt) decomposes to Grt + pyroxene (Pyx) with specific micro-structures [1, 2]. They support that natural analogues (found in mantle xenoliths, diamond inclusions, massif peridotites) record up to several hundreds of kilometre exhumation - all believed to apply to contrasting geological scenarios including mantle convection, kimberlite magmatism and plate tectonics [2-4].

Here we used glass powder with a 'pyrolite minus olivine' composition for polycrystalline dry super-Si Grt synthesis (18 GPa, 1600 °C, 2.3 h) and subsequent decompression (10 GPa, 1450 °C, 0-12 h). All recovered samples have a granular coronitic texture of new Grt+Pyx surrounding relic super-Si Grt cores. Quantified XRD spectra show transformed volumes are similar, ~40%. The mineral chemistry (EDS) of breakdown products differs from that of corresponding equilibrium minerals synthesised along with each decompression experiment. In contrast, most natural analogues are chemically equilibrated requiring that volume diffusion exceeded initial breakdown. Modelling of Si-Al interdiffusion in Grt suggests that grains below 10 μm in size or lamellae spacing are able to chemically equilibrate at temperature-time conditions corresponding to those of both kimberlite eruption and ultra-high pressure metamorphism at convergent plate margins. Larger sizes and spacings require upper mantle residence for equilibration.

Results show that super-Si Grt transformation during decompression occurred partially and within the first minutes, but barely continued during the experiments. By implication, natural analogues record a multi stage process: fast decomposition during decompression (corona formation) before volume diffusion (chemical equilibration and lamellae formation) during sub-continental lithospheric mantle (SCLM) residence before final exhumation to the Earth's surface by different geological processes. Given the affinity of super-Si Grt breakdown microstructure occurrence to Archaean areas at global scale, models for craton stabilisation demand the inclusion of processes suitable for: (1) cargo through the upper mantle, like mantle convection/plumes, and (2) SCLM growth in the Grt-peridotite stability field. Shallower stages would have erased the microstructural record.

Zircon from kimberlites of the Nyurbinskaya pipe as indicator of kimberlite emplacement and lithosphere evolution

Z.V. SPETSIUS[1], E.A. BELOUSOVA[2], W.L. GRIFFIN[2], S.Y. O'REILLY[2] AND A.S. IVANOV[1]

[1]Scientific Investigation Geology Enterprise, ALROSA Co Ltd, Mirny, Yakutia, 678170, Russia (spetsius@cnigri.alrosa-mir.ru)

[2]GEMOC ARC National Key Centre, Department of Earth and Planetary Sciences, Macquarie University, NSW, 2109, Australia (elena.belousova@mq.edu.aTu)

About 300 zircon grains have been recovered from the kimberlite concentrate of the Nyurbinskaya pipe with the aim of finding mantle zircons that would allow estimation of the age of kimberlite emplacement. We evaluated the kimberlitic or crustal origin of individual zircon grains using a two-step approach. The first step included the preparation of mounts, collecting cathodoluminescense images of the zircons, electron microprobe analysis of major elements and LAM-ICPMS analysis of trace elements. These data identified zircons with low content of U (<50ppm) and Y (1-150ppm) and low Nb/Ta (<3) ratio of probable mantle (kimberlitic) origin and zircons of crustal origin with increased Y and U content.

The second step involved U-Pb dating and Hf-isotope analysis. The largest population, consisting of crustally-derived zircons, defines a U-Pb age peak at ca 2700 Ma, probably representing the Archean age of the lower crust below the Nakynsky kimberlite. This main population shows a range of εHf (t) values of 3.2 to -14.6 and T_{DM} crustal model ages between 3.6 and 2.7 Ga, and suggests that at least 70% of the deep crust was formed from 3.2-2.8 Ga ago. The minor age population represented by the kimberlite zircons of the Nurbinskaya pipe gave a weighted mean $^{206}Pb/^{238}U$ age of 381±7 Ma, which is considered as the best estimate for the kimberlite emplacement. The zircons of this younger age population have a narrow range of εHf(t) values of -33.5 to -34.5 and T_{DM} crustal model age of 3.2 Ga.

Are aliphatic monomers of grasses and herbs useful biomarkers for vegetation shifts?

S. SPIELVOGEL[1,2] *, J. PRIETZEL[2], N. DECHAMPS[2], L. BECKER[3] AND G. GUGGENBERGER[3]

[1]Universität Koblenz-Landau (*correspondence: spielvogel@uni-landau.de)

[2]Technische Universität München

[3]Leibniz Universität Hannover

Each plant species has a unique aliphatic composition. The aliphatic monomer composition of differrent grasses and herbs was analyzed to investigate wheter the pattern can be traced back after decay and transformation into soil organic matter (SOM).

We analyzed the aliphatic monomer pattern (e.g. Alkanols, Alkanoic acids, Alkanes) of dominant grasses and herbs as well as of soil samples derived from four different regions where recently vegetation shifts took place or are assumed to have taken place (Bayerischer Wald and Limestone Alps, Germany; Bagé, Brazil; Qinghai, Tibet). Our aim was to develop a robust classification model for SOM source and vegetation history using these biomarkers. The data on the composition of the aliphatic monomers of the grasses and herbs were analyzed with three different classification models (linear, non-linear and binary), to find the best model to classify the different plant species. Based on the discriminant equations obtained, soil samples were classified and the performances of the three classification models were compared.

We yielded a series of monomers corresponding to previously reported hydrolysates [1, 2, 3], that discriminated significantly among the different grass and herb species. Hence, all tested classification models discriminated sufficently among the grass and herb species. Between 56% and 85% of the cases were classified correctly, depending on the respecitve site, the training set and the used model. However, the aliphatic pattern in soils is subjected to changes during decomposition of the plant material and the different biomarker monomers exhibited different turnover rates. Thus, only a multivariate binary classification model that did not rely on quantitative properties and compound ratios was sufficient to classify in average 67% of the soil samples correctly, depending on their decomposition status.

Rates of crystal nucleation and growth from inversion of natural crystal size distributions

VÁCLAV ŠPILLAR* AND DAVID DOLEJŠ

Institute of Petrology and Structural Geology, Charles University, 128 43 Praha 2, Czech Republic (*correspondence: vaclav.spillar@seznam.cz)

Magmatic textures provide sensitive record of physical processes and variables during magma solidification. Quantitative characterization of texture is thus a useful tool for interpreting the thermal regime and rates of crystal nucleation and growth. Here we show that different pairs of nucleation and growth rate functions can result in textures having identical crystal size distributions (CSD). In order to eliminate such ambiguity of CSDs, we use time variation in crystallinity as an additional constraint leading to unique nucleation and growth rates. While the nucleation rate strongly depends on the CSD slope, curvature and fluctuations, the character of growth rate curve is more related to changes in crystallinity. When crystallinity increases quasi-linearly with time, the growth rate diverges to very high values at the beginning and the end of crystallization, due to small area of solid-liquid interface. That is, the growth rate is slowest at moderate crystallinities, when the crystal surface area is largest. This transient behavior also facilitates approach to equilibrium. When we employ relevant thermal cooling model and bracket the total crystallization by liquidus and solidus temperatures, we can estimate the total crystallization time, and scale all rate functions into real units. Estimated rates of crystal growth are inversely proportional to magma chamber size, and increase non-linearly from its interior to the margin. Application to solidification time and CSDs of the Hawaiian lava lakes results in growth rates of about 10^{-11} cm s^{-1}, which is in good agreement with natural observations. The growth rates can be converted to crystallization time for any grain size of interest. In log-linear CSDs, the growth time of the most abundant grain size varies from ~1/10 of the characteristic cooling time for crystals in the pluton interior to ~1/400 for those near the contacts. Relative growth times thus depend on neither a CSD slope nor a magma body size. The changes in crystal size with time allow us to predict the distance of movement due to action of gravitational forces. The crystal travel distance increases quadratically with the magma chamber size, rendering the crystal settling to be most efficient in large reservoirs. For kilometer-sized bodies we predict that a crystal moves across half of a magma chamber even in viscous magmas, up to 10^9 Pa. s.

Stability and breakdown of $Ca^{13}CO_3$ melt combined with formation of ^{13}C -diamond in static experiments up to 80 GPa and 4000 K

A.V. SPIVAK[1]*, YU.A. LITVIN[1] AND L.S. DUBROVINSKY[2]

[1]Institute of Experimental Mineralogy RAS, 142432, Chernogolovka, str. Akademition Osip'yan 4 (*correspondence: spivak@iem.ac.ru)

[2]Bayerisches Geoinstitut, Universitat Bayreuth, Universitatsstraße 30, D-95447 Bayreuth

PT conditions of $Ca^{13}CO_3$ melting, stability of the melts, and their decomposition by the reaction $Ca^{13}CO_3$ = CaO + $^{13}CO_2$ (fluid) are investigated at static pressures of 8.5 – 80.0 GPa and temperatures of 1900 – 4000 K with the use of diamond anvil cell and laser heating. The occurrence of $^{13}CO_2$ is accompanied by formation of ^{13}C-diamond (above 11 GPa) and ^{13}C-graphite (below 11 GPa) that is indicative for the $^{13}CO_2$ breakdown to ^{13}C and O_2. Another 'solution-melt' mechanism of isotope-pure ^{13}C-diamond synthesis was realized in melts of the carbonate $Ca^{13}CO_3$ - ^{13}C-graphite (metastable phase) system in the multianvil press at pressures 8.5 and 20 GPa and temperatures up to 2500 K. It was first found in static high pressure experiment that melting of Ca carbonate is congruent over a wide 11.0 – 80.0 GPa pressure interval at temperatures up to 3400 K. It is also important that the phase region for the Ca carbonate melts is sufficiently wide extending from 2300 to 3500 - 3800 K at the 20.0 – 80.0 pressure range. Of particular interest is the first experimental evidence for diamond formation in the two-phase region CaO + CO_2 (fluid). The use of isotope-distinguished carbonate $Ca^{13}CO_3$ in the diamond anvil cell experiments gives an unambiguous evidence that ^{13}C-diamond has been formed from $Ca^{13}CO_3$ melt by a two-stage decomposition reaction: (1) $Ca^{13}CO_3$ (melt) = CaO + $^{13}CO_2$ (fluid) and (2) $^{13}CO_2$ (fluid) = ^{13}C (diamond) + O_2.

The results are applied to the construction of PT phase diagram for the $CaCO_3$ join (of the CaO – C – O_2 system) up to 80 GPa and 4000 K. The melting and decomposition relations of the $CaCO_3$ join as well as accompanying processes of diamond formation are applied and discussed in the context of the problem of natural 'super deep' diamonds origin in carbonate-rich growth media of the transition zone and lower mantle of the Earth.

[4]Department of Environmental Toxicology, University of California, Davis, CA, USA
[5]Centre for Atmospheric Science, School of Earth, Atmospheric and Environmental Sciences, University of Manchester, Manchester, UK

The budget of atmospheric secondary organic aerosol (SOA) is very uncertain, with recent estimates suggesting a global source of between 12 and 1820 Tg (SOA) a^{-1}. We used a dataset of aerosol mass spectrometer (AMS) observations and a global chemical transport model to produce top-down constraints on the SOA budget. We treated SOA formation from biogenic (monoterpenes and isoprene), lumped anthropogenic and lumped biomass burning volatile organic compounds (VOCs) and varied the SOA yield from each precursor source to produce the best overall match between model and observations. Organic aerosol observations from the IMPROVE network were used as an independent check of our optimised sources. The optimised model has a global SOA source of 140 ± 90 Tg (SOA) a^{-1} comprised of 13 ± 8 Tg (SOA) a^{-1} from biogenic, 100 ± 60 Tg (SOA) a^{-1} from anthropogenically controlled SOA, 23 ± 15 Tg (SOA) a^{-1} from conversion of primary organic aerosol (mostly from biomass burning) to SOA and an additional 3 ± 3 Tg (SOA) a^{-1} from biomass burning VOCs. We used a dataset of 14C observations from rural locations to estimate that 10% of our anthropogenically controlled SOA is of urban/industrial origin, with 90 Tg (SOA) a^{-1} (90%) most likely due to an anthropogenic pollution enhancement of SOA from biogenic VOCs.

Differentiation of impact-melt sheets: Evidence from Manicouagan with implications for the Moon

J.G. SPRAY*, C.D. O'CONNELL-COOPER AND L.M. THOMPSON

Planetary and Space Science Centre, University of New Brunswick, Fredericton, NB E3B 5A3, Canada (*correspondence: jgs@unb.ca)

Introduction

Recent exploration drilling of the late Triassic, ~80-90 km rim-diameter Manicouagan impact structure, Canada, has yielded ~18 km of core from 38 locations, three holes of which are >1.5 km deep [1]. This new data provides unprecedented insight into the internal structure and composition of a relatively large crater. Complemented by an ongoing 10-year (2006-2016) ground-based research project (the Manicouagan Impact Research Program: MIRP), the goal is to better understand impact crater tectonics and the formation and evolution of impact melt bodies. This is being achieved through training undergraduate, MSc and PhD students, in collaboration with PDFs and Research Scientists, as well as colleagues working internationally.

Impact melt characteristics – new revelations

The drilling program has revealed that the Manicouagan impact melt sheet is not of uniform thickness (previously considered ~300 m thick), but includes considerably thicker sections: up to ~1000 m of clast-poor impact melt, underlain by ~400 m of clast-rich impact melt [2]. These thicker sections of melt comprise a monzodioritic Lower Zone (~500 m), a quartz monzodioritic Middle Zone (~250 m) and a quartz monzonite Upper Zone (~275 m). This is only the second impact structure known to unequivocally exhibit differentation (previously, Sudbury was the sole exemplar). Geochemical investigation of the thicker melt sheet sections indicates that they formed via fractional crystallization [2].

Impact melt sheet-footwall relations

Drilling results, coupled with field work, have revealed that the interface between the impact-melt sheet and footwall is not flat, but exhibits more complex 'topography', which strongly implicates the presence of fault-controlled structure [3]. This new evidence allows the construction of hypothetical cross-sections, which provide insight into central peak and terrace collapse formation mechanisms for complex craters on Earth, the Moon, Mars and beyond.

On modeling H^+ and U transport behavior in an acidic plume

N. SPYCHER[1]*, S. MUKHOPADHYAY[1], D. SASSEN[1], H. MURAKAMI[1], S. HUBBARD[1], J. DAVIS[1], AND M. DENHAM[2]

[1]Lawrence Berkeley National Lab., Berkeley, CA 94720, USA (*correspondence: nspycher@lbl.gov)
[2]Savannah River National Lab., Aiken, SC 29808, USA

A nearly 1 km long acidic plume has developed under the F-Area at the U.S. Department of Energy Savannah River Site, South Carolina, from the disposal of low-level acidic radioactive waste solutions into seepage basins overlying relatively permeable, mostly sandy sediments. The disposal operations lasted for about 35 years until 1990, when the seepage basins were solidified and capped. Since then, the groundwater pH in the plume has remained mostly in the 3–3.5 range despite the end of disposal operations and fast groundwater velocities, although U concentration adjacent to the basins has been decreasing exponentially.

Here, we report on exploratory geochemical and reactive transport modeling investigations conducted to assess the relative roles of surface protonation and mineral precipitation in slowing down the rebound of pH at this site, as well as U transport behavior downgradient of the disposal basins. The modeling work is integrated with investigations of 'reactive facies', which aim at identifying specific types of sediments with unique properties affecting reactive transport, then correlating these sediment types with lithologic facies and their associated geophysical signatures for estimation of reactive properties over plume scales.

One- and two-dimensional reactive transport simulations were conducted considering Al and Fe mineral dissolution and precipitation, as well as H^+ and U surface complexation models from the literature. Simulations indicate that H^+ sorption reactions on goethite and kaolinite (primary minerals at the site besides quartz) could buffer pH at the site for long periods of time. The precipitation of Al silicates, hydroxides, and/or hydroxy sulfates could also strongly impede pH rebound at the site. Although the pH is computed to rebound quite slowly, U concentrations could potentially decrease at comparatively much faster rates from dilution with clean recharge water. Simulations results are most sensitive to reactive surface areas, to relative rates of reaction versus acidic discharge, to relative rates of mineral precipitation and dissolution, and to the type of implemented sorption models and parameters. The model sensitivity to heterogeneous fields of permeability and reactive surface areas derived from the reactive facies investigations is also investigated.

Biomineralization and growth mechanism of morphologically controlled strontium carbonate

B. SREEDHAR[1]*, CH. SATYA VANI[1], D. KEERTHI DEVI[1] AND G. PARTHASARATHY[2]

[1]Indian Institute of Chemical Technology (CSIR), Hyderabad-500 607, India (*correspondence: sreedharb@iict.res.in)
[2]National Geophysical Research Institute (CSIR), Hyderabad-500606 (drg.parthasarathy@gmail.com)

Biomineralization is a growing discipline in modern earthscience and is attracting much attention as it helps us (i) to synthesis marine carbonates with required morphology, composition and structure and (ii) to understand and quantify the controlling factors which affects the microbial mineralization in deep marine environments.[1, 2] The biological systems are very effective at controlling crystal growth, especially polymers have been successfully developed to control crystallization of inorganic particles in aqueous solutions. In this work we report the synthesis of araganite type strontium carbonate super structures using Gum acacia and also discussed the growth mechanism of the carbonates.

Gum acacia is a branched polysaccharide containing carbohydrates, amino acids, gulcuronic acid and a glycoprotein complex. The functional groups (-OH) present in arabinose and rhamnose and (-COOH) of glucuronic acids play a crucial role in the growth and formation of metal carbonates whereas the proteinaceous core with amino acids (-NH_2) stabilize the formed metal carbonates and play a key role in mimicking the biomineralization process. The crystallization involves the formation of different hierarchical structures like rice grain, doughnut shaped, flower shaped, hexagonal rods and cross shaped which have never been seen before in natural biominerals. Proteins and polysaccharides with complicated patterns of various functional groups in GA selectively adsorb on to the metal ion thereby hindering the crystal growth, followed by the mesoscale self-assembly of nanometer-scale building block into hierarchical superstructures. The key reaction of CO_2 with Sr^{2+} ions entrapped within GA polymer leads to the growth of beautiful structures of strontianite. Structural characterization of the synthesized materials was investigated by XRD, SEM, EDAX, TEM, TGA-MS and FT-IR.

Fe and S isotope compositions of hydrothermal sulfides from the Northern Lau Basin

B. Sreenivas[1]*, D. Ray[2], A.L. Paropkari[2], A. Mazumdar[2], B. Vijaya Gopal[1], L. Surya Prakash[2], G. Balu[1] and Y.J. Bhaskar Rao[1]

[1]National Geophysical Research Insitute (CSIR), Hyderabad 500007, India (*correspondence: bsreenivas@ngri.res.in)
[2]National Institute of Oceanography (CSIR), Dona Paula, Goa 403004, India

Massive sulfides belonging to the extinct hydrothermal field of the North Lau Basin were studied for their Fe and S isotope compositions. Sulfide samples belonging to pedestal slab, peripheral chimneys (remnants of white smokers) and oxide precipitates filling the hollows of pillowed basalts were studied. Detailed mineralogical and geochemical studies on the same set of samples indicated the similarites between the Lau hydrothermal field and the Trans-Atlantic Geotraverse (TAG) active mound [1]. The sulfides of pedetal slab mainly consisting chalcopyrites and pyrites with minor barite and sphalerite show $\delta^{34}S$ values between 8.4 to 9.6 ‰ (V-CDT). The major constituent of sulfides belonging to peripheral chimney is sphalerite, whlie pyrite and chlcopyrite being minor. The $\delta^{34}S$ values range from 5.5 to 8.3 ‰. These $\delta^{34}S$ values are very similar to those of TAG hydrothermal sulfides [2]. Such high $\delta^{34}S$ values for TAG hydrothermal sulfides were interpreted as a result of mixing of sulfur of sulfate reduction origin and that of the hydrothermal fluids. The high $\delta^{34}S$ values in case of Lau Basin also corroborate the influence of sulfate reduction. The sphalerite-rich sulfides of the peripheral chimney have slightly depleted $\delta^{34}S$ values when compared to the pedestal slab indicating increased effect of hydrothermal solutions in them.

The $\delta^{56}Fe$ values of samples belonging to pedesatl slab show a range between -0.3 to -1.1 ‰ (IRMM-014), while those of the peripheral chimney vary from -0.6 to -1.7 ‰. The oxide precipitates show maximum fractionation in Fe isotope compositions having $\delta^{56}Fe$ values of -0.8 and -3.0 ‰. Among the oxide precipitates, the MnO-rich top layer is characterized by lowest $\delta^{56}Fe$ value indicating the influence of temperatures. Further, role of redox conditions can be envisaged in controlling Fe isotope compositions based on the correlation between $\delta^{56}Fe$ and Ce anomalies.

Environmental geochemical studies were carried out in and around Ranipet industrial area, Tamil Nadu, India to find out the extent of chemical pollution in surface and groundwater due to waste disposal from tannery industries. Ranipet is located at 79°19′ – 79°22′ E longitude and 12°53′ – 12°57′ N latitude, about 120 km from Chennai on Chennai-Bangalore highway and it is chronic polluted area and one of the biggest exporting centers of tanned leather. It is one of the biggest exporting centers of tanned leather in India. The total number of industries located in and around Ranipet town are 240 tanneries along with ceramic, refractory, boiler auxiliaries plant, and chromium chemicals.

Studies were carried out to find out the contamination of surface water bodies due to industrial effluents. The results reveal that the surface water in the area is highly contaminated showing very high concentrations of some of the heavy / toxic metals like Cadmium ranging from 0.2 to 401.4 μg/L (average of 51.1 μg/L), Chromium 2.4 1308.6 (average of 247.2 μg/L), Copper 2.1–535.5 μg/L (average of 95.5 μg/L), Nickel 1.6–147.0 μg/L (average of 36.7 μg/L), Lead 6.4–2034.4 μg/L (average of 467.8 μg/L) and Zinc 20.8–12718.0 μg/L (average of 3760.4 μg/L). The concentration levels of these metals are much above the permissible limits in surface water and are health hazards especially for the people working in the tannery industries. It was observed that the people in the area are seriously affected and suffering from occupational diseases such as asthma, chromium ulcers and skin diseases. Distribution of metals, their contents at different locations, and their effects on human health are discussed in this paper.

Mineral growth and dissolution from rare event methods

ANDREW G. STACK

Oak Ridge National Laboratory. (stackag@ornl.gov)

Computational theory and hardware have advanced sufficiently to allow in-depth examination of free energy landscapes for complex, geologically important reactions. Here, we used two rare event theories, metadynamics and reactive flux, to probe the attachment and detachment of barium ions to the [120]-oriented monomolecular step on barite and compare these reaction rates and mechanisms to those measured experimentally. This reaction was chosen because attachment and detachment of barium ions to these step-edges is thought to be rate limiting and barite scale has been found to inhibit production of oil and geothermal energy in some cases.

Using metadynamics, we found that detachment and attachment of ions does not occur directly to and from solution, but several intermediate states are observed. Starting from a barium kink site making five bonds to three surface sulfates, detachment first proceeds to a bidentate state containing two bonds to two surface sulfates, followed by an inner-sphere adsorbed species (making one bond), then an outer-sphere adsorbed species before completely dissolving.

Reactive flux calculations of the transitions between each of these states revealed that moving from the inner-sphere adsorbed species to outer-sphere adsorbed is limiting the rate of detachment. For attachment, the transition from inner-sphere adsorbed to the bidentate species is rate limiting. Arrehenius activation energies of each of these rate limiting steps were calculated by performing the reactive flux calculations at multiple temperatures. The activation energies and rate constants, compare favorably to those measured experimentally by atomic force microscopy in the case of dissolution.

The implications this study are two-fold. Firstly, the observation of multiple intermediates states implies that mineral growth and dissolution reactions can lead to pools of labile or recalcitrant material in variou states of adsorption onto mineral surfaces. This addresses the longstanding issue of non-steady state dissolution rates. Secondly, the ability to quantitatively probe complex reaction mechanisms on surfaces accurately will be a powerful technique in addressing mineral reactivity and mechanisms.

This research was sponsored by the Division of Chemical Sciences, Geosciences, and Biosciences, Office of Basic Energy Sciences, U.S. Department of Energy.

A multi-isotope study for identifying groundwater movement near disturbed salt domes: Case study Stassfurt, Germany

[1]Federal Institute for Geosciences and Natural Resources (BGR), Hanover, Germany
[2]State Authority of Mining, Energy and Geology (LBEG), Hanover, Germany
[3]University of Bremen, Germany
[4]Brandenburg University of Technology (BTU) Cottbus, Germany

An area of the German part of the Southern Permian basin affected by anthropogenically induced subrosion was investigated for its potential for ongoing salt dissolution induced by groundwater movement. A set of environmental tracers supported by hydrochemical analyses was applied to establish aquifer fingerprints of the covering layers (Quaternary and Triassic) and of flooded parts of the mining area (Zechstein), and revealed prevailing mixing components: A modern groundwater component was identified by the presence of ^{3}H and $^{3}He_{tri}$ which indicates young apparent groundwater ages (0 - 50 a) in the covering layers. Using this, percentages of modern water could be derived for each sample. The presence or absence of ^{14}C in the samples represents an age classification between the modern groundwater component (<50 a) given above, and an old groundwater component (apparent groundwater ages <50 000 a). The trends derived from radiocarbon could generally be validated by low $^{4}He_{rad}$ contents in samples from the modern groundwater component and elevated $^{4}He_{rad}$ contents in the old groundwater. Contact between meteoric water and Zechstein salts could be identified by the presence or absence of Permian crystallization water from the dissolution of e.g. Carnallite and/or Kieserite in the samples. We developed a conceptual model of groundwater flow and interactions between groundwater of the different aquifers in the studied area and discuss potential implications for ground subsidence.

High-pressure calibration of the oxygen fugacity recorded by garnet bearing peridotites

VINCENZO STAGNO, CATHERINE A. MCCAMMON AND DANIEL J. FROST

Bayerisches Geoinstitut, Universität Bayreuth, D-95440, Germany (vincenzo.stagno@uni-bayreuth.de)

The oxygen fugacity within the Earth's upper mantle below ~50 km depth can be measured by performing oxy-thermobarometry determinations on garnet bearing mantle xenoliths. The commonly used equilibrium includes the $Fe_3Fe_2Si_3O_{12}$ garnet component. A knowledge of the mantle oxidation state is important in order to understand the speciation of heterovalent elements and C-O-H-bearing volatile-rich phases.

To date, measurements have shown that the upper mantle (>250 km depth) is typically characterized by a heterogeneous fO_2 between -1 to -5 log units relative to the FMQ oxygen buffer. This range mainly arises from the pressure dependence of the employed oxybarometer, which drives the fO_2 to lower values with increasing pressure.

The aim of this study was to investigate the iron oxidation state of garnet equilibrated with carbonate and graphite/diamond in a typical peridotite mantle assemblage in order to test the current oxythermobarometer at high pressure. Experiments were performed using a layer of garnet sandwiched between oxygen buffering carbon/carbonate bearing assemblages, which fixed the oxygen fugacity at known values at pressures between 3 and 7 GPa and temperature of 1100-1600 °C. Several configurations were tested either in the presence of natural Cr-bearing garnets or hydrous conditions and empolyong both relatively reduced and oxidized starting materials. fO_2 was measured using a sliding redox sensor assemblage empolying Fe-Ir alloy. Using these measurements a re-evaluation of the oxy-thermobarometer calibration was performed. Redox profiles for cratonic mantle were reexamined with implications for carbon speciation in the mantle.

Assessment of carbon needs to renew soil fertility

FOTINI E. STAMATI[1]*, NIKOLAOS P. NIKOLAIDIS[1] AND JERALD P. SCHNOOR[2]

[1]Department of Environmental Engineering, Technical University of Crete (TUC), University Campus, 73100, Chania, Greece (*correspondence: fotini.stamati@enveng.tuc.gr)

[2]Department of Civil and Environmental Engineering, 4105 Seamans Center, The University of Iowa, Iowa City, Iowa 52242

Conversion of natural to agricultural ecosystems induces SOM losses due to changes in land management practices and reductions in litter input. The average rate of soil organic carbon (SOC) stock decline after the conversion of a native land to cropland decreases in time [1] and depends on the previous landuse type (forest, grassland, shrubland), and the decomposition regime (determined by climatic conditions, size of the carbon litter input, texture and other factors). SOC can be depleted by 50% in about 5 years in the tropics and 50 years in temperate ecoregions. On the basis of soil resilience and sustainability of agriculture, the adoption of appropriate agricultural practices for the maintenance of carbon in croplands is a win-win situation because they will prevent erosion and contribute to inherent soil and product quality, biodiversity, fertility, water quality, and agricultural economy [2]. Monitoring field data and modeling exercises are essential for the assessment of the turnover of different carbon pools in order to optimize organic input strategies for carbon sequestration in stable forms so as maintain soil structure and fertility [3]. In this work, grassland to cropland and forest to cropland conversions under different climatic regimes were modeled with ROTH-C. Chronosequence literature data for dryland steppes [4], temperate grasslands [5], mediterranean shrublands [6] and forests in the tropics [7] were used for the modeling. The methodological approach for model caibration and estimation of uncertainty presented by Stamati *et al.* (2011) [4] was followed. Appropriate carbon addition under different climatic regimes and soil textures are suggested for sustainable agricultural practices (carbon sequestration, HUM increase).

Experimental determination of the hydrous basalt liquidus

C.C. STAMPER[1]*, J.D. BLUNDY[1], E. MELEKHOVA[1] AND R.J. ARCULUS[2]

[1]Department of Earth Sciences, University of Bristol, Bristol, BS8 1RJ, UK. (*correspondence: c.stamper@bristol.ac.uk)

[2]Research School of Earth Sciences, The Australian National University, Canberra, Australia

A series of experimental liquidus determinations have been carried out on a hydrous primitive basalt at a range of lower crustal pressures. The starting composition replicates the major element chemistry of an olivine picrite from South East Mountain, Grenada, Lesser Antilles with 15.3 wt % MgO and Mg# = 73. The island is known for erupting primary mantle melts, and products of the arc volcanism from Grenada yield evidence for magmatic water contents of ≤ 6.4 wt % H_2O [1].

The ulimate aim of this experimental series is to map out the topology of the hydrous basalt liquidus. The position of the liquids relative to a mantle adiabat determines the amount of superheating experienced by a magma as it ascends to lower pressures. This in turn has implications for the manner in which mantle-derived melts interact with the crust.

Equilibrium experiments are being conducted using both piston cylinder and TZM apparatus at pressures ≤ 1.7 GPa and water contents of 2.5 and 5.0 wt % at fO_2 = NNO. Experiments on the most hydrous starting composition are ongoing and have bracketed the liquidus between temperatures of 1265-1280°C at 1.3 GPa and 1250-1280°C at 1.7 GPa.

These experiments are also being used to explore phase relations at high temperatures and investigate the potential for multiple saturation points. At 1.7 and 1.3 GPa the liquids phases are olivine, clinopyroxene and Cr-rich spinel.

A further objective of this project is to extend the P-T range of experiments in an attempt to recreate the assemblages found in cumulate xenoliths from Grenada.

Effects of diagenesis in Triassic limestone of Opolskie Voivodesip

K. STANIENDA

Institute of Applied Geology, Silesian University of Technology, 44-100 Gliwice, Poland (Katarzyna.Stanienda@polsl.pl)

Introduction

During Middle Triassic time (Muschelkalk) the SW part of Poland was situated in the SE part of the Germanic Epicontinental Sea. Full profile of Lower Muschelkalk was found in the SW part of Poland (area of Silesia- Opolskie Voivodesip). Formation contains strata of Gogolin Beds, Górażdże Beds, Terebratula Beds and Karchowice Beds [1, 2]. The effects of destructive and constructive diagenesis were observed in Triassic limestone of Opolskie Voivodesip.

Discussion of Results

The effects of destructive diagenesis are longitudinal channels created by sea organisms and micritic coats in marginal areas of allochemes and peloides. Effects of eogenetic stage of constructive diagenesis are: first generation cement (micritic, orthosparitic and palisade), Mg- calcite, early diagenetic dolomite and clay minerals. During mesogenetic stage pseudosparitic, mosaic cement (second generation cement) was formed. It fills in the space in the rock between allochemes and builds together with the micritic cement the rock mass of limestone poor in allochemes. Neomorphic processes like transformation of aragonite into low magnesian calcite, recrystallization of calcite crystals which build the trochites of Crinoideas, recrystallization and agradation of crystals which build the cement and dissolution which caused the formation of stylolites fill in with the iron compounds, were also going during the mesogenetic stage. Telogenetic stage characterized by karst processes, dedolomitization and silification. Effects of karst processes are karst funnels and karst formations present in some areas of strata. During dedolomitization dolomite pseudomorphs were formed. During silification processes small pores in rocks were filled in with quarz or chalcedony and silica concretions, which create special levels in some limestone strata, were formed.

Project was financed from capital of National Center of Science.

Representative analyses of properties of hydrocarbon and non-hydrocarbon fluids in the petroleum industry strictly depend on the quality of the sub- or surface sampling. The exploration & appraisal activities in challenging pressure and temperature environments, as well as difficult fluids such as heavy oils, very high levels of H_2S or CO_2 require a completely new approach. Development and implementation of new technologies is a must, not a luxury.

Experience shows that the majority of non-representative data coming from laboratories are directly due to poor sampling practices and/or inadequate technologies employed. Recent improvements in sampling tools, include innovative approaches to prevent scavenging of H_2S, or absorption of mercury species, utilizing exotic metarials such as Inconel 725, and inert coatings such as Dursan. The increased working range of sampling/analytical equipment is reaching pressures of 1700 bar (25 kpsi) and temperatures of 200°C.

Recent years have also witnessed increased focus on *in situ* measurements at downhole conditions, or as close to the wellsite as possible. Evolution of optical absorption spectroscopic tools such as LFA (Live Fluid Analyzer) led to developemnts of 'downhole laboratories' employing Grating Spectrometer technology, such as IFA (InSitu Fluid Analyzer) providing critical data on fluid properties (C_1, C_2, C_{3-5}, C_{6+}, CO_2, Gas-Oil Ratio, density, viscosity) in real time. The live water pH is now possible, both in the reservoir as well as in the laboratory. Breakthroughs in the mud gas logging are included an unprecedented leap from qualitative/comodity tools to quantiative fluid facies evalaution while drilling in C_{1-6} range, including application of GC/MS and laser MS technologies for the methane stable isotope measurements.

The need for *in situ* measurements requires miniaturization and operational robustness. This article will discuss the latest advances in sampling and measurements along the fluid value chain – from the reservoir to laboratory.

Cadomian igneous rocks from Europe's Variscan belt, Lazovo complex

J. STATELOVA[1]*, A.V. QUADT[2], P. MACHEV[3] AND S. GEORGIEV[4]

[1]GI-BAS, Bulgaria (*correspondence: js@geology.bas.bg)
[2]IGMR, ETH-Zurich, Switzerland (vonquadt@erdw.ethz.ch)
[3]Sofia University, Bulgaria (machev@gea.uni-sofia.bg)
[4]Geological survey of Norway (georgiev@colostate.edu)

The geochemical and the age information contained in the Cadomian/Pan-African orogeny elements in Europe helps to identify portions of the Neoproterozoic-Cambrian plate boundaries [1]. In the Balkanides several types of such elements are known: some of the protolithes of Srednogorie high-grade metamorphic series - intermediate and acid igneous rocks ~590-620 Ma old [2]; Cherni Vrah ophiolite complex - ~560 Ma [3]; and 550 to 1100 Ma old inherited zircon cores detected in all high-grade metamorphic rocks.

We studied one of the easternmost exposures of the Variscan belt in the Balkanides in Tvarditsa mountain. The metamorphites of Lazovo complex cover wide areas of its southern slopes and host the pre-Triassic Tvarditsa pluton [4]. GPA geothermobarometry shows that amphibolite facies conditions were reached [5] in Variscan times [6].

The metamorphites in the eastern parts of Lazovo complex formed over intermediate to basic igneous protholites containing lense- and layer-shaped bodies of pyroxenites. They had different pre-Varsican metamorphic history compared to the garnet-bearing and the two-mica gneisses in the western parts of the complex [5]. The eastern part gneisses studied form thick layers of distictive composition, not related to metamorphic differentiation. They preserve field and geochemical evidence of their magmatic origin. Their trace-element composition suggests subduction-oriented source.

The zircons from the gneisses sudied and from the metapyroxenites have slightly elongated to rounded shapes. They display growth and sector zoning corresponding to igneous conditions of crystallisation. The U-Pb ages of the zircons obtained by LA-ICP-MS cluster at around 600 Ma.

Our data constrain for the first time the protholith age of Lazovo complex metamorphites and allow better correlation with the Neoproterozoic terrains in Eastern Europe.

Tracing magma chambers in the lab: A case study on Lascar volcano

A. STECHERN[1]*, M. BANASZAK[2], R.E. BOTCHARNIKOV[1], F. HOLTZ[1] AND G. WÖRNER[2]

[1]Institute for Mineralogy, Leibniz University of Hannover, Germany (*correspondence: a.stechern@mineralogie.uni-hannover.de)
[2]Geowissenschaftliches Centrum Göttingen, Abt. Geochemie, Göttingen, Germany

Lascar volcano is a calc-alkaline stratovolcano located in the Central Volcanic Zone (CVZ), Northern Chile and represents the most active volcano in this area. The activity of Lascar is characterized by extensive lava flows, domes, and pyroclastic deposits such as the most recent eruption in 1993. Present activity is restricted by vigorous degassing from the open vents. The composition of erupted rocks of Lascar range from poorly porphyritic mafic andesites to dacites.

In this study we combine geochemical analyses with high P-T experiments to investigate possible depth of storage from the pre-eruptive conditions of crystallization on the one hand, as well as the role of magma-mixing and differentiation during magma ascent on the other.

Well-established geo-thermo- and barometers were used to characterize the crystallization conditions of the recent 1993 eruption. Results give evidence for a large temperature interval of crystallization from ~ 850 to 1050°C and pressures between 400 to 500 MPa. Oxygen fugacity was in the range of 1.0 to 2.0 log units above the Ni/NiO oxygen buffer. The analyses of melt inclusions are dacitic to rhyolitic in compositions with rather small concentrations of chlorine, fluorine and sulfur, indicating that the evolved magma was largely degassed.

The major element compositions of Lascar lavas indicate significant changes in the magmatic processes with the alternation of mixing- and fractionation-dominated stages. The compositional variation of deeper magmas (~ 1.3 ± 0.3 GPa) can be reconciled with magma mixing models. The compositional variations of most lavas erupted in 1993 and of a few older samples correspond to crystal fractionation trends, which have been reproduced experimentally at 300 to 500 MPa. Experimental data, geochemical trends and thermo-barometric data indicate that the pre-eruptive depth of the youngest magmas (< 7.1 ka) is rather shallow (~ 500 ± 200 MPa). A possible interpretation of these results is that magma storage in upper crustal levels is mostly dominated by fractional-crystallization whereas deeper magma chambers show clear evidence for magma-mixing processes.

Upscaling pore scale carbonate precipitation rates to the continuum scale

C.I. STEEFEL[1]*, C. NOIRIEL[2], L. YANG[1] AND J. AJO-FRANKLIN[1]

[1]Lawrence Berkeley National Laboratory, One Cyclotron Road, Berkeley, CA 94720, USA (*correspondence: CISteefel@lbl.gov)
[2]Université de Lille, France (catherine.noiriel@univ-lille1.fr)

An integrated approach combining experimental reactive flow columns and continuum-scale reactive transport modeling has been used to compare microscopic and bulk (upscaled) rates of carbonate mineral precipitation. The experiments consisted of the injection of supersaturated, carbonate-rich solutions into calcite packs. Bulk rates of precipitation based on the change in chemistry over the length of the column were compared with spatially resolved determinations of carbonate precipitation using X-ray synchrotron imaging at the micron scale. These data are supplemented by well-stirred reactor experiments to evaluate the rate of precipitation as a function of solution supersaturation in the absence of transport effects. Results indicate good agreement between rates determined with fluid chemistry and with microtomography. The distribution of calcite precipitates shows a nonlinear spatial profile, with the greatest accumulation near the column inlet. Precipitation is greatest on Iceland spar seeds, with crystal morphology of the new precipitates suggesting growth via a 2D heterogeneous nucleation mechanism.

Using the rates of precipitation as a function of supersaturation determined in the well-stirred flowthrough reactors, it is possible to match the spatially-resolved microtomographic data with a continuum reactive transport model *if the generation of new reactive surface area is accounted for*. The experimentally-determined value of 0.90 m^2/g for the specific surface area of the neoformed calcite, added to the initial calcite surface area of 0.012 m^2/g, results in good agreement with the continuum model. The approach used here also demonstrates that it is possible to determine upscaled reactive surface area in porous media if the intrinsic rate (per unit surface area mineral) is known.

Nickel isotope anomalies: Neutron-rich or neutron-poor?

R.C.J. STEELE[1*,2], T. ELLIOTT[1], C.D. COATH[1] AND M. REGELOUS[1,3]

[1]Bristol Isotope Group, Dept Earth Sciences, University of Bristol. Bristol, UK (*correspondence: r.steele@bristol.ac.uk)
[2]Natural History Museum, Cromwell Road, London UK
[3]GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Erlangen, Germany

The solar system is a mixture of many different nucleosynthetic sources. Numerous studies have investigated the nucleosynthetic origins of the solar system by examining isotopic anomalies in meteorites [e.g. 1]. Isotopic anomalies in the most neutron-rich isotopes of Ca, Ti, Cr in primitive meteorites have been interpreted as incomplete-mixing of a highly neutron enriched nucleosynthetic source into the early solar system [2-4]. This source has been variously hypothesised to be a type Ia supernova [5], type II supernova [6] or an AGB star [7]. However, nearly all of the reported measurements of these anomalies have employed normalisation to a pair of lighter-isotopes, assumed not to be anomalous. Hence, in these cases the inference of a neutron-rich anomaly is a point of interpretation since the anomaly could equally well reside on one of the normalising isotopes.

More recently, Ni has been added to the list of elements exhibiting apparent anomalies in its most neutron-rich isotopes, ^{62}Ni and ^{64}Ni [8, 9, 10]. We have made further measurements of Ni isotopes in bulk meteorites, both mass-independently (internally-normalised) and mass-dependently (double-spike), to yield absolute Ni isotope ratios that will better constrain the nucleosynthetic environment from which this incompletely mixed component arose. Preliminary results suggest that, in fact, the anomalies reside on ^{58}Ni and not on ^{62}Ni or ^{64}Ni. If these findings of neutron-poor anomalies are confirmed, they have far-reaching implications for the nucleosynthetic sources of the Ni isotopic anomalies and the identification of the nucleosynthetic sources of the solar system in general.

Silica speciation in aqueous sodium silicate solutions

M. STEELE-MACINNIS[1], C. SCHMIDT[2] AND R.J. BODNAR[1]

[1]Department of Geosciences, Virginia Tech, Blacksburg VA 24061 USA (mjmaci@vt.edu, rjb@vt.edu)
[2]Deutsches GeoForschungsZentrum GFZ, Telegrafenberg, 14473 Potsdam, Germany (hokie@gfz-potsdam.de)

Aqueous alkali silicate fluids can significantly contribute to the mobility of high field-strength elements in the lower crust and upper mantle [1]. The speciation of silica in these fluids is important for understanding the transport of such elements as alkali-silica complexes. Speciation of aqueous fluids and melts in the Na_2O-SiO_2-H_2O system has been previously studied *in situ* for one composition on the H_2O-NS4 join [2]; here, we investigate silica speciation of fluids over a range of compositions in the Na_2O-SiO_2-H_2O system.

The speciation of dissolved silica in aqueous sodium silicate solutions has been studied *in situ* up to 600°C and 2 GPa using Raman spectroscopy and a Bassett-type hydrothermal diamond-anvil cell [3]. Starting materials were either aqueous NaOH solution plus quartz, or water plus sodium silicate glass (NS2 and NS3), yielding bulk compositions from 10 to 70 wt% SiO_2 and various Na/Si ratios. Composition was determined from the dimensions of the sample chamber and the quartz or glass chip, and the densities of the individual phases. The cell was heated until all phases except zircon were dissolved to yield a single fluid phase, which permitted analysis at known fluid composition. Pressure in the cell was determined from the shift in wavenumber of the ν_3-SiO_4 (~1008 cm^{-1}) band of zircon [4].

The assignment of Raman bands to particular dissolved species remains somewhat elusive, so the interpretation is partly qualitative. The main trends observed in Raman spectra of fluids with increasing SiO_2/H_2O ratio include 1) decrease in the intensity of the ~770 cm^{-1} band (monomer); 2) increase in the intensity of the ~1050 cm^{-1} band (assigned to bridging oxygen Si-O stretch [2]); and 3) increase in spectral contributions at ~550-600 cm^{-1} and ~830-1000 cm^{-1}, which have been assigned to Q^n species [*e.g.* 2]. These trends are interpreted to represent increasing polymerization. Opposite trends, interpreted to indicate decreasing polymerization, are observed with increasing Na/Si ratio.

Structure and function of microbial communities associated with barite chimneys in a low-temperature diffuse venting area at the Loki's Castle black smoker vent field at the Arctic Mid-Ocean Ridge (AMOR) were studied by 454-pyrosequencing of PCR amplified 16S rRNA gene sequences and total community cDNA (270 356 reads). White microbial mats present on the barite chimneys, and associated with sibolignid tubeworms directly on the seafloor, where dominated by Sulfurimonas comprising 86-96% of the rRNA-tags. mRNA-tags indicated that vent fluids rich in H_2S (and barium) discharged into the sulfate-rich seawater supported a chemolithoautotrophic lifestyle where reduced sulfur species were oxidized by oxygen or nitrate. CO_2-fixation proceeded via the rTCA-cycle. Scanning electron microscopy revealed that large amounts of thread-like extracellular polymeric material in the microbial mats acted as nucleation points for barite biomineralization. Anaerobic methanotrophs (ANME) of the ANME-1 clade (26%), and the GOM-arc1 group (14.3%) were dominating in the white chimney barite whereas the black flow channel harbored the most diverse microbial community including taxa such as Planctomycetales, 13.5%; Thiotrichales, 10.5%; Thaumarchaeota (MG 1.1. a), 9.4%; Pseudomonadales 7.2%; and Methylococcales, 3.5%. Hence, indicating methane (aerobic/anaerobic), sulfur and ammonia oxidation and heterotrophic metabolisms as dominating processes.

High pressure and high temperature effect on the structural stability of smectites doped with rare earth elements

V.F. STEFANI[1], R.V. CONCEIÇÃO[2] AND N.M. BALZARETTI[1]

[1]Physics Institute, UFRGS, Porto Alegre – RS, Brazil. (vicentestefani@hotmail.com, naira@if.ufrgs.br)
[2]Geoscience Institute, UFRGS, Porto Alegre – RS, Brazil. (rommulo.conceicao@ufrgs.br)

Smectites are phyllosilicates with high cation exchange capacity (CEC) in the interlayers. For these and other features, smectites have been used in various parts of the world as secondary barriers for possible leak of liquids that contain radioactive elements in definitive deposits of nuclear waste disposal. In such case, radioactive cation could be captured by smectite through cationic exchanges. However, very little is known about the stability of smectite under high pressures and high temperatures (HPHT). Preliminar studies developed by our group in dioctahedral calcium smectites showed that the smectite structure is stable, remaining dioctahedric after processing up to 7.7 GPa and at room temperature. This work intends to replace the calcium of the smectite for heavy rare earth elements (REE) using the CEC characteristic of the smectite. We have achieved a cation exchange in smectite using La^{+3} as REE so far. Results in SEM/EDS showed that there was not more evidence of calcium in the sample after CEC procedures; on the other hand, a large amount of lanthanum was present. Our next step is to submit La-rich smectite under extreme conditions of pressure and temperature in order to investigate the structure and chemical changes. To achieve high pressures, hydraulic presses with boards of anvils with toroidal profile and diamond anvil cell (DAC) is being used. SEM, X-ray diffraction and FTIR in situ analysis will be performed on all samples.

The stability and structure of Mg^{2+} bicarbonate and carbonate ion pairs – An experimental and theoretical study

ANDRI STEFANSSON[1], KONO LEMKE[2], PASCALE BÉNEZÉTH[3] AND JACQUES SCHOTT

Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavík, Iceland

The chemistry of Mg^{2+} in aqueous CO_2 solutions is of fundamental importance, both with respect to the reaction mechanism of magnesium carbonate precipitation and in relation to sequestration of CO_2 by carbonate mineralization.

In order to get insight into the coordination and stability of Mg^{2+} bicarbonate and carbonate ion pairs, a combined experimental and theoretical study was conducted. Potentiometric titration and UV-Vis-IR spectrophotometric measurements on dilute solutions were conducted and the stability constants for the $MgHCO_3^+$ and $MgCO_3$ (aq) complexes derived *in situ* at 10-100°C. In addition, density functional calculations were conducted on the hydration environment around the Mg^{2+}, HCO_3^- and CO_3^{2-} and on the respective complexes.

The aquated Mg^{2+} ion is octahedral coordinated. Upon substitution of HCO_3^- or CO_3^{2-} with first shell waters, the coordination changed to five fold with important implication for further reactions and magnesium carbonate mineralization. At neutral to alkaline pH values, the $MgHCO_3^-$ and $MgCO_3$ (aq) ion-pair contribute significantly to the CO_2 speciation in magnesite saturated to supersaturated solutions. Moreover, with increasing temperature, their stabilities increase. However, under alkaline conditions and with increasing temperatures, the solutions become brucite saturated limiting the availability of Mg^{2+} in solution for carbonate mineralization and ion-pair formation.

Fluids on the loose – Capturing meaningful geochronology in sulfides

HOLLY J. STEIN[1,2]

[1]AIRIE Program, Department of Geosciences, Colorado State University, Fort Collins, CO 80523-1482, USA (hstein@cnr.colostate.edu)

[2]Geological Survey of Norway, 7491 Trondheim, Norway

For generations, economic geology students have been taught to tackle the world's giant ore deposits. If you aren't studying an economically important deposit at an operational mine, the value of your work may be perceived as less important. This approach to understanding the non-unique pandemic phenomenon of metal-carrying, sulfur-bearing, and sulfide-precipitating fluids in the crust has stymied our progress in ore geology. We cannot glean crucial and fundamental relationships by simply acquring more and more data from massively chaotic environments fraught by full-time chemical and physical disequilibrium. If we want to understand *how* fluids are transferred in the Earth's crust, *where* fluids originate and *why* they migrate, and how these fluids relate to the observed and unseen rock record, we must turn our attention to locations where fluids have left their simple and indelible mark in the geologic history. This is readily accomplished through study of small metallic-mineral occurrences, and in particular by application of Re-Os geochronology and tracer studies. Dating of many small sulfide-bearing deposits gives us detailed histories of terrane-scale fluid migration events, be they external additions or metamorphic rearrangements of existing volatiles.

As geoscientists we have no truly robust means to correlate through space without the component of time. Without absolute dating, we have no frame of reference beyond immediately visible stacking or cross-cutting relationships. Re-Os studies of sulfides in the Earth's crust have taught us that (1) the duration of large porphyry-style mineralization is an unimportant question as it is different for every deposit and every district and will not help us find ore, (2) the age of sulfide mineralization should not be shoe-horned to agree with associated U-Pb ages for obvious reasons, and (3) excluding true porphyry-style deposits, the mineralization process, in its entirety, commonly spans tens of millions of years.

If you want to understand the ore giants in the world, step back and be sure you understand the less complicated varieties first. Less is more. Good questions demand the right analytical approach. Though easy access to geochemical data tempts us to adopt the get-more-data approach, this will not lead to clarity of understanding.

North Atlantic influence on rainfall in the Dead Sea – Sahel watersheds: Implication for abrupt Holocene climate fluctuations

M. STEIN[1], Y. KUSHNIR[2] AND E.J. KAGAN[1,3]

[1]Geological Survey of Israel, 30 Malkhe Israel St., Jerusalem, 95501, Israel, (motis@vms.huji.ac.il)
[2]Lamont-Doherty Earth Observatory, Columbia University, NY, 10964, USA, (kushnir@ldeo.columbia.edu)
[3]Institute of Earth Sciences, The Hebrew University, Jerusalem, 91904, Israel, (elisa.kagan@mail.huji.ac.il)

Observations of 19th and 20th century precipitation in the Dead Sea watershed region display a multidecadal, anti-phase relationship to North Atlantic (NAtl) sea surface temperature (SST) variability, such that when the NAtl is relatively cold, Jerusalem experiences higher than normal precipitation and vice versa. This association is underlined by a negative correlation to precipitation in the sub-Saharan Sahel and a positive correlation to precipitation in western North America, areas that are also affected by multidecadal NAtl SST variability. These observations are consistent with broad range of Holocene hydroclimatic fluctuations from the epochal, to the millennial and centennial time scales, as displayed by the Dead Sea and Sahelian lake levels and by direct and indirect proxy indicators of NAtl SSTs. On the epochal time scale, the gradual cooling of NAtl SSTs throughout the Holocene in response to precession-driven reduction of summer insolation is associated with previously well-studied wet-to-dry transition in the Sahel and with a general increase in Dead Sea lake levels from low stands after the Younger Dryas to higher stands in the mid- to late-Holocene. On the millennial and centennial time scales there is also evidence for an antiphase relationship between Holocene variations in the Dead Sea and Sahelian lake levels and with proxy indicators of NAtl SSTs. However, the records are punctuated by abrupt lake-level drops and extensive expansion of the desert belt at ~8.1, 3.3 and 1.4 ka cal BP, which appear to be in-phase and which occur during previously documented abrupt major cooling events in the Northern Hemisphere. The catastrophic aridity at 3.3 ka cal BP caused probably the collapse of the late Bronze cultures at the Levant, Mediterranean and Nileland. It sends an important message for the future of modern human culture.

Si isotope signatures in soils by UV femtosecond laser ablation

G. STEINHOEFEL[1], J. BREUER[2], F.V. BLANCKENBURG[1], I. HORN[3], D. KACOREK[4] AND M. SOMMER[5]

[1]GFZ Potsdam, Germany (grit.steinhoefel@gfz-potsdam.de, fvb@gfz-potsdam.de)
[2]University of Hohenheim, Germany (breuer@lachemie.uni-hohenheim.de)

[5]ZALF Müncheberg, Germany (sommer@zalf.de)

Si isotope fractionation during weathering is now commonly mapped at the catchment scale. But we still lack an understanding of the processes that set isotope ratios. These take place at the mineral/pore water interface. We present the first Si isotope data of the principle Si pools in soils determined by a UV femtoseond laser ablation system coupled to a multicollector inductively coupled plasma mass spectrometer (MC-ICP-MS). This approach provides the opportunity to obtain precise and accurate data (1) on bulk sample materials as fused glass beads or pressed powder pellets, (2) at the mineral scale in thin sections and (3) for solutions after Si separation and evaporation. We investiagted two immatured Cambisol profiles developed on paragneiss and sandstone in the Black Forest (Germany), respectively, after the last-glacial maximum. Bulk soils show a largely uniform signature in both soil profiles, which is close to those of primary feldspar and quartz with δ^{30}Si value of around -0.4‰. Clay formation is associated with limited Si mobility and hence preserves the original Si isotope signature of parental minerals. Organic-rich environments can promote intense weathering, which lead to high Si mobilization during clay formation together with significant negative isotope signatures down to -1.0‰ in topsoils. Biogenic minerals, i.e. phytoliths, exhibit negative Si isotope signature of about -0.4‰, which is in the range measured for different European tree species. Their impact in bulk soil signatures is negligible but is likely important for the dissolved Si pool. These results can now be used to reconstruct weathering and Si transport processes in soils to identify the source of dissoved Si in soil and river waters, which are commenly enriched in heavy Si isotopes.

Failure of density functional theory for ground state calculations on TiO_2

GERD STEINLE-NEUMANN[1], VOJTECH VLČEK[1], EVA HOLBIG[1] AND XIANG WU[1,2]

[1]Bayerisches Geoinstitut, Universität Bayreuth, 95440 Bayreuth, Germany
[2]School of Earth and Space Sciences, Peking University, Beijing 100871, China

Electronic structure computations based on density functional theory (DFT) is playing an increasingly important role in the study of material properties, including high pressure properties that are relevant for Earth's interior. The success of DFT-based computations has been limited by the failure of standard implementations of DFT to properly describe the transtion metal-bearing oxides and silicates that are of great importance in the Earth's mantle, especially for Fe-bearing compounds.

There is less appreciation of DFT failures for lighter transition metal-bearing materials. For SiO_2 it is documented that with the local density approximation (LDA) stishovite is predicted stable over quartz which is corrected by the introduction of the generalized gradient approximation (GGA) [1]. However, experimental structural parameters and physical properties of quartz are better reproduced by LDA [1]. Similarly, and not well documented, for TiO_2 DFT in any approximation predicts rutile stable over anatase, in conflict with calorimetry [2].

We have revisited the relative stability of TiO_2 anatase and rutile, as well as other crystalline phases, with highly accurate all-electron methods and various approximations to exchange and correlation, and confirm that rutile is always found stable over anatase. Also, computing harmonic zero point motion energy for the two phases from linear response phonon computations does not stabilize anatase. However, a strong anharmonic character of rutile lattice vibration is revealed that warrants further studies.

High pressure phase relations are better reproduced within DFT, and a proper sequence of high pressure phase stability is reproduced [3]. Zero pressure bulk moduli are all below 240 GPa, sugessting that there are no superhard phases of TiO_2. Higher coordination of high pressure phase leads to stronger localization of the Ti 3d states.

[3]IRSN, 91400 Orsay, France
[4]PTB, 38116 Braunschweig, Germany
[5]"Ring of 5 (Ro5)" is an informal group dedicated to the survey of artificial radioacitvity in the atmosphere

Atmospheric release of radioactivity after the nuclear accident at Fukushima Daiichi started on the 12th of March 2011. Within approximately 10 days contaminated air masses reached Europe. The long range transport resulted in a dilution of the activity concentrations in the air by a factor on the order of 10000 times compared to concentrations reported from Japan. With levels of some tens of mBq m^{-3} at the most, there has been no health safety risk in Europe. The dispersion of the radioactive traces over Europe were followed through the analyses of filters of more than 140 high-volume samplers. Rapid exchange of data was granted through the participation of many laboratories in a network called "Ring of Five (Ro5)" which is an informal information club started in 1983 for this very purpose.

Switzerland was situated at the edge of a corridor with higher levels and saw comparatively low maximum total ^{131}I activities of around 2 mBq m^{-3}. At the end of March the activity ratios of gaseous ^{131}I/particulate ^{131}I recorded in Switzerland were around 4 to 6, while the activity ratio of particulate $^{131}I/^{137}Cs$ was roughly 10. Samples taken with airplanes in the upper troposphere as well as samples from a high altitude station at Jungfraujoch (3500 m a.s.l.) allowed to assess the vertical mixing of the radioactive traces. Temporal evolution of isotopic ratios such as $^{132}Te/^{137}Cs$ or $^{136}Cs/^{137}Cs$ helped to estimate the duration of the major emissions as well as the composition of the source term.

In Switzerland atmospheric deposition of radioactivity was very low with only a few Bq m^{-2} for ^{131}I. This lead to spurious contamination of grass and leafy vegetables (up to a few Bq kg^{-1} fresh weight). Again, at these levels there has been no food safety risk.

Interactions of phosphate and phosphonate with the calcite surface

J. STELLING*, A.K. NOTHSTEIN AND T. NEUMANN

Karlsuhe Institute of Technology (KIT), Institute of Mineralogy and Geochemistry, D-76131 Karlsruhe, Germany (*correspondence: stelling@kit.edu)

Crytsal growth mechanisms of calcite have been studied in detail in the past [1, 2]. The ability of calcite to adsorb P as phosphate from raw, sea and artificial water [3, 4] has been investigated intensively to recover P as a valuable nutrient [5]. Moreover, a detailed understanding of the interaction between phosphonates and calcite is of great interest for large–scale application as scale inhibitor, dispersant or chelating agent [6]. To date, understanding atomic–level processes that govern the kinetics of calcite growth with respect to phosphate and phosphonate anions is still incomplete.

As part of the ReCaWa joint project (Reactivity of Calcite/Water Interfaces), we investigate the sorption and coprecipitation processes of phosphate and phosphonate on calcite surfaces from (super)saturated calcite solutions. Solutions were prepared from p. a. grade chemicals ($CaCl_2$, $NaHCO_3$) in double distilled water (18.2 MΩ·cm), with pH adjusted to 8.2 and I=0.1 mol/L. Phosphate (H_3PO_4, $Na_3PO4{\cdot}6H_2O$) or phosphonate (etidronic acid, HEDP) were added in concentrations from 3–1000 μmol/L and 10–25 μmol/L, respectively. For batch experiments differing amounts precipitated calcium carbonate or limestone powder with varying specific surface area (SSA) and crystal morphology were added to the solutions. Additional and upcoming coprecipitation experiments under strongly defined conditions are performed using a mixed flow reactor (MFR) to allow coprecipitation of homogeneous phosphate or phosphonate containing calcite onto the calcite seed powder.

Experimental results show that phosphate uptake is a function of SSA and formation of HEDP precipitates dependent on the calcite morphology, respectively. Forthcoming analytical work includes the identification of different fixation mechanisms and phosphorus–containing phases using XRD and XAFS spectroscopy at grazing incidence.

Geochemistry of lamprophyres in rare-metal districts related to granitoids

M. ŠTEMPROK[1]*, TH. SEIFERT[2] AND D. DOLEJŠ[1]

[1]Faculty of Science, Charles University, 12843 Praha 2, Czech Republic (*correspondence: miroslav.stemprok@natur.cuni.cz)

[2]Technical University Bergakademie, 09596 Freiberg, Germany

Lamprophyres occur occasionally in mafic-silicic dyke suites of rare-metal (RM) granitoids in Paleozoic provinces of Western and Central Europe, Central Kazakhstan, the Altai, and in Mesozoic provinces of Transbaikalia, Yakutia, Chukotka and Alaska, which host RM (Sn, W, Nb, Ta, Mo, Be) mineralization. We evaluate 190 whole-rock chemical analyses of lamprophyres and variable sets of trace elements in order to uncover any genetic relationships between the melts derived from metasomatized upper mantle and enrichment in RM and alkalies. The lamprophyres correspond to minettes and kersantites with minor spessartites, and have 40-65 wt. % SiO_2, 0.8-9.6 wt. % K_2O, up to 17.8 wt. % MgO, and up to 1450 ppm Cr and 515 ppm Ni. The highest molar $MgO/MgO+FeO^{TOT}$ ratios up to ~0.75 indicate no substantial modification by fractionation or crustal assimilation. The Zr-Hf and U-Th ratios are not decoupled, and the Nb-Ta ratios approach the primitive mantle values. However, absolute concentrations of these elements, which are also considered to be the least mobile in aqueous fluids, show large to extreme enrichments: Zr (27-1420 *vs*. 190 ppm in calc-alkaline lamprophyres [1], 193 ppm in the upper continental crust [2]), Hf (3.5-36 *vs*. 5.2 ppm [1], 5.3 ppm [2]), U (0-29 *vs*. 3 ppm [1], 2.7 ppm [2]), Th (4-75 *vs*. 9 ppm [1], 10.5 ppm [2]), Nb (2-150 *vs*. 13 ppm [1], 12 ppm [2]), Ta (0-16 *vs*. 0.9 ppm [1], 0.9 ppm [2]). These levels in lamprophyres of the RM districts exceed the average abundances of some elements in calc-alkaline lamprophyres or in the differentiated upper continental crust by one to two orders of magnitude. They are also systematically enriched in F (0.04-2.85 *vs*. 0.11 wt % [1]), Rb (43-1490 *vs*. 70 ppm [1]), Cs (2.4-122 *vs*. 3 ppm [1]), Li (14-447 *vs*. 44 ppm [1]), and Sn (1-417 *vs*. 2 ppm [1]) partly due to superimposed greisenization. However, the overall enrichment pattern of lamprophyres and mineralized granites suggests that the source of some components in RM districts can be traced to mantle-derived melts, as previously proposed for the Cornubian province [1].

Experimental study of monazite/melt partitioning

A.S. STEPANOV, J. HERMANN AND D. RUBATTO[1]

The Australian National University, Research School of Earth Sciences, Canberra, Australia

Monazite (LREE, Th)PO_4 is a common accessory mineral and the major host of LREE, Th and U in the Earth's continental crust. Monazite is stable to high temperatures and pressures and is thus a key phase for trace element redistribution during partial melting of crustal rocks. We performed monazite-melt partitioning experiments in a piston-cylinder press over the temperature range 750 to 1200°C and pressures of 10-50 kbar. The starting composition was a synthetic granite mix with about 8 wt% H_2O that was doped with trace elements corresponding to 0.5-3 wt. % of monazite.

Experiments at temperature >800°C and pressure <30 kbar produced melt with monazite. At lower temperatures quartz and plagioclase also formed. At higher pressures, kyanite, coesite, jadeite, apatite, zircon and epidote group mineral start to crystallize. Monazite was produced in all experiments and formed small grains (<5μm across). Laser ablation-ICP-MS analyses of monazite-melt mixes were performed and the monazite composition was calculated using regression analysis. The concentration of some elements was also obtained with Electron Microprobe analysis. These analyses were in good agreement with the monazite compositions obtained by the regression method.

The LREE and Th concentrations of melts coexisting with monazite strongly increase with increasing temperature. The melt composition has less influence on these concentrations. Monazite solubility decreases by 30-40 % with increasing pressure. REE, Th, U, Y and As strongly partition into monazite, whereas other trace elements (Li, Be, B, Sc, Ti, V, Mn, Sr, Zr, Nb, Ba, Hf, Ta, Pb) have monazite/melt partition coefficients lower than 10. Monazite has the highest preference for LREE from La to Nd, with a decrease in partition coefficients for Sm, MREE and HREE. Difference in partitioning of of LREE and HREE tend to decreases with increase of temperature and decrease with increase of pressure. Th partition coffecients are 30 % higher than those for LREE and are indipendent of pressure and temperature. Partition coefficients for U are much lower than for Th and LREE.

The new experimental data provide a basis for calculation of factionation of LREE, Th and U during fractional cristalization and melting in the presence of monazite at crustal conditions and in subduction zones.

Aerosol, clouds, precipitation, radiation, and climate; A global perspective

GRAEME L. STEPHENS

Jet Propulsion Laboratory California Institute of Technology 4800 Oak Grove Dr Pasadena, CA, 91109

The cloud systems of our planet fundamentally shape our climate in the way they affect the flow of radiation in and out of the planet and in the way they connect key processes together to form the hydrological cycle. Despite the many years of cloud observations from space, we have not gained much insight into these key roles. Information about cloud particle size from satellite radiometers, for example, has been derived now for more than two decades but we still have not convincingly determined if this information is in fact related to real cloud physical properties. Nevertheless correlation between this remote sensing particle size information and aerosol content now serves as a basis for parameterization of the so-called indirect effects in climate models, a key tuning knob of climate model sensitivity. Similarly we have also observed precipitation from space for many years but have not been able to tie these observations to actual cloud physical processes and thus precipitation observations alone offer little real insight into how precipitation is likely to be shaped by the broader environment in which it forms. In this talk, we demonstrate that new observations now available for Earth orbiting satellites, when combined together, are advancing our understanding of the processes that connect aerosol, cloud and precipitation together and in turn provide a unique view on how these processes alter the planet's radiation balance. New insights on the effects of aerosol on cloud physical properties will be described as well as how these in turn affect both the water and energy balance of planetary cloud systems. The relevance of these new insights to the climate system and climate change will be emphasized.

Evidence for the formation of a fluorapatite surface layer on nano-sized hydroxyapatite after the exposure to an aqueous solution

VANESSA STERNITZKE*, RALF KAEGI, JANET G. HERING AND C. ANNETTE JOHNSON

Eawag, Swiss Federal Institute of Aquatic Science and Technology, 8600 Dubendorf, Switzerland (*correspondence: vanessa.sternitzke@eawag.ch)

Hydroxyapatite (Ca_{10} $(PO_4)_6$ $(OH)_2$; HAP) is the main constituent of bones and teeth [1]. Its ability to take up fluoride is applied in dental care [2] but also for drinking water purification [3]. Even though much research has been performed on fluoride uptake on HAP [e.g. 4], it is not fully understood how deeply fluoride incorporates into the HAP crystal.

It is believed that fluoride adsorbs to the HAP surface and exchanges for the hydroxide to form the less soluble fluorapatite (Ca_{10} $(PO_4)_6F_2$; FAP) [5]. The uptake capacity of fluoride on the HAP crystal is controlled by the exposure time and pH of the system [4]. A simultaneous formation of fluorite (CaF_2) cannot be ruled out when calcium and fluoride achieve saturation concentration [6]. However, a dissolution of CaF_2 in favour of FAP recrystalization is likely.

Batch studies were performed at 25 °C to investigate the uptake of fluoride as function of pH and initial fluoride concentration on synthetic HAP over an equilibration time of 28 days.

The reacted solids were investigated by Fourier Transform Infrared Spectroscopy (FTIR), which provided estimates on weight percentages on FAP formation on HAP after 28 days. Nano Secondary Ion Mass Spectroscopy (NanoSIMS) and Transmission Electron Microscopy (TEM) analysis gave additional information for a thin layer of FAP on HAP crystals.

To our knowledge it is the first time that the presence of a fluoridated surface layer on a nano-sized HAP crystal was qualitatively *and* quantitatively determined by micro- and spectroscopic analyses.

Ice formation on atmospheric mineral dust particles

OLAF STETZER, ANDRÉ WELTI, LUIS LADINO AND FELIX LÜÖND

ETH Zurich, Institute for Atmospheric and Climate Science, 8092 Zurich, Switzerland (*correspondence: olaf.stetzer@env.ethz.ch)

Mineral dust particles are known to be efficient catalysts for the formation of ice in clouds. In recent field studies by our group at the Jungfraujoch in the Swiss Alps a good correlation of the concentration of ice nuclei with the concentration of large particles during Saharan Dust events at this location was found [1]. Similar results are available from other groups as well e.g. [2].

However, the influence of size, shape, chemical composition, and the modifications of some of these parameters through anthropogenic emissions of pollutants to the atmosphere on the formation of ice is still mostly unknown and needs to be investigated further. This is complicated by the fact that ice in clouds may form via different pathways or mechanisms (immersion freezing, deposition freezing, contact freezing) and the parameters determining their efficiency in forming ice are different.

In our lab we investigate these different ice nucleation mechanisms with individual experiments for the different mechanisms using mineral dust aerosols. In this paper, our recent results on the ice nucleation properties of mineral dust particles for immersion freezing, and contact freezing are presented and compared.

The analysis of the immersion freezing data is done by calculations based on classical nucleation theory (CNT) assuming different assumptions regarding the properties of the mineral dust aerosols. From this analysis, the presence of so-called active sites can be deduced at which the nucleation process takes place preferably [3]. CNT also predicts that ice nucleation is a statistical process and therefore time dependant. To proof this, we conducted a special set of experiments where the residence time in the nucleation chamber is varied between 3 and 19 seconds. The results are again analysed and compared against CNT calculations as explained above and suggest, that immersion freezing is indeed time dependant where the frozen fraction increases with residence time.

Uranium(VI) complexation with lactate and citrate in dependence on temperature (7-65°C)

ROBIN STEUDTNER, KATJA SCHMEIDE AND GERT BERNHARD

Helmholtz-Zentrum Dresden-Rossendorf, Institute of Radiochemistry, P.O. Box 510119, D-01314 Dresden, Germany (r.steudtner@hzdr.de)

After disposal in nuclear waste repositories the chemical and migration behavior of actinides depends on many factors. It is estimated that maximum temperatures in the near field of a repository could reach 300°C in dependence on the waste forms [1] and the host rock [2]. Thus, for the long-term safety assessment, knowledge of the interaction of actinides such as uranium with inorganic and organic ligands at elevated temperatures is required. The amount of organic matter in a repository can be separated in humic substances and in low molecular weight organic substances. A not negligible component of low molecular weight organic substances is the group of carboxylic acid. For example, citric acid is used in nuclear reprocessing [3] and acetic, lactic and formic acid were identified in rock extracts and pore water of Opalinus Clay [4]. Reliable experimental data on the complexation of U(VI) in solution at elevated temperatures are still needed.

Therefore, we studied the U(VI) complexation by lactic acid (pH 3) and citric acid (pH 0-10) in the temperature range from 7 to 65°C. Species distribution and complex formation constants were determined by means of UV-Vis and time-resolved laser-induced fluorescence spectroscopy. In the U(VI) lactate system, we identified the formation of 1:1- and 1:2-complexes. In the presence of citrate, we could characterize five U(VI) complexes in dependence on pH value. The complex formation between U(VI) and these both ligands was found to be endothermic and entropy-driven. The complex stability constants of the U(VI) complexes increase with increasing temperature. This could lead to an increased mobility of U(VI) at higher temperatures.

Early differentiation of terrestrial planets: The relative importance of big impactors and small impactors

DAVID J. STEVENSON

Caltech 150-21, Pasadena CA 91125 USA (djs@gps.caltech.edu)

Planetary accretion arises through discrete events but is often treated as if those events were so frequent and large in number as to produce a continuum (a mass flux and characetristic time interval of accretion). Although there have also been published models that study the effects of discrete large impacts, insufficent attention has been paid thus far to the differences that arise for delivering material through a large number of small bodies and delivering the same mass (at the same epoch) as a small number of large bodies (e.g. Earth or Moon-sized giant impactors). The nature of the impacts is different in respect of the depth to which melting takes place, the extent to which equilibrium is establised between core forming materials and mantle materials, and the pressure range of equilibration. As a result, two accretion scenarios that involve identical sequences (timing and size) of imapct events can have different outcomes (different Hf/W inferred chronologies, different mantle siderophile inventories, different initial core T, etc) according as to the physical models one uses to describe the outcome of different sized impacts. Contrary to what some of the current literature implies, this is *not* merely the issue of the timing of the last giant impact since multiple giant impacts can be responsible for a large fraction of the mass delivery. It is also true that one cannot ignore the background 'drizzle' of smaller bodies (implied by the dynamic friction in the Nice models for example). I will describe semi-quantitatively the range of outcomes according as to the range of possible accretion histories for the terrestrial planets in general but with particular emphasis on Earth. This will also require an update of our current understanding of the mechanisms of core formation and the nature of melting curves and magma oceans in the deep mantle.

The strontium stable isotope composition of seawater during glacial intervals

E. STEVENSON[1], K.W. BURTON[1], F. MOKADEM[1], I.J. PARKINSON[2], P. ANAND[2] AND E. HATHORNE[3]

[1]Present Address: Department of Earth Sciences, Oxford University, Parks Road, Oxford, OX1 3PR, UK
[2]Department of Earth and Environmental Sciences, The Open University, Milton Keynes, MK7 6AA, UK
[3]IFM-GEOMAR, Leibniz Institute of Marine Sciences, University of Kiel, D-24148, Kiel, Germany

The strontium ($^{88}Sr/^{86}Sr$) stable isotope composition of seawater reflects input from continental weathering and hydrothermal exchange at mid-ocean ridges, and output in carbonate sediments. It has been suggested that increased weathering of shelf carbonates accompanying the low sea levels during the last glacial maximum (LGM) will have enhanced the flux of light Sr (from carbonates) to the oceans. However, temperature and species dependent fractionation of Sr stable isotopes during incorporation into marine carbonate has to be quantified in order to accurately reconstruct past seawater compositions.

This study presents high-precision $\delta^{88}Sr$ data, obtained using double-spike TIMs technique. Present-day seawater yields a $\delta^{88}Sr$ composition of 0.356±0.007 ($2\sigma_m$) with no resolvable difference between Pacific, Atlantic and Indian Oceans. *Globigerinoides sacculifer* from sites in the South Atlantic, covering a temperature range of ~10°C, show no systematic variation with temperature. Both *G. sacculifer* and *G. menardii* show systematic variations with growth rate (shell size) with heavier compositions in the larger size fractions. By contrast, *G. aequilateralis* and *G. ruber* show with no systematic variation with shell size. Preliminary $\delta^{88}Sr$ data for *G. ruber* covering the last 70 kyr indicate that there was no resolvable change in the $\delta^{88}Sr$ composition of seawater across the LGM and deglaciation. In this case the postulated enhanced weathering of shelf carbonates during glacial intervals [1], delivering light Sr isotopes to the ocean may not have been as significant as predicted [2] or else was offset by increased production and preservation of carbonates, driving seawater to heavier $\delta^{88}Sr$ values. Alternatively the very long residence time of Sr in the oceans may simply buffer the changes in input or output such that no changes are resolved at the level of precision of this study.

Pb and Sr isotopes and the provenance of the painting materials in 19th century Canada

R.K. STEVENSON[1]*, E.A. MOFFATT[2] AND M-C. CORBEI[2]

[1]GEOTOP and SCTA, UQAM, PO Box 8888, St. Centre-Ville, Montreal, QC H3C 3P8 (*correspondence: stevenson.ross@uqam.ca)

Introduction

Cornelius Krieghoff was a 19th century Canadian artist (1815-1872) of winter landscapes and depictions of aboriginal and rural Quebec life. Like many pre-20th century artists, Krieghoff used a pigment known as lead white composed of a synthetic analogue of hydro-cerussite, often with lead carbonate impurities. Krieghoff used lead white in the preparation layer on the canvas and as a white pigment (either alone or in mixtures to lighten other colours). Calcium carbonate was often added as an extender. Samples of lead white and other Pb-bearing pigments of 15 Krieghoff works painted between 1844 and 1871 were also analysed for Pb and Sr isotopes to provide constraints on pigment sources.

Results

The bulk of the lead isotope data yield isotopic compositions that are consistent with data obtained from lead white in European paintings of the same or earlier periods [1, 2]. However, a few samples yielded lead isotope compositions that were more suggestive of a North American origin. The Sr isotope ratios of the samples range from values consistent with Palaeozoic carbonates to values in excess of present day seawater.

Origin of dissolved metals in produced water from the Devonian Marcellus shale, USA: Sr isotope systematics

BRIAN W. STEWART[1,2]*, ELIZABETH C. CHAPMAN[1,2], ROSEMARY C. CAPO[1,2], RICHARD W. HAMMACK[1], KARL T. SCHROEDER[1] AND HARRY M. EDENBORN[1]

[1]US DOE-National Energy Technology Laboratory, 626 Cochrans Mill Rd., Pittsburgh, PA 15236

[2]University of Pittsburgh, Department of Geology & Planetary Science, Pittsburgh, PA 15260 (*correspondence: bstewart@pitt.edu)

The horizontal drilling and hydrofracturing techniques used for extraction of natural gas from shales of the Marcellus Formation (USA) lead to production of significant volumes of high-TDS (total dissolved solids) waters that have interacted with the source shale and potentially adjacent units. Determining the source of these dissolved salts and understanding local and basinal variations in TDS have direct relevance to exploration methodologies and water management and reclamation.

A series of flowback waters have been collected from drilling operations in a geographic region spanning ~375 km, from northeastern to southwestern Pennsylvania. Most $^{87}Sr/^{86}Sr$ values fall within a narrow range, from 0.7101 to 0.7112; samples from two adjacent wells in Westmoreland County, Pennsylvania, define a second grouping (0.7120-0.7121). This bimodal distribution of flowback values could be a result of hydrofracturing water interacting with different producing members of the Marcellus Formation, or lateral (facies) variations in the isotopic composition of formation salts. The relatively tight clustering of values among geographically distant sites argues against variable influxes of brines from adjacent formations. Marcellus flowback waters contain notably elevated levels of barium and strontium (up to 12, 000 and 5, 000 mg/L, respectively, for the samples in this study). The Ba/Sr ratios of the flowback fluids measured here also vary systematically with geographic location, The combination of Ba/Sr and $^{87}Sr/^{86}Sr$ provide a method for uniquely identifying regional variations in flowback waters.

The $^{87}Sr/^{86}Sr$ ratios of Marcellus waters measured here fall well above Phanerozoic seawater values. Thus, while the Marcellus brines may have a significant seawater component, this has clearly been augmented by a high-$^{87}Sr/^{86}Sr$ source, possibly originating from dissolution of radiogenic minerals within the shale. Ongoing leaching studies of core material from the Marcellus Formation and adjacent units will provide additional insight into the origins of salts in Marcellus waters.

Evolution of andesite magma systems; Egmont Volcano, New Zealand

R.B. STEWART[1]*, A.V ZERNACK[1], M.B. TURNER[2], R.C. PRICE.[3], I.E.M. SMITH[4] AND S.J. CRONIN[1]

A major issue in andesite magmas genesis is explaining disequilibrium crystal, matrix glass and whole rock compositions. Taranaki/Egmont is a high-K andesite volcano in the western North, Island, New Zealand, with a 200, 000 year eruption record. Thirteen recently identified and dated pre-7 ka debris avalanche deposits record the magmatic evolution of the Taranaki volcanic system. Clast compositions show a gradual enrichment in K_2O and LILE with time to high-K andesites in the Holocene. Pre-100 ka magmas include relatively primitive basalts and basaltic andesites and mineral chemistry indicates crystallisation within the lower crust or mantle. Modal rock compositions become more silicic in younger units, and the appearance of late-stage low-pressure mineral phases (high-Ti hornblende, biotite and Fe-rich orthopyroxene), suggests an increase in more evolved magmas with time. Six compositionally distinct Holocene magma batches erupted on 1500-2000 year timescales, synchronous with variations in eruptive frequency in which the largest volume (>0.5 km^3) events erupt the most evolved magmas. We suggest that andesite magmas were generated within a lower crustal 'hot zone' [1]. Matrix glasses in both xenoliths and lavas/tephras are mostly dacitic to rhyolitic in composition and, in younger lavas have a high K_2O content. These glasses may represent some of the partial melts from the 'hot zone'[2]. The disequilibrium observed in the andesites is due to the mixing of these diverse components. A complex and dispersed magma assembly and storage system developed in the upper crust where the magmas were further modified by fractional crystallisation and magma mixing and mingling [2].

Contrasting halogen geochemistry of barren and mineralized breccias of the Sudbury Igneous Complex, Ontario

R.C. STEWART[1]*, J.J. HANLEY[1] AND D.E. AMES[2]

[1]Department of Geology, Saint Mary`s University, Halifax, Canada (*correspondence: stewcraig@gmail.com)
[2]Geological Survey of Canada, 601 Booth Street, Ottawa, Ontario, K1A 0E8, Canada

The potential for the halogen elements (Cl, Br, I) to be used as geochemical indicators for contact-style Ni-Cu-PGE mineralization along the lower contact of the Sudbury Igneous Complex (SIC) has been investigated. Two environments - one barren, and the other containing economic magmatic sulphide ore systems - were compared. The studied host rocks to these deposits are polymict igneous-textured breccias, formed by partial melting of the Archean country rocks (gneisses).

No significant differences in bulk major and trace element geochemistry of rocks between the environments aside from the halogen elements were observed. Two major differences in halogen geochemistry were recognized:

First, mineralized breccias show marked enrichment in I. This is thought to have resulted from the leaching of I from brecciated sulphides by hydrothermal fluids released during contact metamorphism and partial melting of the country rocks, and is unique to those breccias that host sulfides. The anomalous I can be detected for distances of up to several 100 metres from mineralized samples. This observation is consistent with experimental studies which show that I is the most compatible halogen in sulfide liquids [1] leading to I enrichment in environments where sulfide liquids crystallize.

Second, analysis of the soluble fraction (from fluid inclusions) of the halogens reveal that two distinct fluid end-members were trapped in the matrix of the breccias during their crystallization (as mixtures in primary fluid inclusions): a high Cl^-/Br^- fluid phase of probable magmatic origin (exsolved from the SIC), and a low Cl^-/Br^- fluid phase derived from fluid released during dehydration of hydrous minerals in the country rocks. Mineralized breccias contain a much higher proportion of the non-magmatic fluid end-member. This would suggest that footwall partial melting was a critical component to deposit development, possibly promoting sulfide saturation in this local environment or the transportation of ore metals in high salinity fluids of non-magmatic origin (e.g. groundwater, metamorphic fluid).

Sources and input mechanisms of hafnium and neodymium in surface waters of the Atlantic sector of the Southern Ocean

T. STICHEL[1,2]*, M. FRANK[1], J. RICKLI[3], B. HALEY[1], E. HATHORNE[1], C. JEANDEL[4] AND C. PRADOUX[4]

[1]IFM-GEOMAR, Wischhofstr. 1-3, 24148 Kiel, Germany
[2]now at SOEST, University of Hawaii 1680 East-West Rd, Honolulu, USA (*correspondence: tstichel@hawaii.edu)
[3]Bristol Isotope Group, University of Bristol, Parks Road, United Kingdom
[4]LEGOS, 14 av. Edouard Belin, Toulouse 31400, France

The first combined dissolved hafnium (Hf) and neodymium (Nd) isotope and concentration data from surface waters of the Atlantic sector of the Southern Ocean are presented here. The samples were collected along the Zero Meridian (ZM), in the Weddell Sea (WS) and in the Drake Passage (DP) during RV Polarstern expedition ANTXXIV/3 and ANTXXIII/3 in the frame of the International Polar Year (IPY) and the GEOTRACES program. The distribution of Hf and Nd concentrations is overall similar. However, at the northernmost station located 200 km southwest of Cape Town a pronounced increase of the Nd concentration is observed, whereas the Hf concentration at the same time is at its minimum indicating lower amounts of Hf than of Nd released by weathering of the Archean cratonic rocks of South Africa. From the southern part of the Subtropical Front (STF) to the Polar Front (PF) Hf and Nd show the lowest concentrations (<0.12 pmol/kg and 10 pmol/kg, respectively), most probably due to the low terrigenous flux in this area and scavenging of Hf and Nd by biogenic opal. In the vicinity of landmasses the Hf and Nd isotope composition is clearly labelled by terrigenous inputs. Near South Africa Nd isotope values as low as $\varepsilon_{Nd} = -18.9$ indicate unradiogenic inputs supplied via the Agulhas Current. To the south the Nd isotope compositions are relatively radiogenic ($\varepsilon_{Nd} \sim -8$ to -8.5) towards the STF, within the Antarctic Circumpolar Current, in the Weddell Gyre and the Drake Pasage. Near the volcanic Antarctic Peninsula the isotopic data show significant increases to $\varepsilon_{Hf} = 6.1$ and $\varepsilon_{Nd} = -4.0$. implying an enhanced release of Nd and Hf. The Hf isotope compositions in the study area only show a small range between $\varepsilon_{Hf} = 6.1$ and 2.8. The new data show that Hf can be a sensitive tracer for prevailing physical weathering conditions, which is not the case for Nd. Neodymium isotopes show a factor of five larger range than Hf isotopes, which confirms Nd isotopes to be a sensitive tracer for the provenance of weathering inputs to surface waters of the Southern Ocean.

Rapid seawater circulation through animal burrows in mangrove forests — A significant source of saline groundwater to the tropical coastal ocean

T.C. STIEGLITZ[1]*, J.F. CLARK[2] AND G HANCOCK[3]

[1]School of Engineering & Physical Sciences, James Cook University, Townsville, QLD, Australia (*correspondence: Thomas.Stieglitz@jcu.edu.au)
[2]Earth Science, UCSB, Santa Barbara, CA, USA (jfclark@geol.ucsb.edu)
[3]CSIRO Land and Water, Canberra, ACT, Australia (gary.hancock@csiro.au)

A common approach for quantifying rates of submarine groundwater discharge (SGD) to the coastal ocean is to use geochemical tracers such as ^{222}Rn and short lived radium isotopes, which are naturally enriched in groundwater relative to seawater and have well understood chemistries within the marine environment. They occur in both fresh (continental) and saline (marine) groundwaters and thus the water source is often ambiguous. Here, we present a detailed investigation into the tidal circulation of seawater through animal burrows using ^{222}Rn and isotopes of radium in the Coral Creek mangrove forest, Hinchinbrook Island, Queensland, Australia. The study was conducted at the end of the dry season in a creek with no freshwater inputs. Significant export of radionuclides and salt from the forest into the creek indicates continuous tidally driven circulation through the burrows. Results demonstrate that the forest sediment is efficiently flushed, with a water flux of about 30 L/m^2/ day of forest floor, which is equivalent to flushing about 10% of the total burrow volume per tidal cycle. Importantly, annual average circulation flux through mangrove forest floors are of the same order as annual river discharge in the central GBR. However, unlike the river discharge, the tidal circulation should be relatively stable throughout the year. This work documents the importance of animal burrows in maintaining productive sediments in these systems, and illustrates the physical process that supports large exports of organic and inorganic matter from mangrove forests to the coastal zone. It also illustrates the importance of considering saline groundwater sources when interpreting SGD radionuclide tracers in the coastal ocean.

Observationally constrained estimates of carbonaceous aerosol transport and radiative effects

PHILIP STIER[1]*, ZAK KIPLING[1], J.P. SCHWARZ[2,3] AND D.W. FAHEY[2,3]

[1]Department of Physics, University of Oxford, Oxford, UK (*correspondence: philip.stier@physics.ox.ac.uk)
[2]Cooperative Institute for Research in Environmental Sciences, University of Colorado, Boulder, USA
[3]Chemical Sciences Division, Earth System Research Laboratory, NOAA, Boulder, USA

Atmospheric aerosols play an important role in the global climate system. Carbonaceous aerosols stand out through their potential to warm (through absorption and semi-direct effects) and cool (through scattering and indirect effects) climate, depending on their microphysical properties and regional distribution. Current global aerosol models vary drastically in simulated abundance, transport and radiative properties of carbonaceous aerosols and show significant biases when compared to observations [1].

To advance our understanding of uncertainties in global models we utilise observational profile data obtained during the HIPPO aircraft campaigns [2] to constrain the remote transport in two microphysical aerosol climate models, ECHAM-HAM [3, 4] and HadGEM-UKCA [5]. In addition to mass concentrations, the SP2 instrument retrieves information about the mixing state of black carbon, providing constraints on the structural representation in microphysical models. In synergy with absorption optical depth retrievals from the AERONET sun-photometer network, such observations provide a unique constraint on transport and abundance of carbonaceous aerosols.

Comparison of the standard and observationally constrained setups will demonstrate the reduction of uncertainty in the simulated radiative effects. Nudged simulations using sector-specific emission inventories will allow quantifying sectoral contributions and the additivity of the individual contributions to the total carbonaceous radiative effects.

The ash that closed Europe's airspace: Part II, the physical aspects of the Eyjafjallajökull ash

S.L.S. STIPP[1]*, T. HASSENKAM[1], S. NEDEL[1], N. BOVET[1], HEM C.P.[1], BALOGH Z.I.[1], K. DIDERIKSEN[1], E.S. EIRIKSDOTTIR[2], H.A. ALFREDSSON[2], N. OSKARSSON[2], B. SIGFUSSON[3], G. LARSEN[2] AND S.R. GISLASON[2]

[1]Nano-Science Centre, Department of Chemistry, University of Copenhagen, Denmark (stipp@nano.ku.dk)
[2]Institute of Earth Sciences, University of Iceland, Reykjavik, Iceland (sigrg@raunvis.hi.is)
[3]Reykjavik Energy, Iceland

On 14 April 2010, when meltwaters from the Eyjafjallajökull glacier mixed with hot magma, an explosive eruption sent unusually fine-grained ash into the jet stream. It quickly dispersed over Europe. Previous airplane encounters with ash had resulted in sand blasted windows and particles melted inside jet engines, causing them to fail. Therefore, air traffic was grounded for several days. Concerns also arose about health risks from fallout, because ash can transport toxic elements such as fluoride, aluminium and arsenic. For this study, we compared samples of the initial explosive ash with ash from the later, more typical eruption. Using nanotechniques, custom-designed for studying natural materials, we explored the physical and chemical nature of the ash to determine if fears about health and safety were justified and we developed a protocol that will serve for assessing risks during a future event [1].

We used atomic force spectroscopy (AFS) to map the adhesion properties on individual ash particles. With X-ray photoelectron spectroscopy (XPS), we determined the composition of nanometer scale salt coatings. By oscillating an atomic force microscopy cantilever, to which a single ash particle had been glued, we could measure the mass of adsorbed salts with picogram (pg; 10^{-12} g) resolution. The particles of explosive ash that reached Europe in the jet stream were especially sharp and hard, therefore abrasive, over their entire size range, from submillimeter to tens of nanometers. Edges remained sharp, even after 2 weeks of abrasion in stirred water suspensions. From the composition of the particles, we could predict that they would soften and melt at temperatures typical of a jet engine (1500 to 2000 °C).

This paper is the second of a two part presentation, where the first part, by Sigurdur Gislason, focuses on the Eyjafjallajökull eruption, grain size distribution and soluble salt coatings.

Biogeochemical cycling of cadmium in the Tasman Sea: Constraints from cadmium isotopes

C.H. STIRLING[1,2,*], M. GAULT-RINGOLD[1,2], E. BREITBARTH[1] AND E.C.V. BUTLER[3]

[1]Department of Chemistry, University of Otago, New Zealand (*correspondence: cstirling@chemistry.otago.ac.nz)
[2]Centre for Trace Element Analysis, University of Otago, New Zealand
[3]CSIRO Wealth from Oceans Flagship, Hobart Laboratories, Australia

The biogeochemical cycling of cadmium (Cd) is likely to be an important component of the ocean's biological pump, yet the processes controlling its uptake are poorly understood. Stable isotopes of Cd offer the potential to provide new insights into the distribution and cycling of marine Cd, as sizeable 0.1%-level isotopic fractionation in seawater has been demonstrated due to biological uptake by marine phytoplankton [1, 2]. Furthermore, Cd isotopes may prove to be a reliable proxy for past and present nutrient utilization in the oceans. However, the limited results to date reveal the complex interplay of biological uptake, particle 'scavenging', and the mixing of different water masses. Additional datasets are, therefore, required to gain insight into the processes that govern the marine distribution of Cd.

Using multiple-collector inductively coupled plasma mass spectrometry (MC-ICPMS) combined with double spiking techniques, we report the Cd isotopic composition and concentration of depth profile samples collected along a longitudinal transect in the Tasman Sea during the SS01/2010 ('PINTS') voyage — a GEOTRACES Process Study. The sampling transect extended southwards from the sub-tropical Pacific Ocean to the Southern Ocean, characterised by a strong longitudinal gradient with respect to the supply of trace metal-bearing dust, phytoplankton biomass, and oceanic temperature. The Cd isotopic and concentration water column signatures are interpreted in the context of other trace metals and macronutrients that potentially colimit marine phytoplankton growth, as well as oceanographic parameters, such as phytoplankton biomass. These data help elucidate the sources and biogeochemical cycling of Cd in the Tasman Sea, the validity of the Cd/Ca paleonutrient proxy, and the potential of Cd isotopes as a proxy of past nutrient utilization in the oceans.

Depth- and pressure dependent permeability in the upper continental crust — Data from the Urach 3 geothermal well

INGRID STOBER

Mineralogy Geochemistry, University of Freiburg, Germany (ingrid.stober@uni-freiburg.de)

The 4500 m deep research borehole 3 at Urach (South Germany) has been extensively used for hydraulic testing of the crystalline basement since the late seventies. The data permit a general interpretation of the hydraulic properties of the crystalline continental upper crust at different depth intervals. The gneissic basement contains an interconnected fluid-filled fracture system.

Low-pressure hydraulic tests show that the basement on a larger scale can be described as a homogeneous, isotropic aquifer and this characteristic hydraulic behavior persists at least several hundred meters away from the borehole. This demonstrated homogeneity of the aquifer (or fluid reservoir), together with the highly saline water in an interconnected system of copious fractures is characteristic of the continental upper crust in general. On a smaller scale, however, the fractures, crossing the uncased sections in the borehole, define the flow-behavior locally. So, at the beginning of a hydraulic test the pressure data show the influence of wellbore storage and skin, followed by a linear and a bilinear flow-period, and later on by a pseudo-radial flow-period. The transmissivity of the bulk rock can be derived from the data of the pseudo-radial flow-period.

The complete set of test data shows that in the crystalline basement permeability decreases with depth. There is also evidence for pressure dependent hydraulic phenomena, in paricular permeability is found to vary with pressure.

Numerous high-pressure tests, some with well-head pressures of > 600 bar were carried in the Urach 3 borehole. The test data clearly show a P-dependence of permeability. During hydraulic tests with well-head pressures above 176 bar permeability of the crystalline basement increases dramatically, showing the elastic reaction of the rock due to pressure. At pressures below 176 bar the hydraulic data show no significant elastic reaction of the rock. A mathematical description of the pressure dependent increase of transmissivity has been derived from the data.

How do mineral substrates affect calcite nucleation and growth?

Calcite was precipitated in flow-through experiments at 25 °C from supersaturated aqueous solutions in the presence of seeds of calcite and six different silicates: augite, basaltic glass, enstatite, labradorite, olivine, and peridotite. The aim of the experiments was to determine how calcite nucleation and growth depends on the identity and structure of the growth substrate. Calcite saturation was achieved mixing a $CaCl_2$-rich solution with a $NaHCO_3$-Na_2CO_3 buffer in a mixed-flow reactor containing 0.5-2 grams of mineral grains. This led to a calcite saturation index of 0.6 and pH 9.1 for the reactive solution inside the reactor.

Although chemical conditions, flow rate and temperature were identical for all experiments, the onset of calcite nucleation and the amount of calcite being precipitated depended on the identity of the substrate. With calcite as the growth substrate, new calcite crystals formed instantaneously. Calcite nucleated relatively rapidly on olivine, enstatite, and peridotite (mainly composed of Mg-olivine). Scanning Electron Microscope images showed silicate crystals to be almost completed covered with calcite coatings at the end of the experiments. Less calcite growth was found on labradorite and augite, and least on basaltic glass. In all cases, calcite precipitation occurs on the mineral substrate and not adjacent to them.

These findings indicate that calcite nucleation and its subsequent growth depends on the crystal structure of the silicate substrate. Orthorhombic silicate minerals (olivine and enstatite) are the easiest for trigonal calcite to nucleate on. Monoclinic augite and triclinic labradorite show intermediate behavior, whereas basaltic glass with its non-ordered crystal structure is the least favorable platform for calcite growth. The results have implications for CO_2 mineralization in ultramafic and basaltic rocks [1] indicating that trigonal carbonates easier precipitate on crystalline rather than glassy rocks, but even glass surfaces can serve as a substrate for calcite nucleation.

A new methodology for an improved description of radionuclide retardation in safety assessments

M. STOCKMANN[1]*, V. BRENDLER[1], J. SCHIKORA[1], U. NOSECK[2] AND J. FLÜGGE[2]

[1]Helmholtz-Zentrum Dresden-Rossendorf, D-01328 Dresden, Germany (*correspondence: m.stockmann@hzdr.de)
[2]GRS Braunschweig, D-38122 Braunschweig, Germany

Conceptual model

In safety assessments usually the K_d concept with temporally constant values is applied to describe the radionuclide retardation in the far field of a repository.

In this study, the existing transport program r³t [1] used for large model areas and very long time scales has been improved. Implementing the smart K_d concept based on surface complexation allows to consider the impact of varying geochemical conditions.

The new methodology describes the sorption of radionuclides as a function of selected, important environmental parameters E_i such as pH, pCO_2, ionic strength, concentration of the cations Ca^{2+} and Al^{3+} and presence of characteristic mineral phases. The Gorleben site as a potential repository site in Germany has been selected as an exemplary case of application for a proof-of-concept.

Most of the individual parameters E_i were not available in r³t so far. Thus the transport of the respective substances as well as equations describing pH and concentrations of ions as a function of accessible mineral phases had to be implemented. Then the reactive transport model r³t can call pre-calculated K_d values for selected sediments for each time-space point. They are stored in a multidimensional matrix depending on the real geochemical conditions. Figure 1 shows the frequency distribution of the pre-calculated smart K_d values for Am^{3+} and UO_2^{2+}.

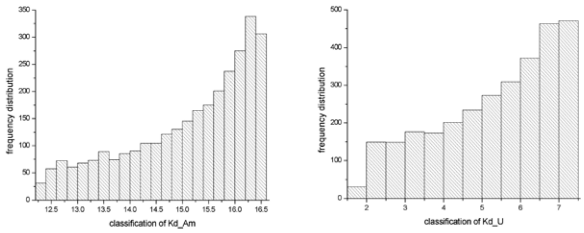

Figure 1: Frequency distribution of the pre-calculated K_d values for Am^{3+} and UO_2^{2+} (in m³/kg).

Combined NanoSIMS and TEM *in situ* analysis of pristine matrix material of ALHA 77307 and Acfer 094

A.N. STOJIC[1]*, F.E. BRENKER[1] AND P. HOPPE[2]

[1]Goethe Universitaet, Institut fuer Geowissenschaften, 60438 Frankfurt/Main, Germany (stojic@em.uni-frankfurt.de)
[2]Max-Planck Institute for Chemistry, P.O. Box 3060, 55020 Mainz, Germany

Only a few structural studies on presolar silicates and oxides exist [1]. Commonly the NanoSIMS mapping technique is used to identify presolar grains in the meteoritic matrix from a polished thin section. To extract these presolar grains for further TEM analysis, a complex and risky lift out procedure by FIB is needed [1], reducing the availability of such grains for structural studies. In contrast, Argon Ion Slicing (ArIS), a recently introduced TEM sample preparation technique in geosciences, yields super large electron transparent areas of up to 40, 000 μm^2 [2]. The availability of extremely large thin foils makes a substantial change in the sequence of procedure steps possible, i.e. preparation of a large thin foil first, followed by the NanoSIMS scan on the previously obtained thin foil (Fig.1). No additional sample preparation for TEM is required once the grains are identified by NanoSIMS.

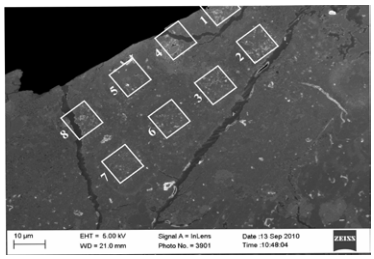

Figure 1: Thin foil section of ALHA 77307 with NanoSIMS scan windows indicated

Pieces of Acfer 094 and ALHA 77307 were ArIS treated until large electron transparent areas were obtained. These TEM thin foils were scanned for oxygen isotope ratios with a Cameca NanoSIMS 50. Based on large O-isotopic anomalies we detected 2 presolar grains (both silicates) out of 8 ion images (10 x 10 μm^2) in ALHA 77307, and 7 presolar grains (6 silicates and one oxide) out of 22 ion images (same size) from Acfer 094.

Multimethod characterisation of nanoparticles in the environment

BJORN STOLPE[1]*, JAMIE LEAD[1], DAN LAPWORTH[2], STEPHANIE HANDLEY-SIDHU[1], JULIA FABREGA[3], TAMARA GALLOWAY[3], JESSICA POOLE[4], CORRINE WHITBY[4] AND IAN COLBECK[4]

[1]Shool of Geography Earth and Environmental Science, University of Birmingham, B15 2TT, UK (*correspondence: b.stolpe@bham.ac.uk, s.handley-sidhu@bham.ac.uk)
[2]British Geological Survey, Oxfordshire, OX10 8BB, UK (djla@bgs.ac.uk)
[3]School of Biosciences, University of Exeter, EX4 4PS, UK (t.s.galloway@exeter.ac.uk)
[4]Dept of Biological Sciences, University of Essex, Colchester, CO4 3SQ, UK (colbi@essex.ac.uk)

A range of techniques for the characterisation of nanoparticles will be presented, and their feasibility in studies of nanoparticle toxicity and environmental behaviour will be discussed. Techniques are often complimentary in the information they provide, and a multimethad approach is therefore recommended for nanoparticle characterisation. Results will be presented from the following studies, carried out at the Facility for Environmental Nanoparticle Analysis and Characterisation (FENAC) at the University of Birmingham:

1. Iron-rich and organic nanoparticles in anoxic groundwater, characterised under oxygen-free conditions by atomic force microscopy (AFM), transmission electron microscopy (TEM), scanning electron microscopy with energy-dispersive X-ray diffraction (SEM-EDX) and field-flow fractionation (FFF).
2. Biogenic hydroxyapatite – relation between metal uptake and particle size/surface area, determined by X-ray diffraction (XRD), BET-surface area measurements, SEM, DLS and zeta-potential measurements.
3. ZnO nanoparticle dissolution and toxicity to marine invertebrates - dependency on particle size and morphology, characterised by TEM, AFM, dynamic light scattering (DLS), zeta-potential measurements and nano-tracking analysis (NTA).
4. Nanoparticle impact on bioremediation of hydrocarbons in aquatic ecosystems - relation to particle size and chemistry, determined by DLS, FFF, TEM and XRD.

Pore scale heterogeneity of porous media influencing the spatial and temporal distribution of microbial metabolic activity

KONSTANTIN STOLPOVSKY[1], MEHDI G. GHARASOO[2] AND MARTIN THULLNER[2]

[1]Department of Earth Sciences – Geochemistry, Utrecht University, the Netherlands (k.stolpovsky@geo.uu.nl)
[2]Department of Environmental Microbiology, UFZ – Helmholtz Centre for Environmental Research, Leipzig, Germany (mehdi.gharasoo@ufz.de, martin.thullner@ufz.de)

Microbial activity plays a crucial role in the cycling of carbon, nutrient elements and contaminants in the environment. This includes porous environments like soils or aquifers. These bacterial habitatats are often characterized by a high temporal variability of substrate supply, and by a high spatial heterogeneity of the porous matrix at the pore scale. As a consequence, microbial growth conditions and the resulting microbial redox activity in natural porous media environments may differ from typical laboratory setups used to study microbial behaviour. Pore scale heterogeneities and the resulting transport regime can lead to highly complex distribution patterns of substrates and the corresponding microbial growth conditions including the frequent occurrence of stress periods for the microbial population. Microorganisms can respond to such stress periods by switching from an active into an inactive or dormant state, and the corresponding microbial abundance and substrate degradation dynamics may exhibit rather complex temporal and spatial patterns.

This study considers an extended modelling concept for the growth and degradation activity of microbial species able to switch between two different physiological states. This concept is implemented into a pore network model which allows simulating the changes of microbial growth conditions in heterogeneous porous media. The model is used to study the impact of pore scale heterogeneities on the distribution and activity of microorganisms in such media and to determine the biodegradation capacity of the microbial population.

Sources, sinks, and reactivity of electrophilic groups within natural organic matter

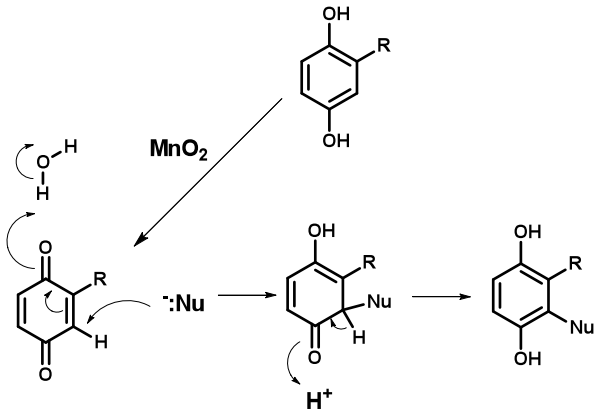
A.T. STONE* AND P.M. FLANDERS

Geography and Environmental Engineering, Johns Hopkins Univ., Baltimore, MD 21218, USA (*correspondence: astone@jhu.edu)

Carbonyl and carboxylate ring substituents are believed to be present in high abundance within natural organic matter (NOM). Their potential impact on the reactivity of dihydroxybenzene/benzoquinone functionalities has not, however, been addressed. Owing to their electron-withdrawing nature, carbonyl and carboxylate ring substituents raise the redox potential necessary for oxidizing dihydroxybenzenes to corresponding benzoquinones. Carbonyl- and carboxylate-substituted benzoquinones generated in this way are far more electrophilic than unsubstituted analogs, and hence capable of Michael-type adduct formation with a wider range of oxygen-, nitrogen-, and sulfur-donor nucleophiles. Heightened electrophilicity also raises rates of competitive hydration reactions.

We have observed these phenomena in experiments employing low MW NOM surrogates. MnO_2 (pyrolusite) readily oxidizes acetoxyhydroquinone to acetoxy-p-benzoquinone and gentisate to carboxy-p-benzoquinone. Unlike unsubstituted p-benzoquinone, p-benzoquinones possessing electron-withdrawing groups rapidly hydrate. Adduct yields increase substantially as the nucleophile concentration is increased, a reflection of more successful competition relative to the hydration pathway.

Benzoquinones are one sub-class of conjugated ene carbonyls capable of Michael-type adduct formation. It is possible that oxidation reactions, e.g. by manganese(III, IV) oxyhydroxide crusts within oxic sediments, generate other reactive, transient electrophiles. Knowledge of their sources and sinks may improve our understanding of elemental and functional group incorporation into NOM.



Cosmogenic nuclide measurements of Pleistocene glacial erosion

JOHN STONE*, ZACHARY PLOSKEY, BERNARD HALLET AND MARC JAFFREY

Dept of Earth and Space Sciences, University of Washington, Box 351310, Seattle, WA, 98195, USA (*correspondence: stn@uw.edu, zploskey@uw.edu, hallet@uw.edu, mjaffrey@uw.edu)

Glacial erosion plays a crucial role in landscape evolution at high altitudes and high latitudes, at the nexus between mountain building, surface processes and climate. Yet we lack a quantitative basis for incorporating glacial erosion into numerical models of these processes, and have few specific estimates of glacial erosion over 10^5-10^6 year timescales. We have developed a method of measuring past glacial erosion rates using cosmogenic nuclide depth profiles in bedrock. We are using this to determine glacial erosion histories, improve glacial erosion laws, and incorporate these into geomorphic process models.

Cosmogenic nuclide measurements on rock and soil surface samples have been widely used to estimate erosion rates in continuously exposed landscapes. Conversely, measurements on glaciated bedrock have been used primarily to date ice retreat, or, where such ages are compromised by prior exposure, to identify the sites as areas of limited glacial erosion. However, because the survival of nuclides produced beneath glaciated surfaces depends on subsequent glacial erosion, depth profiles accumulate information about the cumulative erosion history. Nuclide concentrations, concentration gradients and ratios are all sensitive to the history of exposure and erosion; we can use inverse methods to recover long-term average erosion rates of glaciated landforms from these data. Published cosmogenic nuclide measurements from glaciated bedrock surfaces suggest that these methods will be widely applicable to the study of mid- to late-Pleistocene erosion beneath glaciers and ice sheets.

Observational and modeling study of the relationship between aerosols and super-cooled cloud fraction

TRUDE STORELVMO[1], ULRIKE LOHMANN[2] AND YONG-SANG CHOI[3]

[1]Yale University, New haven, CT, USA (trude.storelvmo@yale.edu)
[2]ETH-Zurich, Zurich, Switzerland (ulrike.lohmann@env.ethz.ch)
[3]Ewha Womans University, Seol, Korea (ysc@ewha.ac.kr)

Recent observational and modeling studies indicate that aerosols may have a strong effect on Earth's energy budget via their influence on mixed-phase clouds. Global climate studies have predicted aerosol interaction with mixed-phase clouds to warm the current climate, but estimates are uncertain because mixed-phase cloud processes in GCMs are highly parameterized and have to date been poorly constrained by satellite data. Here, we present global and regional distributions of the frequency of supercooled cloud water and its link to aerosols from two global climate models (GCMs), compared to a new satellite data set. Both GCMs link ice formation at temperatures between -40 and 0 degrees C to the simulated concentrations of aerosols with ice nucleating ability (IN), assigning different freezing efficiencies to the different insoluble aerosol species (mineral dust, bio-aerosols and soot). Consequently, both models generally simulate an anti-correlation between aerosol abundance and supercooled liquid water in clouds, a finding that was recently qualitatively confirmed by satellite observations. By studying the relationship between aerosols and the supercooled cloud fraction (SCF) from the GCMs and from the NASA spaceborne lidar instrument CALIOP (cloud-aerosol lidar with orthogonal polarization), we get strong indications of how aerosols may influence mixed-phase clouds. We argue that with the new validation of SCF and its link to aerosols, GCM estimates of aerosol effects on climate via their influence on mixed-phase clouds may become more reliable.

The magmatic, metamorphic, mineralisation and plate tectonic evolution of continents

CRAIG D. STOREY[1]* AND MARTIN P. SMITH[2]

[1]School of Earth and Environmental Sciences, University of Portsmouth, PO1 3QL, UK (*correspondence: craig.storey@port.ac.uk)
[2]School of Environment and Technology, University of Brighton, BN2 4GJ (martin.smith@brighton.ac.uk)

Around 60% of continental crust was formed by the end of the Archaean and since then some form of plate tectonics has driven periods of supercontinent formation (at c.2.7 Ga, 1.9 Ga, 1.1 Ga and 0.35 Ga). Net growth of new crust declined in the Proterozoic and Phanerozoic and at the same time there has been a change in the mode of subduction from predominantly flat in the Archaean to progressively steeper towards the present day. This, along with the gradual cooling of the Earth, has resulted in marked changes in the preserved magmatic, metamorphic and mineralisation record. The first appearance of high-pressure metamorphic rocks, implying either overthickened crust or subduction, occurs in the Late Archaean around 2.7 Ga. There is a step-change in the magmatic products of subduction at the Archaean-Proterozoic transition from dominantly TTG through sanukitoid to calc-alkaline (basalt-andesite-diorite-rhyolite) as the main mode, which is most likely a result of a change in subduction angle and the development of a mantle wedge. This marks the onset of a form of modern plate tectonics. Whilst subduction magmas have been continuously produced they have also been continuously destroyed at continental margins, except at times when supercontinents formed, leading to pronounced peaks in crystallisation ages of detrital zircons. World-class ore deposits also correlate with the supercontinent cycle. During the Palaeoproterozoic (c.2.4-2.1 Ga) there was a period of anomalously low net continental growth followed by a peak of growth and mineralisation at c.1.9-1.8 Ga. We show how Fe-Oxide and related Cu and Au deposits can be linked to this cycle by measurement of Nd isotopes within titanite. The results imply that fertile mafic crust was incubated on the margins of the Archaean craton in the early Palaeoproterozoic but mineralisation did not occur until an arc was initiated at the margin and hence provided a heat and fluid source for mobilisation and concentration of the metals. The implication is that the formation and preservation of new continental crust is related to plate tectonics and the supercontinent cycle, which in turn controls the concentration and preservation of world-class ore deposits.

The mid-depth $\Delta^{14}C$ anomaly during termination 1, Do hydrothermal vents play a role?

LOWELL D. STOTT[1]* AND AXEL TIMMERMANN[2]

[1]Department of Earth Sciences, University of Southern California, Los Angeles, 90089 (stott@usc.edu)
[2]Department of Oceanography, University of Hawaii at Manoa, 1000 Pope Road, Marine Sciences Building, Honolulu, HI 96822 (axel@hawaii.edu)

The ~-190‰ drop in surface ocean and atmosphere $\Delta^{14}C$ during the last glacial termination cannot be explained entirely by ^{14}C production change and thus appears to require a flux of ^{14}C-depleted carbon into the upper ocean/atmosphere or a repartitioning of carbon in the ocean. A deglacial $\Delta^{14}C$ stratigraphy from deep Pacific cores does not exhibit a -190‰ decline as observed in upper ocean records during the 'Mystery Interval' [1]. There are large benthic ^{14}C-age excursions in several deglacial records from intermediate water depth cores at low latitudes but not in higher latitude cores [2]. These observations lead us to consider whether the flux of ^{14}C-depleted carbon from hydrothermal sites in the Pacific played a role in the Mystery Interval $\Delta^{14}C$ changes. Recent studies document liquid CO_2 and CO_2-rich fluids accumulationin in sediments that blanket active vents. The storage and net flux of CO_2 from the sediments is regulated by a CO_2-hydrate cap at the sediment/water interface. The temperature dependence of CO_2 hydrate stability is a possible mechanism for affecting storage and release of CO_2 and CO_2-rich fluids from sediments. We explore a hypothesis where hydrothermal systems act as a 'capacitor' for CO_2 storage-release. CO_2-hydrate stability expands upward to shallower depths during glaciation, reducing the net flux of ^{14}C-depleted CO_2 to the ocean. During deglaciation, CO_2-hydrate stability deepens, releasing ^{14}C-depleted CO_2 from sediment reservoirs. A ~3ºC temperature increase at intermediate depths in the Pacific during T1 would have lowered the hydrate stability horizon several hundred meters and released ^{14}C-depleted carbon to the upper ocean/atmosphere. This would explain why abyssal water masses were not anomalously old during the last glacial and why the -190‰ decrease in $\Delta^{14}C$ during the Mystery Interval is not observed at deep water sites.

Sampling the Earth's mantle

A. STRACKE

Westfälische Wilhelms Universität, Institut für Mineralogie Corrensstrasse 24, 48149 Münster, Germany (stracke.andreas@uni-muenster.de)

The Earth's mantle is isotopically highly heterogeneous, certainly on the kilometer scale of the melting region, but perhaps even on a smaller scale. During partial mantle melting and melt extraction, instantaneous melts from a range of depths are mixed to different extents, eventually forming the melts sampled by oceanic volcanism. Mixing of partial melts from a range of different source components has an averaging effect that biases the isotopic composition of the melts compared to those of their mantle sources. The isotopic composition of oceanic basalts hence reflects only a limited extent of the isotopic heterogeneity present in the mantle.

The relative amount of melt mixing is reflected in the correlations between isotope ratios and different trace element parameters. For OIB, where melt extraction occurs over a short depth interval underneath a thick oceanic lithosphere, little melting of refractory, depleted mantle components occurs. Consequently, melts from the enriched mantle components do not become significantly diluted, resulting in few correlations between isotope and trace element ratios, but also a close correspondence of enriched melt and average enriched source signatures. In ridge-related settings, in the absence of a thick oceanic lithosphere, the depleted mantle components melt to a large extent, and the enriched melts are diluted significantly during partial melting and melt extraction. Melts from the enriched source components, however, still dominate the final erupted melt and obscure the true extent of mantle depletion in mid ocean ridge basalts (MORB). Hence the depleted components of the Earth's mantle are expected to be isotopically more extreme than even the most depleted MORB.

Care must be taken, therefore, to extrapolate the isotopic variation observed in oceanic basalts directly to mantle heterogeneity. Before attributing the isotopic signatures of the basalts directly to those of the mantle, it needs to be understood how partial melting samples and averages heterogeneous source components. Only then can we infer the distribution of heterogeneous source components, their size, mineralogical, chemical and isotopic composition, which is a prerequisite for inferring the origin of the various heterogeneous materials in the Earth's mantle.

Pb concentrations, stable isotopes and ^{210}Pb in seawater, phytoplankton, zooplankton, sardines, anchovy from the Gulf of Lion

EMILIE STRADY[1], ALAIN VERON[1], JEAN FRANCOIS CHIFFOLEAU[2] AND OLIVIER RADAKOVITCH[1]

[1]University Paul Cezanne, CEREGE laboratory, Aix en Provence, France (strady@cerege.fr, radakovitch@cerege.fr, veron@cerege.fr)
[2]IFREMER, LBCM, Nantes, France (jfchiffo@ifremer.fr)

Introduction

The COSTAS project aims at understanding the trophic transfer of metallic contaminants through seawater, phytoplankton, zooplankton, sardine and anchovy populations in the Gulf of Lion (NW Mediterranee). Its originality is to combine the ecology of the trophic web and the biogeochemistry of the metallic contaminants. We present here preliminery results of bioaccumulated lead in each compartment at four stations, which were emphasized by analysing for the first time and in the same samples ^{210}Pb activity as a proxy of natural lead and $^{204, 206, 207, 208}$ Pb stable isotopes as proxy of anthropogenic Pb in the environment.

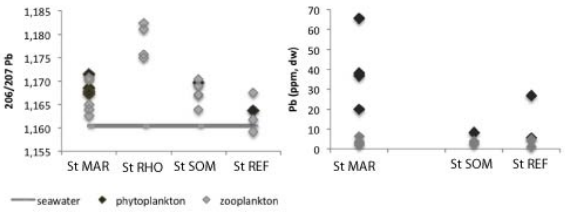

Figure 1: preliminary $^{206/207}$Pb and Pb concentrations in seawater, phytoplankton and zooplankton in the Gulf of Lion.

Results and discussion

Higher Pb concentrations in phytoplankton than in zooplankton (Fig 1) confirm the low ability of Pb to bioaccumulate in zooplankton. Pb isotopes ratios show different signatures among stations, despite constant Pb concentrations, close to the seawater signal in station far from the coast (St REF) and close to the radiogenic signal (1.175) in the Rhone station (St RHO). Emphasis on the relation between isotopes signals, Pb concentrations and plankton size/species will conduct to better understand the assimilation of Pb by plankton.

Review on biogeochemistry of microbial coal-bed methane

DARIUSZ STRĄPOĆ[1,2,3]

[1]Dariusz BioGeoChem LLC, Houston, TX 77077 USA (strapoc@gmail.com)
[2]Indiana University, Bloomington, IN 47405, USA
[3]Formerly: ConocoPhillips, Houston, TX 77079 USA

Microbial methane accumulations have been discovered in multiple coal-bearing basins over the past two decades. Such discoveries were originally based on unique biogenic signatures in the stable isotopic composition of methane and carbon dioxide. Basins with microbial methane contain either low-maturity coals with predominantly microbial methane gas or uplifted coals containing older, thermogenic gas mixed with more recently produced microbial methane. Recent advances in genomics have allowed further evaluation of the source of microbial methane, through the use of high-throughput phylogenetic sequencing and fluorescent in situ hybridization, to describe the diversity and abundance of bacteria and methanogenic archaea in these subsurface formations. However, the anaerobic metabolism of the bacteria breaking coal down to methanogenic substrates, the likely rate-limiting step in biogenic gas production, is not fully understood. Coal molecules are more recalcitrant to biodegradation with increasing thermal maturity, and progress has been made in identifying some of the enzymes involved in the anaerobic degradation of these recalcitrant organic molecules using metagenomic studies and culture enrichments. In recent years, researchers have attempted lab and subsurface stimulation of the naturally slow process of methanogenic degradation of coal [1].

Discussion includes description of (i) how occurrences of microbial methane accumulations in coal beds are identified through the use of geochemical tools such as stable isotopes; (ii) geological and hydrogeological constraints of such accumulations; (iii) the origin and composition of coal as the substrate and implications to microbial methane formation; (iv) methods of analysis of microbial metabolic pathways and microbial communities involved in biodegradation of various moieties of coal's organic matter; (v) attempts of stimulation of enhanced microbial methane generation in coals.

Challenges to predicting the fate of emerging classes of organic micropollutants in subsurface environments

TIMOTHY J. STRATHMANN[1]*, MICHAEL MACHESKY[2], KEVIN FINNERAN[3] AND TIAS PAUL[1]

[1]Univ. Illinois, Dept. Civil & Environ. Engr., Urbana, IL 61801 USA (*correspondence: strthmnn@illinois.edu)
[2]Illinois State Water Survey, Champaign, IL 61820 USA
[3]Clemson Univ., Environ. Engr. Earth Sci., Anderson, SC 29625 USA

Widespread detection of emerging micropollutants (e.g. antibiotics, hormones, personal care products) in soil and aquatic environments has raised serious concerns that necessitate improved understanding of processes controlling their environmental fate. However, existing models and reaction mechanisms are inadequate for predicting the fate of micropollutants that possess complex structures and functional groups not usually present in more commonly studied contaminants. Here, we describe recent efforts to characterize processes and mechanisms contributing to the fate of two widely detected classes of antibiotic micropollutants (sulfonamides, fluoroquinolones). First, we describe a novel microbially mediated-abiotic transformation mechanism for the antibiotic sulfamethoxazole (SMX) in subsurface environments. Rapid dissipation of SMX is observed in iron-reducing soil microcosms, and mechanistic studies demonstrate that SMX transformation occurs via abiotic reactions of sorbed Fe(II) with an isoxazole group in the SMX structure, a moiety not previously reported to be amenable to reductive transformation in soil environments.

The complex poly-ionogenic structures of some micropollutants have complicated efforts to predict sorption and speciation in subsurface environments. For example, the unique characteristics of zwitterionic fluoroquinolone (FQ) structures (presence of both positively and negatively charged groups) lead to complex electrostatic interactions with charged surfaces that cannot be accounted for by isotherm or point-charge surface complexation models. Here, we describe the application of a charge-distribution (CD) surface complexation model for zwitterionic species sorbing to variably charged oxide minerals. Model formulation includes functional group-specific inner- and outer-sphere bonding interactions with mineral surfaces, in accordance ATR-FTIR spectroscopic observations. CD model predictions agree closely with measurements of FQ sorption to three oxide soil minerals (TiO_2, α-FeOOH, and γ-AlOOH) collected over a wide range of pH, ionic strength and FQ concentrations.

Multiple sulfur isotopic evidence for multiple origins of late Archean and early Paleoproterozoic sediment-hosted pyrite, Quadrilátero Ferrífero of Minas Gerais

H. STRAUSS[1]*, A.R. CABRAL[2], A. CORDING[1] AND N. KOGLIN[3]

[1]Institut für Geologie und Paläontologie, WWU Münster, 48149 Münster, Germany (*correspondence: hstrauss@uni-muenster.de)
[2]Technische Universität Clausthal, Lagerstätten und Rohstoffe, 38678 Clausthal-Zellerfeld, Germany
[3]Julius-Maximilians-Universität Würzburg, Institut für Geographie und Geologie, 97074 Würzburg, Germany

Multiple sulfur isotopes were measured in different types of pyrite (detrital, framboidal, euhedral, finely disseminated) from a late Archean to early Proterozoic metasedimentary succession in the Quadrilátero Ferrífero of Minas Gerais, southern São Francisco craton, Brazil. Samples derive from the Moeda Formation, a coarse clastic, metaconglomeratic unit, and carbonaceous phyllite of the Batatal Formation. The Moeda Formation rests unconformably on Archean greenstone rocks and is conformably overlain by the Batatal Formation. The depositional age for both sedimentary units is bracketed between 2580 and 2420 Ma [1].

Multiple sulfur isotope results display distinct differences between the type of pyrite and the stratigraphic position of the host metasedimentary rocks. This offers the potential for resolving pyrite provenance and formation, for distinguishing prevailing metabolic pathways, and identifying the overall oxidation state of Earth's atmosphere.

All pyrite samples show clear mass-independently fractionated sulfur isotopes, defining a slope of -1 in a $\Delta^{36}S/\Delta^{33}S$ plot. This confirms previously published data and underlines the interpretation of a low atmospheric oxygen abundance [2]. Combining $\delta^{34}S$ and $\Delta^{33}S$, detrital and euhedral pyrite from the Moeda metaconglomerate exhibit largely positive values of $\Delta^{33}S$ (up to +8‰). In contrast, framboidal pyrite from the Moeda Formation has negative multiple sulfur isotope values. Pyrite from the overlying Batatal Formation displays also mostly negative $\delta^{34}S$ and $\Delta^{33}S$ values. These results indicate at least two different metabolic pathways archived: microbial turnover of elemental sulfur and sulfate reduction.

[3]Géosciences Montpellier, Univ. Montpellier 2, Montpellier cedex 5, France (Fleurice.Parat@gm.univ-montp2.fr)

We consider high-S apatites to be apatites with ≥0.7 wt.% SO_3. High-S apatites of magmas with rhyolitic melt are of particular interest because experimental data suggest that such apatites are 'over enriched' in S relative to equilibrium crystal-melt partitioning processes. In Pinatubo dacite, 29% of all investigated apatites (N=69) include high-S concentrations. Conversely, the dominant apatite populations of silicic oxidized magmas are medium- (0.3-0.6 wt.% SO_3) and low-S (<0.3 wt.% SO_3) apatites (also at Pinatubo), which are consistent with crystallization from melt at or below S saturation at various temperatures.

Explanations for high-S apatites range from inheritance (from mafic magmas or country rock) to S exchange between apatite and anhydrite as a consequence of close petrographic association of both phases in systems containing anhydrite (e.g. at Pinatubo). The compositional fingerprint (e.g. REE, Sr) ties high-S apatites to the same melt environment as the dominant populations, and thus makes inheritance unlikely. Finding low-S apatite inclusions in anhydrite in conjunction with the lack of consistent rimward enrichment of S of anhydrite-hosted apatites, argues against S exchange between these two phases.

To generate high-S apatite, we envision a process that we call 'fluid-enhanced crystallization,' whereby the high-S signal is controlled by the presence of a S-rich fluid adjacent to a growing apatite while other compositional characteristics are mostly controlled by the silicate melt. This process would be consistent with observed reverse S zonation towards the rim, small scale and strong changes in S content within single grains, occurrence of low- to high-S apatites as inclusions together in single host minerals, and compositional similarity among low- to high-S apatites. At Pinatubo the existence of such S-rich fluid is corroborated by S isotopes of anhydrite as well as growth features of anhydrite. A suitable source for S-rich fluids would be fluids derived from degassing underplated mafic magmas.

Post-collisional magmatism during Variscan orogeny: The Furcatura pluton (Danubian domain, Romanian Southern Carpathians)

C. STREMTAN[1], J. RYAN[1], V. ATUDOREI[2] AND I. CHERATA[3]

[1]Dept. of Geology, University of South Florida, Tampa, US (cstremta@mail.usf.edu)
[2]Dept. of Earth and Planetary Sciences, University of New Mexico, Albuquerque, US
[3]Dept. of Geology, "Babes-Bolyai" University, Cluj-Napoca, Romania

Exploratory geochronological data indicate that the Furcătura pluton (312 ±2.8 Ma) was emplaced during the Hercynian orogeny. This late stage magmatism is essentially granitic/granodioritic, lacking associated basic rocks. Furcatura pluton (FP) is remarkably heterogeneous, showing wide ranges for most of the petrographical and geochemical parameters. The metaluminous to slightly peraluminous (average A/CNK of 1.04) granitoids are high-K (K_2O/Na_2O of 0.51-1.63) calc-alkaline, while some samples have shoshonitic affinity (maximum K_2O of 5.61). They lack significant Eu anomalies (average Eu/Eu* of 0.94) and have subparallel REE patterns, with ΣREE ranging from 51.11 to 203.7. The heterogeneous character of the FP is further reflected in the $\delta^{18}O$ values of the quartz separates, ranging from 7.37 to 11.59‰, with the highest values measured in the late magmatic aplitic veins. In conventional discrimination diagrams, as well as reflected by their trace elemental compositions, FP granitoids show both I- and S-type granite features. Geochemical evidence suggests the pluton was derived from a heterogeneous, primarily (lower?) crustal source, with subordinate additions of mantle-derived melts (e.g. low Nb/U and Ce/Pb). However, based on available data, contributions from a previously subduction-enriched mantle component can not be completely ruled out. Therefore, the FP granitoids may provide clues for deciphering the processes involved in the production of post-collisional magmas.

[5]Department of Geology and Pedology, Mendel University of Agriculture and Forestry, Zemědělská 3, 61300 Brno

Laser ablation with induction coupled mass spectroscopy (LAICPMS) and laser induced breakdown spectroscopy (LIBS) became widely used in geological sciences. For quantification procedure of methods based on laser ablation, the matrix matched standards are required. Such standards, are largely lacking, especially for geological applications. We aimed at filling this gap by analyzing minerals, rocks, fused powdered rocks, sol-gel derived and plasmochemically deposited mineral analogues to identify possible candidate materials. The homogeneity and trace elements contents of the above mentioned materials were examined using μ-PIXE, LAICPMS-screening and by PIXE/PIGE/INAA techniques. Major/minor elements were studied using EPMA. PIGE is capable to detect some light elements that are not detectable by X-ray spectroscopic methods. INAA provides reliable informations about trace element composition of examined materials, with favourable detection limits compared with the majority of common analytical techniques.

Constraints on Earth outgassing history from Ar isotope composition of Devonian atmosphere

FINLAY M. STUART AND DARREN F. MARK

Isotope Geosciences, Scottish Universities Environmental Research Centre, East Kilbride G75 0QF, UK

The noble gases have long been used to show that the terrestrial atmosphere resulted from the outgassing of the Earth's interior rather than capture of the solar nebula during accretion. The primordial and radiogenic isotopes of the noble gases combine to make them a powerful tool for determining the time and tempo of Earth outgassing. Our understanding of the outgassing history of the Earth is largely derived from measurements of He, Ne, Ar and Xe isotope in samples of modern mantle, crust and atmosphere. Despite several attempts [1] there has been no unequivocal measurement of the isotopic composition of noble gases in ancient atmosphere.

We have now determined the Ar isotope composition of pristine samples of the 404 Ma Rhynie chert using a new multi-collector mass spectrometer and a low blank laser extraction technique. $^{40}Ar/^{36}Ar$ are systematically lower than the modern air value, and are not accompanied by non-atmospheric $^{38}Ar/^{36}Ar$ ratios. We conclude that the Rhynie chert has captured Devonian atmosphere-derived Ar. The data indicate that the $^{40}Ar/^{36}Ar$ of Devonian atmosphere was at least 3 % lower than the modern air value. Thus the Earth's atmosphere has accumulated at least $5 \pm 0.2 \times 10^{16}$ moles of ^{40}Ar in the last 400 million years, at an average rate of $1.24 \pm 0.06 \times 10^{8}$ mol ^{40}Ar/year. This overlaps the rate determined from ice cores for the last 800, 000 years [2] and implies that there has been no resolvable temporal change in outgassing rate since the mid-Palaeozoic. The new data require outgassing early in Earth history, and suggest that pristine samples of Archaean and Proterozoic chert may prove useful as palaeo-atmosphere tracer.

Glacier-derived dissolved organic matter (DOM) provides a significant source of ancient, yet highly bioavailable C to downstream ecosystems. The remnants of ancient peatlands and forests since overrun by glaciers have been invoked as a source of this ancient, labile DOM. Here we challenge this hypothesis, demonstrating that DOM exported from glaciers is predominantly anthropogenic and enters glaciers in a pre-aged form. C-containing aerosols, mainly from biomass and fossil fuel burning, are the original source of this aged-glacier DOM. Once deposited on glacier surfaces, aerosol DOM is exported downstream, providing an energy subsidy to aquatic ecosystems. As deposition of combustion products is a global phenomenon, we propose that all ecosystems are receiving this ancient, labile C subsidy. In vibrant ecosystems, the labile DOM windfall is presumably rapidly processed, its signal lost and impact masked. In frigid glacier environments, these inputs stand out, making glaciers sentinel ecosystems for the study of perturbation to global biogeochemical cycles through anthropogenic deposition. This deposition is predicted to increase in the future as emissions of combustion derived aerosols accelerates along with industrial growth.

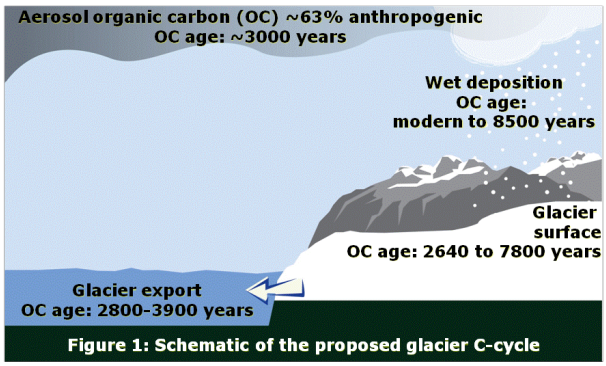

Figure 1: Schematic of the proposed glacier C-cycle

Climatically driven changes in sediment supply on the SW Iberian shelf since the Last Glacial Maximum

R. STUMPF[1]*, M. FRANK[1], J. SCHÖNFELD[1] AND B.A. HALEY[1,2]

[1]Leibniz Institute of Marine Sciences (IFM-GEOMAR), Wischhofstraße 1-3, 24148 Kiel, Germany (*correspondence: rstumpf@ifm-geomar.de)
[2]College of Oceanic & Atmospheric Sciences, 104 Ocean Admin. Bldg., Corvallis, OR 97331-5503, USA

The assemblage of marine sediments on the SW Iberian shelf reflects various ambient particle sources that have undergone significant changes as a function of prevailing weathering and transport regimes since the Last Glacial Maximum (LGM). The relatively rapid, decadal scale Mediterranean overturning circulation permits mixing of suspended particles from the entire Mediterranean Sea. They are entrained into the suspended particulate matter (SPM) carried by Mediterranean Outflow Water (MOW), which enters the Eastern North Atlantic through the Strait of Gibraltar and spreads at intermediate water depth in the Gulf of Cadiz and along the Portuguese continental margin. Further major sediment sources that have potentially contributed to the budget of SPM along the flow path of MOW on the SW Iberian shelf are North African dust and river transported particles from the Iberian Peninsula. In order to reconstruct climate and circulation driven changes in the supply of sediments from these sources over the past ~23 000 years, radiogenic Nd, Sr, and Pb isotope records of the clay-size sediment fraction were produced from three gravity cores in the Gulf of Cadiz (577 m) and on the Portuguese shelf (1745 m, 1974 m). These records were supplemented by time series of clay mineral abundances and clay mineral ratios from the same set of samples. Contrary to expectations, the transition from the LGM to the Holocene was not marked by very strong changes of the source areas of the sediments deposited on the SW Iberian shelf. However, the Heinrich stadial 1 and the African Humid Period are marked by significantly different isotopic records. The data also suggest that the continental chemical weathering regime changed with prevailing climate conditions and supplied the SW Iberian shelf with variable clay mineral abundances from essentially the same source rocks.

High methane oxidation rates in ferruginous lake Matano

A. STURM[1], S.A. CROWE[2], C.A. JONES[2], K.L. LESLIE[1], D.E. CANFIELD[2], S. NOMOSATRYO[3], A. MUCCI[4] AND D.A. FOWLE[1]

[4]Earth and Planetary Sciences, McGill University, Montréal, Canada

Lake Matano is the 8th deepest lake on the planet and is the world's largest known ferruginous basin [1]. This ancient lake is persistently stratified, and beyond its high Fe content, it is characterized by extremely low SO_4^{2-} and very high CH_4 concentrations. It has been proposed that CH_4 consumption in the lake occurs via a novel pathway in which CH_4 oxidation is coupled to the reduction of Fe and Mn (hydr)oxides [1]. To investigate the pathways of CH_4 consumption, we monitored methane oxidation rates with a ^{14}C-CH_4 tracer, both with and without the addition of a suite of electron acceptors including Fe and Mn (hydr)oxides. Our initial measurements yield volume specific rates as high as 0.8 μmol l^{-1} d^{-1}, comparable to modelled rates from C isotope and CH_4 concentration profiles [1]. Our measured rates, without added electron donor, are 7 orders of magnitude higher than those reported for the Cariaco Basin [2] and approximately 10 to 50 times higher than in Big Soda Lake, Nevada [3]. Considering the ultra-oligotrophic nature of Lake Matano, these are remarkably high rates. Electron acceptor addition experiments are in progress and these results will be discussed. Our results to date clearly show that CH_4 is an important component of the C cycle in Lake Matano and by extension ferruginous systems in general.

Laboratory experiments and modeling of CO_2 dissolution in water for carbon sequestration

M. STUTE[1,2]*, D. FERNANDEZ DE LA REGUERA[1] AND J.M. MATTER[1]

[1]Lamont-Doherty Earth Observatory, Palisades, NY 10964
[2]Barnard College, New York, NY 10027
(*correspondence: martins@ldeo.columbia.edu)

The injection of CO_2 gas in the dissolved phase is an alternative to that of supercritical CO_2 if the depth of the formation is <800m, or where immediate solution trapping is desired because of safety concerns. The most efficient way to dissolve CO_2 in water is downhole in order to take advantage of the increased hydrostatic pressure. We conducted experiments in a 100m long 'well' set up in the staircase of a Manhattan building to study the dynamics of the dissolution process. CO_2 was added at the top of the well with a sparger and the dissolution process was monitored downstream by image processing technology.

The experimental results reveal that bubble size and density decrease along the flow path as expected. However, the rate of dissolution decreased along the flow path with bubbles dissolving rapidly initially and extremely slowly afterwards. As the bubbles decrease in size, they became harder to dissolve, due to effects of rigidity of the gas-liquid interface and the presence of low solubility gases in the water and gas. The degree of dissolution could be considerably enhanced by using a passive mixer or an active downhole submersible pump. The dissolution process was simulated using the Darcy-Weisbach equation and a one-dimensional multi-gas numerical gas exchange model. Besides CO_2, common impurities such as N_2, O_2, noble gases, H_2, H_2S and gas tracers (SF_6 and SF_5CF_3) were included in the model. Extrapolation of the model parameters to real-world injection scenarios (e.g. the Carbfix pilot project in Iceland [1]) illuminate the role that the dissolved gas composition, the purity of the CO_2, and temperature play in controlling the efficiency of CO_2 dissolution for storage in geologic formations.

Geochemical and biological controls on the product of microbial U(VI) reduction

MALGORZATA STYLO[1]*, DANIEL S. ALESSI[1], BENJAMIN USTER[1], JUAN S. LEZAMA-PACHECO[2], JOHN R. BARGAR[2] AND RIZLAN BERNIER-LATMANI[1]

[1]Environmental Microbiology Laboratory, Ecole Polytechnique Federale de Lausanne, EPFL, Lausanne CH 1015, Switzerland (*correspondence: malgorzata.stylo@epfl.ch)

[2]Stanford Synchrotron Radiation Lightsource, Menlo Park, CA 94025, USA

Bioremediation of the uranium-contaminated subsurface involves the reductive transformation of soluble U(VI) species to less mobile U(IV) species by the *in situ* stimulation of indigenous microorganisms. The U(IV) mineral uraninite, $UO_{2(s)}$, is considered the most desirable product of bioreduction due to its low solubility and high stability under reducing conditions. However, the formation of uraninite may be inhibited under certain geochemical conditions, leading to the formation of biomass-associated U(IV) complexes, referrred to as monomeric U(IV).

In this study we examine the role of medium composition and extracellular polymeric substances (EPS) as inhibitors or promoters of uraninite precipitation. Uranium L_{III} edge X-ray absorption spectroscopy and a wet chemical extraction technique are used to differentiate between U(IV) species. It was previously reported that under controlled conditions in a simple medium containing bicarbonate and PIPES buffer at pH 6.8 (BP), the reduction of U(VI) by *Shewanella oneidensis* led to the formation of uraninite. In contrast, in a more complex Widdel Low Phosphate (WLP) medium, contaning numerous salts, the reduction by the same bacterium led to the formation of monomeric U(IV).

The results show that varying concentrations of NaCl (i. e, ionic strength alone) cannot acount for the molecular U(IV) production observed in WLP medium. The presence of phosphate or calcium ions in the medium has a larger influence on the U(VI) bioreduction product, leading to an increase in monomeric U(IV) formation. Moreover, bacterial EPS production indirectly affects U(IV) speciation. The product of U(VI) reduction in BP medium by a mutant of *Shewanella oneidensis* deficient in EPS production was richer in monomeric U(IV) than that of the wild-type under the same conditioon.

This work begins to explore the complexity of the factors influencing the product of U(VI) reduction. More in-depth investigation of the biological and geochemical factors influencing uranium bioreduction is warranted.

Analysis on environmental and economic sustainable development

SU HAO[1]* AND XU WEN-LAI[2]

[1]School of Economics & Management, Southwest Jiaotong University, ChengDu, 610031, PR China (*correspondence: shenyuren007@sina.com)

[2]College of Environment and Civil Engineering, Chengdu University of Technology, Chengdu 610059, China

Eco-environment is the basis for social and economic development, and the two have the unity of opposites. Depletion of natural resources for eco-development will inevitably affect the environment. Today, the deteriorating eco-environment makes human beings aware that the past social economic development was at the expense of the eco-environment. Human beings must seek coordinated development of soc-economy and the eco-environment.

Now take Chengdu city as an example, we have researched the region's vertical coordination of ecological environment and social economic development from 2001 to 2010. This research employed the method of Principal Component Analysis (PCA) to determine the ecological environment and socio-economic index weight. Based on the index weight, we set up the established evaluation model for sustainable development. And we found the regional ecological environment and socio-economic interaction law. From 2001 to 2010, social and economic development level of Chengdu were steadily rising, and the ecological environment of the ten years were basically flat, no improving. During the ten years, the construction of the ecological environment was far behind the social and economic development.

Quantitative identification of reservoir fluid properties and boundary shifts by laser-induced fluorescence

JIN SU[1,2], SHUICHANG ZHANG[1,2], GUANYOU ZHU[1,2], BIN ZHANG[1,2] AND XIAOMEI WANG[1,2]

[1]Research Institute of Petroleum Exploration and Development, PetroChina, Beijing 100083, China
[2]State Key Lab of Oil Recovery Elevation, Research Institute of Petroleum Exploration and Development, PetroChina, Beijing 100083, China

In an oil-gas reservoir with multi-stage structural movement, both hydrocarbons and reservoir bitumen may have suffered from multi-stage mixture, alteration and deconstruction, which results in difficulties to reconstruct migration and adjustment histories of hydrocarbons due to many factors that affect the reconstruction. However, direct evidence for different phases of hydrocarbon migration, variations in oil-gas properties and shifts of oil-water boundaries could be obtained from fluid inclusions of oil-gas reservoirs, which can record primary components and temperature-pressure conditions of hydrocarbon migration and charge. Thus, the present study uses quantitative assessment parameters, such as fluorescence strength and maximum emission waves of organic fluid inclusions, to characterize variations related with oils, gases and water in reservoirs so as to reconstruct adjustment processes of hydrocarbon reservoirs.

The Tarim Basin in China has experienced multi-cycle structural activities, and several developed petroleum systems are vertically superimposed or horizontally distributed in the basin. the present research quantitatively investigates fluorescence characteristics of reservoir sandstones, delineates the difference in fluorescence characteristics for oil-bearing or condensate-bearing reservoirs using λmax (maximum radiofluorescence wave length) and △λ (a wave length between 2/1 I_{max}), quantitatively analyzes the relationship between the primary oil-water boundary when hydrocarbon charge occurred and the present-day boundary, deduces reasons resulting in the elevation of oil-water boundaries based on structural evolution, and particularly, distinguishes dominant migrating pathways from all the oil-bearing reservoir beds according with the comparison of I_{max} (maximum radiofluorescence intensity) between present-day and old reservoirs. Therefore, the laser-induced fluorescence quantitative analysis can also play a significant role in investigating variations in paleo-oil-water boundaries, determining paleo-oil-column height, demonstrating oil saturation and wettability of reservoirs, and simulating displacement pressure of reservoirs as well.

Biodegradation of petroleum hydrocarbon in shallow groundwater from carbon and sulfur isotope evidence

SU XIAO-SI, LV HANG* AND ZHANG WEN-JING

Jilin University, Changchun, China, 130021
(*correspondence: lvhangmail@163.com)

Biodegradation is one of main natural attenuation processes in petroleum hydrocarbons contaminated groundwater [1]. Carbon and sulfur isotopes may have been markedly kinetic-fractionated during biodegradation process [2], which provides a powerful tool to reveal mechanism of petroleum hydrocarbons biodegradation. In an oilfield area in Northeast China, oil-bearing saline water moves upward and infiltrates into the shallow groundwater resulting from the accident and the area of groundwater-contaminated plume is about 8000m^2. Concentration of Total Petroleum Hydrocarbons (TPHs), dissolved Inorganic Carbon (DIC) and dominant terminal electron accepters or donators, $\delta^{13}C_{DIC}$ and $\delta^{34}S_{SO42-}$ have been analyzed.

Analytical results show that the spreading direction of contaminated plume is controlled by groundwater flow. And the concentrations of SO_4^{2-} and pH increase along groundwater flow in the central line of the plume while TPH and DIC decrease. The $\delta^{13}C_{DIC}$ values of the uncontaminated groundwater range between -9.5 and 8.0‰$_{PDB}$, while the contaminated is characterized by a significant depletion of ^{13}C with $\delta^{13}C_{DIC}$ of -18.3~-18.5‰$_{PDB}$. Furthermore, the concentration of DIC is negatively correlated with the value of $^{13}C_{DIC}$. It is deduced that the increase of DIC results from the biodegradation of petroleum hydrocarbon in groundwater. Meanwhile, the ^{34}S in the contaminated groundwater with the $\delta^{34}S_{SO42-}$ of 25.0‰ ~ 48.1‰$_{CDT}$ is depleted to the uncontaminated groundwater with the $\delta^{34}S_{SO42-}$ of 19.2‰ ~13.9‰$_{CDT}$. The Rayleigh model calculation [3] shows that the biodegradation of petroleum hydrocarbon with the bacterial sulfate reduction has occurred in the contaminated aquifers.

The alteration sequence of PGM in the gossan of the Aguablanca Ni-Cu-(PGE) sulphide deposit, SW Iberia

S. SUÁREZ[1]*, H.M. PRICHARD[2], F. VELASCO[1], P.C. FISHER[2] AND I. MCDONALD[2]

[1]UPV/EHU. Dep. Mineralogy & Petrology. Barrio Sarriena s/n 48940 Spain (*correspondence: saioa.suarez@ehu.es)
[2]Cardiff University. School of Earth and Ocean Sciences. Main Building. Park Place. Cardiff CF10 3AT (UK)

The gossan outcrops overlying the Aguablanca magmatic deposit [1] (situated in the Ossa-Morena Zone in SW Iberia) host significant total PGE contents of up to 5 ppm, with Pt and Pd dominant over Rh, Os, Ir and Ru. A detailed survey of the PGE distribution was carried out in this gossan in order to understand the processes that change primary magmatic PGM during weathering in an oxidising, low-T environment. PGE were investigated in host relic PGM (by SEM-EDS) and as traces in the host Fe-oxides and oxyhydroxides that form the gossan (by LA-ICP-MS) [2].

The study showed a gradual alteration of the PGM and release of PGE during the gossan formation, including: (i) initial breakdown of the already slightly altered, primary PGM [3] (24% of the total PGM located); (ii) formation of partially oxidised Pt-Pd-phases (3%), with a composition close to 'Pt_2O' and "(Pt, Pd)O'; (iii) formation of numerous oxidised Pt- and Pd-(±Cu-Fe, Bi-Te)-phases (68%), with a composition usually close to "$(Pt, Pd)O_2$" and "$(Pt, Pd)_3O_4$". Palladium-rich hydroxides were also identified. These phases all appear to have formed from alteration of earlier PGM to form pseudomorphs. Among them, Pt-rich PGM are more frequent and always appear better preserved than Pd-rich PGM; (iv) formation of Fe-Ni-Cu-(±Pt-Pd)-oxides (5%), mainly in patches that may include relic precursor PGM; and lastly, (v) incorporation of PGE into ferruginous supergene products, with a greater dispersion of Pd than for the other PGE. LA-ICP-MS analyses showed that Pt, Ir and Rh in oxides are mainly located close to sulphide relicts. In contrast, Pd accompanied by Cu, Ni, Bi or Te, occur widely distributed within the different generations of Fe-oxides.

These observations suggest that the sequence of alteration of igneous PGM in a gossan is likely to be one of PGE-oxide formation followed by dispersion of the PGE into the Fe-oxides. This work adds to the understanding of the evolution of PGM in the surface environment.

Late-Cretaceous alkaline continental magmatism associated with Deccan Continental Flood Basalt sequences of Saurashtra in Western India

D.V. SUBBA RAO*, E.V.S.S.K. BABU, G.VIDYASAGAR AND B.MADHUKAR

National Geophysical Research Institute, Hyderabad, India (*correspondence: dvsubbarao@ngri.res.in)

The Saurashtra region in Western India consists of seven volcano-plutonic complexes (plugs) occurring within the Deccan Continental Flood Basalts of WDVP. The three major plugs occurring at Junagadh (Girnar), Barda and Alec Hills pipe-like igneous intrusions located along the E-W trending Narmada-Son lineament. Alkaline magmatism is represented by lamprophyres and nepheline syenites forming as minor composite intrusions which are spatially and temporally related and occur chiefly within the diorites in the upper part of the Girnar Complex. Nepheline syenite is generally cream coloured, spotted black and pinkish red with pyroxene and nepheline respectively and consists of a granitoid aggregate of alkali feldspar, nepheline, sodalite, cancrinite and aegerine. In lamprophyric sills, Cpx occurs as microphenocrysts of small rounded to prismatic crystals which show the characteristic oscillatory zoning (X_{Mg} = 0.65–0.77) and amphiboles which are of calcic variety (X_{Mg} = 0.48 to 0.65). X_{An} in plagioclase varies from 25 to 96. These alkaline rocks have higher concentration of total alkalies (8.0 to 14.57wt %), Al_2O_3 (22.2wt %), LILE and ΣREE as well as highly fractionated REE patterns. The available data suggest that they are products of fractionation of an alkali basic magma from which early crystallization of lamprophyres took place under high PH_{20} conditions followed by nepheline syenites which crystallized at lower PH_{20} under relatively dry conditions from the residual liquids. The occurrence of high MgO dykes (olivine tholeiites, Opx bearing pyroxenite dykes and ankaramite dyke), the essexite pluton and deep-seated lineaments coupled with the presence of strong positive gravity anomalies in the Saurashtra region reflect prevalence of an underlying sub-surface high density component in the Girnar and most of the other plugs in the region.

Volume and ionic conductivity measurements of H_2O ice at high pressure and temperature

E. SUGIMURA[1]*, T. KOMABAYASHI[1], K. OHTA[1], K. HIROSE[1,], N. SATA[2], Y. OHISHI[3] AND L.S. DUBROVINSKY[4]

[1]Dept. of Earth and Planet. Sciences, Tokyo Tech., 2-12-1 Ookayama, Meguro, Tokyo 152-8551, Japan (*correspondence: sugimura@geo.titech.ac.jp)

[4]Bayerisches Geoinstitut, Universität Bayreuth, Bayreuth 95440, Germany

We examined isothermal volume (V) compression of H_2O ice based on *in situ* x-ray diffraction measurements at 33-79 GPa and 873 K, and its ionic conductivity at 20-60 GPa up to 920 K using impedance spectroscopy (IS) technique. High pressure (*P*) and temperature (*T*) conditions were generated by using an externally-heated diamond anvil cell. The anomalous volume reduction likely due to the hydrogen bond symmetrization was observed at 50-53 GPa and 873 K, while the previous study at room temperature reported that the highly compressible phase associated with the symmetrization is present at 40-60 GPa. There is no volume discontinuity in the isothermal compression, which contadicts the proposed first order *P-T* boundary between ice VII and superionic ice [2, 3]. In addition, *in situ* IS measurements shows that the ionic conductivity of ice monotonically increases with increasing *T*, and exhibits superionic conduction (>10^{-1} S/cm) above 580-720 K at 20-60 GPa, which is the first experimental evidence of the superionic conduction in H_2O ice at high pressure. This suggests that superionic ice appears at sufficiently lower *P-T* than the proposed triple point.

Combining above results with the existing planetary isentropes [4], superionic H_2O ice is stable at *P-T* conditions corresponding to the interiors of Neptune and Uranus, the ice giants. The presence of superionic ice in these planets possibly accounts for the non-dipolar and non-axis symmetric structure of their magnetic fields.

The system SiO_2-H_2O revisited: Equation of state to very high temperatures and pressures including critical behavior

MIROSLAV ŠULÁK* AND DAVID DOLEJŠ

Institute of Petrology and Structural Geology, Charles University, 128 43 Praha 2, Czech Republic (*correspondence: miroslav.sulak@natur.cuni.cz)

The system SiO_2-H_2O represents a simple model for metasomatism and hydrous melting in the lower crust and upper mantle. In this binary, the upper critical end point (UCEP), where complete miscibility between concentrated aqueous fluids and hydrous silicate melts occurs, is located at 1100 °C and 9.5 kbar [1], near the geothermal subduction gradient with important consequences for aqueous devolatilization *vs*. melt generation in the subducting slab. We have derived a new equation of state for aqueous silica, which combines intrinsic thermal properties of SiO_2 units with volumetric contributions resulting from solvent compression in the hydration sphere. The concentration scale is mole fraction, which enables the difference between standard states at infinite dilution and pure substance to be linked *via* excess energy of mixing represented by symmetric Margules term (*W*). In addition, the pressure-temperature locus of the UCEP provides two additional constraints on energy-composition relationships, thus reducing the effective number of independent parameters of the equation of state. The Gibbs energy of SiO_2 (aq) has the form: $\Delta G = a + bT + cT\ln T + dP + eT\ln\rho_w$, where ρ_w is the density of aqueous solvent at pressure and temperature of interest. The thermal part is assembled from constant enthalpy, entropy, and heat capacity, whereas the pressure term employs constant volume of the unhydrated species. Additional contribution arises from the pressure-volume work necessary to compress solvent molecules from bulk density to the density in hydration shell due to electrostriction, and it is related to solvent volumetric properties only [2]. The model was calibrated by 342 experimental quartz solubilities at 25-1100 °C and 0.001-20 kbar and ranging from 9 ppm to 70 wt.%, yielding a = -963.5 kJ mol^{-1}, b = 844.3 J K^{-1} mol^{-1}, c = -124.1 J K^{-1} mol^{-1}, d = 2.26 J bar^{-1} mol^{-1}, e = -16.65 J K^{-1} mol^{-1}, and W = 29.1 kJ mol^{-1}, with overall accuracy of 1.3 kJ mol^{-1}. In contrast to previous studies, our new model is capable of addressing SiO_2 behavior in dilute aqueous fluids and hydrous melts, including their supercritical mixtures.

Agriculture's impact on the Si cycle by accelerated biomineralisation

LEIGH SULLIVAN[1,2] AND JEFFREY PARR[1,2]

[1]Southern Cross University, Australia (*correspondence: leigh.sullivan@scu.edu.au)
[2]Plantstone Pty Ltd, 90 Zouch Rd Stoney Chute 2480

Biogenic silica plays a major role in the global cycling of silicon [e.g. 1] and in processes such as mineral weathering, soil acidification, and regulation of atmospheric CO_2. Phytoliths form by silicon biomineralisation within plants (especially grasses) and constitute a major pool of biogenic silica. Biogenic silica production rates reported for natural vegetation communities have a mean of ~70 $kgSiO_2ha^{-1}yr^{-1}$ [e.g. 2, 3, 4], but vary widely from only 2 $kgSiO_2ha^{-1}yr^{-1}$ to up to 1, 380 $kgSiO_2ha^{-1}yr^{-1}$ for a tropical bamboo forest [5]. This data indicate a global silica phytolith production rate of ~1 billion tons of SiO_2yr^{-1} prior to agricultural development.

However, many agricultural crops and pastures are based on silica-accumulating grass species that produce silica phytoliths far in excess of that produced by most natural vegetation communities. For example, silica phytolith production rates in grass crops such as rice, wheat, sugar cane and bamboo are usually an order of magnitude greater than those observed for most natural vegetation communities [6, 7, 8] and can be over 3, 000 kg per ha^{-1} yr^{-1} [8].

Accelerated silicon biomineralisation consequent of agriculture not only results from higher silicon uptake within such crops but also by the increased biomass produced by agricultural practices such as fertilisation and irrigation.

Further factors that impact the global silicon cycle from this process include: 1) the large area being cultivated annually with high silica phytolith producing crops and pastures (e.g. ~0.7 billion ha under cereal crops alone), and 2) the slow turnover rates of silica phytoliths (e.g. >300 yrs under tropical rainforests [4] and grasslands [3]).

The results presented here show that agriculture, by greatly accelerating the production of biogenic silica from the cultivation of high silica phytolith producing plants, has considerably impacted the silicon cycle with implications for other silicon-associated geochemical processes. Such implications are explored in this paper.

2575 Ma age of Nuvvuagittuq metamorphic garnet

N.C. SULLIVAN[1], E.F. BAXTER[1] AND S.J. MOJZSIS[2]

[1]Dept. of Earth Sciences, Boston University, Boston, MA (norasull@bu.edu, efb@bu.edu)
[2]Dept. of Geological Sciences, University of Colorado, Bolder, CO (mojzsis@colorado.edu)

The recent discovery of pre-3.75 Ga metasedimentary rocks in the Nuvvuagittuq supracrustal belt (NSB) of northern Quebec, Canada, provides a new suite of rocks to further our understanding of Eoarchean Earth process. The NSB includes a CaO-poor (cummingtonite) amphibole, plagioclase, biotite, quartz and garnet-bearing mafic schist. The exact age and history of this rock is being debated: associated zircon ages give a minimum age of 3.77 Ga [1], and a $^{146}Sm/^{142}Nd$ isochron suggests that the NSB includes components as old as ca. 4.28 Ga [2].

Garnet Sm-Nd geochronology is a valuable tool to elucidate the tectonic and metamorphic histories of mafic rocks; recent improvements in sample preparation have improved both the accuary and precision with which we are able to date the growth of garnet [3]. Although garnet dating in the cummingtonite amphibolite rocks will not resolve the age debate, it will tell us when the most recent garnet-forming metamorphic event occured at which time Nd isotopes were last mobilzed and exchanged among metamorphic phases.

After crushing and hand picking a visually clean garnet separate we performed partial dissolutions to remove micro-inclusions. Using a three step sequence of acids: concentrated HF, concentrated $HClO_4$, and 7N HNO_3, acid-cleansed garnets showed high $^{147}Sm/^{144}Nd$ ratios (~6.0) indicating that low Sm/Nd micro-inclusions were eliminated. However, replicate preparations produced significant scatter in the isochron towards older apparent ages indicative of contamination from an older inherited high Sm/Nd inclusion phase (likely zircon). Adding a fourth aqua regia step to the partial dissolution sequence cleansed the garnet of these contaminants yielding slightly higher $^{147}Sm/^{144}Nd$ (~6.1) and a robust three point garnet-matrix isochron age of 2574.70 ± 0.72 Ma (MSWD=0.77). This new age represents the youngest age associated with the NSB and implies the terrane underwent a final greenschist-amphibolite grade heating event after the final ca. 2.7 Ga crustal growth episode documented by metamorphic overgrowths on zircons [4].

Subduction volcanism is generally considered to form a 'subduction barrier' that efficiently recycles volatile components contained in subducted slabs back to the Earth's surface. Nevertheless, subduction of sediment and seawater-dominated pore fluids to the deep mantle has been proposed to account for the non-radiogenic elemental abundance and isotopic pattern of heavy noble gases (Ar, Kr, Xe) in the convecting mantle [1]. To verify whether and how subduction fluids preserve a seawater signature, we determined noble gas and halogen compositions of the exhumed mantle wedge peridotite and eclogite from the subduction-related Sanbagawa metamorphic belt, southwestern Japan, in which relicts of slab-derived water are contained as hydrous mineral inclusions or aqueous fluid inclusions.

The observed noble gas and halogen compositions of the peridotite [2] and eclogite samples shows striking similarites with marine pore fluids, challenging a popular concept that the water flux into the mantle wedge occurs only by hydrous minerals in altered oceanic crust and sediment. These results indicate that subduction and closed system retention of marine pore fluid occurs to depths of at least 100 km, necessitating a reassessment of the dominant transport mechanism and source of water in subduction zones. Further subduction of a small amount of marine pore fluid can account for the heavy noble gas composition observed in the convecting mantle.

Temperature controls of sulphur isotope fractionation during sulphate reduction by *Thermodesulfobacterium* and *Desulfovibrio* strains

JIA-LIN SUN[1], LI-HUNG LIN[1], SAUL-WOOD LIN[2], JIE-WEI SHIU[2] AND PEI-LING WANG[2]

[1]Department of Geosciences, National Taiwan University
[2]Institute of Oceanography National Taiwan University

Sulphate reducers are known to fractionate sulphur isotopes during dissimilatory sulphate reduction. Unravelling the factors controlling the fractionation pattern would be essential to identify the contribution of each enzymatic pathway at the cellular level, interpret the isotopic signatures in geological materials, and track the sulphur cycling in natural occurrences. This study examined the sulphur isotope fractionation patterns catalyzed by a thermophilic *Thermodesulfobacterium*-related strain and a mesophilic *Desulfovibrio gigas* over wide temperature ranges.

The *Thermodesulfobacterium*-related strain grew between 34 and 85 °C with an optimal temperature at 72 °C and the highest cell-specific sulphate reduction rate at 68 °C. The isotope fractionation ($\varepsilon^{34}S_{sulphate\text{-}sulphide}$) ranged between 9.1 and 25.7 ‰ over temperatures ranging from 51 to 77 °C. The fractionations remained at high levels for the growth above 55 °C and decreased significantly for the growth at 51 °C. The *D. gigas* grew between 10 and 45 °C with an optimal temperature at 36 °C and high cell-specific sulphate reduction rates between 30 and 36 °C. The isotope fractionation ranged between 8.5 and 52.0 ‰ over temperatures ranging from 19 to 39 °C and peaked at 24 °C. The relationships between the fractionation and temperature for two strains in this study in part resembled those previously reported for *Archaeoglobus*-related strains but distinct from those for *D. desulfuricans*, *T. indicus* and *Desulfobacterium autotrophicum*, suggesting that the isotope fractionation is controlled by the complex combinations of contribution from individual pathways. Measurements of multiple isotopes are warranted to reconcile the modelled uncertainty.

Soil water movement traced by oxygen isotope in the Mu Us sandy land, North China

SUN JIANG*, RAO WENBO, SUN XUE

Institue of Isotope Hydrology, School of Earth Sciences and Engineers, Hohai University, Nanjing, 210098, China (*correspondence: taiyangfeng23@126.com)

Soil water is very important to plant growth because of arid climate in the Mu Us sandy land. However, knowledge on soil water movement of this region is little till now. In this study, oxygen isotope compositions of soil water in the dune profiles at Henan Village are investigated and then soil water movement is explored.

Two dune profiles with the depth of 3.75m are bored at a about 12 h interval before and after a thunderstorm in the same site at Henan where average annual precipitation is about 400mm but average annual evaporation is up to 2000mm [1]. Soil water is extracted from samples after they are sent to the laboratory by the vacuum-distillation apparatus and then is analyzed for $\delta^{18}O$ via MAT253.

$\delta^{18}O$ value of soil water changes greatly between -0.96 and -7 in the upper part with the depth of about 1.8m but fluctuates constantly within a narrow range of -6 ~ -8 in the lower part of the first profile (before thunderstorm). $\delta^{18}O$ value of soil water also has a large variation from -2.87 to -7.54 in the upper part and a similarly narrow range in the lower of the second profile (after thunderstorm). The isotopic data have three implications: (1) the evaporation only impact water isotope in the upper profile with the 1.8m depth; (2) the thunderstorm event carries more negative oxygen isotopic composition into the upper profile; (3) since soil water in the lower profiles has $\delta^{18}O$ value more positive than that of local groundwater [2], they seem not to be of same origin. In addition, the average infiltration rate of this precipitation is about 15cm per hour through calculation.

As a result, the precipitation infitration is only limited to the 1.8m depth under the land surface although there is a large amount of the precipitation for the thunderstorm event in a short time. It is thus inferred that vertical infiltration of the precipitation through the dunes might have little recharge to groundwater.

Geochronology of continental volcanic-type gold mineralization in East Tianshan, Western China: Constraints from Ar-Ar isotope of Shiyingtan gold deposit

SUN JINGBO[1]*, CHEN WEN[1], LI HUAQIN[1], JI HONGWEI[2,1] AND LI JIE[2]

[1]Laboratory of Isotope Geology, Institute of Geology, CAGS, Beijing, 100037 China (*correspondence: jingbo95003@126.com)

[2]China University of Geosciences (Beijing), Beijing, 100029 China

The East Tianshan area in northwest China locates on the boundary between Tarim plate and Kazakhstan-Junggar plate. Both plates had experienced a complicated breakup and collision since late Precambrian, accompanied by large-scale thrust and continental volcanism [1]. Previous studies suggested two stages of continental volcanism: the first stage occurred between Late Carboniferous and Early Permian with isotopic age of 310~290Ma; the second stage occurred between Late Permian and Early Triassic with isotopic age of 260~240Ma. The Shiyingtan gold deposit locates in the extensional tectonic-magmatic belt of Queleage in East Tianshan area, composing mainly of NO.I, NO.II, NO.III ore bodies, with ores held by both gold-bearing quartz veins and altered andesite. Andesite, hornblende andesitic dacite, amygdaloidal andesite, volcanic breccia agglomerate lava and volcanic breccia of Permian are the exposed strata within mined area.

In order to study the metallogenic epoch of Shiyingtan gold deposit, altered andesite ores were sampled from NO.I ore body, from which sericite is extracted for ^{40}Ar-^{39}Ar isotope dating analysis by step-heating, yielding a plateau age (Tp) of 304.2±1.3Ma and isochron age (Ti) of 304.7±4.9Ma (initial ratio of $^{40}Ar/^{36}Ar$=292±10). This mineralization age of 304Ma in Shiyingtan gold deposit is in great concordance with the age of ore-bearing volcanic rocks, deposition of gold occurred in extensional tectonic stage of post-orogenic between late Carboniferous Kazakhstan-Junggar and Tarim plates, developing in the extensional area of shear flank.

This work was supported by the Science and Technology Research Project of China (No.: 2007CB411306; 200911043-13; 1212011120293).

Geochemical characteristics of the Shaxi-Changpushan porphyry Cu-Au deposit: Significance to ore formation

S.C. SUN, S.G. HE AND F. JIANG*

Institute of Disaster Prevention Science & Technology, Yanjiao, 101601, Beijing, China (grg@fzxy.edu.cn)

Introduction

The Shaxi-Changpushan porphyry copper (gold) deposit is located in the northwestern Luzong volcanic basin. It also belongs to the north of the middle and low part of the Yangtze iron and copper metallogenic zone with the multiple location of faults, where Fanshan-Tongling deep fault and Tan-Lu fault belt come through the whole mineralization region and result in serious rock deformation in Jurassic [1].

Methods and Results

Basd on geochemical studies and literatures [2-10], including chemical analysis on bulk rocks, rare earth and trace element studies, fluid inclusion, S and O isotopic analysis, we present significant proofs for the copper-(gold) mineralization in Shaxi porphyry copper-gold deposit. The sulfur isotope dada show that the magma has the characteristics of deep source. Compared with the other large and supper-large porphyry copper deposits in China and the adjacent copper mineralized areas, ore-forming processes and conditions were analyzed. Our study indicates that the ore-forming fluids and materials were dominated with the magmatic origin, whereas the meteoric water played small role in the ore-forming processes. There are great potentialities to form a large porphyry copper deposit from the point view of tectonic evolution and geochemical characteriscs in Shaxi-Changpushan Cu-Au ore district.

Oceanic Anoxic Events and Cenozoic large scale molybdenum mineralization

WEIDONG SUN[1], CONGYING LI[1,3], HONG ZHANG[1,3], XING DING[2], MINGXING LING[2] AND WEI-MING FAN[1]

[1]Key Laboratory of Mineralogy and Metallogeny, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, P. O. Box 1131, Guangzhou, PR China

[2]Key Laboratory of Isotope Geochronology and Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, P. O. Box 1131, Guangzhou, PR China

[3]Graduate University of the Chinese Academy of Sciences, Beijing 100049, PR China

Half of the world's Mo reserve is hosted in Cenozoic porphyry-copper (Cu)-molybdenum (Mo) and porphyry-Mo deposits along the west coast of the American continents with nearly no Mo porphyry deposits along the west coast of the Pacific Ocean. In contrast, most Mo deposits in Eastern Asia are located along the Qinling-Dabie orogenic belt and in Northeastern China. Here we show that the large scale Mo mineralization along the west coast of the American continents is mainly due to the partial melting of Mo enriched sediments formed during oceanic anoxic events (OAEs) in the Jurassic and the Cretaceous. Porphyry-Cu-Mo deposits in the American continents are formed through partial melting of Mo-rich OAE sediments carried by flatly subducted oceanic crust in the east Pacific. High-fluorine (F) porphyry-Mo deposits are mostly located in the Colorado mineral belt (COMB), which are formed through direct partial melting of high grade metamorphosed Mo-rich OAE sediments in backarc settings, induced by the roll back of the flatly subducted east Pacific slab. Most low-F porphyry-Mo deposits have closer spatial relationship with porphyry-Cu-Mo deposits and are formed through partial melting of metamorphosed OAE sediments induced by arc magmas. In contrast, Mo porphyry deposits in Eastern Asia belong to low-F type, likely formed through partial melting of metamorphosed Mo rich sediments. Molybdenum deposits in Northeastern China were likely also due to Mo rich sediments formed during OAEs, whereas those from the Qinling orogenic belt were likely related to sediments formed in Triassic backarc settings.

Extraction time for soil water of desert sand used in stable isotope analysis

SUN XUE*, RAO WENBO AND SUN JIANG

Institue of Isotope Hydrology,School of Earth Sciences and Engineers, Hohai University, Nanjing, 210098, China (*correspondence: sunxue217@yahoo.cn)

Vacuum distillation has been widely used to extract soil water for stable isotopic analysis in studies of water cycle Distillation time is very crucial to complete soil water extraction. In this study, experiments of extracting water from dune sand of the Chinese desert are carried out to determine optimal extraction time.

Seven 30g sand samples with 10% moisture and known water isotopes are prepared and the distillation temperature is set at 105°C for the experiments of soil water extraction. The samples are vacuum-distilled for 4min, 8min, 12min, 16min, 20min, 25min and 30min, respectively (Fig. 1). Extracted water is analyzed for δ^2H and $\delta^{18}O$ by MAT253.

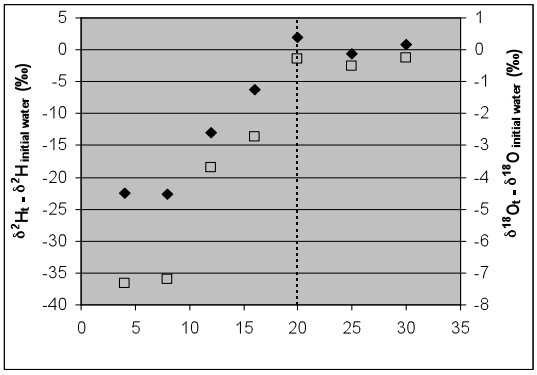

Figure 1: Isotopic variation of water extracted from sand samples.

As shown Fig.1, δ^2H_t-$\delta^2H_{initial}$ and $\delta^{18}O_t$-$\delta^{18}O_{initial}$ gradually increase with time. They arrive to zero (‰) at 20min and then tend to be constant. This result indicates it need take at least 20min to completely extract soil water from desert sands. For different types of soils, the extraction time is distinct [1]. To be on the safe side, we suggest 28min for extracting water from sands in the Chinese deserts. Certainly, water extraction of over 30min is insignificant. Our conclusion agree well with West *et al*. (2006) [2].

[1] Landon *et al*.(1999) *Journal of Hydrology* **224**, 45–54. [2] West *et al*. (2006) *Rapid Commun. Mass Spectrom* **20**, 1317–1321.

Episodic events of the Western North China Craton and North Qinling Orogenic Belt, in central China: Revealing by detrital zircon U–Pb ages

YONG SUN, CHUNRONG DIWU, HONG ZHANG, QIAN WANG, ANLIN GUO AND LONGGANG FAN

State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi'an, 710069, China (diwuchunrong@163.com)

Detrital zircon U-Pb geochronology serves as a proxy to study of crustal evolution and provenance discrimination. In order to unravel episodic events and their tectonic relationship of the North China Craton (NCC) and North Qinling Orogenic Belt (NQOB), detrital zircons from modern river sands and metasedimentary rocks are collected and dated by LA-ICPMS. Although the western NCC (Ordos terrane) is covered by Mesozoic-Cenozoic basin sediments, the U-Pb dating results have shown that the age populations of detrital zircons from the western NCC with prominent U–Pb age peaks at 2475 Ma and 1850 Ma, which indicates the western NCC (Ordos terrane) also has early Precambrian basement similar to the eastern and central craton. In addition, a significant number of early Paleozoic (520-400 Ma) zircons have bee found in the western NCC, which is quiet different from the eastern NCC and is considered to be related to the collision between the NQOB and the NCC.

The age spectra of detrital zircons from the NQOB presents a complex age pattern, which reveals four major age groups of Neoarchean (2.6–2.4 Ga), Neoproterozoic (1.0–0.85 Ga), early-middle Paleozoic (450-350 Ma) and early Mesozoic (250–170 Ma). As indicated by the U-Pb isotopic data that the NQOB could be an independent terrane at least prior to the Neoproterozoic and once a portion of the Grenville orogenic belt during the 1.2-0.8 Ga with a peak of ~1.0 Ga. In other words, the NQOB has its unique geological evolution history obviously different from those of the NCC and the Yangtze Craton. The complete collision between the NQOB and the NCC perhaps took place at Paleozoic (450-400 Ma).

Predicting reservoir fluid properties using absolute concentrations of canned cutting gas components

YONGGE SUN

Department of Earth Science, Zhejiang University, Hangzhou 310027, P.R. China

The canned cutting gas data are the most frequently used geochemical approach to characterize reservoir fluid properties during petroleum exploration. Traditionally, canned cutting gas analyses are semi-quantitative and usually reported as C_1 through C_5 normalized, therefore increasing the uncertainty in respect to fluid prediction. Here, we developed a quantitative method for canned cutting gas analyses, and together with their carbon isotopic compositions and molecular parameters to identify reservoir fluid types and barriers.

The canned cuttings are received from the well site. Samples are routinely analyzed at intervals varying from 10 to 30m. A known volume of cuttings are homogenized with water in a gas-tight blender and a sample of head space is analyzed for methane, ethane, propane, butane and pentane. For absolute concentrations of cutting gas components, an internal standard is chosen and the relationship of GC response factor between standard and aimed gas components is constructed. By adding known amount standard into canned cutting system before GC analysis, absolute concentrations of canned cutting gas components can be calculated and reported as μmol.

If neglecting the lose of gas during drilling and transport to surface, degassing efficiency is the most important factor to influence absolute concentrate of gas components, which strictly depends on temperature and its holding time and rock characters. Here, temperature and its holding time are investigated and the results show that concentration of gas components goes up with an increase of temperature up to 60°C and then keep stable, while the holding time is a not a significant factor where there is almost no change from 30min to 60min. Stable carbon isotopic compositions of gas components are less affected by degassing efficiency and this is in agreement with the observation by GeoMark.

A case study from the Panyu low-uplift of Baiyun depression, South China Sea is presented. Quantitative data, integrated with DST results, preliminary criteria can be made to define whether the oil and/or gas reservoir identified by normal logging is a commercial pay zone, and therefore for further DST planning.

Experimental study of solution-mineral interaction in the Qisanba uranium deposit, NW-China

SUN ZHANXUE[1], ZHOU YIPENG[2] AND LIU JINHUI[2]

[1]Laboratory of National Defence Key Discipline of Radioactive Geology and Exploration Techniques (East China Institute of Technology), Fuzhou, Jiangxi 344000, China (*correspondence: zhxsun@ecit.edu.cn)

[2]Key Laboratory of Nuclear Resources and Environment (East China Institute of Technology), Ministry of Education, Nanchang, Jiangxi 330013, China (ypzhou@ecit.cn)

Introduction

The Qisanban U deposit is hosted by a sandstone aquifer with groundwater whose TDS ranging roughly from 8-12 g/L. All the past pilot acid and alkaline *in situ* leach uranium mining tests failed due to serious chemical plugging during the mining processes. To develop a new solution mining technique, leaching test of uranium ores in ammonium bicarbonate solution was carried out. The TDS of the solution was maintained around 2 g/L by dilution using fresh water, and the pH was kept as 6.0-6.3 by pumping CO_2 into the solution.

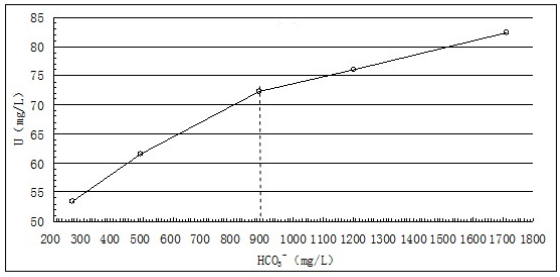

Figure 1: Uranium vs. HCO_3^- concentration of the solution

Result and discussion

The experiments showed that uranium can be leached effectively from the ores in ammonium bicarbonate solution without any chemical plugging. A new bicarbonate solution uranium mining technique based on groundwater dilution may be proposed.

First finds of 'Alloclasite' (Fe,Co,Ni) AsS in Ni sulphides of Bangur Gabbro, Orissa, India

P.V. SUNDER RAJU

National Geophysical Research Institute (A Council of Scientific and Industrial Research) Hyderabad, India-500606 (perumala.raju@gmail.com)

The diarsenides and sulfarsenides of Fe, Co and Ni have a widespread geological occurrence; they exhibit complex paragenetic and compositional relations, and are commonly associated with economically important minerals, such as PGM and gold. We found mineral phase consist of enriched amounts of (Fe, Co, Ni) (As, S) $_2$ phases in Ni-S phases of Bangur gabbro in Orissa. The age of Bangur Gabbro is ~3.1 Ga. The eastern part of the Indian Shield is composed of a high-grade metamorphic terrain known as the Chhotanagpur Craton in the north and a granite- greenstone terrain known as the Singhbhum Craton in the south. The latter is mainly composed of several granitoid batholiths, which are largely surrounded and intervened by supracrustal rocks. Both Bangur and Baula (21°15'38' to 21°16'55' North and 86°.19'14' to 86°20'10' East) in the eastern part of Indian shield have been studied earlier by earlier workers [1], but petrological data (i.e. magma evolution and ore forming processes) are scanty. We report here the presence of mineral phase consists of (Fe, Co, Ni) (As, $S)_2$. There is complete solid solution series exist between alloclasite- cobaltite- gresdorffite. The observed assemblages and solid solution agree well with experimental data on Fe-Co-Ni-As-S system.

Aerosol optical properties and direct radiative effect over India based on satellite remote sensing measurements

ANU-MAIJA SUNDSTRÖM[1]*, PEKKA KOLMONEN[2], LARISA SOGACHEVA[2], EDITH RODRIGUEZ[2], MERI HANNUKAINEN[1], KSENIA ATLASKINA[1] AND GERRIT DE LEEUW[1,2,3]

[1]P.O. Box 64, 00014 University of Helsinki, Finland (*correspondence: anu-maija.sundstrom@helsinki.fi)
[2]Finnish Meteorological Institute, Climate Change Unit, Erik Palmen Aukio 1, 00101, Helsinki, Finland
[3]TNO, Utrecht, The Netherlands

Aerosols affect Earth's radiation budget directly by scattering and absorbing solar radiation, and indirectly by modifying the microphysical properties of clouds. However, large uncertainties still exist in current estimates of the aerosol effects on climate, mainly due to aerosols strong temporal and spatial variation (e.g. [1]). India is one of the world's most populated countries. Along with the continuously increasing population and economic growth the increase of the anthropogenic pollutants is evident. Large emissions of aerosol and precursor gases transported from these regions can have significant impacts on air quality and climate on both regional and global scales.

In this work a measurement-based approach is applied to study the aerosol optical properties and to estimate the aerosol direct radiative effect over India. To assess this, observations from satellite instruments, such as AATSR (Along Track Scanning Radiometer onboard ENVISAT) and CALIOP (Cloud-Aerosol Lidar with Orthogonal Polarization onboard CALIPSO) are used along with a radiative transfer code. The data consists of observations between 2006 and 2010. Preliminary results show e.g. that over areas with elevated aerosol optical depths the fine particles can account for over 80% of the total aerosol extinction.

W-Sn ores of the Svetloye deposit: Mode of formation from isotope, fluid inclusion and modeling studies

T.M. SUSHCHEVSKAYA[1], A.JU. BYCHKOV[3], A.V. IGNATIEV[2], S.S. MATVEEVA[3], J.A. POPOVA[3], N.I. PRISYAGINA[1] AND T.A. VELIVETSKAYA[2]

[1]Vernadsky Institute of Geochemistry RAS, Moscow, Russia (tms@geokhi.ru)
[2]Far East Geological Institute, Vladivostok, Russia
[3]Moscow StateUniversity

Large Svetloye W-Sn deposit (Chukotka, North- East of Russia) is located in the apical part of a leucogranite stock. The deposit is composed of a series of quartz veins among the flyschoid rocks (T_{1-2}), cut by the dikes (K_1). The veins are dominated by the quartz- wolframite- cassiterite- arsenopyrite-muscovite mineral assemblage. The later sulfide and quartz-fluorite –calcite assemblages are of limited development. Fluid inclusion study showed, that productive mineral association was formed by aqueous low-salinity sodium chloride fluids at T 350-270°C, P 0, 5-1, 0 kbar. The remarkable low salinity (<5% mass) was cryometrically found for the earliest magmatic fluids from primary magmatic fluid inclusions and fluid phase of melt inclusions in quartz from leucogranites of the stock. W and/or Sn ore formation was accompanied by increasing in alkalinity and degree of oxidation of fluids. Boiling of ore-forming fluids was rather typical of the central part of the deposit. Isotopic (H, O, Ar) study of minerals [1] and oxygen isotope zonality of host granites witness to precipitation of cassiterite-wolframite ores presumably from magmatic fluids strongly diluted with meteoric waters, interacted with wall rocks.

Analysis of possible role of main factors of W-Sn precipitation, such as cooling, boiling, interaction with wall rocks and mixing of genetically different fluids have been modelled with the help of HCh software package [2]. Natural data are best consistent with model of mixing of ore-forming solutions with exogenic fluid, reequilibrated with host rocks, as it was found for the Sn-W Iultin deposit, situated in the same ore province [3].

Strontium stable isotope variations in lunar basalts

CHELSEA N. SUTCLIFFE[1], KEVIN W. BURTON[1], IAN J. PARKINSON[2], DAVID COOK[1], BRUCE L.A. CHARLIER[2] FATIMA MOKADEM[1] AND ALEX N. HALLIDAY[1]

[1]Department of Earth Sciences, University of Oxford, South Parks Road, Oxford OX1 3AN, UK
[2]Department of Earth and Environmental Sciences, The Open University, Walton Hall, Milton Keynes, MK7 6AA, UK

In the terrestrial environment strontium (Sr) stable isotopes may experience significant fractionation, both at low- and high-temperatures, involving carbonate precipitation [1] and plagioclase crystallisation [2], respectively. Recent data for lunar basalts suggests that these rocks may possess light Sr stable isotope compositions ($\delta^{88}Sr$ = +0.16±0.07) [2] relative to mantle derived terrestrial basalts ($\delta^{88}Sr$ = +0.30±0.07) [2, 3]. However, few samples have been analysed thus far, and at the ±50 ppm precision of these measurements, obtained using an MC-ICP-MS [2, 3], such variations cannot be clearly resolved.

This study presents high-precision (±10 ppm) double spike TIMs data for $^{87}Sr/^{86}Sr$ and $^{88}Sr/^{86}Sr$ for a suite of lunar basalts and anorthosites. These data confirm the light Sr stable isotope compositions observed previously for lunar rocks [2] but also demonstrate that there are significant and resolvable variations in $\delta^{88}Sr$ ranging from +0.348 for a lunar norite to +0.151 for a high-Ti Mare basalt. These variations, taken with those for evolved terrestrial basalts, are most simply explained by the preferential incorporation of the heavy isotopes of Sr into plagioclase with a fractionation factor of ~1.0002 for $^{88}Sr/^{86}Sr$ [2]. These results clearly indicate that for the Moon primary igneous processes alone can produce significant variations in $\delta^{88}Sr$, without the recycling that may occur on Earth.

^{129}I as an oceanographic tracer in the Japan Sea

T. SUZUKI[1]*, M. MINAKAWA[2], S. OTOSAKA[3] AND O. TOGAWA[3]

[1]Japan Atomic Energy Agency, Aomori 035-0053, Japan (suzuki.takashi58@jaea.go.jp)
[2]National Research Institute of Fisheries Science, Kanagawa 236-8648, Japan
[3]Japan Atomic Energy Agency, Ibaraki 319-1195, Japan

Introduction

Iodine-129 is a natural occurring radionuclide with a half life of 15.7 Ma. During last six decades, ^{129}I has also been released in the environment by nuclear weapons testing and the operation of nuclear fuel reprocessing plants.

The Japan Sea is a semi-enclosed marginal sea. The turnover time of water was reported about a few hundred years which was much shorter than that of the Pacific Ocean. Some of long-lived artifical radionuclides, therefore, would be useful tracers to study the oceanic circulation in the Japan Sea. In this paper, we summarize our recent studies of the Japan Sea using ^{129}I.

Experimental

To investigate the potential of ^{129}I as oceanographic tracer in the Japan Sea, seawater samples were collected at 7 stations by cruises of R/V Soyo-Maru and T/S Osyoro-Maru in 2007. Iodine isotopic ratios were measured by an accelarator mass spectrometry at the Mutsu Office of the Japan Atomic Energy Agency.

Results and Discussion

1. Fractions of ^{129}I source in surface seawater were estimated using a natural isotopic ratio and fission yield. This estimation suggests that ^{129}I in surface seawater consists of natural occurring (2%), weapons testing (10%) and reprocessing plants (88%) [1].
2. The averaged surface concentration of ^{129}I in a subarctic circulation was higher than that in a subtropical circulation. Taking account of the location and the total amount of ^{129}I released from reprocessing plants in EU, this different concentration would indicate that ^{129}I released from those plants is supplied to the Japan Sea.
3. The concentration of ^{129}I in the Japan Sea bottom water (JSBW) was higher than that of the natural level. This result indicates anthropogenic ^{129}I is transported vertically by winter convection [2] and the turnover time of the JSBW is estimated to be about 200 years.

Selenate reduction by iron-reducing bacteria isolated from Bangladesh soil

Y. SUZUKI[1]*, R. OYAMA[1], H. SAIKI[1], K. TANAKA[2] AND T. OHNUKI[3]

[1]School of Bioscience and Biotechnology, Tokyo University of Technology, 1404-1 Katakura-cho, Hachioji, Tokyo 192-0982, Japan (*correspondence: yosuzuki@bs.teu.ac.jp)
[2]Institute for Sustainable Sciences and Development, Hiroshima University, 1-3-1 Kagamiyama, Higashi-Hiroshima, 739-8530 Japan
[3]Advanced Research Center, Japan Atomic Energy Agency, Tokai, Ibaraki 319-1195, Japan

Introduction

Microbial reduction of highly soluble selenate and selenite to insoluble elemental selenium is an important phenomenon affecting the mobility of selenium and useful to remediation of Se-contaminated soils. Previously, we had reported the selenite reduction by *Shewanella putrefaciens* [1]. In this study, we examined the selenate reduction by iron-reducing bacteria isolated from Bangladesh soil.

Experimental

Soils from Samta Village, Jessore, Bangladesh were used to start an enrichment culture with H_2 as a potential electron donor and Fe(III)-EDTA as a electron acceptor (Fe-medium). The enrichment was purified by serial dilution with Fe-medium. Analysis of 16S rRNA sequence of the isolate was conducted. Selenate reducing ability of the isolate was examined in an anaerobic medium containing 5 mM Na_2SeO_4 with a gas phase of H_2-CO_2 (80:20). Effect of iron on the selenate reduction was investigated in media containing 5 mM Na_2SeO_4 and 0-20 mM Fe(III)-EDTA. Precipitates occurred in the media were analysed by XANES spectroscopy.

Results and Discussion

An iron-reducing bacterium, designated L1, was isolated by the serial dilution. Results of 16S rRNA analysis showed that L1 is a novel species and close to *Desulfotomaclum guttoideum* and *Clostridum celerecrescens*. L1 grew in the medum with 5 mM selenate. Cell density of L1 increased with reduction of selenate to selenite, meaning that the bacterium respires selenate. Followed by the selenate reduction, selenite was reduced to elemental selenium forming red precipitates. In the presence of Fe(III), the red precipitates were initially formed and later they turned black precipitates. The XANES analysis indicated that the red and black precipitates contained Se (0) and Se (-II), respectively.

Cathodoluminescence of quartz as a reflection of the evolution of the Teplice Caldera

KATEŘINA ŠVECOVÁ[1], KAREL BREITER[2] JAROMÍR LEICHMANN[1]

[1]Department of Geological Sciences, Masaryk University, Kotlářská 2, CZ-61137 Brno, Czech Republic (175727@mail.muni.cz) (leichman@sci.muni.cz)
[2]Institute of Geology AS CR, v. v. i., Rozvojová 269CZ-165 00 Praha 6, Czech Republic (breiter@gli.cas.cz)

The late-Variscan Altenberg-Teplice Caldera (ATC) is situated in the Eastern Krušné Hory Mts./Erzgebirge on both sides of the Czech-German border. The studied borehole Mi-4, situated in the western part of the ATC, crossed all volcanic units of the caldera fill in the thickness of 950m.

According to Breiter *et al*. [1], the ATC consits of five volcanic phases. Two oldest units composed of the basal rhyolites (BR) and overlying dacites (DC) are calc-alkaline in character and may probably represent a product of high-degree melting of a immature material of the lower crust. Three younger units of Teplice rhyolite (TR1-3) are high-K calc-alkaline in character, significantly enriched in Rb, Th and HREE. This younger part of the ATC should be interpreted as a product of low-degree high-temperature melting of much more evolved crustal material.

The inner structure of quarz crystals was studied using cathode luminescence with hot-cathode (HC 2) and scanning luminescence (microprobe CAMECA SX100). Quartz grains from the ATC show intensive zonning in both modes of observations. The oldest unit, BR is charakteristic with nearly violet luminescence with weak zonning. In many cases these are just fragments of much larger grains and there are carbonate veins going trough the quartz. In DC unit have quarz grains dark blue luminiscence and no zonning. Quartz grains in three younger units TR1-3 have blue luniscence in hot CL with dark center and lighter margins. Significantly more intensive zonation appears in scanning luminescence. Very tiny zones symetrically rimm the core, dissolution of individual zones could be often documented. Some grains appears as fragments only. Majority of grains were corroded during their evolution. This has resulted in sometimes very bizarre shapes of grains. Quartz grains from the uppermost extrusive unit, rhyolite lava (TR3) are mostly rounded (2 mm diam.), often with granophyric overgrowth.

Surface complexation evidence that amino acids prefer special sites on oxide surfaces

D.A. SVERJENSKY[1]*, R.M. HAZEN[2], D. AZZOLINI[1], N. LEE[1] AND K. KLOCHKO[2]

[1]Johns Hopkins University, Baltimore, MD 21218 USA (*correspondence: sver@jhu.edu)
[2]Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC 20015 USA

Adsorption data for a variety of amino acids on rutile, amorphous titanium dioxide and hydrous ferric oxide covering wide ranges of pH, ionic strength and surface loading have been analyzed with the extended triple-layer model (ETLM), ATR-FTIR spectroscopic studies and quantum chemical approaches [1-4]. The results provide a consistent picture of the surface speciation of amino acids on oxides. The ETLM analysis requires a surface site density of 3.0 sites/nm^2. Each amino acid adsorbs in at least two ways to oxide surfaces: at low surface loadings, a species 'lying down' on the surface; at high surface loadings, a species 'standing up' on the surface. We focus here on glutamic acid (H2Glu) and dihydroxyphenylalanine (DOPA or H3DP) on rutile. At the highest loadings, about 0.47 sites/nm^2 are occupied by the 'standing up' Glu attached through the distal carboxylate to a surface functional group >TiO (OH^{2+}). The attachment consists of one inner-sphere bond and one H-bond. The amount of Glu adsorbed corresponds to about 16% of the total site density. However, this type of attachment cannot take place on the ideal (110) face of rutile which overwhelmingly predominates on our rutile sample in SEM pictures. The reason is that groups such as >Ti $(OH)_2$ or >Ti (OH)O are not present on the ideal (110) face. They are present on (111) or (101), suggesting that at least 16% of the (110) surface in our sample consists of (111) or (101) structures that contain the special functional groups that Glu prefers. A similar conclusion applies to DOPA. At high loadings, DOPA attaches to two Ti as (>TiOH^{2+})>TiHDP- with one inner-sphere bond and one H-bond from the two phenolic groups on the DOPA the separation of which (2.78 A) almost exactly matches the two >TiOH groups (2.77 A), but only when these are exposed on the (101) plane. Overall, the ETLM analysis indicates that both Glu and DOPA at high loadings prefer special functional groups that are not available on the ideal (110) plane, implying that most amino acid adsorption is on steps on (110) surfaces of rutile and similar structures on other oxides. HRTEM studies are underway to test this suggestion.

Trace element analysis in quartz by using laser ablation ICP-MS: A tool for deciphering magma evolution

M. SVOJTKA*, L. ACKERMAN AND K. BREITER

Institute of Geology, Academy of Sciences CR, 16500 Praha 6, Czech Republic (*correspondence: svojtka@gli.cas.cz)

Quartz is one of the most abundant mineral in the Earth's continental crust and is a common and most resistant rock-forming mineral in silica-oversaturated rocks. During post-magmatic and metamorphic alterations, trace elements are relatively stable in quartz crystal lattice. We have used laser ablation ICP-MS technique to (1) evaluate the chemical composition of igneous quartz from two comagmatic granitic and rhyolitic suites and (2) correlate cathodoluminiscence internal structures and trace element patterns in quartz to define relations of element chemistry and zonation.

Internal structure of quartz grains was studied by cathoduluminiscence (CL) on the electron microprobe. Trace element (Li, Be, B, Rb, Sr, Ba, Pb, Ge, Al, P, Ti, Cr, Mn) concentrations were measured using a New Wave UP-213 laser ablation system connected with sector-field single collector ICP-MS (Thermo Element 2). Laser was fired at repetition rate of 20 Hz and energy of 8-10 J/cm^2. All data were calibrated against the external standard NIST SRM612 glass and silica contents were used for internal standardization. Time-resolved signal data were processed using the Glitter software; caution was taken to constrain the signal to chemically homogeneous parts of the crystals and to avoid any inclusions and inhomogenities that can be potentially present in the analysed.

Our pilot samples were taken from the late-Variscan magmatic system of the A-type in eastern Krušné hory Mts. (N Bohemian Massif). The rhyolite samples from borehole Mi-4 represent evolution of the Altenberg-Teplice caldera, whereas the granite sample from borehole CS-1 document vertical zonality of the comagmatic Cínovec pluton.

Cathodoluminescence images of quartz grains (crystals and their fragments) from the rhyolite show distinct domains with a characteristic bright and dark luminiscence: the cores are dark (poor in Ti, and enriched in Al and Ge), whereas rims are bright (rich in Ti and poor in Al). Quartz grains from granites are homogeneous, without any CL zonation. Evolution from the deeper protolithionite to the upper zinnwaldite granite is documented by increase of Al, Ge, B, Sr, Ba, and decrease of Ti-contents in quartz.

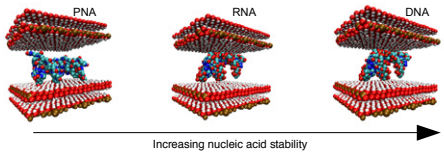
Computer simulation of clay mineral – biomolecule interactions

JACOB B. SWADLING[1], PETER V. COVENEY[1]* AND H. CHRISTOPHER GREENWELL[2]

[1]Centre for Computational Science, Department of Chemistry, University College London, WC1H 0AJ, UK (*correspondence: p.v.coveney@ucl.ac.uk)

[2]Department of Earth Science, Durham University, Durham, DH1 3LE, UK

We show simulations of various 25-mer sequences of single stranded RNA, in bulk water and with aqueous montmorillonite clay [1]. Over timescales of only a few nanoseconds, specific RNA sequences fold to characteristic secondary structural motifs, which do not form in the corresponding bulk water simulations. Our simulations show that, in aqueous Ca^{2+} environments, RNA can tether to the clay surface through a nucleotide base leaving the 3′ end of the strand exposed, providing a mechanism for the regiospecific adsorption and elongation of RNA oligomers on clay surfaces.



We study the structural stability of three different nucleic acids, intercalated at varying degrees of hydration within a magnesium aluminum layered double hydroxide (LDH) mineral host and free in aqueous solution [2]. The nucleotides investigated are ribose nucleic acid (RNA), deoxyribose nucleic acid (DNA), and peptide nucleic acid (PNA), all in duplex form. Our simulations show that DNA has enhanced Watson-Crick hydrogen-bonding when intercalated within the LDH clay layers, compared with intercalated RNA and PNA, whilst the reverse trend is found for the nucleic-acids in bulk water. The tendency for LDH to alter the stability of the three nucleic acids persists for higher temperature and pressure conditions. These results suggest that a mineral based origin of life may have favored DNA as the information-storage biomolecule over potentially competing RNA and PNA, providing a route to modern biology from the RNA world.

Chronology of fluvial incision in the upper Ganges inferred from *in situ* cosmogenic isotopes

Z. SWANDER[1]*, A. DOSSETO[1], D. FINK[2] AND C. MIFSUD[2]

[1]GeoQuEST Research Centre, School of Earth and Environmental Sciences. University of Wollongong. Wollongong, NSW, Australia (*corresponence: zjs785@uow.edu.au, tonyd@uow.edu.au)

[2]Australian Nuclear Science and Technology Organization. Lucas Heights, NSW, Australia (fink@ansto.gov.au, cxm@ansto.gov.au)

Although past climatic cycles are well constrained, little is known about their effect on catchment erosion and sediment transport. For instance, what is the role of climate variability on river aggradation/degradation cycles in tectonically active settings? The Alaknanda River, one of the two major tributaries of the Ganges River, constitutes an ideal area for studying this question. From its glacial headwaters sourcing sediment from 7, 000+ meter peaks, fueled by meltwater and the summer monsoon that annually brings the river to sustained flood levels; the Alaknanda River transports a tremendous volume of sediment to the fertile floodplain and the delta of the Ganges River. Sediment transport dynamics has fluctuated in the past with episodes of fluvial aggradation and incision. Recently, Ray and Srivastava (2010) have used OSL dating to provide a chronology of the episodic formation of river terraces, showing that it occurred during two phases: between 45 and 25 ka, and between 18 and 11 ka. A detailed knowledge of fluvial incision chronology is still lacking. Cosmogenic radionuclides (CRN) ^{10}Be and ^{26}Al can be used to determine how long a bedrock surface has been exposed to cosmic rays at the Earth's surface. This can be used to quantify the timing of fluvial incision through bedrock or overlying sediments. With this aim in mind, we have collected bedrock samples along the Alaknanda River at strategic sites. Results will inform on the timing of fluvial incision in this catchment, which when combined to the chronology of river aggradation, will provide a detailed understanding of river dynamics in the lower Himalayas. By comparing these results to regional climatic records, we will be able to identify the role of climate on catchment dynamics in a tectonically active environment.

Regulation of atmospheric pCO_2 by the North Pacific Ocean since the last interglacial

GEORGE E.A. SWANN[1] AND ANDREA M. SNELLING[2]

[1]School of Geography, University of Nottingham, University Park, Nottingham, NG7 2RD, UK (*correspondence: george.swann@nottingham.ac.uk)

[2]NERC Isotope Geosciences Laboratory, British Geological Survey, Keyworth, Nottingham, NG12 5GG, UK (asnel@bgs.ac.uk)

The large 80-100 ppmv variations in atmospheric pCO_2 documented in ice-cores from Antarctica over glacial-interglacial cycles provide an essential forcing mechanism in driving the climate system. Existing research on the terrestrial biosphere as well as the low latitude and Southern Oceans are capable of explaining c. 50% of this variability when invoking mechanisms including deep water upwelling, stratification and the biological pump. Evidence is presented here, using new diatom oxygen, silicon and carbon isotope data, that changes in the strength of the North West Pacific Ocean biological pump and the regional halocline also played a key role in acting as both a net sink and source of CO_2 between MIS 5e and MIS 4.

Methods

δ^{18}O and δ^{30}Si were analysed following a combined step-wise fluorination procedure with measurements made on a Finnigan MAT 253 with an analytical reproducibility of 0.4‰ and 0.06 ‰ respectively [1]. Diatom δ^{13}C was analysed using a Costech elemental analyser linked to an Optima mass spectrometer via cold trapping with an analytical reproducibility of 0.3‰.

Results/Discussion

Whereas the regional water column is characterised by an inefficient biological pump and significant ventilation of CO_2 to the atmosphere in MIS 5e, a more efficient siliceous pump during MIS 5b-c led to a reduction in such exchanges. Both intervals culminate with increased meltwater input, establishing a stratification boundary and inhibiting further productivity as well as large scale ventilation of CO_2. Such changes would have helped drive the climate system through the MIS 5 sub-stages and into the last glacial period.

A microbially-mediated deep terrestrial nitrogen cycle at Henderson Mine, CO

ELIZABETH D. SWANNER* AND ALEXIS S. TEMPLETON

Department of Geological Sciences, University of Colorado, Boulder, CO 80309, USA
(*correspondence: swanner@colorado.edu)

The existence of life in deep terrestrial subsurface rocks has been established at multiple sites, yet few studies have investigated the origin of nutrients that support such life. At Henderson Mine, CO, subsurface fluids drain from boreholes at 3000' depth, supporting a diverse microbial community based on 16S rRNA gene surveys. The fluids of several boreholes contain nitrogen in multiple oxidation states, including NH_4^+ at 5-100 μM. Fluid mixing trends show a correlation between NH_4^+ and degree of water-rock interaction, and so we ask whether subsurface NH_4^+ is sourced geologically or biologically. As this Mo deposit developed from partial melting of the lower crust, it is plausible that a sedimentary source of nitrogen was mineralized into NH_4^+, which then substituted for K^+ in silicate minerals in the stockworks. We used FTIR microscopy to detect and quantify NH_4^+ in from biotites and other mineral phases. We also investigate whether biological nitrogen fixation of N_2 supplies the microbial community with NH_4^+. In the borehole fluids with the highest NH_4^+ (~100 μM), we amplified the *nifH* gene from DNA extracts of filtered fluids, but not from borehole fluid DNA where NH_4^+ concentrations were lower. We use a phylogenetic and quantitative PCR-based approach to evaluate whether *nifH* belongs to the novel phylum of bacteria first detected in these samples, the Henderson candidate division.

Our geochemical calculations predict that nitrification (NH_4^+ and NO_2^- oxidation) is favorable in the high NH_4^+ borehole, and so we next asked whether nitrifiers were present. The DNA from the high-NH_4^+ borehole fluid was the only sample to contain 16S rRNA sequences from archaea and the bacterial genus *Nitrospira*. From this sample, we amplified the gene for archaeal ammonium oxidation, *amoA*, but not the bacterial version of the gene, suggesting that archaeal ammonium oxidizers (AOA) are better adapted to this environment. Finally, we amplified a novel *nxrB* gene encoding the beta subunit of nitrite oxidoreductase specific to nitrite-oxidizing *Nitrospira*. Amplification of genes for nitrogen fixation and nitrification support the existence of a subsurface nitrogen cycle. The ubiquity of Mo in enzymes of the nitrogen cycle may dictate the energy sources utilized by microbes in this subsurface Mo mine.

Is there really a mixing-zone stable carbon and oxygen isotope signal?

PETER K. SWART

Division of Marine Geology and Geophysics, Rosenstiel School of Marine and Atmospheric Sciences, University of Miami, Miami Fl 33149 (pswart@rsmas.miami.edu)

A number of distinctive changes in $\delta^{13}C$ and $\delta^{18}O$ signals of carbonates in response to different diagenetic phenomena have been proposed. For example, sub-aerial exposure surfaces are typically characterized by extreme depletions in the $\delta^{13}C$ and a slight enrichment in $\delta^{18}O$, the vadose zone is characterized by constant and depleted $\delta^{18}O$ values, but wildly varying $\delta^{13}C$, the freshwater phreatic zone possesses negative $\delta^{13}C$ values which are not so variable as the vadose zone, the mixing-zone is characterized by a co-varying trend from negative to positive $\delta^{13}C$ and $\delta^{18}O$ values, and finally the marine phreatic zone has values of both $\delta^{13}C$ and $\delta^{18}O$ which are fairly positive. In this presentation the interpretation of the co-varying trend in the mixing-zone is questioned. Instead it is proposed that this trend really represents a range of varying amounts of recrystallization taking place in the freshwater phreatic zone. The significant change in interpretation is based on observations from several deep cores in the Bahamas which have penetrated shallow-water carbonates which were deposited and sub-aerially exposed during the numerous sea-level changes during the Pleistocene. During the last glacial period sea level fell at least 120 m below its present position. Based on present interpretation of the co-varying stable C and O isotopic record at this level no freshwater water lens would have been present. Clearly a significant freshwater lens was present extending downwards as much as 40 m, coincidently corresponding to the zone of covariation between the C and O isotopes.

The Archean anorthosite-monzogranite magmatic association of the Narryer Gneiss Terrane, Western Australia

P.J. SYLVESTER[1] *, A.K. SOUDERS[1], J.L. CROWLEY[2] AND J.S. MYERS[3]

[1]Department of Earth Sciences, Memorial University, St. John's, NL A1B 3X5, Canada (*correspondence: psylvester@mun.ca)
[2]Department of Geosciences, Boise State University, 1910 University Drive, Boise, Idaho 83725-1535 USA
[3]Department of Applied Geology, Curtin University, Perth, WA 6845, Australia

The Narryer Gneiss Terrane is located in the Yilgarn Craton, Western Australia [1]. A layered anorthosite-gabbro-ultramafic intrusion called the Manfred Complex [2] is exposed just northeast of Mount Narryer. The complex is about 3.73 Ma old based on U-Pb zircon geochronology [3]. It is engulfed and disrupted by two banded granite gneisses. Meeberrie gneiss is mainly derived from monzogranites that have U–Pb zircon ages of 3.68–3.60 Ga [3, 4], although minor components are as old as 3.73 Ga [5]. Dugel gneiss formed from younger monzogranite to syenogranite magmas emplaced at 3.38–3.35 Ga [3, 4, 5]. Because the Manfred Complex is older than all but one component of the gneisses, it has been thought to be unrelated to the major magmatic events that produced the monzogranitic intrusions.

We have sampled additional anorthositic rocks from the Narryer Gneiss Terrane and determined their ages by LA-ICPMS U-Pb zircon geochronology. These rocks include anorthosite, leucogabbro, gabbro, amphibolite and peridotite. Anorthosites and leucogabbros located near 7 Mile Bore, north of the Jack Hills give ages of 3.73-3.63 Ga, similar to the ages for the Meeberrie gneiss, whereas northeast of Mount Dugel, north of Billabidy well, leucogabbros formed at about 3.3 Ga, similar to ages for the Dugel gneiss. Northwest of Mount Dugel, the anorthosites formed at about 3.5 Ga; this age is similar to tonalitic to monzogranitic protoliths of the Eurada gneiss, emplaced at 3.49–3.44 Ga [5].

The correspondence of ages of anorthosites and monzogranites in the Narryer Gneiss Terrane suggests that these rocks may represent a previously unrecognized, but distinctive magmatic association of the Archean.

Most recent developments in AMS technologies

H.-A. SYNAL, T. SCHULZE-KÖNIG, M. SEILER, M. SUTER, CH. VOCKENHUBER AND L. WACKER

Laboratory of Ion Beam Physics, ETH Zurich, Schafmattstr. 20, 8093 Zurich, Switzerland (synal@phys.ethz.ch)

In charge state 1+, molecular interferences can be efficiently suppressed in multiple collisions of ions with stripper gas atoms or molecules. This made a new class of AMS spectrometers possible using compact acceleration systems at terminal voltages of about 500 kV. At ETH an even more compact spectrometer was developed using a vacuum insulated high voltage platform operated at 200 kV (MICADAS). Such systems can be regarded as state-of-the-art, matching the requirements of high performance radiocarbon dating.

Recent investigations performed at ETH to explore the basic principle behind the detection technique in particular of radiocarbon at even lower energies has opened novel opportunities to further reduce size and complexity of radiocarbon detection systems. Here, the use of He as a stripper is the key to minimize energy and angular straggling in connection with charge exchange and molecule dissociation processes. Dissociation cross section of mass 14 molecules in He gas have been found to be fairly constant at energies between 40 and 100 keV and are sufficiently large to reduce the intensity of molecular beams extracted from a graphite target by 10-11 orders of magnitude. Another important fact is the high yield of charge state 1+ at energies as low as 45 keV where values of more than 75% have been observed.

In a proof-of-principle experiment, using ions at 45 keV as they are extracted from the source and a molecule dissociation unit kept at ground potential, the feasibility of radiocarbon dating measurements over the entire ^{14}C dating range have been demonstrated.

Apart form radiocarbon, He as stripper gas has also striking advantages for other radionuclides. In particular, the detection of actinides in charge state 3+ at stripping energies of about 300 keV will become possible at unparalleled efficiencies.

The role of volcano-plutonic complex for simulation of origin of rare-metal granites from Transbaikalia, Russia

L.F. SYRITSO (BADANINA)[1]*, V.S. ABUSHKEVICH[2], E.V. BADANINA[1] AND E.V. VOLKOVA[1]

[1]St. Petersburg State University, Department of Geochemistry, University emb. 7/9, St.-Petersburg, 199034, Russia (*correspondence: Liudmila_Syritso@mail.ru)
[2]Institut of Geology of Precambrian RAS, St. Petersburg

The composition of rocks, melts (on the basis of melt inclusions study), isotopic-geochemical and geochronological characteristics (Rb-Sr and Sm-Nd isotopic systems) of rare-metal granites and accompanying sub-volcanic rocks in the ore clusters of Transbaikalia (Orlovka, Etyka, Shumilovka Li-F granites – Ta deposits, Scherlovaya Gora granites, greisen and rhyolite – Sn-W deposit, Bukuka – vein-greisen W deposit) were studied [1-3]. Close age interval of its formation, a similarity of geochemical specialization, crustal isotope-geochemical characteristics with signs of depleted of finite terms of series of differentiation allow us to consider the association of acid rock as a co-genetic volcanic-plutonic complexes. [4]. Dedicated rock types - ongonites, rhyolites, ongorhyolites, trachyrhyodacites – differentiates by the P-T regimes of crystallization, by the specialization of volatile, by the concentration levels of trace elements in the melts, by the isotopic and geochemical characteristics. These indicators reflect the levels of origin of melts, their degree of differentiation and extent of mantle-crust interaction. Ascertained shift of the isotopic compositions of late members of the series of differentiates toward depleted is reflected in a reduction of IR_{Sr} and, on the contrary, increasing of $^{147}Sm/^{144}Nd$ and values of ε_{Nd} (T), and occurs simultaneously with the accumulation of trace elements. Such situation may be explained by additional juvenile (depleted) component in the form of fluid phase with mantle characteristics produced by plume processes of Northeast Asian hot mantle field [5].

Kinetics of Fe-isotope exchange with pyrite at hydrothermal conditions

DREW D. SYVERSON[1], W.C. SHANKS, III[2] AND W.E. SEYFRIED JR.[1]

[1]Department of Geology and Geophysics, University of Minnesota, Minneapolis, MN 55414 (syve0063@umn.edu, wes@umn.edu)
[2]U.S. Geological Survey, 973 Denver Federal Cent, Denver, CO 80225 (pshanks@usgs.gov)

The lack of data for the rates of Fe mass transfer between hydrothermal fluids and Fe-bearing minerals presents a challenge to the interpretation of subseafloor alteration processes at mid-ocean ridges (MORs). Field studies have relied on observations made from experiments performed at ambient conditions and also equilibrium theoretical models to understand the processes and mechanisms of sulfide precipitation/recrystallization [1-3]. Quantification of rates of isotopic exchange will add constraints to the chemical and isotopic evolution of hydrothermal vent fluids and minerals.

The rate of Fe-isotopic exchange between pyrite and hydrothermal fluid ($FeCl_{2\,(aq)}$) was examined at 350C, 500 bars using an isotopically enriched ^{57}Fe tracer at pyrite saturation equilibrium. The experimental design took advantage of liquid sulfur hydrolysis to buffer redox and pH, ensuring that pyrite is the only Fe-bearing mineral in the system exchanging with the hydrothermal fluid. The degree of Fe-isotopic exchange between $FeCl_{2\,(aq)}$-pyrite rapidly approached ~100% within days ($2.14*10^{-6}$ mmol/s). The low pH (in situ) and conditions of high dissolved sulfur may facilitate isotope exchange, as has been reported for sulfur isotope systematics [4] at similar chemical and physical conditions.

Speciation of the measured concentrations of dissolved ΣCl, H_2S, H_2, ΣFe^{++}, ΣSO_4^{--} and pH indicate that the fluid is saturated with respect to pyrite. Moreover, measured dissolved H_2 is in excellent agreement with that predicted from phase equilibria calculations, confirming that full equilibrium was achieved. The reaction quotient for $S^0 + H_2 \Leftrightarrow H_2S$ equilibrium was also determined ($\log K_{eq} \sim 4.1$).

The rapid rate of isotopic exchange between pyrite and fluid at acidic, high temperature systems, such as back-arc basins, implies that sulfide minerals may record the effects of short term temporal isotopic/chemical perturbations.

Effects of prolonged volcanic activity of the Paraná continental flood basalts on the paleogeography, salt geochemistry and presalt oil resources of the South Atlantic rift

PETER SZATMARI

Petrobras Rio de Janeiro Brazil

The recent discovery and intense exploration of giant oil deposits in Early Cretaceous presalt sediments of the South Atlantic rift offshore Brazil (Santos, Campos and Espírito Santo Basins), adjacent to the Paraná Continental Flood Basalt province, has thrown a new light on the complex interaction between continental flood basalts, rift evolution, and rift lake chemistry. Rifting started in the uppermost Jurassic to lowermost Cretaceous with the deposition of fluvial, fresh water lacustrine and then saline lacustrine terrigenous sediments. The continental Paraná flood basalts were dated onshore at 134.6±0.6 Ma (Thiede and Vasconcellos, 2010, *Geology*), possibly related to the Valanginian Weissert Oceanic Anoxic Event. Offshore, basalt volcanism in the rift continued intermittently to 115 Ma, intercalating with presalt sediments. The flood basalts, associated with dikes, sills, and thermal uplift, blocked the entrance of sea water from the south into the southward widening rift. The main source of sediments changed from Proterozoic granites and Paleozoic sandstones to basalts. Farther out into the rift lake, terrigenous sediments gave place to the deposition of thick lacustrine limestones, dolomites, and Mg-silicates from solutions rich in Ca, Mg and silica supplied by the eroding basalts. In latest Aptian time, the entry and repeated desiccation of sea water under an arid climate led to the deposition of stratified salt, several km thick. Ca- and Mg-rich solutions from the eroding basalts, interacting with basin brines, caused the halite to be interlayered with the Ca-Mg chloride tachyhydrite. The subsequent leaching of the carbonates by CO_2 degassing from the basalts was essential to create the high-permeability oil reservoirs sealed by salt.

Mesoarchaean suprasubduction zone ophiolite in the Tartoq Group, SW Greenland

KRISTOFFER SZILAS[1], VINCENT J. VAN HINSBERG[2] AND ALEXANDER F.M. KISTERS[3]

[1]Geological Survey of Denmark and Greenland, Øster Voldgade 10, 1350 Copenhagen, Denmark (ksz@geus.dk)
[2]University of Oxford, South Parks Road, Oxford, UK
[3]Stellenbosch University, Matieland 7602, South Africa

The Tartoq Group comprises supracrustal rocks of dominantly volcanic origin in several discrete fault-bounded blocks. The main lithological units include: pillow lavas, dykes, gabbros, and serpentinites. Peak metamorphic conditions range from greenschist facies to upper amphibolite and lower granulite facies.

LA-ICP-MS U/Pb zircon age dating of an orthogneiss sheet that was intrusive into the supracrustal rocks yield a minimum age of 2.996 ± 0.006 Ga for the Tartoq Group.

The mafic metavolcanic rocks are dominated by tholeiitic basaltic compositions (MgO = 6-10 wt.% and FeO^T = 12-14 wt.%). They possess negative primitive mantle-normalised Nb-anomalies (Nb_N/La_N = 0.5-0.8). Pillow lavas, dykes and gabbros have similar flat chondrite-normalised REE patterns (La_N/Sm_N = 0.8-1.0), which together with serpentinite cumulate/mantle, indicate that they form a co-magmatic assemblage resembling that of an ophiolitic ocean floor sequence. La, Y, and Nb values are similar to those of modern back-arc basalts and Th/Yb vs. Nb/Yb also indicates a subduction zone component in the source of the volcanic sequence. The serpentinites have SCLM-like PGE patterns.

The structural relations combined with geochemical, and metamorphic data suggest that the Tartoq Group is a slab of Mesoarchaean suprasubduction zone oceanic crust, which after shallow subduction, was emplaced in an exhumation wedge, retrogressed by fluid input, imbricated with marginal orthogneisses, and folded and thrust into several tectonic slices and slabs with the orthogneisses.

Arsenic speciation and sequential extraction studies

T. SZOCS AND A. BARTHA

Geological Institute of Hungary, Stefánia út 14., 1143 Budapest, Hungary (szocst@mafi.hu, bartha@mafi.hu)

Shallow groundwater speciation studies were carried out using a field separation method in two regions of Hungary. Sequential extractions using the Tessier *et al*. [1] method was applied to evaluate the arsenic content distribution in each fractions. The speciation studies showed a redox environment which can promote remobilization under reductive conditions at almost each site. The sequential extractions revealed that a relatively high proportion of the arsenic could be found in the very stable residual fraction, which was also detected in other regions and by other methods (Routh and Hjelmquist [2]). At these sites the arsenic content of the groundwater was lower than at sites where the arsenic is in the more easily leachable form.

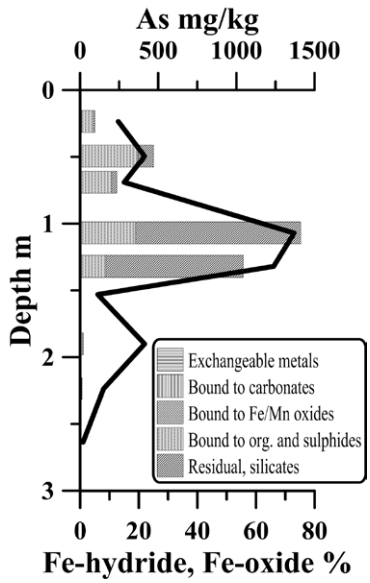

Figure 1: Distribution of arsenic in the extracted fractions versus depth**.**

This study was financed by Hungarian National Research Fund grant K67967.

New Method for the Disposal of Excavated Rocks Containing Arsenic

We have developed the adsorption-layer system as a simple and effective disposal method for disposing excavated rocks containing toxic elements like arsenic (As). This system is composed of a bottom adsorption layer and a low-permeability soil cover that incase the altered rock. The low-permeability soil cover lowers the water infiltration rate while the adsorption layer scavenges As leached out from the rock.

Discussion of Results

The altered rock sample used in this study was collected from a tunnel project in Hokkaido, Japan, and is composed of silicate minerals (*e.g.* quartz and plagioclase), calcite (minor mineral) and pyrite (trace mineral). Sequential extraction showed that the rock was capable of releasing as much as 18.4 mg of As per kg of altered rock. Based on these results, we conservatively estimated the amounts of natural and artificial adsorbents required to capture all of the leachable As content of the rock and tested these calculations through column experiments. All four adsorbents when used in the bottom adsorption layer effectively lowered the As released from 185 μg/L to below the drinking water standard of 10 μg/L (Figure 1). These results indicate that the adsorption-layer system is an effective countermeasure for the disposal of excavated rocks enriched in As.

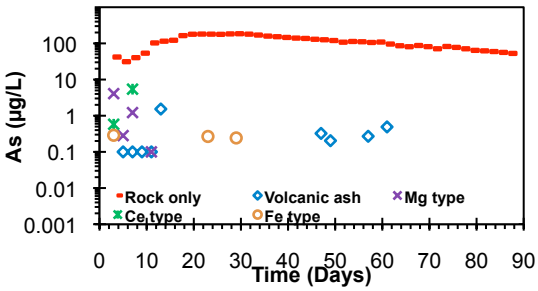

Figure 1: Evolution of As concentration in the effluent with and without adsorption layer. Missing points denotes concentrations below the detection limit of ICP-AES+Hydride generation.

Towards past climate reconstruction of speleothems by atmospheric sampling LA-ICPMS

D. TABERSKY[1], I. DE MADDALENA[1], M.B. FRICKER[1], R. DIETIKER[1], D. FLEITMANN[2] AND D. GÜNTHER[1]*

[2]University of Bern, Institute of Geological Sciences and Oeschger Centre for Climate Change Research

Trace elemental distributions in paleoclimatic archives such as stalagmites represent a precious source of information on past climate variability. Analytical procedures play a pivotal role in the assessment of monthly to sub-annual trace metal variations in these paleoclimate archives [1]. The analysis of stalagmite samples requires a method that allows for the quantification of major and minor trace elements in high spatial resolution. This demand can be addressed by laser ablation combined with detection by inorganic mass-spectrometry.

Classically, airtight ablation cells are utilized for laser ablation strategies. Following the tradition of sealed cell designs, a *low dispersion high capacity laser ablation cell* was developed [2]. However, even such a cell is restricted to samples less than 25 cm in length and therefore, it cannot host the majority of stalagmite samples without modification. Large samples have to be broken or cut into smaller pieces, which unfortunately leads to the destruction of many years of valuable information. Atmospheric sampling rudiments enabled by recent developments [3] and/or quasi-closed cell designs [4] promise to overcome this limitation and provide full-scale climatic records.

This study investigated potential sample inlet systems by computer modeling of gas flow characteristics of new sample-transportation device geometries. Based on the results of computational flow dynamics, prototype inlet systems were built and characterized. Results are compared to those obtained by large closed cell approaches. Further, the newly developed method was applied to investigate seasonal trace element variations in a stalagmite sampled from Sofular Cave in northwestern Turkey.

FT-ICR/MS and quantum chemical studies of aqueous polyoxometalates

M.A. TACZKOWSKA[1], K.H. LEMKE[1]*, S.A. SADJADI[1] AND T.M. SEWARD[2]

[1]Department of Earth Sciences, University of Hong Kong, Pokfulam Road, Hong Kong, SAR (*correspondence: kono@hku.hk)

[2]SGEES, Victoria University of Wellington, Wellington, New Zealand

Mass spectrometric and quantum chemical studies of aqueous oxometalates, for instance, polyoxotungstate and polyoxomolybdate clusters, provide a suitable means of delivering molecular-scale information on the speciation, distribution and abundance of such moieties in crustal fluids. This study presents Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometric data pertaining to the stability of polyoxomolybdate and polyoxotungstate clusters as well as mixed polymolybdotungstate clusters. We also report theoretical geometries and energies of the above clusters using B3LYP/aug-cc-pVDZ level theory in combination with SDD ECPs for W and Mo. Ion cluster experiments have been conducted on a Bruker 7T FT-ICR mass spectrometer with electrospray ionization capability. The mass spectrometer has also been modified to include a leak valve system used to introduce solvents and conduct solvation studies of ion clusters. Ion clusters generated from electrosprayed aqueous solutions containing Na_2MoO_4 and Na_2WO_4 salts (1-50mM) include the polyoxomolybdates $[Na_{2m+1}Mo_mO_{4m}]^+$ ($m \leq 11$), polyoxotungstates $[Na_{2n+1}W_nO_{4n}]^+$ ($n \leq 20$), and the mixed polymolybdotungstates $[Na_{2\,(m+n)+1}Mo_mW_nO_{4\,(m+n)}]^+$ ($m+n \leq 5$) (see below). We also identified several gas-phase polyoxometalates with magic numbers (abundance anomalies) as well as pure and mixed doubly- and triply-charged polyoxometalate clusters. Thermodynamic data obtained for the stepwise solvation of individual polyoxometalate clusters with H_2O will be presented and compared with hydration energies obtained from quantum chemical calculations.

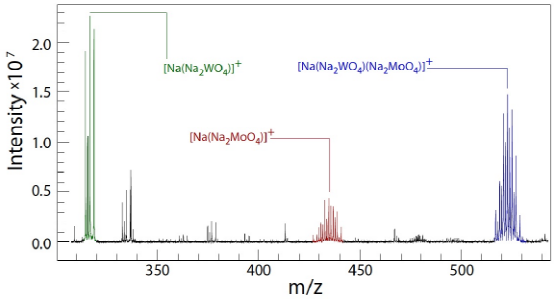

Figure 1: Positive-ion ESI-MS of aqueous Na_2MoO_4/Na_2WO_4 solution.

Mineralogy of the sodic-calcic hydrothermal alteration host rocks of the Esfordi, Choghart and Chadormalu magnetite-flourapatite deposits, Bafq area, Central Iran

S. TAGHIPOUR[1], A. KANANIAN[2] AND J. DONOVAN[3]

[1]School of Geology, College of science, University of Tehran, Tehran, Iran (taghipour@khayam.ut.ac.ir)

[2]School of Geology, College of science, University of Tehran, Tehran, Iran (taghipour@khayam.ut.ac.ir)

[3]CAMCOR, University of Oregon, Eugene, Oregon, 97403, USA (donovan@uoregon.edu)

The Esfordi, Choghart and Chadormalu Ap-Mt deposits are located in the bafq area, Central Iran. Flourapatite is one of the most important mineral in the studied area. This mineral is formed in primary and secondary generations. On the basis of the EPMA analysis, flourapatite is characterized by high CaO (54-57), P_2O_5 (40-43) and minor amount Na_2O, SiO_2, F, Cl contents. Amphibole is the major mineral in the igneous rocks, sodic-calcic alteration and mineralization zones. This mineral has been found both phenochryst and needle inclusions in the apatite, magnetite, plagioclase and quartz minerals. The phenochryst of amphibole has altered to the brown biotite, chlorite and calcite. Chemically, two different amphiboles occur in the sodic-calcic alteration zone. The first type is edenite to ferro-edenite in the contact of igneous rocks, which has replaced by altered bodies. It has Na+K > 0.5 %, Mg# values 0.46 and highest Ti, AlVI values. The second type amphibole occurs in the sodic-calsic alteration zones and commonly replaced edenite with Na+K<0.50 and Mg# values of 0.67. The composition of them is between actinolite to magnesiohornblende. Also amphibole is a very important mineral in the mineralization zone. Chemically, it is actinolite to ferro-actinolite with average Mg# values of 0.57. On the basis of the palagioclase-amphibole geothermometer (Holland and Blundy 1994) this assemblage has formed in the 525-549° C and 1.2-1.7 kbar pressures, so evolution of the main hydrothermal process has occur in the shallow crust levels.

Normalized REE profiles in zircon, ancient or modern, have been used as an indicator of environmental conditions. In this regard, excursions from an otherwise smooth trend among the lanthanides (i.e. positive Ce anomalies and negative Eu anomalies) are thought to be related to changes in valence ratios in response to the intrinsic oxygen fugacity of the system in which the host zircon crystallized. REE partitioning systematics and the magnitude of anomalies are generally not considered in conjunction with direct measurement of valence ratios of Ce or Eu within zircon, which requires very specialized instrumental capability.

We present Ce L_{III}-edge and Eu L_{III}-edge XANES spectra from ancient Jack Hills and Acasta Gneiss zircon grains. These analyses represent the first attempt to directly constrain valence in ancient grains, where trace element concentrations can be as low as 2 ppm for Eu and 7 ppm for Ce. Jack Hills grains studied here (4.0-4.1 Ga), show distinct positive Ce anomalies but indicate only minimal Ce^{4+} in XANES (<20%). Zircon grains from the Acasta Gneiss (3.6-3.9 Ga), by contrast, show domains with variable Ce^{4+} content (40-100%). The variable valence ratios of the two populations, by virtue of not being dominated by a single species, suggests that no dominant process resets valence over geological timescales and that considerable information may be obtained from a combined study of REE profiles and associated valence speciation in zircon.

Intracrystal microstructures in alkali feldspars from apparently fluid deficient felsic granulites: A chemical and TEM study

L. TAJCMANOVA[1], R. ABART[2], R. WIRTH[3], G. HABLER[2], LUIZ F.G. MORALES[3] AND D. RHEDE[3]

Samples of apparently ‘dry’ high-pressure felsic granulites from the Bohemian Massif (Variscan belt of Central Europe) contain large perthites with several generations of exsolution features. The contacts between the orthoclase-rich host and the plagioclase precipitates of the first generation and the contact between the orthoclase-rich host and large kyanite, quartz and garnet inclusions is lined with a thin rim of albite This albite was formed at a late stage of the petrogenetic history related to fluid infiltration and associated albitization. In the vicinity of the large inclusions the plagioclase precipitates of the first perthtite generation become significantly depleted and the perthite microstructure coarsens composed dominantly of tweed orthoclase.

The primary exsolutions probably formed by spinodal decomposition at around 850-900°C during the high pressure stage (16-18 kbar). The second generation of albite-rich precipitates was formed at around 600-500°C. TEM investigations revealed that the interfaces between the second generation plagioclase lamellae and the orthoclase rich host are coherent or semi coherent. The formation of albite linings at phase boundaries and of patch perthite produced incoherent interfaces. The patch perthites, albitization and secondary coarsening in the vicinity of large inclusions developed below 400°C contemporaneously with fluid infiltration in the course of deuteric alteration.

Constraining the P-T conditions of melting in stromatic migmatites from Ronda (S. Spain)

L. TAJCMANOVA[1], O. BARTOLI[2], B. CESARE[3]* AND A. ACOSTA-VIGIL[4]

[1]IMP-ETHZ, Zurich, Switzerland
[2]Dipartimento di Scienze della Terra, Univ. Parma, Italy
[3]Dipartimento di Geoscienze, Univ. Padova, Italy
(*correspondence: bernardo.cesare@unipd.it)
[4]IACT, CSIC, Granada, Spain

We have studied fine-grained stromatic metatexites occurring c. 400 m below the contact with the Ronda peridotite (Ojén unit, Betic Cordillera, SE Spain). These rocks contain Qtz + Pl + Kfs + Bt + Fib + Grt + Ms + Ap + Gr ± Ilm and have a main foliation defined by alternating layers of biotite and fibrolite and thin (~ 0.5 cm) leucosomes. Garnet occurs in very low modal amount (<1%). Muscovite is an armored inclusion or texturally retrograde.

Microstructural evidence of melting in the migmatites includes *pseudomorphs* after melt films, euhedral feldspars, and *nanogranite* inclusions in garnet. Remelted nanogranites show granitic compositions. The latter microstructure demonstrates that garnet crystallized in the presence of melt.

We have constructed two pseudosections: one for the bulk rock in the MnNCKFMASHT system, and the other for the composition of the remelted nanogranite inclusions in the NCKFMASH system. Calculated isopleths for chemical parameters of garnet (X_{Mg}, X_{Grs}), biotite (X_{Mg}, X_{Ti}) and plagioclase (An content) in the Qtz-Pl-Kfs-Bt-Grt-Sil-melt field match the actual values in the rock. The *P-T* conditions of equilibration were estimated at 4.5-4.8 kbar, 680-700 °C. These *P-T* conditions overlap with the low-T tip of the melt field in the pseudosection for the nanogranite composition. They are also consistent with the complete experimental remelting of nanogranites at 700°C.

These results indicate that nanogranites represent the anatectic melt generated at, or soon after, muscovite melting, and that garnet is able to trap melt inclusions also at temperatures lower than those of biotite breakdown melting.

Projection of future climate change by aerosols along the Representative Concentration Pathways (RCPs) with a global climate model

TOSHIHIKO TAKEMURA

Research Institute for Applied Mechanics, Kyushu University, 6-1 Kasuga-koen, Kasuga, Fukuoka 816-8580, Japan (toshi@riam.kyushu-u.ac.jp)

Projection of climate change in the 21st century due to aerosols is simulated by an aerosol global climate model, SPRINTARS [1-4], along the emission scenarios of the Representative Concentration Pathways (RCPs) in this study. SPRINTARS is coupled to an atmosphere-ocean general circulation model, MIROC, developed by the Atmosphere and Ocean Research Institute (AORI)/University of Tokyo, National Institute for Environmental Studies (NIES), and Japan Agency for Marine-Earth Science and Technology (JAMSTEC) [5]. It includes the radiation, cloud, and precipitation processes related with the aerosol direct, semi-direct, and indirect effeects of main tropospheric aerosols (black carbon (BC), organic matter, sulfate, soil dust, and sea salt) as well as the transport processes. The model treats not only the aerosol mass mixing ratios but also the number and mass concentrations of cloud droplets and ice crystals as prognostic variables. All RCPs' scenarios (RCP2.6, RCP4.5, RCP6.0, and RCP8.5) which are used in climate simulations for the Fifth Assessment Report of the Intergovenmental Panel on Climate Change (IPCC AR5) are applied in this study. Sulfate aerosols, which have the negative direct radiative forcing and a role of cloud condensation nuclei, are gradually decreasing almost over the globe, on the other hand, BC aerosols, which have the positive direct radiative forcing and a role of ice nuclei, are still increasing. Therefore the total aerosol effects on the climate system may be largely different between 20th and 21st centuries.

We would like to thank the contributors of development of SPRINTARS and MIROC. This study is partly supported by the Funding Program for Next Generation World-Leading Researchers in Japan.

Where life meets rocks: Understanding P cycling during the early phases of soil formation

F. TAMBURINI[1]*, S.M. BERNASCONI[2], V. PFAHLER[1], E. BÜNEMANN[1] AND E. FROSSARD[1]

[1]Group of Plant Nutrition, Inst. of Agricultural Sciences, ETH Zürich, Eschikon 33, 8315 Lindau, Switzerland (*correspondence: federica.tamburini@ipw.agrl.ethz.ch)
[2]Geological Institute, ETH Zürich, Sonneggstrasse 5, 8092 Zürich, Switzerland (stefano.bernasconi@erdw.ethz.ch)

Deglaciated forefields are natural environmental laboratories where the interactions betweeen life and the inorganic realm can be investigated. The forefield of the Damma glacier, located in the Swiss Alps, has been extensively studied in the framework of a multidisciplinary project (BigLink) aiming at a better understanding of the initial phases of soil formation and development. A key aspect is to determine how nutrient availability changes along the chronosequence and which are the processes driving these changes. While the influence of soil development on the distribution of phosphorus (P) forms in soil is known, still little information is available on the rates and relative importance of the processes driving these changes. Here, we present data on the stable isotopic signature of oxygen bound to P in phosphate (δ^{18}O-P) extracted from soils (between 12 and 300 years old) and plants sampled along the chronosequence.

We performed a sequential extraction of P from soils of different age including a resin extraction (plant available P), an hexanol extraction (microbial P) and an HCl extraction (as a proxy for mineral P). We also extracted P from monocotylendon grasses. All P pools were then analyzed for their δ^{18}O-P. We also measured δ^{18}O in water from soils and plants, and soil phosphatase. The mineral pool bears the signature of igneous material and shows no significant change along the sequence. The isotopic signatures of the plant available and microbial P pools are more variable and already at the very first site, they show a significant deviation from the parent material, being close to temperature-dependent equilibrium with water. Phosphorus extracted from grasses shows even heavier values and reflect equilibration with leaf water.

Phosphate from plant residue and, to a lesser extent, organic matter mineralization contribute to the plant available P pool. But overall, our data suggest P is rapidly cycled in the soil by the microbial community, starting very early in the soil development.

Sources and cycling of nitrogen in the Gulf of Trieste (N. Adriatic Sea)

S. TAMŠE[1]*, P. MOZETIČ[2] AND N. OGRINC[1]

[1]Jožef Stefan Institute, Jamova 39, 1000 Ljubljana, Slovenia (*correspondence: samo.tamse@ijs.si)
[2]Marine Biological Station Piran, National Institute of Biology, Fornače 41, 6330 Piran, Slovenia

The sources of nitrate were determined using the stable isotope approach in the Slovenian part of the Gulf of Trieste and its main river tributaries Rižana and Dragonja. The sampling was performed in May, August and November 2010. At both river mouths impacts on the nitrogen cycle from municipal sewage or agriculture were observed through elevated nitrate concentrations and $\delta^{15}N_{NO3}$ values. This was most probably due to leaching of organic fertilizers from agricultural land and was more pronounced in August in Rižana and in November in Dragonja. Mixing along the salinity gradient was the main control on the spatial variations in isotopic composition of nitrate in the investigated part of the Gulf of Trieste. The relation between the isotopic composition of nitrate and its concentration showed that nitrate at most marine sampling locations was the result of mixing between its marine and terrestrial origins. In May, a strong terrestrial influence of river Rižana was observed at locations 'K 0 m' and 'ERI2 0.3 m' (Bay of Koper) with more negative $\delta^{13}C_{POC}$ values. The impact of nitrification was observed in November at all sampling locations at depths from 10 – 20 m. The correlations between $\delta^{15}N_{PN}$ and NO_3^- concentration indicated that NO_3^- assimilation was a major source of N in particulate organic matter (POM) in all sampling months. The low values of fractionation factors ε (0.4‰, 1.1‰ and 1.4‰), compared to other studies, were probably the consequence of different phytoplankton species and different growth conditions. The carbon isotopic mass balance calculation of POM revealed high contributions of allochthonous OM from freshwater inflows in May. The proportion of allochthonous vs. autochthonous OM decreased with depth. On the other hand the POM in August and November was mainly of autochthonous origin. In November a higher contribution of allochthonous OM was observed only at the surface.

COB and POB

We found near-primitive and phenocryst-poor lavas from NW Rota-1 volcano in the Mariana arc. These magnesian basalts are petrographically distinct cpx-olivine basalt (COB) and plagioclase-olivine basalt (POB). Fo content of olivines and Cr# of spinels are higher in COB than in POB. Moreover, COB is lower in Zr/Y and Nb/Yb and TiO_2, Al_2O_3, Na_2O, P_2O_5, Nb, Ta, Zr, Hf, HREE and Y than POB both at MgO = 8 wt. % and at estimated primary magmas, suggesting that COBs formed from higher degrees of mantle melting. COB has Ba/Nb, Th/Nb, $^{87}Sr/^{86}Sr$, $^{208}Pb/^{206}Pb$ and $^{207}Pb/^{206}Pb$ that are higher than for POB, and also have steeper light REE-enriched patterns and lower $^{143}Nd/^{144}Nd$, indicating that COB has a greater subduction component than POB. $^{176}Hf/^{177}Hf$ values between COB and POB are the same and Hf behavior in COB and POB is similar to those of Zr, Y and HREE, suggesting that Hf is not included in the subduction component, which produced the differences between COB and POB.

Mantle Diapir or mantle wedge plume

These estimated subduction components suggest flush melting of subducting sediment of the uppermost part of the slab at the temperature between phengite-out and monazite-out temperature (~900 °C) and rutile-out and garnet-out (~1000 °C) [1]. We suggest that high temperature at the base of mantle wedge (>1000 °C) combined with slab-derived metasomatic agents (hydrous sediment addition) ultimately lead to enough partial melting and buoyancy to initiate diapiric ascent. Degrees of mantle melting of primitive COB and POB are ~24 % and 18 %, respectively. Diapiric ascent of hydrous peridotite mixed heterogeneously with sediment melts may be responsible for the NW Rota-1 basalts.

General depositional features of the carbonate platform gas reservoir of the Lower Triassic Jialingjiang Formation in the Sichuan Basin of Southwest China: Moxi gas field of the central basin

XIUCHENG TAN[1,2]*, LING LI[2], HONG LIU[2], BING LUO[2], YAN ZHOU[2], JIAJIE WU[2] AND XIONG DING[1,2]

[1]State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation. Southwest Petroleum University, Chengdu, Sichuan 610500, China (*correspondence: tanxiucheng70@163.com)
[2]School of Resource and Environment, Southwest Petroleum University, Chengdu, Sichuan 610500, China

The general depositional features of the carbonate platform gas reservoir of the Lower Triassic Jialingjiang Formation in the Sichuan Basin of southwestern China were addressed based on a case study of the representative second member of the Formation (termed as Jia 2) in the Moxi gas field of the central basin. The features mainly include depositional setting, lithology, depositional structure, depositional sequence and reservoir space. These results lead to a conclusion that the Jialingjiang reservoir (the second member in particular) is not of a tidal flat deposition in an intertidal (to supratidal) environment as previously suggested but of restricted and evaporative carbonate platform deposition in a subtidal environment. The tidal-flat like (i.e. platform flat) facies occur only in the Jia 2^2-B layer. Moreover, the restricted-evaporative carbonate platform facies can be divided into 5 sub-facies and 23 micro-facies, of which the facies of grain shoal and dolomitic flat are relatively favorable for reservoir development. Their depositional model, distribution and evolution were further tentatively suggested, as the facies are subject to paleo-tomography and sea level variations. These results provide supplement to the present hot studies of the Permian-Triassic gas reservoir geology in China, as the Jialingjiang Formation has been investigated much less in comparison with the underlying Lower Triassic Feixianguan and Upper Permian Changxing formations.

Specific sorption of Th(IV), Np(V) and U(VI) on biogenic Mn oxide

K. TANAKA[1]*, Y. TANI[2] AND T. OHNUKI[3]

[1]Institute for Sustainable Sciences and Development, Hiroshima University, Higashi-Hiroshima, 739-8530 Japan (*correspondence: kt0830@hiroshima-u.ac.jp)
[2]Institute for Environmental Sciences, University of Shizuoka, Shizuoka 422-8526, Japan
[3]Advanced Science Research Center, Japan Atomic Energy Agency, Tokai 319-1195, Japan

Intoroduction

Sorption of radioactive elements on mineral surfaces is one of important processes which retard their migration in natural environments. Manganese(IV) oxide has attracted much attention because of its strong sorption property. Recently, it is accepted that the formation of Mn oxide is microbially mediated in most of Mn oxide deposits. Therefore, we investigated the sorption behavior of actinides on biogenic Mn oxide.

Methods

Sorption experiments of Th(IV), Np(V) and U(VI) on biogenic and synthetic Mn oxides were carried out in 10 mmol/L NaCl solution. We used *Acremonium* sp. strain KR21-2, a Mn-oxidizing fungus, to prepare biogenic Mn oxide [1]. Abitic Mn oxide (δ-MnO_2) was synthesized according to Villalobos *et al*. [2]. The biogenic or synthetic Mn oxide was put into 10 mmol/L NaCl solution. Then, stock solution containing ^{232}Th(IV), ^{237}Np(V) and ^{238}U(VI) was added to the NaCl solution. Solutions aftter sorption experiments were sampled by filtration with a 0.2 μm filter to measure actinide concentrations using an ICP-MS.

Results and Discussion

Sorption experiments showed that Th(IV) and U(VI) were strongly sorbed on synthetic Mn oxide. Neptunium(V) was also strongly sorbed on synthetic Mn oxide. In contrast, Np(V) was not sorbed on biogenic Mn oxide at all. Uranium(VI) was sorbed less on biogenic Mn oxide than on synthetic Mn oxide. Difference of the sorption behavior of Np(V) and U(VI) between biogenic and synthetic Mn oxides may be caused by the difference of their sorption properties. Sorption of Th(IV) on biogenic Mn oxide decreased with increasing pH. Thorium(IV) sorbed on biogenic Mn oxide was desorbed into solution phase with increasing time. This is possibly due to complexation of Th(IV) with organic ligands released from fungal cells.

Re-evaluation of the B isotopic fractionation between $B(OH)_3$ and $B(OH)_4^-$ using methods beyond harmonic level

MAO TANG, QI LIU AND YUN LIU*

State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (Liuyun@vip.gyig.ac.cn)

Since Hemming and Hanson (1992), B isotopic signature of carbonates has been used as a proxy to indicate the paleo-pH value of seawater and paleo-pCO_2 up to at least 13 Ma. This largely depends on the isotopic fractionation factor between B $(OH)_3$ and B $(OH)_4^-$ (e.g. Spivack *et al*. 1993; Sanyal *et al*. 1995; Palmer *et al*. 1998; Pearson and Palmer, 1999; Sanyal *et al*. 2000; Palmer and Pearson, 2003). However, the B isotope proxy was questioned recently for the unclear mechanisms of B incorporation into carbonates especially using NMR techniques (e.g. Klochko *et al*. 2009). Furthermore, the fractionation factor between B $(OH)_3$ and B $(OH)_4^-$ is not completely established. Kakihana and Kotaka (1977) suggested 1.019 at 25 °C, but subsequent theoretical studies suggested a larger value (e.g. Liu and Tossell, 2005; Zeebe, 2005; Rustad and Bylaska, 2007). Klochko *et al*. (2006) measured the fractionation factor between B $(OH)_3$ and B $(OH)_4^-$ using pH-shift method. Their new value is 1.0272 ± 0.0006 in seawater at 25 °C. Their pure water result contains much larger uncertainty (2 per mil at 25 °C and about 5 per mil at 40 °C). Rustad *et al*. (2010) investigated the fractionation factor in pure water through a series of computational quantum chemistry methods. They found DFT methods could not produce a fractionation factor close to the experimental value (1.031), and extrapolated MP2 results were also significantly different. Their results raised questions about the suitability of DFT methods to deal with B species in solution.

In this study, we use theoretical methods beyond harmonic approximations to study B isotope fractionation. Large anharmonic effects are found for some B-bearing compounds. This is the first study to show that B isotope fractionation is affected significantly by its anharmonicity. B isotope system hence becomes another which requires theoretical treatments beyond harmonic approximations. Unfortunately, all the previous studies including our previous work (Liu and Tossell, 2005) used Bigeleisen-Mayer equation which is purely based on harmonic approximations to deal with B isotope fractionation. Those previous results therefore need to be re-evaluated.

Separation of arsenate and phosphate for the measurement of the isotope composition of the oxygen in arsenate

X.TANG[1], Z. BERNER[1] AND S. NORRA[1,2]

[1]Institute of Mineralogy and Geochemistry, Karlsruhe Institute of Technology 76131, Germany
[2]Institute of Geography and Geoecology, Karlsruhe Institute of Technology, Karlsruhe 76131, Germany

The investigation of the isotopic composition of oxygen in As-oxyanions may offer some new insights into the development of arsenic enriched groundwaters [1]. A basic analytical requirement is, however, the quantitative separation of the various dissolved oxyanionic species which may coexist in the water. Among the several potentially interfering oxianions the separation of phosphate and arsenate appears to be a challenging task due to their very similar chemical behavior.

In this study, tests were carried out using the anion exchange resin Amberlite IRA-400. 250 mL of solution containing 15mg/L of phosphate and 1 mg/L of arsenate was mixed with 1 g of resin, and stirred with 500 rpm at 21°C for 2 hours. It was found that IRA-400 adsorbed both arsenate and phosphate to 99.9%. Subsequently, experiments were carried out to strip selectively arsenate and phosphate. Using 1 mol/L CH_3COOH, HCl and HNO_3 arsenate was desorbed to 66.3%, 91.1% and 95.8%, respectively, but in the same time also some phosphate went into solution (60.1%, 4.9% and 5.0%, respectively). At lower pH (2 mol/L HCl or 2 mol/L HNO_3) the concentration of phosphate in the leachate was below detection limit, and 99% of the arsenate was released from the resin.

Because for the isotope analysis arsenate is precipitated as Ag_3AsO_4, the presence of large amounts of Cl^- ions in solution is disadvantageous due to the coprecipitation of AgCl. Therefore, for isotopic work 2 mol/L HNO_3 appears to be an optimal desorption agent for the selective release of arsenate and phosphate from Amberlite IRA-400. After the desorption experiments the resin could be regenerated under alkaline conditions by using 1 mol/L NaOH.

Mineral CO_2 sequestration in mine waste rock: Column experiments

E.K. TANGWA[1*,2], I.F. WALDER[2] AND A. LUNDKVIST[3]

[1]Depart. of Geology, Univ. Tromso, 9037, Tromso, Norway (*correspondence: elvis.k.tangwa@uit.no)
[2]Kjeoy Research and Education Center, 8412 Vestbygd, Norway (ifwalder@kjeoy.no)
[3]LKAB, Kiruna Sweden, SE-98186 Kiruna

Basic silicates are the main source releasing Ca, Mg and possibly Fe for carbonate mineral formation. This paper presents the results from column experiments using two waste rocks: type 1 and type 2 from the Kiruna iron mine, Sweden. The main objective of the test is to understand reactions rates and conditions necessary to scale up these experiments.

Ten columns holding 5-6 kg of these waste rocks, including a column with actinolite rich material, have been running at ~18ºC, for 6-15 months, with water flow rates (0.3-2 ml/min). The columns are continously injected with 2-3 ml/min CO_2, except one control column. The two types of waste rocks have similar chemistry and mineral composition (plagioclase + actinolite + quartz + biotite + muscovite + calcite + pyrite ± aptite); however, type 2 waste rock has a significantly higher magnetite content. Water samples have been collected weekly for all columns and regularly analyzed for major cations and anions, alkalinity and pH.

The main sources of cations are actinolite and calcite. Calcium concentration is relatively high (250-100 mg/l), during the first months possibly due to calcite dissolution and later due to actinolite dissolution. Magnesium and iron is low and indicates secondary mineral formation. Type 2 waste rocks have a high neutralizing capacity, with pH slowly dropping from 8 to about 5.5-6. Element release rate for the control column (no CO_2) is 1-2 orders of magnitude less than the other columns, indicating that carbonic acid is a effective leaching agent. There is a moderate to strong positive correlation between Ca, Mg and K release rate and pH and HCO_3^-. Mass loading depends upon flow rate; however there is higher element concentrations in column with a lower flow rate. Up to 70% of the calcium has been removed within the first 14 months of leaching.

We developed an equilibrator inlet-proton transfer reaction-mass spectrometry (EI-PTR-MS) method for fast detection of volatile organic compounds (VOCs) including dimethyl sulfide (DMS) and isoprene dissolved in seawater. Dissolved VOCs extracted by bubbling pure nitrogen through the sample was continuously directed to the PTR-MS. DMS reached equilibrium with an overall response time of 1 min, and the detection limit was 50 pmol per Liter at 5-s integration [1]. The EI-PTR-MS instrument was deployed during a research cruise in the western North Pacific Ocean. Comparison of the EI-PTR-MS results with results obtained by means of membrane tube equilibrator-gas chromatography/mass spectrometry agreed reasonably well on average. EI-PTR-MS captured temporal variations of dissolved DMS and isoprene concentrations, including elevated peaks associated with patches of high biogenic activity. These results demonstrate that EI-PTR-MS was effective for highly time-resolved measurements of VOCs in the open ocean [2]. Further measurements will improve our understanding of the biogeochemical mechanisms of the production, consumption, and distribution of VOCs in the ocean surface.

Oxygen isotope geochemistry beneath paleofumaroles

D. TANNER*, J.A. MAVROGENES AND R.W. HENLEY

RSES, Australian National University, ACT 0200, Australia (*correspondence: dominique.tanner@anu.edu.au)

Little is known about the chemical processes operating beneath fumaroles. However recent detailed documentation of sulfosalt assemblages has shown that mineral deposits such as El Indio, Chile and Summitville, Colorado contain quenched sulfosalt melt assemblages. Thus, these deposits provide a snapshot into the fracture-controlled plumbing systems hundreds of metres beneath paleo-solfatara. Independent temperature estimates suggest deposition of quartz and sulfosalts at ~ 675°C. This study focuses on the oxygen isotopic composition of euhedral quartz crystals (~200 microns in diameter) grown within sulfide/sulfosalt melt.

In situ stable isotope microanalyses of quartz separates from sulfosalt assemblages were performed using the SHRIMP II at the Australian National University. Intricate zonation of aluminium concentration in quartz (~2 micron growth bands) was mapped using the electron microprobe, and then targeted using a 20 micron spot on SHRIMP II.

Preliminary results indicate that the $\delta^{18}O$ of quartz crystals from the El Indio and Summitville deposits exhibit a wide range in isotopic compositions (3.7‰-17.1‰) – with variation of up to 11‰ within an individual crystal.

We interpret the heavy oxygen which exceeds the values of the 'magmatic water box' to be evidence of kinetic fractionation during hydrous silica deposition and subsequent dehydration.

Rogue hafnium isotopes in Lac de Gras kimberlites, Canada: Ultradeep vs. shallow mantle processes

S. TAPPE[1]*, D.G. PEARSON[1], B.A. KJARSGAARD[2], G.M. NOWELL[3] AND D. DOWALL[3]

[1]Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada (*correspondence: tappe@ualberta.ca)
[2]Geological Survey of Canada, Ottawa, Canada
[3]Earth Sciences, Durham University, Durham, UK

The Hafnium isotope compositions of kimberlites and related rocks tend to fall significantly below the terrestrial Nd-Hf isotope array, which is primarily defined by the compositions of oceanic basalts. Previous models suggested that this peculiar feature may fingerprint isolated ancient oceanic crust within the kimberlite magma source region [1], invoking the mantle transition zone as a viable source location. Based on new Nd-Hf isotope data for Greenland kimberlites [2], it was recently argued that departure from the terrestrial array can be equally well explained by interaction between convective mantle-derived carbonate-rich melts and phlogopite-rich metasomes residing in lower reaches of cratonic lithosphere.

Here, we present an extensive geochemical and Sr-Nd-Hf isotope data set for fresh 75-to-45 Ma hypabyssal kimberlites from the Lac de Gras area, central Slave craton, Canada. Although the Lac de Gras kimberlites mineralogically resemble South African Group-I kimberlites, their Sr-Nd isotope compositions are transitional between kimberlites and orangeites. Epsilon Hf ranges between -15 and +5 at relatively restricted epsilon Nd (-5 to 0), and these isotope systematics define a near vertical array that is at an even wider angle to the terrestrial Nd-Hf isotope array than the South African kimberlites. Furthermore, in data closely filtered to eliminate the effects of crustal contamination, there are pronounced negative correlations between the $^{176}Hf/^{177}Hf$ ratios and proxies of phlogopite-rich metasomes such as K_2O and TiO_2, which suggests that, similar to the Greenland kimberlites, the Lac de Gras proto-kimberlite magmas aquired 'rogue' Hf isotope compositions through interaction with long-term enriched mantle lithosphere. Based on the observation that the 'steep' Lac de Gras kimberlite Nd-Hf isotope array runs towards the unradiogenic metasomatic G10 garnet compositions from the Slave lithospheric mantle, we speculate that rogue Hf isotope compositions of Lac de Gras kimberlites may be linked to ancient fluid metasomatism that also facilitated diamond growth within the Slave cratonic lithosphere.

Geochemical constraints on petrogenesis and geotectonic setting for Silurian basalts of the Prague Synform (Bohemian Massif)

Z. TASÁRYOVÁ[1,2]*, V. JANOUŠEK[1,2], J. FRÝDA[1,2], Š. MANDA[1,2], P. ŠTORCH[3] AND J. TRUBAČ[1,2]

[1]Faculty of Sciences, Charles University, Albertov 6, Praha 2, 128 43, Czech Republic (*correspondence: zuzana.tasaryova@geology.cz)
[2]Czech Geological Survey, Klárov 3, Praha 1, 118 21, Czech Republic
[3]Institute of Geology, Academy of Sciences, Rozvojová 269, Praha 6, 165 00, Czech Republic

Similar to the other peri-Gondwanan terranes, the Prague Synform preserves the evidence of intense basic volcanic activity during Silurian. Studied alkaline basaltic volcanism was controlled by deep-seated faults, both parallel and perpendicular to the longitudinal axis of the synform, providing ascent paths for mantle-derived magmas.

The basalts are characterized by steep REE patterns [1] (La_N/Yb_N~3.5–13.5; Gd_N/Yb_N~1.8–3.6) lacking Eu anomalies, high LILE abundances, low Zr/Nb ratios (5.4–12), positive Ti anomalies in NMORB-normalized spiderplots, $^{87}Sr/^{86}Sr_{425}$ of 0.7028–0.7046 and positive ε_{425} values (+6.9 to +4.3), i.e. characteristics transitional between EMORB and OIB. Correlations of Sr and Nd isotopic data with independent geochemical parameters (e.g. mg#, 1/Sr, 1/Nd, Zr/Nb) document a general contamination (AFC) trend during Silurian. Nevertheless, temporal shifts from evolved to more primitive basaltic compositions are obvious within individual fault-related volcanic centres.

These features require primary melt generation by a low degree of partial melting of a garnet peridotite. The incompatible element ratios suggest within-plate setting, transitional between that of OIB and CRB [2]. Temporal progression from evolved to more primitive basaltic compositions could be explained in terms of diminishing crustal contamination of mantle-derived magmas. Given the geochemical variation in basalts and the well documented existence of Neoproterozoic continental basement, the geotectonic setting for the Prague Synform in the Silurian time can be characterized by progressive attenuation and rifting of continental lithosphere due to asthenosphere upwelling.

This study was funded by Grant Agency of the Czech Republic (P210-10-235).

Elemental and isotopic composition of cultured scleractinian corals

I. TAUBNER[1]*, F. BÖHM[1], J. FIETZKE[1], A. EISENHAUER[1], D. GARBE-SCHÖNBERG[2] AND J.EREZ[3]

[1]Leibniz Institute of Marine Sciences, IFM-GEOMAR, Kiel, 24148, Germany (*correspondence: itaubner@ifm-geomar.de)
[2]Institute of Geosciences, Christian-Albrechts-Universität, Kiel, 24118, Germany
[3]Institute of Earth Sciences, The Hebrew University of Jerusalem, 91904, Israel

Scleractinian corals are known for strong vital effects with respect to stable isotope and trace element incorporation. Nevertheless, they have successfully been used as proxy recorders for a variety of environmental parameters, including pH and temperature. Understanding the processes inducing 'vital effects' is essential for a successful application of these proxies.

To investigate the effects of pH and temperature, a branching scleractinian coral of the genus *Pocillopora* was grown under controlled laboratory conditions in natural seawater at (i) a temperature range from 22 to 28°C at constant pH; and (ii) a pH range from 7.8 to 8.3 at constant temperature. Samples were analyzed for boron, oxygen, carbon, and calcium isotopes, as well as Sr/Ca and Mg/Ca ratios.

Covariation of coral Mg/Ca and Sr/Ca with ambient carbonate ion concentration and temperature was recently explained by Cohen *et al*. [1] and Gaetani *et al*. [2] with a Rayleigh distillation model where the efficiency of cation utilization in a calcifying fluid increases with $CaCO_3$ saturation and temperature. This model implicitly predicts a significant positive correlation of the skeletal calcium isotopic composition with seawater pH and temperature.

The Rayleigh model can quantitatively explain the relatively high Ca isotope ratio observed in coral aragonite. However, no significant change in Ca isotope ratios was observed, neither with temperature nor pH. While Mg/Ca ratios increase with temperature as expected with the Rayleigh model, they show only 10% of the predicted Mg/Ca variations for the investigated pH range. Furthermore Sr/Ca showed no change with pH whereas Sr/Ca vs. temperature displayed a steeper slope than expected for inorganic aragonite precipitation [3]. Consequently, our data suggest that simple application of the Rayleigh model cannot explain the proxies incorporated to our cultured corals.

Characteristics of arsenic distribution in the Holocene sediment deposits of South-Western Bangladesh

M. TAUHID-UR-RAHMAN[1], A. MANO[1], K. UDO[1], Y. ISHIBASHI[2] AND Y.H. HAN[2]

[1]DCRC, Tohoku University, Japan, (liton2005@gmail.com)
[2]Dept. of CEE, Tajago University, Japan

The geochemistry of aquifer sediments coupled with the groundwaters of Kalaroa, south-western Bangladesh was studied with the object of elucidating As distribution to investigate its sorption and mobility. The role of the channel slope and sediment diameter on the sediment depositional process has been revealed evidently by the observations obtained from the borehole lithology. Results showed that trapped As on sediment matrix could be a function of the sediment diameter, its surface area and relative radio-carbon age. These observations were corroborated significantly with the findings obtained from laboratory leaching and adsorption tests. It was found that the brown clay which has the smallest particle diameter could adsorb as much as 98% of As from the contaminated groundwater (500 μg/L) while relatively lower As (74%) was captured by the medium grained particles having relatively larger diameters and smaller areas. Based on the adsorption capability, the sediment types may be ranked such as; brown clay > black clay > very fine sand > fine sand >medium sand. Presence of As was also observed to be greatly dependent on the availability of its (As) carrier minerals particularly Fe and Al oxides along the aquifer depth. The two younger sediment types such as brown clay and very fine sand were observed as the main sources in releasing the As into the groundwater, as they have contained organic carbon that may be sufficient enough to get decomposed under the microbial activities. The positive correlations that were obtained for As with Fe, Al, HCO_3, and DOC from the groundwater analysis strongly support such As release mechanism.

Late Paleocene sea surface cooling in Southeast New Zealand

K.W.R. TAYLOR[1]*, C.J. HOLLIS[2], L. HANDLEY[1,3], H.E.G. MORGANS[2], E.M. CROUCH[2], S. SCHOUTEN[3] AND R.D. PANCOST[1]

[1]Organic Geochemistry Unit, School of Chemistry, University of Bristol, Cantock's Close, BS8 1TS, UK (*correspondence: kyle.taylor@bris.ac.uk, luke.handley@gmail.com, r.d.pancost@bris.ac.uk)

[2]Geological and Nuclear Sciences, P.O Box30-368, Lower Hutt, NZ (c.hollis@gns.cri.nz, h.morgans@gns.cri.nz, e.crouch@gns.cri.nz)

[3]Department of Marine Biogeochemistry and Toxicology, Royal Netherlands Institute for Sea Research, P.O. Box 59, 1790 AB Den Burg, Texel, Netherlands (stefan.schouten@nioz.nl)

A particularly intriguing aspect of the Paleocene is the apparent dramatic enrichment of ^{13}C in the carbon isotopic composition of the ocean-atmosphere reservoir at c. 60-57 Ma, which is associated with isotopic evidence for cooling [1]. Increases in organic content and siliceous microfossil abundance offshore New Zealand suggest an associated increase in oceanic productivity [2]. However, it is uncertain if these signals are a local response to global cooling or are due to other factors, such as regional oceanographic changes or sea level changes. To address this uncertainty, we have developed sea surface temperature records (SST) to evaluate the magnitude of cooling across a range of sites, with particular focus in the southwest Pacific region.

Here we construct SSTs from mid-Waipara River, NZ (c. 55°S) and the eastern margin of the Campbell Plateau (ODP site 1121, 62°S) across the Paleocene using TEX_{86}. We find a general cooling trend of c. 3°C correlated to the onset of the Paleocene Carbon Isotope Maximum (PCIM) from 60.5 to 58 Ma. A similar trend is also apparent in preliminary data from Paleocene strata at Bass River, New Jersey, USA (c. 27°N). Moreover, we reveal a more pronouced cooling interval in the uppermost 13 m of the 83 m thick Paleocene strata at Mid-Waipara coincident with elevated TOC and isotopically heavy organic carbon ($\delta^{13}C$>-25‰), indicating an enhanced local response to climate changes. We reconstruct biomarker records to investigate ecological changes associated with cooling at Mid-Waipara, and use compound specific carbon isotope analysis of higher plant biomarkers to interrogate carbon cycle dynamics.

Mycorrhizal weathering through space and time: Implications for the long-term carbon cycle

L.L. TAYLOR[1], S.A. BANWART[2], J.R. LEAKE[1] AND D.J. BEERLING[1]

[1]Animal and Plant Sciences, University of Sheffield, UK (*correspondence: L.L.Taylor@sheffield.ac.uk)

[2]Cell-Mineral Research Centre, Kroto Institute, University of Sheffield, UK

Several recent hypotheses strongly link plants and their fungal symbionts to the long-term carbon cyle via their impact on the release of calcium and magnesium from silicate minerals: (a). Primary productivity controls the nature, extent and rate of biological weathering [1]; (b). Mycorrhizal fungi direct this weathering activity toward nutrient-rich minerals more effectively than roots [2]; (c). The evolution of ectomycorrhizal fungi could have contributed to CO_2 drawdown in the Cretaceous [3]. In contrast to the ancestral arbuscular-mycorrhizal fungi, ectomycorrhizal fungi can exude copious amounts of organic acids and they prevent most of the host root system from interacting directly with the soil [2]. In models of the long-term carbon cycle [4], plant weathering and response to changes in atmospheric CO_2 are usually represented by empirical functions. We have previously integrated simple yet rigorous rate laws into such a model to test the third hypothesis (c), but we used global mean temperatures along with a simplistic empirical function to represent net primary productivity [3]. We now continue to explore the effects of weathering by plants and mycorrhizal fungi through geological time, linking our weathering model to the Hadley Centre general circulation model [5] and the Sheffield Dynamic Global Vegetation Model [6] to produce weathering and primary productivity maps for the modern day and for several Mesozoic and Cenozoic timeslices. Comparison of our results with published observations provides support for hypotheses (a) and (b).

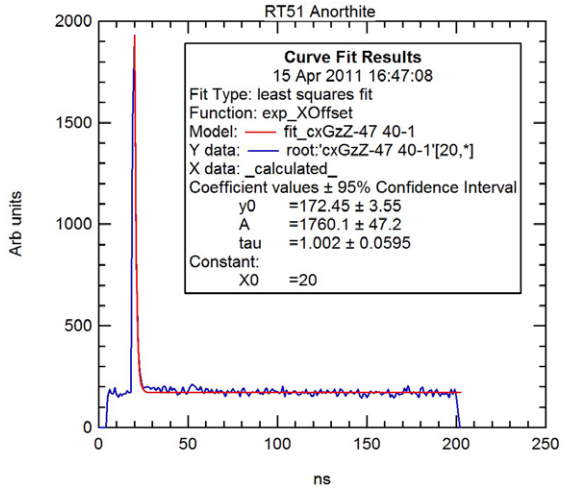
Time resolved luminescence of framework silicates

R.P TAYLOR[1,2]*, J.F.W. MOSSELMANS[1], A.A. FINCH[2] AND P.D. QUINN[1]

[1]Diamond Light Source, Didcot, OX11 0DE, UK (*correspondence: rpt5@st-andrews.ac.uk)
[2]Dept. of Earth Sciences, St Andrews, KY16 9AL, UK (aaf1@st-andrews.ac.uk)

The development of the new Time Resolved X-ray Excited Optical Luminescence (TR-XEOL) facility at the i18 microfocus beamline at the Diamond Light source allows the comparison of time resolved luminescence data collected at this facility to be compared with data collected from Photoluminescence (PL) and cathodoluminescence excitation. The presentation shows results from luminescent centres in the blue and ultra-violet regions from a number of framework silicates including feldspar, quartz and sodalite. Our results show differences between XEOL Photoluminescence and Cathodoluminescence spectra which provide insights into the physical nature of the centres causing the light emitted.

We show lifetime measurements for UV and blue centres XEOL. Many samples show differences in the lifetime between pulsed laser and pulsed X-ray excitation with the X-ray excitation showing significant increases in decay lifetimes. Samples typically display a doubling of the value of the shortest lifetime component. We hypothesise that the differences in the lifetimes of the emissions probe the nature of the absorption and energy transfer mechanism within the mineral. The luminescence signal can be analysed both by energy to differentiate between alternative emission pathways and as a time resolved signal to probe the mechanisms involved in absorption, energy transfer, and other factors affecting the relaxation lifetimes. We make preliminary inferences on the physical nature of the centres involved in UV-blue luminescence in framework silicates. Fig 1 shows a XEOL spectra from RT51 a single crystal Anorthite feldspar Alaska (Smithsonian Institute) fitted with a single exponential.



Calculated stability of osumilite, sapphirine and biotite in K_2O-FeO-MgO-Al_2O_3-SiO_2-H_2O-TiO_2-O (KFMASHTO)

K. TAYLOR-JONES[1]*, R. POWELL[2] AND T.J.B. HOLLAND[1]

[1]Department of Earth Sciences, University of Cambridge, Cambridge, CB2 3EQ, United Kingdom (*correspondence: kat32@cam.ac.uk)
[2]School of Earth Sciences, University of Melbourne, Victoria 3010, Australia.

With the advent of the new Holland & Powell internally-consistent thermodynamic dataset [1], in the form of the initial release of the dataset (tc-ds61. txt) on http://www. esc. cam. ac. uk/people/academic-staff/tim-holland, and http://www. metamorph. geo. uni-mainz. de/thermocalc/, calculation of the stability of osumilite, sapphirine and biotite can be undertaken in a much improved way. This has necessitated the development of new activity-composition (a-x) relations for the minerals as the underpinning relationships from the dataset generation have changed, as well as recognition of shortcomings in earlier models. The osumilite a-x model is a major reworking of the previously used one. The sapphirine a-x model is built on our recent work [2], with changes relating to the way sapphirine end-members are now incorporated in the dataset. Dataset annite, and the attendant a-x model for biotite, takes account of the fact that 'annite' in experiments contains significant ferric iron. We present calculated pressure-temperature projections (petrogenetic grids) for quartz-saturated systems at high and ultrahigh temperature crustal conditions in K_2O-FeO-MgO-Al_2O_3-SiO_2-H_2O (KFMASH), K_2O-FeO-MgO-Al_2O_3-SiO_2-H_2O-O (KFMASHO), and K_2O-FeO-MgO-Al_2O_3-SiO_2-H_2O-TiO_2-O (KFMASHTO), and calculated compatibility diagrams, to illustrate the phase equilibria.

Nd isotopic compositions in the central Indian Ocean

HIROFUMI TAZOE[1]*, HAJIME OBATA[2], HISAO NAGAI[3] AND TOSHITAKA GAMO[2]

[1]Institute of Radiation Emergency Medicine, Hirosaki University(*correspondence: tazoe@cc.hirosaki-u.ac.jp)
[2]Atmosphere and Ocean Research Institute, the University of Tokyo
[3]College of Humanities and Sciences, Nihon University

Nd isotopic composition in seawater is controlled by input from surrounding terrestrial sources, boundary exchange process, lateral transportation, and mixing water masses. During global thermohaline circulation, the Indian Ocean receives deep waters originated from the Southern Ocean, and its warm and salty surface waters return to the Atlantic Ocean via Southern Ocean. Low-salinity waters of the North Pacific origin are injected at the eastern side of the Indian Ocean via the Indonesian Throughflow. The fingerprints of the Pacific waters might be traced in the intermediate water in the southeastern Atlantic Ocean. On the other hand, Nd isotope data are too scarce to precisely describe Nd isotopic signatures of the main water masses in the Indian Ocean. In this study, vertical profiles of Nd isotopic compositions in the ceantral Indian Ocean are presented.

Seawater samples were obtained both with Teflon coated X-type Niskin samplers with CTD-carosel multi-sampling system and the PVC large volume sampler during R/V Hakuho-Maru KH-09-5 cruise (2009. 11. 6 - 2010. 1. 12). From each 10L of seawater, rare earth elements (REEs) were preconcentrated by Fe coprecipitation. After removal Fe by di-isopropyl ether, REEs were purified with ion exchange resin. Further Nd separation was performed by TRU Resin and Ln Resin (Eichrom Tec.). Nd isotopic compositions were measured by thermal ionization mass spectrometer (Finnigan MAT 262).

In the sampling station, ER-10 (19°59′ S, 72°33′E, 4343m), of the central Indian Ocean, wide ranges of Nd isotopic composition were observed. The ε_{Nd} values decreased from surface (ε_{Nd} = -5.7) to high salinity Subantarctic Mode Water at 600 m depth (ε_{Nd} = -9.3). Antarctic Intermediate Water showed also relatively low ε_{Nd} values, though the water mass between 1000 m and 1500 m depth, whose salinity and oxygen concentration were low, had higher ε_{Nd} values (-6.3 - -5.9). This radiogenic Nd signal could be derived from the Indonesian Throughflow and affect the Nd compositions of Antarcitc and Atlantic intermediate water.

Ubiquitous subaerial weathering during emersion of the Fortescue Late Archean igneous province, Western Australia

Y. TEITLER[1]*, P. PHILIPPOT[1], M. GERARD[2], F. FLUTEAU[1] AND G. LE HIR[1]

[1]IPGP, Université Paris 7-Denis Diderot, 1 rue Jussieu, Paris, France (*correspondence: teitler@ipgp.fr)
[2]IMPMC, 4 place Jussieu, Paris, France (martine.gerard@impmc.jussieu.fr)

The 2.77Gy old Mount Roe paleosol at Whim Creek, Fortescue Group, Western Australia, is a reference weathering profile, used for constraining maximum concentrations of atmospheric oxygen and greenhouse gases (CO_2, CH_4) during the Late Archean. Inferences on Early Earth atmospheric composition, however, are based on the interpretation of reconstructed chemical profiles which are not supported by direct mineralogical observations. This in turn resulted in a number of controversies that remain to be solved. The Whim Creek paleosol occurs at the top of a vesicular, subaerial basaltic flow exposed along two km-scale outcrops located about 5 km away from each other. It mainly consists of fresh footwall basalt progressively grading to a 5 meters thick brecciated chloritic-rich zone showing evidence of corestone weathering, overlain by a 5 to 20 meters thick sericitic-rich zone. Clastic sediments are often inter-bedded between the top sericite zone and the overlying basaltic flow. This is consistent with a significant time gap between deposition of footwall and hanging wall lava flows, a required condition to develop a thick weathering profile. Similar weathering profiles have been identified both along the same stratigraphic level some 100 km away from the Whim Creek locality (Sherlock River) and in the younger 2.74 Gyr old Kylena Formation. This indicates that basalt weathering was a long-lasting process of wide geographic influence.

Meter scale blue-greenish titanite-rich bodies containing primary weathering-related phyllosilicates (Berthierine, Smectite) were found as hard cores within the sericite zone at both Whim Creek and Sherlock River localities. In addition, remnants of bedded-parallel diaspore/pyrophyllite deposits containing carbonaceous material were found in the Whim Creek sericite zone. Field and petrological investigations indicate that both the phyllosilicates and diaspore horizons predate sericitization.

These occurrences are the first relic testimony of the original weathering profiles documented in rocks older than 2.2 Gyr, thus representing unvaluable new means for inventorying the Late Archean paleoclimatic conditions.

U-Pb and Lu-Hf isotopic constraints on the genesis of a Variscan two-mica granite from Carrazeda de Ansiães

R.J.S. TEIXEIRA[1], A.M.R. NEIVA[2], M.E.P. GOMES[3] AND T. ANDERSEN[4]

[1,3]Department of Geology, UTAD, Apartado 1013, 5001-801 Vila Real, Portugal (rteixeir@utad.pt, mgomes@utad.pt)
[2]Department of Earth Sciences, University of Coimbra, 3000-272 Coimbra, Portugal (neiva@dct.uc.pt)
[4]Dep. of Geosciences, Univ. of Oslo, PO Box 1047 Blindern, N-0316 Oslo, Norway (tom.andersen@geo.uio.no)

The Carrazeda de Ansiães area is located in the Portuguese sector of the Central Iberian Zone and is characterized by abundant S-type granites. LAM-ICPMS U-Pb geochronology confirms that one of those granites (Cabeça Boa granite) has been emplaced during the last ductile deformation phase (D_3) of the Variscan orogeny, showing an age of 327 ± 3 Ma. LAM-ICPMS Hf isotope data of the magmatic zircons show a wide range of negative εHf_t values (from -8 to -4), indicating that they could have been derived from heterogeneous crustal anatectic melts. Detrital zircons from a host chlorite phyllite yield a major group of Neoproterozoic ages (561 – 574 Ma), but there are also Mesoproterozoic, Paleoproterozoic and Neoarchean ages. The inherited zircon cores from the granite superficially match the age pattern of the host metasediment. Furthermore, a significant number of inherited zircon cores from the granite has εHf_t values similar to those of the detrital zircons of the chlorite phyllite, suggesting that this metasediment could have been one of the sources involved in the genesis of the granite. However, the average εHf_{320} for the detrital zircons is ca. -19 and is much more evolved than the magmatic zircons with average εHf_{320} (ca. -6), supporting that the melt was not exclusively controlled by the detrital zircons. Therefore, a more juvenile melt source, possibly indicated by the tonalite enclaves in the granite, must also have been involved in its genesis. So, the detrital zircons are interpreted as a contaminant during ascent and emplacement and not a source for the melt. The U-Pb isotope data of detrital zircons of the chlorite phyllite indicate that its maximum depositional age is ca. 578 Ma. The presence of Mesoproterozoic zircons (ca. 1.1 – 1.2 Ga) in the chlorite phyllite argues in favour of a peri-Amazonian location of its Neoproterozoic/Early Paleozoic depositional basin, close to West Avalonia. A West African Craton provenance could also be admitted, if a long distance river transportation of Mesoproterozoic zircons, from the southwest Baltica or Arabian–Nubian Shield, is considered.

PGE perspective on Early Cretaceous oceanic anoxic event: Pacific vs. Tethyan domains

M.L.G. TEJADA[1,2], K. SUZUKI[2], A. ISHIKAWA[2,3], T. NOZAKI[2], R. SENDA[2], G. RAVIZZA[4] AND J.I. KIMURA[2]

[1]NIGS, Univ of the Phils, Quezon City, 1101 Philippines
[2]IFREE, Japan Agency for Marine-Earth Science and Technology, Yokosuka, 237-0061 Japan
[3]ESA, The Univ of Tokyo, Tokyo, 153-8902 Japan

Mapping of the Os isotope composition of organic-rich sediments formed in Early Cretaceous oceans, Tethys (Gorgo a Cerbara, Italy) and Pacific (DSDP Site 463 and ODP Site 1207B), supports the global occurrence of oceanic anoxic event OAE 1a. In this study, PGE abundances of the same sedimentary sections, together with their Os isotope composition are used to investigate whether or not a meteorite impact had caused the changes in marine conditions that led to oceanic acidification and oxygen depletion at that time. Alternatively, was it the massive volcanism of the Ontong Java Plateau, in southwest Pacific Ocean that solely led to the early Cretaceous global marine anoxia?

In both oceans, based on results from the Selli Level horizon at Gorgo a Cerbara and its equivalent at Site 463, a negative excursion of the seawater Os isotope composition coincides with the OAE1a interval. These results suggest input of unradiogenic Os into the oceans, attributable to both mantle and meteoritic materials. However, no meteoritic signature is evident from the abundances and the inter-element ratios of the PGEs for both sections. The Ir abundance at Site 463 section is 24-285 ppt and fall within the range for that of Gorgo a Cerbara, which are lower than the values for other known large impact horizons. Selli Level-equivalent horizon including the interval that yielded the highest concentration of Re and other PGEs at Site 463 have non-chondritic Os/Ir and Pt/Ir values of 1.5-41 and 14-76, (vs. chondritic values of 1.03 and 2.0). At both sites, PGE abundances and interelement ratios point to a massive volcanic eruption, during the emplacement of the Ontong Java Plateau (+Manihiki and Hikurangi plateaus), as the most likely explanation for the seawater Os isotope excursions coinciding with the anoxia event in both Tethyan and Pacific oceans 120 m. y. ago.

Shooting ranges represent places of extreme point source contamination. It endangers the natural environment and especialy soil by release of risk elements (RE) e.g. Pb, Sb, Zn, Cu, Ni, Sb a Ag. This study monitors the loosening of selected RE from bullets and their fate in the soil.

Bullets' weathering represents RE input into soil; in monitored shooting range it was max. 7 g Pb kg^{-1}. The bullet with mantle, collected from shooting mound, was studied by Scanning electron microscopy (SEM) with EDAX detection. The bullet core is composed almost solely of Pb (Figure 1a). Other parts of the bullet have far more diverse composition and serve as another source of RE (Cu, Zn) in soil. Generally, the mantle is made of Fe with inner and outer Cu coating. The observed bullet is surrounded by coroded mantle and a mixture of iron oxides - detected by Raman spectroscopy. The remaining Cu layer can be seen inside of the mantle (Figure 1b) and in a mixture of coroded mantle and newly created Fe-oxides (Figure 1c). X-ray powder diffraction detected these newly formed Fe oxides and whewellit in the bullets surroundings and on the mantle surface. The Fe oxides and whewellit can serve as RE sorbent. A possible RE mobilisation was examined by BCR extraction.

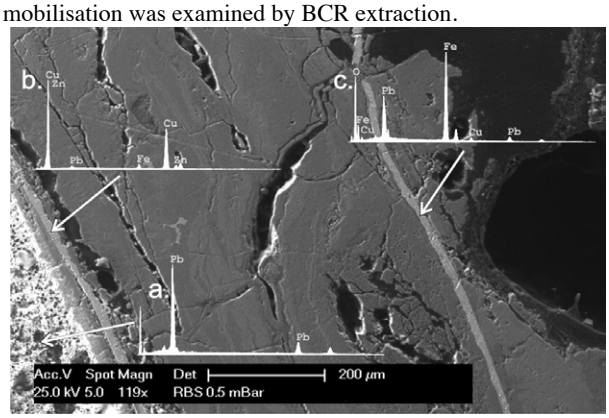

Figure 1: SEM image of bullet mantle with EDAX analysis.

The geochemical properties of manganese occurences of Isparta, Turkey

Y. TEKER[1] AND M. KUŞCU[2]

[1]Disaster and Emergency Management Presidency, Ankara, Turkey (yelizteker@gmail.com)

[2]Süleyman Demirel Üniversity, Department of Geological Engineering, Isparta, Turkey (mkuscu@mmf.sdu.edu.tr)

The manganese occurences of Isparta are located in Bağıllı, Havutlu and İmrezi areas. Havutlu manganese occurence and Bağıllı manganese occurence are found in Tesbihli formation of Ladinian (Triyassic), İmrezi manganese occurence is found in Ispartacay formation of Triyassic-Jurassic. Manganese mineralizations are seen generally cutting radyolarite in stockwork, lenticular and normal vein forms. Pyrolusite, psilomelane, braunite, todorokite, cyrptomelane, rhodochrozite, manganese phosphide, jacobsite, manganocalcite, pyrite, magnetite, hematite and goethite are determined as ore minerals in the manganese occurences.

In the manganese occurences, average composition is 20.19 % MnO, 2.98 % Fe_2O_3 and 70.63 % SiO_2. The diagrams prepared by using trace elements show that manganese mineralizations are determined in the hydrogenetic area and this also supported with the ratio of Fe/Mn of mineralizations.

Copper speciation in organic wastes by X-ray absorption spectroscopy

M. TELLA[1]*, S. CHATAING[1], B. COLLIN[2], M.A. DIOT[2], M.N. BRAVIN[3] AND E. DOELSCH[1]

[1]CIRAD, UPR Recyclage et risque, F-34398 Montpellier, France (*correspondence: marie.tella@cirad.fr)
[2]CEREGE, CNRS-UPCAM UMR6635, F-13545 Aix en Pce, France
[3]CIRAD, UPR Recyclage et risque, F-97408 Saint-Denis, La Réunion, France

The benefits of the use of organic wastes as fertilizers and soil amendments should be assessed together with potential environmental and toxicological impacts due to the presence of trace elements. The knowledge of trace elements speciation is essential to better understand their behavior after the spreading of organic wastes on soils and to predict their bioavailability. The present work aimed at studying speciation of copper (Cu) in various organic wastes (sewage sludge, composts and animal manure), which exhibit moderate to high levels of copper (24 to 340 mg kg^{-1} dry matter). These wastes were selected because they are commonly used in several countries as fertilizer or soil amendment (Réunion-France, Magacascar, Senegal). Size fractionation was first performed to account for the complexity of wastes and X-ray absorption spectroscopy (XAS) has been combined with different analytical approaches to determine speciation.

Organic wastes exhibited a fairly large enrichment in Cu in smaller solid fractions (0.2-20 μm) in comparison with raw wastes (130 to 1 900 mg kg^{-1} dry matter). X-ray Near-Edge Structure Spectroscopy (XANES) spectra were recorded on smaller solid fractions and analyzed by linear combination fitting (LCF) of references spectra. Analyses of pre-edge and inflexions in the absorption edge of spectra indicated that Cu is present in both Cu(I) and Cu(II) oxidation states. Therefore, LCF results showed that all small fractions are well fitted by different amounts of Cu(I)-S and Cu(II)-O in both octahedral and axial elongated octahedral (~square planar) geometries (Table 1).

	Cu(I)-S	Cu(II)-O	
		octahedral	square planar
Sewage sludge	60%	40%	≤10%
Composts	30%	40%	30%
FF-MSWC	≤10%	40%	60%

Table 1: LCF results for small size fractions of wastes (FF-MSWC=fine fraction from municipal solid waste composts)

In conclusion, Cu possesses its own chemical status and environments for each type of organic wastes, which could lead to different mobility after spreading on land.

Origin of Miocene volcanic rocks from Eskisehir, NW Anatolia, Turkey

S. TELSIZ[1]*, A. TEMEL[1] AND A. GOURGAUD[2]

[1]Hacettepe University, Geological Engineering Department, 06800 Beytepe, Ankara, Turkey (*correspondence: stelsiz@hacettepe.edu.tr)
[2]Université Blaise Pascal, OPGC, Laboratoire CNRS 'Magmas et Volcans' 5 rue Kessler-63038, Clermont-Ferrand Cedex, France

Volcanic rocks from Eskisehir region containing pyroclastic products (deposits) and lavas/domes with basaltic and andesitic composition occurred in Early-Late Miocene age (19.5-7.9 Ma) based on Ar-Ar radiometric dating. Volcanic products in the region have both alkaline and calcalkaline characteristics; and their composition range from tephrite to ryholite. It was determined that the samples of 19.5-16.8 Ma age and basaltic trachyandesite to ryholitic composition with 0.703885-0.710988 and 0.512317-0.512489 $^{87}Sr/^{86}Sr$-$^{143}Nd/^{144}Nd$ isotopic ratios and low Nb/La<1 values were derived from a subduction zone and/or a lithospheric source enriched by crustal contamination process. On the other hand, it was concluded that the younger samples (13.6-7.9 Ma) with trachybasalt and tephritic composition with 0.703470-0.703505 and 0.512884-0.512930 isotopic ratios and high Nb/La>1 values were generated from an asthenospheric source with a low degree of partial melting, in the absence of crustal and lithospheric contribution.

Olivine and pyroxene surface reactivity during H_2-generation

ALEXIS S. TEMPLETON[1], LISA E. MAYHEW[1], THOMAS P. TRAINOR[2], PETER ENG[3] AND THOMAS M. MCCOLLOM[4]

[1]Department of Geological Sciences, University of Colorado, Boulder, CO 80309, USA (templeta@colorado.edu)
[2]Department of Chemistry, University of Alaska, Fairbanks, AK 99775, USA
[3]Consortium for Advanced Radiation Sources, University of Chicago, Chicago IL 60637
[4]Laboratory for Space Physics, University of Colorado, Boulder, CO 80309, USA

The hydrothermal alteration of ultramafic rocks is commonly invoked as a key source of H_2 available for subsurface lithoautotrophic microbial communities. At a mechanistic level, H_2 generation is intimately related to changes in the oxidation state of Fe and the temperature-dependent partitioning of Fe into secondary phases such as serpentine, Fe-rich brucite and magnetite. However, few experimental studies have directly examined the dynamic links between solid-phase Fe speciation and the extent of H_2-generation during multi-stage serpentinization reactions.

We will present a series of hydrothermal experiments designed to measure microscale changes in distribution and speciation of Fe during electron transfer reactions between olivine and pyroxene surfaces and saline fluids. Polished slabs and powders of olivine and pyroxene have been suspended in flexible Au/Ti reaction cells at 230°C-300°C, and the serpentinization reactions have been arrested after a few days, a few weeks and a few months to measure progressive changes in mineral surface chemistry as H_2 is evolved. Surface-sensitive X-ray scattering and spectroscopic measurements have been combined to measure the growth of new mineral phases (e.g. lizardite detected by surface X-ray diffraction), to determine the redistribution of Fe and Si within the reaction interface (using reflectivity and total external reflection X-ray fluorescence measurements), and to measure changes in the speciation and oxidation state of Fe (using surface-sensitive Fe XANES analyses). In particular, we are monitoring the formation of Fe(II)-brucite and Fe(II)/(III)-bearing serpentine during incipient reactions, and the subsequent formation of magnetite, as $[H_2]$ variably increases.

To date, little information exists regarding the rates and mechanisms of olivine serpentinization below 200°C. However, we will also speculate about how our interfacial measurements could be used to probe changes in surface-controlled electron transfer processes when H_2-consuming microorganisms colonize olivine and pyroxene surface under highly reducing conditions.

Extracellular electron transfer in microbial environments

L. TENDER

Center for Bio/Molecular Science and Engineering, Naval Research Laboratory, Washington DC, USA (leonard.tender@nrl.navy.mil)

Dissimilatory metal-reducing bacteria (DMRB), such as Geobacter and Shewanella spp., occupy a distinct metabolic niche in which they acquire energy by coupling oxidation of organic fuels with reduction of insoluble extracellular electron acceptors (i.e., minerals). Their unique extracellular electron transfer (EET) capabilities extend to reduction of anodes (electrodes maintained at sufficiently positive potentials) on which they form persistent, electric current generating biofilms. This capability makes DMRB useful as anode catalysts in microbial fuel cells (MFCs) for alternative energy generation and degradation of organic wastes. One hypothesis describing the mechanism of EET by Geobacter and Shewanella spp. involves superexchange in which electrons are conducted by a succession of electron transfer reactions among redox proteins associated with the outer cell membranes, aligned along pilus-like filaments (e.g. pili), and/or throughout the extracellular matrix. Here theory is presented, previously developed to describe superexchange within abiotic redox polymers, to describe superexchange within DMRB biofilms grown on anodes. This theory appears to apply to recent *ex situ* measurements of electrical conductivity by individual pilus-like filaments of S. oneidensis MR-1 and G. sulfurreducens DL1, referred to as microbial nanowires. Microbial nanowires have received much recent attention because they are thought by some to impart electrical conductivity to DMRB biofilms and because of the prospect of microbe-produced conductive nanomaterials. This theory appears to apply to preliminary *in situ* demonstration of electrical conductivity of an anode-grown G. sulfurreducens DL1 biofilm. Characterization by cyclic voltammetry is also presented of glassy carbon BMAs (biofilm modified anodes) of DL1 (a wild type strain), KN400 (a variant that generates higher current density), and mutant strains in which outer membrane c-type cytochromes S or Z (OmcS, OmcZ) were deleted. These BMAs were characterized at 1) state of transition from planktonic cells grown utilizing fumarate as their electron acceptor to anode bound cells utilizing the anode as their electron acceptor; 2) during biofilm growth; 3) when fully grown; and 4) when fully grown under non-turnover condition after subsequently starved of acetate. The results indicate interesting aspects of EET by G. sulfurreducens DL1.

New insights into mantle and crustal processes from high-temperature magnesium isotope fractionation

F.-Z. TENG[1]*, W.-Y. LI[2] AND S.-A. LIU[2]

[1]Department of Geosciences & Arkansas Center for Space and Planetary Sciences, University of Arkansas, Fayetteville, AR 72701, USA (fteng@uark.edu)

[2]School of Earth & Space Science, University of Science & Technology of China, Hefei, Anhui 230026, China

Equilibrium isotope fractionation generally decreases with increasing temperature and is expected to be insignificant at high temperatures. By contrast, kinetic isotope fractionation associated with chemical diffusion and Soret effect can be extremely large at high temperatures as shown by recent experiments. However, the extent to which kinetic isotope fractionation may occur in nature remains uncertain.

Here we report large high-temperature kinetic Mg isotope fractionation in zoned olivines and equilibrium Mg isotope fractionation among mantle and crustal minerals. Significant Mg isotope fractionation (>0.4 ‰ variation in $^{26}Mg/^{24}Mg$) was found in over 60 olivine grains from Hawaii, which reflects isotope fractionation associated with inter-diffusion of Mg and Fe during magmatic differentiation. Large Mg isotope fractionation, up to 1.1 ‰ in $^{26}Mg/^{24}Mg$, was found between coexisting garnet and omphacite in 5 orogenic eclogites, and between coexisting spinel, cpx, opx and olivine in 13 mantle peridotites. The large inter-mineral isotope fractionation reflects equilibrium partitioning of Mg isotopes between coexisting minerals as evidenced by the temperature-dependent isotope fractionation, lack of mineral zoning, and absence of intra-mineral isotopic variations, as well as equilibrium oxygen isotope fractionation among these minerals. The direction of inter-mineral equilibrium Mg isotope fractionation among these mantle and crustal minerals agrees with theoretical predictions, suggesting that inter-mineral Mg isotope fractionation is primarily controlled by the Mg-O bond strength, with stronger bonds favoring heavier Mg isotopes.

Our results demonstrate that both equilibrium and kinetic isotope fractionation can occur during high-temperature geological processes, with great potential applications. Kinetic isotope fractionation associated with chemical diffusion can be used to identify diffusive transport in zoned minerals, which is key for using chemical zoning to constrain magmatic timescales. Large equilibrium Mg isotope fractionation among mantle and crustal minerals can potentially be used as a high-precision geothermometry in mantle and crustal geochemistry.

Solvent effect on the precipitation of Mg-carbonate

HENRY TENG AND JIN WANG

Dept. Chemistry, The George Washington University, Washington, DC 20052 (hteng@gwu.edu)

Low temperature synthesis of anhydrous magnesite continues to be an outstanding geochemical problem despite our improved understanding in the Mg-CO_3 system (e.g. formation of various hydrated forms and basic hydromagnesites). Presently, the prevalent hypothesis for the lack of magnesite crystallization under ambient conditions seems to focus on the strongly hydrated Mg^{2+} ions (compared to Ca^{2+}). It is hypothesized that the robust hydration shell around Mg^{2+} lowers the cation's activity and provides a barrier for the access of CO_3^{2-}. We intend to explore the possibility of magnesite crystallization in the presence of alcohol which could potentially replace H_2O or dislodge the water cage around Mg^{2+}. We hypothesize that (1) the presence of alcohol in water will distort or weaken the rigid water shell around magnesium ions due to the change in solvent dielectric properties and the water-alcohol interactions to facilitate the interaction of Mg^{2+} and CO_3^{2-}; and (2) dry conditions in pure alcohol may lead to the formation of anhydrous magnesite. We found that $MgCl_2$ and guanidine carbonate (GC) can be used as reactants since both show workable solubility in methanol (me).

Four batches of reactions have been carried out between $MgCl_2$ and GC in water and methanol (Mg-aq + GC-aq; Mg-me +GC-aq; Mg-aq + QC-me; Mg-me + QC-me). The presence of methanol in water greatly accelerates the precipitation, but none of four batches led to the formation of magnesite. FT-IR and XPS revealed the presence of CO_3 in the products, but XRD analysis identified either amorphous phases or could not be matched with the diffraction patterns of any known Mg-CO_3 salts in the database. The sample synthesized in the presence of water were found to be amorphous nanoparticle aggregates, while that formed in pure methanol exhibits a well-crystallized thin platelet assembly morphology. It appears that methanol is able to facilitate Mg-CO_3 crystallization, but the presence of minute amount of H_2O in solvent or in air still found a way to be incorporated in the crystal structure, confirming the high affinity of Mg^{2+} toward water molecules.

Phytoavailability and bioaccumulation of vanadium in the soil in Panzhihua Region, S.W. China

YANGUO TENG[1], JIE YANG[1] AND ZHENGQI XU[1,2]

[1]College of Water Sciences, Beijing Normal University, Beijing 100875, China (teng1974@163.com)
[2]Department of Geochemistry, Chengdu University of Technology, Chengdu 610059, China (xuzhengq@163.com)

Vanadium is a ubiquitous trace metal in the environment, which is an essential trace element for living organisms, but the excessive content is harmful to human beings, animals and plants. A biogeochemical investigation of vanadium in the soil was carried out in Panzhihua region, SW China.

The content of vanadium was detected in different land-use districts soil. The total content of vanadium in different land-use districts characterized that: smelting area (range 208.1-938.4 mg/kg, average 532.1 mg/kg) > mining area (range 111.6-591.2 mg/kg, average 312.7 mg/kg) > urban park (range 94.0-183.6 mg/kg, average 119.8 mg/kg) ≈ agricultural area (range 71.7-227.2 mg/kg, average 113.0 mg/kg).

Based on improved BCR sequential extraction, the chemical speciation of vanadium (acid-soluble, reducible, oxidisable and residual) were determined. In the soil from four different land-use districts, the fraction of vanadium in each sequential extraction characterized that residual > oxidisable ≥ reducible > acid-soluble.

The phytoavailable content of vanadium was characterized that: the polluted areas (mining area 18.8-83.6 mg/kg, smelting area 41.7-132.1 mg/kg and the unpolluted area (agricultural area 9.8-26.4 mg/kg, urban park 9.9-25.2 mg/kg); while the phytoavailable proportion of vanadium was characterized that: the polluted areas (mining area 6.50-24.30%, smelting area 6.89-24.54%) and the unpolluted area (agricultural area 8.39-21.15%, urban park 8.20-23.72%).

In study area, The concentrations of vanadium in beet leaf samples were in the range of 6.5-42.8 mg/kg, and in mongo leaf samples were in the range of 3.0-22.7 mg/kg. In addition, the content of vanadium in samples in urban park was slightly lower than that of other three areas. The biological adsorption coefficient (BAC) of vanadium in study area showed that vanadium was weak or intermediate accumulated by plants. A pot experiment showed that alfalfa had strong metal adaptability and high accumulation of vanadium.

This study is granted by China Natural Science Foundation (No.41073068) and Doctoral Program of Specialized Research Fund for University (20090003110021).

Megacryst compositional heterogeneities in plagioclase ultraphyric basalts (PUBs)

F.J. TEPLEY, III*, A. LANGE, A. BURLEIGH, R. NIELSEN AND A. KENT

College of Earth, Ocean and Atmospheric Sciences, Oregon State University, Corvallis, OR 97331, USA (*correspondence: ftepley@coas.oregonstate.edu) (langea@geo.oregonstate.edu, burleian@onid.orst.edu, nielsenr@geo.oregonstate.edu, kentad@geo.oregonstate.edu)

Plagioclase ultraphyric basalts (PUBs) are common in many oceanic tectonic settings particularly along slow to intermediate spreading ridges; however, the nature of their petrogenesis remains unclear. We have examined samples from the South West Indian Ridge (SWIR; ultraslow), Juan de Fuca Ridge (JdF; slow to moderate) and the Blanco Transform (pull apart), and more generally the global distribution of PUBs and their chemistries. Our work focuses on measuring major- and trace-element compositions and *in situ* Sr-isotopic compositions of plagioclase, and hosted melt inclusions, with the goal of documenting the extent to which the phenocrysts represent a coherent suite of genetically related material, and of understanding the dynamics of magma storage, transport and evolution within the oceanic crust.

Analyses of plagioclase and their hosted melt inclusions from all three study sites demonstrate both unchanging intra-grain compositions and considerable inter- and intra-grain variability in major- and trace-element compositions. Preliminary *in situ* Sr-isotopic data shows minimal differences between crystal and host glass. For those exhibiting compositional variability, each plagioclase megacryst analyzed appears to have a distinct history representing a complex crystal cargo, each crystal of which may have experienced a different petrogenetic history.

Globally, the distribution of PUBs is limited to ridges with ultraslow to moderate rates of spreading. Accumulated data suggest that PUB host glasses show a similar range in composition as global MORB glasses. For example, a plot of K_2O/TiO_2 versus MgO shows that there is no preferred liquid composition for PUB as compared to worldwide MORB glasses.

We believe that the compositional heterogeneites exhibited in PUB megacrysts are a result of complex crystallization histories involving melts of varying composition, changes in the physical conditions of crystal growth, and complex crystal exchange mechanisms.

The behavior of vanadium between water and basalt

MASASHI TERADA AND SHIKAZONO NAOTATSU

3-14-1, Hiyoshi, Kouhokuku, Yokohama, Kanagawa, Japan (tera.masa1106dgmail.com, sikazono@applc.keio.ac.jp)

In the surrounding area of Mt. Fuji, central Japan, it has been reported that vanadium concentration is relatively high (0.05-0.1 (mg/l)) in ground water and river water, due to the dissolution of vanadium from basalt. This concentration is 50 to 100 times high compared to the normal concentration of vanadium in natural waters. However a compositional relationship between surface waters and rocks has not been reported. The reason is vanadium is usually not considered as a contaminant in the water. Therefore, this study experimentally examines the behavior of vanadium in ground water and basalt interaction, and the migration behavior of vanadium in ground water in the surrounding area of Mt. Fuji based on the experimental study. In the experiment, the basalt samples of different ages were used and the experiment on the dissolution and adsorption of vanadium from the basalt was performed. The behavior of vanadium dissolved in aquifers in Mt. Fuji area was considered. The results of the dissolution adsorption experiments showed that the dissolved vanadium species in water were affected by pH and dissolved oxygen. In addition, the vanadium in basalts is considered to be contained in magnetite, in pyroxene and in the volcanic glass and to have adsorbed onto each minerals surface. The extraction experiment of vanadium from them revealed the existing chemical forms of vanadium are different in different basalt samples.

Application of NICA-Donnan model to modelling of Eu(III) solubility in the presence of deep groundwater humic substances

M. TERASHIMA*, M. OKAZAKI, K. IIJIMA AND M. YUI

Gelogical Isolation Research and Development Directorate, Japan Atomic Energy Agency, 4-33 Muramatsu, Tokai-mura, Naka-gun, Ibaraki 319-1194, Japan (*correspondence: terashima.motoki@jaea.go.jp)

Modelling of radionuclide bindings by deep groundwater humic substances (HSs) is a key subject for assessing the carrier effects of HSs on migration of radionuclides in geological disposal system of high level radioactive waste. The NICA-Donnan model of which generic parameters are prepared [1, 2] is one of the most useful models for the modelling of metal-ion bindings by soil and surface water HSs in a variety of solution conditions. However, its applicability to the deep groundwater HSs has yet to be elucidated. In this study, to clarify the applicability of the NICA-Donnan model and its generic parameters, the Eu(III) solubility simulated by the model and parameters were compared to the experimentally obtained solubility in the presence of HSs isolated from deep groundwaters at the depth of 250 to 500 m in Horonobe area, Hokkaido, Japan.

The solubility experiments showed the results that apparent solubility of Eu(III) were not enhanced in the presence of the deep groundwater HSs (i.e. fulvic acids or humic acids), while the solubility was enhanced in the presence of Aldrich humic acid. The NICA-Donnan model and its generic parameters successfully simulated the solubility enhancement by the Aldrich humic acid. However, they could not simulate the apparent solubility in the presence of the deep groundwater HSs. These results suggest that the NICA-Donnan model and/or its generic parameters cannot be applied to the modelling of trivalent radionuclide bindings by the deep groundwater HSs in the Horonobe area. Based on the Eu(III) binding characters of HSs, the reason on the disagreements between the experiments and the simulations will be discussed.

This study was partly funded by the Ministry of Economy, Trade and Industry of Japan.

Transition of a pyrrhotites to antiferromagnetic state induced by cation vacancies

A.V. TEREHOVA *, V.V. ONUFRIENOK AND A.M. SAZONOV

Siberian Federal University, Krasnoyarsk, Russia (*correspondence: VOnufriynok@yandex.ru)

Pyrrhotites have the NiAs crystal structure in which a fraction of cation sites is unoccupied. The temperature (T_0) at which the total magnetic moment of the two sublattices is zero (antiferromagnetic) depends on the chemical composition. It can change from 558 K ($Fe_{10}S_{11}$) to 593 K (Fe_7S_8). Accordingly, concentration of vacancy: from 9.1% to 12.5 %.

There was studied the dependence of the magnetization on the temperature of the pyrrhotite samples after being synthesized at 1273 K. The synthetic pyrrhotites were investigated with a thermoballistic apparatus in a field of $10^6/4\pi$ A/m. The phase and chemical composition was monitored by using the methods of X-ray diffraction (XRD).

The influence of concentration vacancies on the temperature to transition of the pyrrhotites to the antiferromagnetic state was considered on the basis of calculating the magnetic moment of the two sublattices using the molecular field method. Integral of the exchange interaction: $J_{11} = 6.55 \cdot 10^{-21}$ joules; $J_{22} = 5.21 \cdot 10^{-21}$ joules, $J_{12} = J_{21} = 6.52 \cdot 10^{-21}$ joules. For pyrrhotites ($Fe_{10}S_{11}$- Fe_7S_8) the Neel point $T_N = 593$ K (pyrrhotites transition temperature to the paramagnetic state).

samples temperature	Concentration of cation vacancies, %				
	9.1	9.9	10.7	11.6	12.5
T_0, K	¶548	¶568	¶578	¶588	¶593
	#558	#578	#588	#593	#593
Specific magnetization of the samples; $\sigma \cdot 10^{-7}$, T $\cdot m^3/kg$					
T = 293 K	#13.70	#14.91	#16.26	#17.84	#19.05
¶ as calculated; # the experimental data					

Table 1. Temperature to transition of pyrrhotites to the antiferromagnetic state (if the inequality $T_0 < T_N$).

As it is shown in the table, tendency to decreasing of temperature to transition pyrrhotites to the antiferromagnetic state with increasing concentration of cation vacancies is observed both experimental data and the theoretical calculation results.

Zeolitization of aluminosilicate waste materials in soil as a tool for soil remediation

R. TERZANO

Dept. of Agro-forestry and Environmental Biology and Chemistry (Di.B.C.A.), University of Bari, I70126 Bari, Italy (r.terzano@agr.uniba.it)

Zeolites are largely used in soil remediation technologies by exploiting their well-known high cation exchange capacity. Beside this property, zeolites possess large pores and internal cavities. Such pores can be used to trap scarcely soluble heavy metal (HM) precipitates, thus chemically reducing their solubility and physically isolating the contaminant at the microscopic level.

Zeolite synthesis can be easily promoted in soil at low temperatures by adding Si- and Al-containing materials in alkaline conditions. As a consequence of this process HM are stabilized as micro or nano clusters of oxides and hydroxides trapped inside the structure of crystalline zeolites or physically and chemically immobilized by amorphous 'geopolymers' [1-4].

In this process, waste materials such as coal fly ash, blast furnace slag, building wastes, glass and aluminum refuses can be profitably employed, together with cheap alkali reagents (e.g. NaOH, KOH, lime).

The process has been successfully applied to Cu [2], Cd [4], Ni [5] and Cr(VI) polluted soils.

Promoting zeolite synthesis in soil can be a promising methodology to effectively stabilize HM in polluted sites, especially in combination with other physico-chemical or biological remediation processes.

Mineral weathering and mobilization of trace metals in the rhizosphere: The role of root exudates

R. TERZANO[1]*, L. MEDICI[2], T. MIMMO[3], N. TOMASI[4], R. PINTON[4] AND S. CESCO[3]

[1]Di.B.C.A., Bari Univ., 70126 Bari, Italy (*correspondence: r.terzano@agr.uniba.it)
[2]I.M.A.A.–C.N.R., 85050 Tito Scalo (PZ), Italy
[3]Fa.S.T., Bolzano Free Univ., 39100 Bolzano, Italy
[4]Di.S.A., Udine Univ., 33100 Udine, Italy

The mobilization of trace elements in the soil-plant system takes place essentially in the rhizosphere, where roots are intimately in contact with soil. In the rhizosphere, conditions such as pH modification, changes in red-ox potential, high concentrations of organic ligands (either of vegetal or microbial origin), and the modulation of soil-enzyme and microorganism activities, can strongly influence and modify the biogeochemical cycles of several elements, thus causing changes in their availability for plant nutrition.

One class of these elements is composed by the trace metals; some of them are essential for plants even if in small concentrations and are amongst the micronutrients, such as Fe, Zn, Mn. Trace-metal solubility and availability can be influenced, among other factors, by the presence in soil of organic complexing agents that can induce metal mobilization from stable mineral phases. Among these compounds, root exudates such as low molecular weight organic acids (e.g. citric acid, malic acid, oxalic acid), phenolic compounds (e.g. flavonoids), siderophores, can be cited. These molecules can strongly contribute to mineral weathering in rhizosphere and, therefore, to the mobilization of trace metals. The mobilized trace metals, in function of the element and of its concentration, can be either essential nutrients or toxic elements for plants.

Within this context, the objective of this research is to study the mineral weathering processes occurring in the rhizosphere, with particular attention addressed toward the processes involved in trace-metal mobilization and the role of natural organic chelating agents, such as low molecular weight organic acids, phenolic compounds and siderophores. Possible synergic or competitive effects, using pure chemicals as well as exudates collected from plants, on trace-metal solubilization and on mineral weathering occurring among these compounds are being evaluated.

This research is supported by Italian M.U.R.S.T. (FIRB RBFR08L2ZT).

Plio-Pleistocene evolution of water mass exchange and erosional input in the Fram Strait

CLAUDIA TESCHNER[1], MARTIN FRANK[1], BRIAN HALEY[2], MARCUS CHRISTL[3], CHRISTOPH VOGT[4] AND JOCHEN KNIES[5]

[1]IFM-GEOMAR, Wischhofstr.1-3, Kiel, Germany (cteschner@ifm-geomar.de)

[3]Laboratory of Ion Beam Pysics, ETH Zurich, Switzerland
[4]FB Geowissenschaften, University of Bremen, Germany
[5]Geological Survey of Norway, NO-7491 Trondheim, Norway

We determined the isotopic composition of neodymium (Nd), lead (Pb) and beryllium (Be) of past seawater to reconstruct water mass exchange and erosional input between the Arctic Ocean and the Norwegian-Greenland Seas (NGS) over the past approximately 5 Myr. For this purpose, sediments of ODP site 911 (leg 151) from 900 m water depth on Yermak Plateau in the Fram Strait were leached to extract the isotopic composition of past bottom water from early diagenetic metal oxide coatings on the sediment particles [1].

Nd isotope signatures extracted from site 911 agree well with the present day deep water εNd signature of -11.8 ± 0.4 [2]. Overall the Nd isotope composition was more radiogenic in the core section older than 2.7 Ma (εNd = -9 to -10) and then progressively decreased to less radiogenic values (εNd = -11 to -12) similar to the present isotopic composition. $^{206}Pb/^{204}Pb$ ratios evolved from 18.7 to more radiogenic values around 19.2 between 2 Ma and today.

The εNd data indicate that mixing of water masses from the Arctic Ocean and the NGS has controlled the Nd isotope signatures of deep waters on the Yermak Plateau since the onset of the Northern Hemisphere Glaciation (NHG). In contrast, the $^{206}Pb/^{204}Pb$ of deep waters in the Fram Strait appears to have been dominated by glacial weathering inputs from old continental landmasses, such as Greenland or parts of Svalbard since 2 Ma. The changes in the εNd and $^{206}Pb/^{204}Pb$ were similar to those found for the central Arctic Ocean and the North Atlantic (derived from Fe-Mn crusts).

A record of cosmogenic ^{10}Be normalized to ^{9}Be in the same leaches shows a strikingly similar short term variability to those of εNd and $^{206}Pb/^{204}Pb$ suggesting that all three isotope systems have been influenced by the same process controlled by the extent of continental ice sheets and the associated weathering inputs.

Atmospheric dust input to the Northern Gulf of Aqaba

N. TEUTSCH[1]*, O. TIROSH[2], A. TZIPORI[2], U. DAYAN[3] AND Y. EREL[2]

[1]Geological Survey of Israel, Jerusalem, 95501 Israel (*correspondence: nadya.teutsch@gsi.gov.il)
[2]Institute of Earth Sciences, Hebrew University of Jerusalem, Israel
[3]Department of Geography, Hebrew University of Jerusalem, Israel

Atmospheric dust is considered a major source of nutrients to the open sea and major oceanic gyres. However, the contribution of airborne material to the nutrient budget of coastal marine environments was usually neglected because their supply from continental surface runoff was considered adequate. The Gulf of Aqaba situated at the north of the Red Sea is located in an extremely arid region with practically no runoff input, and therefore provides an ideal site to investigate the role of airborne dust in nutrient budget. The major objectives of this study are to quantify the role of atmospheric dust in the nutrient balance of the oligotrophic waters of the Gulf of Aqaba and to characterize the atmoshperic dust input associated with different synoptic conditions.

Suspended dust samples were continuously collected ca. every ten days for almost four years in the northwestern corner of the Gulf of Aqaba, on the pier of the Interuniversity Institute for Marine Sciences, Eilat, Israel. After collection, samples underwent sequential dissolution in order to dissolve first water-soluble salts, then carbonates and oxides, and finally Al-silicates. Dust load vary seasonally from low values in the summer to higher values in the fall, varying values in the winter and highest values in the spring. Major element chemistry points to the main phases extracted at each leaching stage and trace elements are mainly associated with the major elemental trends. Occasionally the dust samples contained elevated concentrations of anthropogenically-emitted metals (e.g. Pb, Zn, Cu) that could be attributed to changes in synoptic conditions. Elemental ratios point to seasonal and synoptic-control on the sources of the dust which in turn determine the solubility of the dust.

Tropical hydrologic cycle variability in the Florida Straits during Marine Isotope Stages 2 and 3

T.R. THEM II[1]*, M.W. SCHMIDT[1] AND J. LYNCH-STIEGLITZ[2]

[1]Department of Oceanography, Texas A&M University, College Station, TX 77843, USA (*correspondence: theo1085@tamu.edu)
[2]School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta, GA, 30332, USA

Reconstructions of North Atlantic salinity variability during the last deglacial suggest that major reorganizations in the tropical hydrologic cycle are linked to North Atlantic Meridional Overturning Circulation (AMOC) and high-latitude climate change [1, 2]. However, it remains unclear if the same mechanisms are responsible for the abrupt climate oscillations during Marine Isotope Stages (MIS) 2 and 3. Here, we generate high-resolution records of sea surface temperature (SST) and $\delta^{18}O_{SEAWATER}$ ($\delta^{18}O_{SW}$, a proxy for surface salinity) from 20-39 ka ago by combining Mg/Ca paleothermometry with $\delta^{18}O$ measurements in shells from the surface-dwelling foraminifera *Globigerinoides ruber* in Florida Margin cores KNR166-2-JPC26 (24°19.61'N, 83°15.14'W; 546 m depth; 18-240 cm/kyr sed. rate) and JPC29 (24°16.93'N, 83°16.24'W; 648 m depth; 8-20 cm/kyr sed. rate). As an additional proxy of salinity variability resulting from riverine input into the Gulf of Mexico, we also measure Ba/Ca ratios in the same *G. ruber* shell material. Finally, benthic $\delta^{18}O$ values in the same cores were measured as a proxy for changes in Florida Current transport, based on the procedures outlined in [3, 4]. Our initial results show that increased Ba/Ca ratios (increased riverine influence), decreased $\delta^{18}O_{SW}$ values (fresher surface salinity) and increased benthic $\delta^{18}O$ values (suggesting increased Florida Current transport) correlate with the abrupt onset of interstadial phases in the NGRIP $\delta^{18}O_{ICE}$ record.

Post-depositional thermal history of the 4364–3060Ma zircon-bearing metasandstones of the Illaara and Maynard Hills granite greenstone belts, Western Australia

E.R. THERN[1]*, F. JOURDAN[2], N.J. EVANS[3], B.J. MCDONALD[3], M. DANISIK[3], R.A. FREW[2] AND D.R. NELSON[4]

[1]DIAP, Curtin Univ., Perth, WA, Australia (*correspondence: eric@thern.org)
[2]WA Argon Isotope Facility, Curtin Univ., Perth, Australia
[3]CSIRO ESRE, Perth, Australia
[4]School of Natural Sciences, Univ. of Western Sydney, Australia

The post-depositional thermal history (spanning 3060Ma to 26Ma) of the ca. 3060Ma Illaara and Maynard Hills granite greenstone belt metastandstones (peak metamorphism of upper greenschist facies) is characterized by a combination of SHRIMP U-Th–Pb, Ar/Ar and (U-Th)/He geochronology.

Ar/Ar multi-grain tourmaline results defining two plateau ages of ~2940Ma on a cross-cutting quartz-tourmaline vein provide a minimum depositional age for the metasandstones. Post depositional stratiform qtz-tourmaline veins are a common occurrence in Archean quartzites, and can be useful in assigning minimum depositional ages and timing of hydrothermal fluids.

SHRIMP U-Th–Pb data of >275 rutile analyses from 8 metasandstone samples reveal a complex history of events between deposition of metasandstones (ca. 3060 Ma) and the subsequent folding, thrusting and granitic intrusions (ca. 2730-2630 Ma, regional D1 to D3 events). Some individual rutile grains yield multiple dates which span from before the maximum depositional age of the quartzite at ca. 3060Ma to the last major metamorphic and granitic event at ca. 2630Ma. These rutiles exhibit weakly defined core-rim younging profiles which represent multiple stages of metamorphic growth or Pb-loss reset events. These results suggest that under protracted greenschist metamorphic conditions rutile can retain signatures of multiple thermal events and even retain some of their original detrital characteristics.

Ar/Ar plateau ages on muscovites from both greenstone belts show that late to post deformation planar-foliation recrystalization at ca. 2605Ma (possibly coeval with the end of D3) marks the end of high-grade tectono-thermal events.

(U-Th)/He on zircon at ca. 230Ma defines exhumation and temperatures <180C for these metasandstones, similar to fission track results throughout the Yilgarn. Goethite (U-Th)/He ages of 26Ma are likely coeval with Fe-rich meteoric fluid influx and associated zero-age Pb-loss and Fe enrichment in metamict zones of both rutile and zircon within the metasandstones.

Past ocean temperatures and coupled U/Th and ^{14}C measurements from deep-sea corals

NIVEDITA THIAGARAJAN, JESS ADKINS AND JOHN EILER

Department of Geological and Planetary Sciences California Institute of Technology 1200 E California Blvd, Pasadena, CA 91125

Deep-sea corals are a unique archive in paleoceanography. They have large banded skeletons that allow for high resolution records and have a high uranium content allowing for accurate calendar ages independent of radiocarbon age measurements. One problem with using deep-sea corals for long records is that it is difficult to date a large numbers of corals accurately and precisely. Unlike sediment cores, fossil fields of corals have no inherent stratigraphy and each individual coral must be separately dated.

Here we present the results of 'reconnaissance radiocarbon age analyses' made at NOSAMS on 519 *Desmophyllum dianthus* (*D. dianthus*) collected from the New England Seamounts and South of Tasmania. We will also present the results of 80 more deep-sea corals measured on the Gas-Source AMS also at NOSAMS in WHOI. We find that the coral populations respond to rapid climate change events and are sensitive to climatically driven changes in thermohaline circulation, productivity, $[O_2]$ and $[CO_3^{2-}]$.

Once dated however, their use as a paleoceanographic archive is complicated by the isotope and trace-metal disequilibria in their skeletons relative to co-existing seawater. However two tracers that overcome these vital effects are paired U-series and radiocarbon dates and clumped isotope measurements. Here we will present preliminary data of YD and H1 corals from the New England Seamounts collected from 1000-2600m of water depth in the North Atlantic where all three tracers are measured in the same corals.

We find that the temperature profile of the ocean during both the YD and H1 coral population is constant with depth. The average potential temperature of the Younger Dryas profile is 1.6 ± 0.5°C while the average potential temperature of the Heinrich 1 profile is 3.1±0.9°C. If one outlier in the H1 profile is removed the average temperature becomes 2.3±0.5°C. We will discuss implications for salinity gradients in the water column during these time periods as well changes in the circulation of the ocean.

Using ToF-SIMS to study biomarkers

V. THIEL[1]*, M. BLUMENBERG[1], C. HEIM[1], J. LAUSMAA[2], T. LEEFMANN[1], J. REITNER[1], S. SILJESTRÖM[2] AND P. SJÖVALL[2]

Time-of-flight secondary ion mass spectrometry (ToF-SIMS) is a technique designed to analyze the composition and lateral distribution of molecules and chemical structures on surfaces. A beam of high-energy ions (primary ions) bombards the sample surface, resulting in the emission of secondary ions from the outermost molecular layers of the sample. Analysis of these ions with respect to mass yields a mass spectrum which contains chemical information about the sample surface. During the measurement, the primary ion beam is scanned over a selected analysis area and individual mass spectra are recorded from each raster point within this area. The acquired data can then be used to produce (i) ion images, which show the signal intensity of selected secondary ions across the analysis area, and (ii) mass spectra from selected regions of interest on the sample surface.

These capabilities have generated much interest in the use of ToF-SIMS for the characterization of lipids and other organic biomolecules at the microscopic (μm-) level (see [1] and [2] for reviews). Here we introduce static ToF-SIMS imaging mass spectrometry as a tool for organic geochemical analyses. After describing the ToF-SIMS analysis principles, experiments on selected sample types relevant in geobiology and organic geochemistry are reported, namely soft (microbial cell matter, sediments), hard (microbialites), and liquid (fluid inclusions) samples. This presentation aims to put the potential of ToF-SIMS for organic biomarker approaches up for discussion, considering not only the strengths, but also current drawbacks and limitations for which further development would be beneficial for the field.

Raison d'être of X-ray spectromicroscopy for geochemistry

JUERGEN THIEME[1], JULIA SEDLMAIR[2], MAREIKE MATHES[2], JOERG PRIETZEL[3] AND JOHN COATES[4]

[1]NSLS-II, Brookhaven National Laboratory, Building 817, Upton, NY-11973, USA (jthieme@bnl.gov)
[2]Institute for X-Ray Physics, University of Goettingen, Friedrich-Hund-Platz 1, 37077 Goettingen, Germany
[3]Lehrstuhl fuer Bodenkunde, Technische Universitaet Muenchen, 85350 Freising-Weihenstephan, Germany
[4]Dept. for Plant and Microbial Biology, University of California, Berkeley, CA-94720, USA

X-ray microscopy in the sub-keV X-ray energy range uncovers structures down to 10 nm size, at higher X-ray energies structure sizes down to 30 nm can be imaged. The technique is capable of imaging specimens directly in aqueous media. X-ray microscopy images can be used for tomographic reconstructions of thick samples. By choosing the used X-ray energy appropriately, it is possible to perform spectro-microscopy studies. X-ray fluorescence can be used as a highly sensitive method to identify trace elements. Comprising, the combination of microscopy and spectroscopy is a powerful tool for addressing key questions in many scientific areas, e.g. to study structures in the environment showing dimensions on the nanoscale. Applications to scientific issues in geochemistry, geomicrobiology, and in soil and environmental sciences will be used to show the significance of this tool for science. X-ray images show the appearance of structures on the nano- and microscale. X-ray tomography conveyed morphological changes of humic substances due to biologically induced redox changes. Using the spectromicroscopy potential, the distribution of organic and inorganic components in such samples has been studied. NEXAFS spectra have been analyzed for major chemical constituents. This reveals e.g. the influence of extraction methods on the properties of humic sub-stances. Spectromicroscopy allows the study of carbon nanotubes and their influence on the environment. X-ray fluorescence spectromicroscopy studies of the spatial distribution, the chemical state of sulfur and its co-localization with iron in soils were performed. X-ray spectroscopy and spectromicroscopy has been used to study the release of sulfur from war debris from World War II into urban soils, an issue of rising importance.

(*correspondence: bruno.thien@psi.ch)

During their aqueous alteration, AVM French nuclear glasses exhibit a large range of behaviour, in spite of a small range of composition. AVM glasses alteration rates are controlled by two phenomena: (i) precipitation of secondary phases, mostly aluminous hectorites [1], and (ii) diffusion of water across a more or less protective gel layer. Magnesium contained in these glasses enhances the precipitation of these secondary phases, leading to a partial or total dissolution of the gel layer. This dissolution increases the glass alteration rates. On the other hand, Mg also incorporates in the gel, increasing his passivation properties [2]. The predominance of one of these two phenomena depends on the initial composition of the glass and on the initial composition of the solution (Fig. 1).

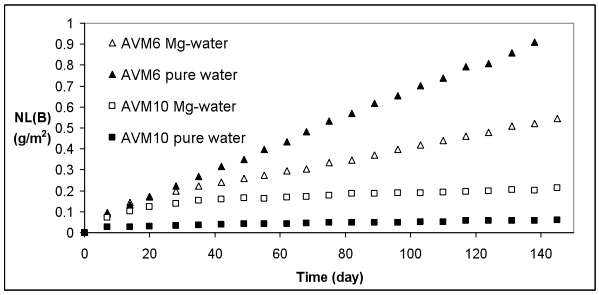

Figure 1: Quantities of altered glass for 2 different AVM glasses, AVM 6 and AVM 10, leached in pure water and in Mg-water.

Magma sources at Eyjafjöll and adjacent South Iceland central volcanoes

MATTHEW THIRLWALL*, CHRISTINA MANNING AND DAVE LOWRY

Dept of Earth Sciences, Royal Holloway, University of London, Egham TW20 0EX, UK

(*correspondence: m.thirlwall@es.rhul.ac.uk)

We present Pb-Sr-Nd-Hf-O isotopic data for Quaternary transitional basaltic rocks of the six central volcanoes of the South Iceland flank zone. These are amongst the deepest melts in Iceland based on high Dy/Yb and low Na_2O/TiO_2. Each volcano shows limited ranges in isotopic composition, but Eyjafjöll Sr-Nd-Hf-O data lie systematically between Heimaey at more depleted isotopic compositions to the SW, and Katla and Tindfjöll at more enriched compositions to the E and N respectively. A tight $^{143}Nd/^{144}Nd$ – $\delta^{18}Ool$ correlation at Eyjafjöll extends from the mantle-like $\delta^{18}O$ of Heimaey to +4.2‰ values in Katla and Hekla olivines. Detail provided by double-spike Pb data shows however that Katla eruptives are not a possible enriched mixing end-member as they have relatively elevated ^{208}Pb, and indeed 3 or more mixing components would be required to explain the Pb isoopic compositions of Eyjafjöll and Tindfjöll eruptives.

The Nd-O isotopic correlation at Eyjafjöll is present in samples from several interglacial stages and could only result from crustal contamination if Eyjafjöll was underlain by an early Quaternary basement of hydrothermally-altered Katla-like volcanics. Given that the bulk of Katla has developed more recently than Eyjafjöll, this seems implausible. The +4.2‰ olivine $\delta^{18}O$ observed at Katla, Hekla, and in some Tindfjöll and Eyjafjöll lavas, is consistent with the value proposed in Icelandic low-$\delta^{18}O$ mantle [1]. It is associated also with low K/Nb and low Na_2O/TiO_2 suggesting that it is co-hosted with recycled oceanic crust that in the flank zone is most effectively tapped by deep melts.

Sea-water ^{231}Pa and ^{230}Th measurements, understanding the proxy in the S.E. Atlantic?

A.L. THOMAS AND G.M. HENDERSON

Department of Earth Sciences, South Parks Road, Oxford, OX1 3AN (*correspondence: alext@earth.ox.ac.uk)

A recent paleo record of ^{231}Pa/^{230}Th from the South Atlantic [1], has been interpreted as evidence for reversed flow of deep water at the last glacial maximum relative to the modern circulation. The ability of the ^{231}Pa/^{230}Th proxy to accurately reflect past paleoceanographic conditions is crucial to the interpretation of such down core records, and this accuracy has been questioned in another recent study [2], using an inverse approach to test whether paleo data is consistent with modern circulation. Currently, our understanding of the controls on sedimentary ^{231}Pa/^{230}Th, limits the robustness of our interpretations of this proxy. We present new ^{231}Pa and ^{230}Th measurements from the South Atlantic, collected on a UK-GEOTRACES cruise (D357; GA10) at 40°S, and compare to local sedimentary data to shed light on the regional controls on sedimentary ^{231}Pa/^{230}Th and hence asses the robustness of down core interpretations. By comparison with data from elsewhere in the Atlantic this data indicates the role of water masses and processes such as boundary scavenging on the ^{231}Pa/^{230}Th proxy and therefore points to the robustness of the proxy for past reconstruction.

Pre-Sturtian euxinia and ocean chemistry: Evidence from the Coppercap Formation in Northwest Territories, Canada

K. THOMAS[1], C. HALLMANN[1], F. MACDONALD[2], R. SUMMONS[1] AND S. ONO[1]

[1]Massachusetts Institute of Technology, Cambridge, MA (katthomas@mit.edu, hallmann@mit.edu)

[2]Harvard University, Cambridge, MA (fmacdon@fas.harvard.edu)

The mechanisms that lead to the onset of the Late Proterozoic global glaciations are yet unresolved but can be correlated through globally observed chemostratigraphical changes [1]. In interpreting the geochemical evidence from this time period, critical analysis of global versus regional effects [2] comes into play in determining the true extent of marine euxinia. Here we present a geochemical record of paired carbonate associated sulfate ($\delta^{34}S_{CAS}$) and pyrite ($\delta^{34}S_{pyr}$), organic carbon ($\delta^{13}C_{org}$) and carbonate ($\delta^{13}C_{carb}$) along with lipid biomarker analysis of the Coppercap Formation in the Northwest Territories, Canada, which was deposited just prior to the onset of the Sturtian glaciation.

Trimethylarylisoprenoids carotenoid-derived lipids indicative of purple and green sulfur bacteria were found throughout the section and indicate persistent euxinia in the shallow sediments deposited in a syn-rift basin. We observe an average $\Delta^{34}S_{CAS\text{-}Pyr}$ of ~ 25‰ which is typical for Neoproterozoic deposits [3] [4]. Increased burial of organic carbon and sedimentary sulfide is implicated from an isotopic shift in $\delta^{13}C_{carb}$ and $\delta^{34}S_{CAS}$. Severe euxinic conditions mid-section is evidenced from increased concentrations of arylisoprenoids and which coincides with a ~15‰ increase in $\delta^{34}S_{CAS}$, showing an interplay between more restricted conditions and marine ingressions. The implications of these geochemical signals and biomarker distributions are placed into a context of the onset of the Late Proterozoic glaciations.

Negative sulfur-MIF anomalies in metasomatized eclogites from Siberia

E. THOMASSOT[1], C. ROLLION-BARD[1], D.G. PEARSON[2], N. ASSAYAG[3] AND M. FIALIN[3]

[1]CRPG/CNRS, Vandoeuvre-lès-Nancy, France
[2]University of Alberta, Edmonton, AB, Canada
[3]IPG–Paris et Université Paris VI, France

Sulfur Mass Independent Fractionations (S-MIF), likely formed in the Archean atmosphere, are preserved in sedimentary rocks formed prior to 2.5 Ga [1]. Their recyclage into the mantle has been identified in metasedimentary sulfides included in diamonds, which carry significant S-MIF [2, 3]. However in both metasediments and diamond inclusions, most S-MIF values (carried by insoluble S-species) are positive, whereas the material balance of sulfur cycled from Archean atmosphere to sedimentary reservoirs requires that the average of all S-MIF is 0. Despite this requirement, the record of a negative S-MIF reservoir (likely dissolved in the oceans) is mostly absent, with only barite and sulfide of hydrothermal origin having these characteristics but representing a quite modest reservoir in size. Here we present a detailed petrological study coupled with *in situ* S-isotope measurements in 4 sulfides (~500μm in diameter) extracted from a mantle eclogite xenolith from the Mir kimberlite (Siberia). They consist of complex assemblages of (1) classic mantle sulfides (intergrowths of pyrrhotite and pentlandite) with (2) K-rich sulfides (djerfisherite) invaded by (3) veinlets of alteration-related minerals (mainly chlorite), resulting from multi-stage metasomatic processes [4]. Because of this complexity, we performed *in situ* multiple S-isotope measurements using a new Caméca ims 1280-HR2, allowing precise measurement with a spatial resolution < 20 μm, with precision for $\Delta^{33}S$ better than ±0.1 ‰.

Despite mineralogical heterogeneities, $\delta^{34}S$ in each sulfide has a narrow range (± 0.9 ‰). Most suprisingly, they show significant, exclusively negative MIF, ranging from 0 to -0.42‰ (±0.1 ‰, n=18). Metasomatic djerfischerite rims show smaller isotopic anomalies which cannot be clearly distinguished outside of uncertainty. We interpret the negative $\Delta^{33}S$ in the primary sulfides as reflecting an imprint of hydrothermal circulation in Archean oceanic crust. The smaller anomalies in the rims may reflect later reequilibration during modal metasomatism. Hence the signature appears to be evidence of a more widespread reservoir with negative $\Delta^{33}S$ that may balance the Archean S-MIF budget. The new S isotope data also provide further support for subducted oceanic crust as the protoliths of Siberian eclogites.

Extreme ^{15}N-enrichments in 2.72-Gyr-old sediments: Evidence for a turning point in the nitrogen cycle

C. THOMAZO[1]*, M. ADER[2] AND P. PHILIPPOT[3]

[1]UMR CNRS 5561 Biogéosciences, Université de Bourgogne, Dijon, France
(*correspondence: christophe.thomazo@u-bourgogne.fr)
[2]Equipe de géochimie des isotopes stables, Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Université Paris Diderot, UMR 7154 CNRS, F-75005 Paris, France
[3]Equipe de geobiosphère actuelle et primitive, Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Université Paris Diderot, CNRS, F-75005 Paris, France

Although nitrogen is a key element in organic molecules such as nucleic acids and proteins, the timing of the emergence of its modern biogeochemical cycle is poorly known. Recent studies suggests the establishment of a complete aerobic N biogeochemical cycle at about 2.68 Gyr. Here, we report new bulk nitrogen isotope data for the 2.72 billion-year-old sedimentary succession of the Tumbiana Formation (Pilbara Craton, Western Australia). The nitrogen isotopic compositions vary widely from +8.6‰ up to +50.4‰ and are inversely correlated with the very low $\delta^{13}C$ values of associated organic matter defining the Fortescue excursion (down to about -56‰).

We argue that the main driver of this exceptional high $\delta^{15}N$ values is the isotope fractionation associated with microbial ammonia oxidation, the produced nitrite and nitrate being totally converted to gaseous N_2O or N_2 by denitrification. The expression of this isotope fractionation in the rock record suggests that a small increase in oxidant availability allowed water column colonization by ammonia oxidizing micro-organisms, but was too limited to allow ammonium to be fully used up. The subsequent decrease of $\delta^{15}N$ values down to modern values 5 ±3‰ by 2.6 Gyr probably reflects a redox increase of at least part of the water column, leading to the establishment of a chemocline interface (localized either in the water column or in the sediment) where ammonium is quantitatively oxidized by denitrification as in modern environments. This study allows us to date precisely the onset of the oxidative part of the nitrogen cycle at 2.72 Gyr. We see the first evidence for ammonium oxidation, nitrification, and denitrification, which implies an increase in the availability of electron acceptors and probably oxygen in the Tumbiana depositional environment, 300 million years before the oxygenation of the Earth's atmosphere.

Uranium series analysis of 2006 Augustine volcanics: An investigation into the timescales of magmatic processes

J.A. THOMPSON* AND M.K. REAGAN

University of Iowa, Iowa City, Iowa 52245
(*correspondence: jennifer-cash@uiowa.edu)

The frequent eruptions (5 eruptions in the last century) and the narrow range of erupted products (dacites to andesites) in conjunction with excellent documentation of the 2006 eruption by the Alaskan Volcano Observatory (AVO) make Augustine an ideal location for investigating the time-scales of magma mixing and differentiation. Toward this end, a set of 17 representative samples of the 2006 eruption were analyzed for ^{238}U, ^{230}Th, ^{226}Ra, and ^{210}Pb abundances, as well as major and trace element concentrations.

All samples from Augustine have consistent excesses of (^{230}Th) over (^{238}U). Similar excesses in other andesitic lavas have been explained by slab or lower crustal melting with residual garnet, or differentiation from basalt generated by melting mantle in the presence of garnet or Al-rich pyroxene. We prefer the latter explanation based on documentation for basaltic parental magmas (Larsen *et al*. 2010), and a lack of evidence for garnet fractionation with differentiation. Variations in ($^{230}Th/^{232}Th$) values vary independently of SiO_2 concentrations, suggesting that the mixtures of melts and crystals making up the differentiated magmas have average ages as high as 54 Ka.

Our most mafic sample (an enclave with 53 wt % SiO_2) has ($^{226}Ra/^{230}Th$) = ~1.2. With increasing concentrations of SiO_2, the ($^{226}Ra/^{230}Th$) values decrease to ~1 at SiO_2 ~ 56 wt. %, increase to 1.45 at SiO_2 ~ 59 wt %, then decrease to ~1 in samples with >61 wt. % SiO_2. These data suggest that three magmas mingled and mixed during the 2006 eruption: basaltic andesites with Ra excesses generated by mantle melting; a 59 wt % SiO_2 magma with Ra excesses generated from incongruent melting of youg plutonic materials, and 61-62 wt % SiO_2 andesites with relatively long crustal residence times.

Excesses of (^{210}Pb) over (^{226}Ra) were measured in the most mafic and silicic samples at Augustine, whereas intermediate samples had either equilbrium ($^{210}Pb/^{226}Ra$) or small ^{210}Pb deficits. The excesses in the basaltic andesites were likely generated during degassing within a compositional boundary layer. Excesses in high silica samples were likely produced by localized degassing through porous networks of vesicles.

Best practices for ensuring consistent coral geochronology

W.G. THOMPSON

113A Clark Lab, MS # 23, Woods Hole Oceanographic Institution, Woods Hole, MA 02543

The goal of geochronology is to supply an accurate timescale for earth processes, and U-Th coral dating has been sucessfully used to infer the history of sea level change. However, it is widely acknowledged that U-Th coral geochronology is strongly impacted by diagenetic artefacts over much of its practical dating range [1]. Improved understanding of the major diagenetic processes producing significant artefacts in coral ages has inspired a vigorous debate over best practices in coral geochronology [2]. Traditional approaches rely on screening criteria to identify corals that have behaved as a closed system, while newer approaches seek to quantify and correct for the diagenetic processes directly. Regardless of the preferred approach for U-Th age interpretation, it is clear that differences in screening criteria and assumptions about the oceans past uranium isotope ratio have considerable influence on the conclusions inferred from U-series coral data. Using new and existing data, and fundamental statistical analysis, we demonstrate the sensitivity of U-Th coral geochronology to small differences in age interpretation practices. Furthermore, we suggest simple and practical steps that can be taken now to make the interpretation of coral ages more objective and consistent; a fundamental goal of geochronology.

Volatile short lived iodocarbons from biotic and abiotic sources affecting atmospheric chemistry

U.R. THORENZ*, M.KUNDEL, J. BOSLE AND T. HOFFMANN

Johannes Gutenberg-University, Institute for Inorganic and Analytical Chemistry, Duesbergweg 10-14, 55128 Mainz (*correspondence: ute.thorenz@uni-mainz.de)

Atmospheric Iodine chemistry in the lower troposphere gained more attention in the last decade, because of its ozone depleting capacity [1]. The oxides formed during this reaction may also undergo further oxidation and form polyoxides which then play a role in new particle formation [2]. Precursors of both reactions are iodocarbons found in the marine atmosphere. These Iodocarbons are emitted by different macroalgae [3] and are also produced by abiotic reactions [4]. The investigation of both release pathways is the aim of the presented study.

The method developed uses thermodesorption gas chromatography negative chemical ionisation mass spectrometry TD-GC-NCI-MS. Using the negative ionisation mode the method detection limits were reduced by on order of magnitude compared to electron impact. (LOD: Iodomethane 2.01 pg, Iodethane 0.98 pg, Iodchloromethane 0.26 pg, Iodbromomethane 7.37 pg, Diiodmethane 8.61 pg)

To investigate the biotic release pathway we treated different algae species with various ozone mixing ratios and measured iodocarbon and inorganic iodine release of the algae. We found a correlation on ozone concentration and iodine as well as organo-iodine release. A good correlation was found for iodine release and place of growth, meaning that algae growing above or in the intertidal zone release less iodine than algae in the sublittoral zone.

dT investigate the abiotic pathways of forming iodocarbons a chamber experiment was done using particulate HOI and fulvic acid. The particles were formed by an atomizer and crossed a chamber with a residuance time of 160 seconds. Even after this short reaction time the formation of iodomethan was seen.

Rapid changes in North Atlantic deep ocean circulation during the MIS 5a/4 glacial inception

D.J.R. THORNALLEY[1]*, S. BARKER[1], I.R. HALL[1] AND G. KNORR[2]

[1]School of Earth and Ocean Sciences, Cardiff University, Park Place, Cardiff, CF10 3AT, UK (*correspondence: ThornalleyDJ@cf.ac.uk, BarkerS3@cf.ac.uk, Hall@cf.ac.uk)

[2]Alfred Wegener Institute, Bussestrasse 24, D-27570 Bremerhaven, Germany (Gregor.Knorr@awi.de)

Earth's climate during the Plio-Pleistocene epoch has been characterised by oscillations between glacial and interglacial conditions, thought to be related to changes in the Earth's orbit, as well as feedbacks including variations in atmospheric CO_2 and ice albedo. Detailed examination of the last glacial termination (and earlier terminations) has revealed that millennial-scale changes, probably involving variation in the Atlantic meridional overturning circulation (AMOC), play a critical role in the mechanism of glacial termination. Conversely, very little is known about the AMOC during the onset of glacial conditions and the associated millennial-scale variability.

Here, we investigate North Atlantic deep ocean circulation during the Marine Isotope Stage 5a to 4 glacial inception ~70, 000 years ago, an interval which contains Dansgaard-Oeschger events 19 and 20 and also marks the onset of full glacial conditions, involving a rapid lowering of sea-level an abrupt decrease in atmospheric CO_2. Using a range of geochemical and sedimentological methods applied to marine sediment cores, we present high resolution (100-200 year) proxy reconstructions of deep water circulation and chemistry from depth transects in both the eastern and western North Atlantic. The chronology of the cores is tightly constrained, enabling us to examine the precise timing of deep ocean chemistry and circulation changes with respect to the decrease in sea-level and atmospheric carbon dioxide.

Strontium behaviour during bioreduction in nitrate impacted sediments

C.L. THORPE[1], G.T.W. LAW[1], I.T. BURKE[2], J.R. LLOYD[1], S. SHAW[2] AND K. MORRIS[1]*

[1]Research Centre for Radwaste and Decommissioning, SEAES, University of Manchester, M13 9PL, UK (*correspondence: kath.morris@manchester.ac.uk)

^{90}Sr is a contaminant at nuclear sites, has a ~30 year half life and has high potential mobility in ground waters. Here, we explored the behaviour of Sr^{2+} during sediment bioreduction under varying pH and NO_3^- amendments. During NO_3^- reduction, enhanced Sr^{2+} sorption to sediments occurred as alkalinity developed as a result of OH^- and HCO_3^- formation during denitrification [1, 2]. During development of metal reducing conditions, Sr^{2+} was then re-released to solution in microcosms with a final pH < 9 suggesting that Sr^{2+} had been preferentially sorbed to Fe(III)-bearing mineral phases during NO_3^- reduction and reductive dissolution of Fe(III)-phases was controlling Sr^{2+} solubility. In microcosms with a final pH > 9, Sr^{2+} was retained on sediments throughout bioreduction presumably to its association with stable carbonate phases which become oversaturated at high pH. Further investigation of these systems with X-ray absorption spectroscopy, electron microscopy and modelling indicated that that at pH < ~9, Sr^{2+} forms outer sphere complexes in the sediment whilst at pH > ~9, incorporation into carbonate phases is possible. Overall, Sr^{2+} behaviour during bioreduction is complex with high pH bioreducing conditions showing potential for co-treating Sr^{2+} with a range of radioactive contaminants.

Rb-Sr and Sm-Nd isochron ages of the Dongmozhazhua and Mohailaheng Pb-Zn ore deposits in Yushu area, southern Qinghai and their geological implications

TIAN SHIHONG[1,2]*, HOU ZENGQIAN[3], YANG ZHUSEN[1], LIU YINGCHAO[3] AND SONG YUCAI[3]

[1]Institute of Mineral Resources, CAGS, Beijing 100037, China (*correspondence: s.h.tian@163.com)
[2]Key Laboratory of Metallogeny and Mineral Assessment, MLR, Beijing 100037, P.R. China
[3]Institute of Geology, CAGS, Beijing 100037, China

Dongmozhazhua and Mohailaheng Pb-Zn deposits in Yushu area of Qinghai Province are representative Pb-Zn deposits in the Cu-Pb-Zn polymetallic mineralization belt of the northern part of the Nujiang-Lancangjiang-Jinshajiang area, which are in the front belt of Yushu thrust nappe system. The ages of the Dongmozhazhua deposit have been determined by the Rb-Sr isochron method for sphalerite; whereas, the ages of the Mohailaheng deposit have been determined by the Rb-Sr isochron method for sphalerite and the Sm-Nd isochron method for fluorite. The age of Dongmozhazhua deposit is 35.015 ± 0.034 Ma ($(^{87}Sr/^{86}Sr)_0$= 0.7088072 ± 11) for sphalerite. The age of Mohailaheng deposit is 32.22 ± 0.36 Ma ($(^{87}Sr/^{86}Sr)_0$=0.70851380 ± 89) for sphalerite and 31.75 ± 0.28 Ma ($(^{143}Nd/^{144}Nd)_0$= 0.51236150 ± 54) for fluorite with an average of 32 Ma. Combined with geological and geochemical data, it is concluded that the Dongmozhazhua and Mohailaheng deposits formed during the same geological event and the metals have the same source. Together with regional mineralization geological setting, a possible tectonic model for metallogeny of Dongmozhazhua and Mohailaheng Pb-Zn deposits has been established. These two ages are close to the ages of the Pb-Zn deposit in Lanping basin of the southern part of the Nujiang-Lancangjiang-Jinshajiang area and in Tuotuohe basin of the northern part of the Nujiang-Lancangjiang-Jinshajiang area, indicating that it is possible that the narrow 1000 km-length belt controlled by thrust nappe system in the eastern and northern margins of Tibetan plateau would be a giant Pb-Zn mineralization belt.

Speciation and thermodynamic properties of Manganese(II) and Nickel(II) chloride complexes in hydrothermal fluids: *In situ* XAS study

YUAN TIAN[1]*, JOËL BRUGGER[2], WEIHUA LIU[3], BARBARA ETSCHMANN[2], STACEY BORG[3], DENIS TESTEMALE[4], BRIAN O'NEILL[1] AND YUNG NGOTHAI[1]

[4]Institut Néel, Département MCMF, France

Aqueous Mn (II) and Ni (II) chloride complexes play an important role in Mn/Ni transport and deposition in hydrothermal ore-forming systems. Understanding metal transport and deposition relies on our knowledge of the metal speciation transported in hydrothermal fluids and thermodynamic properties of each species.

Synchrotron based XAS technique was used to measure *k*-edge spectra of Mn (II) and Ni (II)-bearing solutions with increasing temperature and salinity. Mn (II) and Ni (II) exhibit similar XANES spectral evolutions to other divalent transition metals, which reveals that octahedral species predominante at room temperature, while tetrahedral species become more important with increasing temperature and sanility. *Ab initio* XANES simulations and EXAFS refinements determined the structure of predominant end-member species $M(H_2O)_6^{2+}$ and $MCl_3(H_2O)^-$ and demonstrated that fully chlorinated complex MCl_4^{2-} is not stable in hypersaline brines (M = Mn, Ni). This result, together with previous studies of aqueous chloride complexes of Fe (II)[1] and Co (II)[2] revealed the difference in the two pairs of transition metals to form high order chloride complexes: Mn-Fe and Ni-Co. The former member forms $MCl_3(H_2O)^-$ at high temperature and high salinity while latter member forms fully chlorinated complex under the same conditions. XANES spectra were used to calculate formation constants and thermodynamic properties of $MCl_3(H_2O)^-$ species which can explain the strong fractionation between the proposed couple metals in hydrothermal systems.

Craton destabilization and alkaline magmatism in equatorial East Africa

JOHN V. TIBERINDWA[1,2], KLEMENS LINK[1], ERASMUS BARIFAIJO[2] AND STEPHEN F. FOLEY[1]

[1]Geocycles Research Centre and Institute for Geosciences, University of Mainz, 55099 Mainz Germany
[2]Department of Geology, Makarere University, Kampala, Uganda

Several types of alkaline magmatism are typically related to specific locations on and around cratons. Diamond-bearing kimberlites are restricted to craton centres, many lamproites occur around craton edges, and ultramafic lamprophyres are associated with areas where cratons are rifted. The Tanzanian craton is an example of a craton at an intermediate stage of destabilization. It is supported by warm upwelling mantle and its surface is at an elevation of >1, 100m. However, unravelling the petrogenesis is complicated by the confluence of cratonic magmatism with the East African Rift. We have reassessed alkaline magmatism around the Tanzanian craton and find a negative correlation between K/Na ratios in rocks and distance from the craton. Potassium-rich rocks have generally been associated with the western rift branch because of the occurrence of kalsilite-bearing volcanic rocks there, but also occur at the eastern edge of the craton. The association of potassium with cratons is attributed to melting at >140 km depth to form mixed source regions containing phlogopite pyroxenite and peridotite. In the western branch of the rift, the base of the lithosphere is interpreted to plunge to deeper levels towards the north beneath a saddle of cratonic lithosphere that links the Tanzanian and Congo cratons [1]. K/Na of magmas decreases towards the south where melting occurs closer to the surface. Here, amphibole rather than phlogopite is involved in melting. In southern Kenya (eastern rift), olivine phenocrysts have high Ni contents that are interpreted to indicate melting of a different type pyroxenite, namely garnet pyroxenites that are also found as xenoliths [2]. Due to the combination of craton destabilization and continental rifting, the pattern of magmatism around the Tanzanian craton shows a great variety of contemporaneous magmatism which is similar to that stretched over more than 1, 200 million years during several stages in the Labrador Sea rift [3].

Peering through the diagenetic window for Archean phototrophs

M.M. TICE[1]*, J. CAI[1], C.-T. LEE[2] AND D.R. LOWE[3]

[1]Department of Geology & Geophysics, Texas A&M Univ., College Station, TX 77843 (*correspondence: mtice@geos.tamu.edu, jjcc@neo.tamu.edu)
[2]Department of Earth Science, Rice Univ., Houston, TX 77005 (ctlee@rice.edu)
[3]Department of Geological & Environmental Sciences, Stanford Univ., Stanford, CA 94305 (drlowe@stanford.edu)

Because Fe^{2+} can be oxidized by several environmentally-relevant pathways, it is not currently known what process produced banded iron formations prior to the oxygenation of the atmosphere [1]. In contrast, Mn^{2+} is not known to be oxidized by anoxygenic organisms and is not as photochemically reactive as Fe^{2+}. It has therefore been suggested that sedimentary Mn(IV) minerals should be regarded as the geologic marker of oxygenic photosynthesis [2]. Unfortunately, these minerals are some of the first electron acceptors to be reduced during sedimentary diagenesis [3], so their absence in sedimentary rocks of a given age does not necessarily indicate the absence of oxygenic photosynthetic bacteria at that time. Seeing through the window of diagenetic metal reduction is therefore critical to reconstructing a manganese proxy record of the evolution of oxygenic photosynthesis.

Diagenetic carbonate minerals in hematitic cherts of the 3.26 Ga Fig Tree Group preserve a range of rare earth element (REE) distributions with end-members consistent with minimally modified seawater (superchondritic Y/Ho and no middle REE enrichment) and sedimentary pore fluids in iron-reducing diagenetic zones (chondritic Y/Ho and middle REE enrichment). Low Mn/Fe ratios and seawater-like REE distributions are present in ankerite in deep-water hematitic banded iron formation. Ankerite and dolomite in shallow-water jaspers preserve elevated Mn/Fe ratios that correlate inversely with degree of diagenetic alteration inferred by REE distributions. No primary Mn(IV) minerals have been observed in any of these rocks. We show that this pattern is most consistent with a lack of Mn(IV) minerals prior to diagenetic alteration and the absence of oxygenic phototrophs during deposition of Fig Tree banded iron formation.

Dating granites from the Erzgebirge by different methods – A comparison

M. TICHOMIROWA[1] AND J. PFÄNDER[2]

[1]Institute of Mineralogy, TU Bergakademie Freiberg, D-09599 Freiberg, Germany
[2]Institute of Geology, TU Bergakademie Freiberg, D-09599 Freiberg, Germany

Granites from the Erzgebirge mark the final stage of the Variscan Orogeny. Therefore, they are important time marks to unravel the evolution of late and post-orogenic processes. Until now, there is still a large scatter of ages obtained at different laboratories and by different methods for these igneous rocks. The granites display very distinct geochemical and petrological patterns. 'Early' granites were almost undifferentiated and consist mainly of biotite granites. 'Later' granites were strongly differentiated and appear as two-mica granites or Li-mica granites. Some of the 'latter' granites belong to fluorine-rich varieties. In addition to geochemical magmatic differentiation, many granites were severely overprinted by hydrothermal activity which was often related to ore-forming processes. Multiple overprint processes may hamper precise and accurate dating of such granites because of the possible disturbance of dating systems.

Recently, an age difference of about 9 (±3) Ma was established between two granite suites belonging to the 'early' and 'late' stage by the single zircon evaporation method [1]. We present new age data (Pb/Pb on zircon, U/Pb SHRIMP on zircon, U/Pb conventional dating, Rb/Sr on mineral separates, Ar/Ar on mica) for these and further granite suites from the Erzgebirge (Eibenstock, Aue-Schwarzenberg, Kirchberg, Bergen, Frauenstein). The data will be discussed in light on duration of igneous processes as well as on precision of dating methods.

Effects of Louisville seamount subduction: Geochemical evidence from central Tonga-Kermadec arc volcanoes

C. TIMM[1], I.J. GRAHAM[1], M.I. LEYBOURNE[1], C.E.J. DE RONDE[1] AND J. WOODHEAD[2]

[1]GNS Science, PO Box 30-368, Lower Hutt, New Zealand
[2]School of Earth Sciences, The University of Melbourne, Melbourne, Victoria 3010, Australia

Alkaline Louisville seamount lavas and volcaniclastics were subducted beneath the Tonga arc since ~4 Ma, while the locus of seamount-arc intersection moved southward with time. Presently, Louisville material is subducting beneath the northern Kermadec/southern Tonga arc nearby the arc volcanoes Monowai, 'U', 'V'. Basalts recovered from all three volcanoes during the NZAPLUME III expedition show MORB-type REE patterns with enrichments of LILE and negative Nb anomalies. Lavas from Ata Island (located ~250 km N of 'V') however have higher La/Sm, Sm/Yb (and Th/Yb) than lavas from Monowai, 'U' and 'V', suggesting the input of fluid-immobile elements, such as LREE, MREE and Th from the slab into the mantle wedge beneath Ata Island. Conversely more radiogenic Sr and Pb isotopic compositions are found in lavas from volcano 'U' and 'V', consistent with input of fluid-transported Sr and Pb from subducted Louisville material beneath these volcanoes. Because dehydration of the slab requires lower temperatures than melting, we suggest that both the higher fluid-immobile, more to less incompatible element ratios (and slightly lower $^{143}Nd/^{144}Nd$) in the Ata Island lavas, and the higher Sr and Pb isotopic composition in the 'U' and 'V' lavas may reflect the influence of subducting Louisville material transported to the mantle wedge via aqueous fluids and hydrous melts and/or bulk mixing at different locations and times.

A paradox between Mg and Li isotope ratios during weathering

E.T. TIPPER[1,2], D. CALMELS[2], J. GAILLARDET[2], P. LOUVAT[2], F. CAPMAS[2] AND B. DUBACQ[1]

[1]Dept. of Earth Sciences, University of Cambridge, UK (ett20@cam.ac.uk)
[2]IPGP-Université Paris 7, Paris, France

The sources and processes that release mineral-bound (Mg) to solute Mg during chemical weathering are surprisingly under-constrained, but are critical for a complete understanding and quantification of its global biogeochemical cycle and chemical weathering. Magnesium isotope ratios ($^{26}Mg/^{24}Mg$ expressed as $\delta^{26}Mg$) in the river waters of the Mackenzie basin show in excess of 1‰ variability. In suspended sediments $\delta^{26}Mg$ values show in excess of 3‰ variation and correlate with the Ca/Mg ratio, a strong indication that the rock composition is controlled by a mixture of carbonate and silicate minerals. Riverine $\delta^{26}Mg$ values do not show the same control. Rather, they show coherent trends suggesting that Mg isotopes are more likely controlled by process-related fractionation. In particular, we highlight a linear positive covariation (R^2=0.81) between Li ($^7Li/^6Li$) and Mg isotope ratios in the rivers waters of the Mackenzie Basin and in four of the world's largest rivers. This is therefore representative of the average processes occurring at a global scale. Li is not present in appreciable quantities in carbonate rocks, but Mg can be. Therefore Mg isotope ratios are not being dominated by processes linked to carbonate dissolution. Li isotopes have often been interpreted in term of process controlled fractionation linked to silicate weathering and clay and previous work has demonstrated that during weathering, Mg and Li isotopes show opposite discrimination. Waters are often enriched in the light isotope of Mg and the heavy isotope of Li compared to the rocks they drain. The data present a paradox because any covariation between $^7Li/^6Li$ and $^{26}Mg/^{24}Mg$ would be anticipated to show a negative slope, rather than the positive slope observed. This paradox could be very simply resolved by interpreting the isotopic compositions as mixtures of different water bodies (such as groundwaters and surface waters for example) but this is not supported by concomitant variation in Mg/Li ratios. Modelling results show that the co-variation is more likely related to fractionation linked to clays. Coupled modelling of Mg and Li enables both the fractionation factors associated with such processes to be estimated, and the proportion of Mg that is incorporated into secondary phases, enhancing our current understanding of solute Mg at spatial scales from the critical zone to the continental scale rivers.

On the thermal and dynamic requirements for mantle melting

M. TIRONE* AND J. GANGULY

Department of Geosciences, Univ. of Arizona, Tucson, 85721 AZ, USA (*correspondence: max.tirone@gmail.com)

Our understanding of the petrological geodynamics of the Earth's mantle can be improved by numerical simulations supported by a comparison of the results with observable quantitites. Melting in the upper mantle is the end-product of dynamic and petrological processes. The description of these processes is usually based on several simplifying assumptions. However, a more realistic approach should consider the complex interplay among the petrological and dynamical aspects. Here we present a multistage numerical procedure to characterize the thermal and dynamic conditions of the mantle that ultimately control the melting process as a function of time and space during mantle upwelling. (1): A parameterized mantle convection model is used in conjuction with a thermodynamic approach and an optimized mineralogically dependent viscosity model to determine the thermal structure of the mantle from top to bottom using several constraints such as the melting temperature requirement to generate komatite magmatism in the Archean and plume melting in more recent time. (2): The viscosity and the thermodynamic models and the thermal state at the CMB from the thermal history study are then applied to model the geodynamic evolution of a thermal plume. (3): The thermal and dynamic evolution at shallow depth (but below the mantle solidus) is then used to constrain the melting process which is investigated using a coupled two-phase flow model and a thermodynamic formulation for melt that is modified from pMELTS.

The whole procedure illustrates the interconnection among a wide range of factors, such as thermal history, CMB temperature, mantle viscosity, thermal structure of plumes, evolution and composition of melt.

Here stage (3) is applied to the case of melting under a moving plate (e.g. Hawaii) which is discussed in some details. In particular it is shown how the thermal and dynamic interaction of the plume with the lithosphere affects the melt distribution and composition and how it is related to the various stages of magma emplacement. A source component of melt detected by the model is clearly provided by the lithospheric mantle. Pyroxenite cumulates are obtained by partial crystallization of underplated melt. Bathymetry appears to be correlated with the thermal erosion of the lithosphere.

Influence of glass composition on Si and Ca isotope measurements by SIMS

L. TISSANDIER*, C. ROLLION-BARD AND G. CARO

CRPG/CNRS, BP 20, 54501, Nancy, France (*correspondence: tix@crpg.cnrs-nancy.fr)

Isotopic data obtained by *in situ* mass-spectrometry are affected by instrumental mass fractionation effects related to the nature of the sample. This 'matrix effect' can cause large deviations from the real value and needs to be accurately evaluated in order to obtain precise stable isotope ratios. To constrain these matrix effects, we measured Ca and Si isotopes in a series of silicate glass standards spanning a wide compositional range ($7 < SiO_2 < 72$; $0 < Al_2O_3 < 56$; $0 < CaO < 50$; $0 < MgO < 32$; in wt%). Measurements were performed on a CAMECA IMS1270 at the CRPG/CNRS, Nancy France. We used a multicollection mode, and the different isotopes were measured on Faraday cups. Regardless of the composition of the glass, internal precision was better than 0.1‰, and external reproducibility ranges between 0.15 and 0.35‰ (2σ). The isotopic compositions of Ca and Si in these samples were also measured by TIMS and ICPMS, respectively.

In these different standard glasses, Ca and Si isotopic signatures show a clear compositional dependence. To a first order, instrumental mass fractionation is controlled by the silica content of the glass. However, smaller effects can also be observed for samples with identical silica content, e.g. when substituting Ca for Mg. These results show that the degree of polymerization of the glass is the key parameter for understanding these matrix effects, but it has to be completed by other factors considering the nature of the different constituing elements. Based on these results, we derived a new empirical law, linking compositional parameters to the degree of polymerization of the glass and instrumental fractionation. In Fe-free compositions, instrumental mass fractionation, spanning more than 20‰ in $\delta^{30}Si$ and $\delta^{44}Ca$, can be accurately corrected using this method. After correction, the dispersion of the results is less than 1‰ around the mean value, and this correction is much more successful than other proxies previously used (SiO_2 content, NBO/T,...). Correcting instrumental fractionation effects in glasses containing Fe is more complex since this element can occur in several oxidation states in glasses.

Hydrogeochemistry, groundwater quality and pollution potential studies of Satna City, Madhya Pradesh, India

R.N.T. TIWARI RABINDRA

Department of Geology, Government P.G. Science College, Rewa – 486001 Madhya Pradesh, India (rntiwari03@rediffmail.com)

Hydrogeochemical investigations were carried out in Satna City (Latitude 230 58' : 240 30'N, Longitude 80 0 21' : 81 0 23') Madhya Pradesh, India. In the study area, Limestones of Bhander Group, Vindhyan Supergroup (Neoproterozoic) are exposed. A total of 30 groundwater samples were collected during Post-monsoon season of 2010 and subjected to analysis for chemical characteristics. The main hydrochemical facies are Ca-Mg-HCO_3 and Ca-Mg-SO_4 –cl types. As per classification, most of the samples are normal chloride, normal carbonate, moderate to very hard in nature. The concentration of sulphate was higher due to gypsum bands associated with shale formation. In few samples concentration of fluoride exceeds maximum permissible limit (>1.5 mg/l) due to fluorite bearing mineral associated with aquifer. The concentration of nitrate in groundwater samples of the area is also exceeded beyond the permissible limit of 45mg/l. The consumption of water having nitrate concentration in excess of 100 mg/l may reduce the oxygen carrying capacity of the blood, particularly in infants causing infantile methemoglobinaemia. The analytical results reveal that most of the samples containing high nitrate also have high chloride and potash. In the absence of a possible geogenic source of chloride in the area, application of nitrogen rich fertilizer seem to be possible source. The comparison of analysed data with WHO (1984) and ISI (1991) indicate that groundwater samples of the area are more or less suitable for drinking.

Besides these, pollution potential has been estimated by DRASTIC modeling which suggests that the area is highly susceptible to pollution. A proper attention and water quality programme is needed to check the groundwater pollution.

EBSD Study of Lattice Preferred Orientation (LPO) of the harzburgite NWA 5480

B.J. TKALCEC* AND F.E. BRENKER

Goethe University, Geoscience Institute, 60438 Frankfurt, Germany (*correspondence: tkalcec@em.uni-frankfurt.de)

Classified as belonging to the Howardite-Eucrite-Diogenite (HED) group of achondrites, the olivine-rich diogenite Northwest Africa 5480 is thought to represent an ultramafic cumulate formed within a magma chamber in the upper mantle of the differentiated asteroid 4 Vesta, or a Vesta-like body [1]. Dominated by olivine (57 vol%) and orthopyroxene (42 vol%) NWA 5480 has further been classified a harzburgite [2], whereby the distribution of olivine and orthopyroxene is very heterogeneous, with some areas displaying up to 90% of either of the two minerals. In this study, structural analysis was performed on the olivine grains of NWA 5480 using electron backscatter diffraction (EBSD), which allows us to measure and visualize the crystallographic orientation of the crystal axes to discover any lattice preferred orientation (LPO) [3]. The sample was categorized into two regions for targeted analysis: (a) Zone A, dominated by coarse-grained olivine, and (b) Zone B, dominated by orthopyroxene-olivine schlieren. A total of 1361 EBSD crystallographic orientation measurements of coarse-grained olivine were recorded from 58 sites (each site covering 1 mm2) within Zone A and a total of 148 measurements of finer-grained olivine were recorded from 20 sites within Zone B. Only EBSD measurements with a mean angular deviation (MAD) of <1 were accepted and recorded. The EBSD results of Zones A and B display pronounced yet distinctly differing LPOs, suggesting two separate deformation processes and/or events. A comparison with olivine LPO in terrestrial cumulates and deformed mantle peridotites illustrates the unlikeliness that the olivine LPO from Zone A of NWA 5480 was formed through cumulation or compaction processes. In contrast, a distinct similarity to the olivine LPO formed by pencil glide ((0kl)[100] glide system), typical of plastic deformation in the terrestrial mantle, causes us to consider alternative formation processes for NWA 5480, including the feasibility of convection within the Vestan mantle.

Splittings, satellites and fine structure in the soft X-ray spectroscopy of the actinides

J.G. TOBIN

Lawrence Livermore National Laboratory, Livermore, CA, USA, (Tobin1@LLNL.Gov)

Despite the limitations imposed by their sometimes high levels of radioactivity, there has recently been remarkable progress in the soft X-ray spectroscopy of the actinides, particularly that of Plutonium (Pu) and Uranium (U). For example, synchrotron-radiation-based X-ray absorption spectroscopy (XAS) and X-ray photoelectron spectroscopy (XPS) played important roles in the progress of the understanding of Pu electronic structure, [1-5] leaving only the last issue of electron correlation before a complete understanding is achieved. [6] Two examples of the manifestations of the large spin-orbit splitting in the 5f states are (1) the large disparity in the 4d branching ratios of Pu and U (Fig 1.), and (2) the presence of the pre-peak structure in U and its absence in Pu. Even more recently, we have begun experiments upon the important nuclear fuel system UO_2, [7-9] which also exhibits strong electron correlation. [7] Our new measurements using Resonant Inverse Photoelectron Spectroscopy (RIPES) and X-ray Emission Spectroscopy (XES) [10] indicate new satellite structure, to complement that already observed in XPS [9] and XAS. [7, 8]

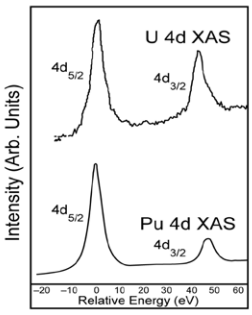

Figure 1 Comparison of the 4d XAS in elemental U and elemental Pu. From Ref 5.

Plugging of porous media and rock fractures using ureolysis-driven calcite precipitation

D.J. TOBLER* AND V.R. PHOENIX

School of Geographical and Earth Sciences, University of Glasgow, Glasgow, G12 8QQ, UK (*correspondence: dominique.tobler@glasgow.ac.uk)

Ureolysis-driven calcite precipitation has shown great potential in a wide range of applications, including solid-phase capture, concrete crack remediation, soil stabilisation and carbon sequestration. Here, this process is investigated as a means of reducing the primary porosity and/or secondary fracture porosity of host rocks surrounding nuclear waste repositories in order to control or prevent radionuclide transport. Several studies have used simple sand column experiments to determine the best approach to plug pore spaces between grains; however, a field deployable approach that ensures a homogenous and stable seal has not yet emerged. Furthermore, there is no study that assessed the potential of this method to seal rock fractures. This is important as the hydraulic regime in fractures is very different compared to grain porosity.

Here, flow-through experiments in various media (sand columns, fractured / non-fractured rock cores) were carried out to examine the potential of ureolysis–driven calcite precipitation to seal primary and secondary porosity effectively and homogenously. The 'plugging efficiency' was examined as a function of varying injection strategies, flow rate, urea and Ca^{2+} concentration and the addition of a grout (e.g. silica nanoparticles). The temporal change in porosity was monitored by the decrease in hydraulic conductivity, and the local spatial distribution of the calcite fill was quantified using scanning electron microscopy.

Results from sand column / sandstone rock core experiments show that under continuous flow conditions, a gradient in calcite fill developed along the flow path of the column / core. In contrast, static conditions (i.e. no flow) permitted the reaction to occur homogenously throughout the column / core resulting in a stable plug. Note that under both static and continuous flow conditions, new bacteria needed to be injected every 1-2 days due to embedment of the bacteria within the forming precipitates. Initial results from fractured rock core experiments indicate that bacteria less likely 'attach' to fracture surfaces, which significantly lowers rates of ureolysis and calcite precipitation within the fracture. The use of a saline fixative and varying flow rates will be tested to increase the reaction yield.

A variably enriched mantle wedge and contrasting melt types during arc stages following subduction initiation in the southwest Pacific

ERIN TODD[1], JAMES B. GILL[2] AND JULIAN A. PEARCE[3]

[1]Dept. of Earth and Planetary Sciences, University of California, Santa Cruz, USA (todd.erin@gmail.com)
[2]Dept. of Earth and Planetary Sciences, University of California, Santa Cruz, USA (jgill@pmc.ucsc.edu)
[3]School of Earth, Ocean and Planetary Sciences, Cardiff University, Cardiff, CF10 3YE, UK (PearceJA@cardiff.ac.uk)

Mantle sources at the initiation of Vitiaz arc magmatism in the SW Pacific (≥45Ma) have isotope ratios similar to the mantle currently underlying the Havre Trough and adjacent back-arc basins. The early Vitiaz melt source was not only a mixture of depleted mantle plus small amounts of slab-derived component, but also includes an enriched FOZO component that makes it 'Pacific' in character. This old enriched component anchored SW Pacific arcs untils opening of the Lau Basin. Preferential melting of the enriched component leaves a more depleted residue. The Vitiaz nascent- and proto-arc, preserved in subaerial Eocene to lower-Oligocene rocks in Viti Levu, Fiji and 'Eua, Tonga, are similar in age and magma types to the earliest Izu-Bonin-Mariana (IBM) arc. Like IBM, Yavuna and 'Eua basalts range from boninitic to tholeiitic in composition. 'Eua is LREE-depleted whereas Yavuna ranges from LREE-depleted to LREE-enriched. The early arc was characterized by extreme variations in HFSE and HREE, reflecting large variations in percent melting, extending to very high degree melting necessary to generate low boninitic trace-element concentrations. Early bonintic melts have a more enriched quality (isotopically and in LREE/HREE) than tholeiitic melts. The end of Yavuna arc magmatism coincides with formation of the South Fiji Basin (SFB) (~20-30 Ma). Rocks of the Yavuna Group are unconformably overlain by late Oligocene to early Miocene rocks of the Wainimala Group, so 'second arc' edifices were at least in part deposited on Eocene to early Oligocene arc basement. Yavuna and Wainimala rocks show similar ranges for $^{143}Nd/^{144}Nd$ but variation in $^{176}Hf/^{177}Hf$ defines an array steeper than the Mantle Array in Hf-Nd isotope space. Higher $^{176}Hf/^{177}Hf$ ratios for Wainimala rocks indicate a more depleted source mantle than existed prior to SFB spreading.

Magmatic evolution of lunar highland rocks estimated from trace elements of plagioclase in regolith

S. TOGASHI[1], N.T. KITA[2], A. TOMIYA[1] AND Y. MORISHITA[1]

[1]Geological Survey of Japan, AIST, Tsukuba 305-8567, Japan (*correspondence: s-togashi@aist.go.jp)

SIMS analyses of plagioclases and the host magma

The SIMS trace element analyses of plagioclases in lunar regolith are performed in order to estimate compositions of host magmas of FAN and Mg-suite rocks. We reexamined partition coefficients of trace elements between plagioclase and magma by taking account of the compositional dependence. The estimated host magmas of FAN have low Ba (48-115ppm), Sr (90-152ppm), and TiO_2 (0.5 to 1.3%).

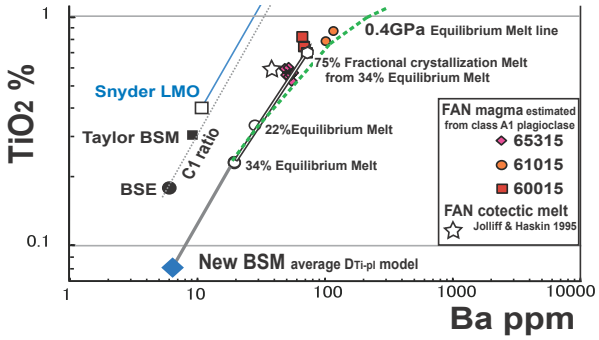

Figure 1: The estimated host magmas of FAN. Snyder LMO [1], Taylor BSM [2], FAN cotectic melt [3]

Model for FAN magma evolution

We developed an igneous evolution model for magmas of FAN and Mg-suite rocks by using phase relations based on MELTS program. We propose a new Bulk Silicate Moon (BSM) model with high Al_2O_3 (6.1%), sub-chondritic Sr/Al and Ti/Ba ratios and chondritic Sr/Ba ratios. High degrees (22-34% or more) of equilibrium melting of the BSM could produce the primary FAN magma under high pressure (0.4-3GPa), whether the BSM is partially or totally molten at the initial stage.

Transformation of iodide to organic iodine in soil-water system

Y.S. TOGO[1,2] AND Y. TAKAHASHI[1]

[1]Hiroshima University, Hiroshima 739-8526, Japan (yoko-togo@aist.go.jp, ytakaha@hiroshima-u.ac.jp)
[2]National Institute of Advanced Industrial Science and Technology, Ibaraki 305-8567, Japan

Iodine is an important trace element for human beings according to the following reason: (i) iodine deficiency is one of the world's most prevalent disease, (ii) radioactive iodine can be released by the use of nuclear energy. To predict iodine behavior in natural systems, speciation of iodine is essential because mobility of iodine is different among each species. In this study, we determined chemical forms of iodine in soil and pore water using X-ray absorption near edge structure (XANES) and high performance liquid chromatography (HPLC)-ICP-MS, respectively.

Materials and methods

Soil and pore water samples were collected at five depths: 0, 3, 6, 9, and 12 cm under flooded condition in Yoro area, Chiba, Japan. Brine water, which contained I^-, was supplied from top of the soil column. Iodine concentration in soil samples were determined by alkaline extraction method [1]. Chemical forms of iodine in soil were deterined by K-edge XANES (SPring-8, BL01B1) [2]. Iodine mapping of soil grain was obtained at beamline 37XU (SPring-8) by a micro-XRF technique. Iodide, iodate, and organic iodine in pore water were separaterly detected by HPLC-ICP-MS using anion exchange column and size exclusion column. Soil incubation experiments were performned using soil collected at 3 cm depth (soil : Milli-Q water = 1 : 1) under oxic and unoxic conditions.

Results and Discussion

Concentration of iodine in soil was highly correlated with that of organic carbon content. According to XANES and micro-XRF, iodine in soil exists as organic iodine at any depths. On the other hand, pore water collected at a 0–6 cm depth containing 50–60% of organic iodine bound to dissolved organic matter and the rest was I^-. At a 9–12 cm depth, 98% of iodine was I^- in the aqueous phase. The distribution coefficient of organic iodine in the soil-water system was more than 10-fold greater than that of iodide. Soil incubation experiments demonstrated that dissociation of iodine from organic iodine to I^- occurred under anoxic condition. Mobility of iodine is strongly affected by organification of iodine under oxic condition and dissociation from organic matter as I^- under anoxic condition.

Comparison of ^{4}He and ^{14}C dating, noble-gas temperatures and stable isotope (δ^2H, δ^{18}O) data for groundwater in stratified aquifers (Tomsk-7, S.E. Siberia)

I.V. TOKAREV[1]*, R. KIPFER[2,3], Y. TOMONAGA[2], M.S. BRENNWALD[2] AND E.A. VERESCHAGINA[1]

[1]IEG RAS, Sredniy 41, of. 519, Saint-Petersburg, 199004 (*correspondence: tokarevigor@gmail.com)
[2]Eawag, Swiss Federal Institute of Aquatic Science and Technology, CH-8600 Dübendorf
[3]Institute of Geochemistry and Petrology, Swiss Federal Institute of Technology (ETH), CH-8092 Zürich

The groundwater of six stacked aquifers in the south-eastern part of Siberia near the former Tomsk-7 nuclear research facility has been studied.

Groundwater ages were estimated by ^{4}He concentrations and ^{14}C-activities, and paleoclimate conditions were reconstructed using dissolved noble gas concentrations (and the corresponding noble-gas temperatures) in combination with stable isotope data (δ^2H, δ^{18}O) [1, 2].

^{4}He ages of the four lower aquifers vary from 2 to 15 ka, and increase with depth and along the flow path with increasing distance from the recharge area. Depleted δ^2H, δ^{18}O as well as noble-gas concentrations based recharge temperatures of 0.5-2 °C indicate that the water infiltrated during cold climate state. Such cold climate conditions prevailed in the studied region between 5 and18 ka BP.

In general, ^{14}C-ages for the four lower aquifers are consistent with the He-ages (6-33 ka), whereby the ^{14}C ages tend to be higher than He-ages. The estimation of the ^{14}C-ages is quite robust as the aquifer matrix hardly contains any carbonates. The age difference can be explained by uncertainties in the calculation of the He-ages, which is strongly depends on the assumed aquifer porosity. The mean porosity is only vaguely known due the interbedding of sands and clays.

A strong shift of δ^2H and δ^{18}O data in the upper aquifer layers indicates that these layers were temporarily frozen during the Younger Dryas.

In conclusion, stable isotopes, noble-gas temperatures, and dating show consistent results and can be used to analyze groundwater dynamics on large time scales and to validate conceptual and numerical groundwater models.

Geochemical modeling for boron removal by a permeable reactive barrier using magnesium oxide

C. TOKORO[1]*, J. KURAMI[1], S. MORIYAMA[2] AND K. SASAKI[2]

[1]Waseda University, Tokyo 169-8555, Japan (*correspondance: tokoro@waseda.jp, nightmarev.dtk@akane.waseda.jp)

[2]Kyusyu University, Fukuoka 819-0395, Japan (s-moriyama09@mine.kyushu-u.ac.jp, keikos@mine.kyushu-u.ac.jp)

Geochemical models for boron removal by magnesium oxide was constructed from experimental results obtained in batch test [1]. Partial dissolution of magnesium oxide, precipitation of brucite and MgB $(OH)_5$, and complex ion formation of MgB $(OH)_4^+$ were considered. First order kinetics were also considerd for precipitation or disolution of these minerals. These models successfully expressed experimental results of pH and concentration of boron/magnesium ion in solution.

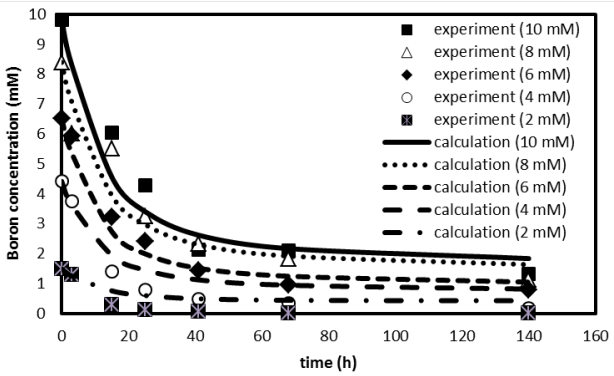

Figure 1: Comparison between experimental data and geochemical model analysis for boron concentarion change over time.

The above model was also confirmed to fit to the observed data in continuous column tests in combination with one dimensional advection-diffusion equation. This model is practically useful to predict the long term performance of PRB to treat borate using MgO for several decades.

Physicochemical controls on adsorbed water film thicknesses in unsaturated porous media

TETSU K. TOKUNAGA

Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA (tktokunaga@lbl.gov)

Large volumes of Earth's subsurface contain pores with water present as wetting films residing between mineral surfaces and a nonwetting fluid. These variably water-saturated environments include soils, deep unsaturated rock formations, and deep reservoirs containing hydrocarbons and CO_2. Water in these environments is retained by both capillarity and adsorption, with the adsorptive component most sensitive to solution chemistry and interfacial properties at both solid-water and water-fluid (gas, immiscible liquid, or supercritical fluid) interfaces. It is important to understand how the thickness of adsorbed water films varies with system properties because film thickness can control flow and transport within the aqueous phase, and because reactions at mineral surfaces are strongly influenced by the contacting fluid phase. The thickness of films is dependent on the component of the wetting phase chemical potential denoted the matric potential in soils and the disjoining (capillary) potential in deep reservoirs. The Derjaguin-Landau-Verwey-Overbeek (DLVO) theory combines electrostatic and van der Waals contributions to predict water film potential versus thickness relations, and is frequently applied in studies of mineral-water-mineral and mineral-water-hydrocarbon systems. However, adsorbed water films confined between mineral surfaces and nonwetting fluid phases are not present over the full range of disjoining potentials because a pore scale dependent threshold capillary pressure needs to be exceeded to allow coexisitence of both fluid phases in pores. In this study, capillary scaling [1] is used to predict ranges of matric (disjoining) potentials within which adsorbed water films can exist in gas-water-mineral systems and in supercritical CO_2-water-mineral systems [2]. We then apply DLVO models to calculate adsorbed water film thicknesses in these systems [3]. These calculations predict that under many conditions found in the subsurface, thicknesses of adsorbed water films are less than 20 nm. Moreover, the calculations predict a very wide range of potentials over which thicknesses of adsorbed films are less than 2 nm.

Mantle degassing rates and gas loss from atmosphere: A view from xenology

I. TOLSTIKHIN[1]*, B. MARTY[2] AND A. HOFMANN[3]

[1]Geological Institute, RAS, Apatity, and Space Research Institute, RAS, Moscow, Russia (*correspondence: igor.tolstikhin@gmail.com)
[2]CRPG-CNRS, 54501 Vandoeuvre-Les-Nancy, France
[3]Max-Planck-Institut für Chemie D-55128 Mainz, Germany

To understand evolution of gas species of the Earth - atmosphere system, ^{244}Pu-^{238}U-Xe systematic is crucial and must be included in any model related to gas loss / gain by the Earth reservoirs. The initial ^{244}Pu/^{238}U = 0.01 in meteorites and terrestrial zircons [1] is known; correspondingly the closed-system ^{136}Xe (Pu)/^{136}Xe (U)= 40. These ratios, bulk silicate earth [^{238}U] = 38 ppb, present day ^{136}Xe (Pu) / ^{136}Xe (U) ≤ 0.2, proposed for the mantle [2, 3], and amount of ^{136}Xe (Pu) ≤ 0.05 tmol in the atmosphere, constrain the evolution of terrestrial volatiles.

(1) The MORB-source mantle (one reservoir model is considered) has been degassed severely, so that only about 0.01% of the initially available Xe has survived 4.5 Gyr long degassing [4, 5]). Recent degassing models based on U-Th-He and K-Ar systems, e.g. [6], postulate a low degassing and are inconsistent with this constraint. (2) This model predicts a late time for the atmosphere closure to Xe loss, about 4 Gyr ago, and simultaneous loss of other gases, which seems highly improbable. Introducing into the deep earth an early, small, less-degassed, nearly-isolated reservoir allows reconciliation of observed and modelled noble gas abundances in the Earth [5].

Albitite related to iron oxide mineralization: Melt inclusion evidence for a magmatic origin

C.M. TOMÉ[1]*, F. TORNOS[1] AND M. WÄLLE[2]

[1]Instituto Geológico y Minero de España, Madrid, Spain (*correspondence: c.tome@igme.es)
[2]Institut of Geochemistry and Petrolgy, ETH, Zurich, Switzerland

Albitite is an uncommon rock present in very different geological settings. The dominant mineralogy consists almost entirely by albite and quartz with some other accessories but, despite its simple mineralogy, this rock is of unclear origin. A metasomatic source is dominantly proposed, especially for the albitite related to iron oxide, W-Sn and Nb-Ta-Zr-REE-rich mineralization. There are only few studies that propose a magmatic origin for this rock, usually in ophiolitic complexes. In this study we describe some large intrusive mesozonal bodies of porphyritic albitite related to magnetite mineralization in the Ossa Morena Zone (SW Spain) and we report the existence of true silicate melt inclusions in this type of rocks. These melt inclusion data indicate that the rocks are primary and not metasomatic in origin.

Crystallized silicate melt inclusions in phenocrysts of quartz in both fresh or slightly altered albitite were analyzed by LA-ICPMS. Melt inclusion show an 'albitic' composition with SiO_2 (72%), Al_2O_3 (13%) and Na_2O (8%) as major elements. In agreement with the compatibility model, trace elements such as Sr, Ba, V, Zr, P and other major elements like Ti and Mg are compatible with the bulk-mineralogy of the rock whereas incompatible elements as well as ore metals stay in the residual melt represented by the melt inclusions. The quartz phenocrysts also show some sporadic magnetite blebs coexisting with the silicate melt inclusions, suggesting the existence of an iron oxide melt phase segregated from the silicate melt and related to the formation of the mineralization.

This melt inclusion study toghether with the field relationships and the petrography demonstrates that not all the albitite related to iron oxide mineralization is a consequence of the pervasive sodic alteration of previous plutonic rocks but also product of highly differenciated felsic magmas. We also adress the posible link between these melts and the formation of magmatic and hydrothermal magnetite mineralization.

Experiments on the wetting properties of precious metal-rich sulfosalt melts against MSS

ANDREW G. TOMKINS

School of Geosciences, Monash University, Clayton 3800 Victoria, Australia (andy.tomkins@monsh.edu)

In a significant proportion of magmatic sulfide ore deposits, Pt, Pd, Au and Ag (precious metals), correlate strongly with As, Bi, Sb and Te. In these deposits, the majority of the precious metals can be locked in platinum-group minerals (PGM). The majority of these PGM consist of Pt and Pd complexed with one or more of the semi-metals As, Sb, Bi and Te. In addition, domains rich in non-PGM sulfarsenides, such as gersdorffite and nickeline, with very high precious metal concentrations are found within some ores. These observations imply that these semi-metals play a critical role in controlling the distribution of precious metals in some deposits.

Piston cylinder experiments have been used to study the wetting behavior of As-rich sulfosalt melts against monosulfide solid solution (MSS). This is important information because the wetting propoerties of a melt against its solid crystal framework control melt migration processes; a wetting melt requires about an order of magnitude less volume than a non-wetting melt to form an interconnected permeable melt network, which allows melt migration.

Experiments show that range of As-rich melt compositions wet MSS, including those that contain significant proportions (1 – 45%) of precious metals. Interestingly, sulfosalt melts that are extremely Au-rich or Pt-rich (> ~40% Au; > ~ 50% Pt + 5% Au) do not wet MSS. These results imply that if a late stage As-rich sulfosalt melt is able to form either through magma contamination with something like carbonaceous shale (which tend to be As-rich), or simply through fractionation of the sulfide melt (many sulfosalt minerals crystallise at lower temperatures than MSS) it should preferentially partition incompatible Bi, Sb, Te, Pt, Pd, Au and Ag. Furthermore, where the proportion of As-rich sulfosalt melt exceeds ~ 0.2% of the rock volume, an interconnected melt drainage network will be able to form along MSS crystal triple junctions. Because sulfarsenide melt is significantly more dense than MSS, it would then be able to drain downwards, further scavenging precious metals. The greater the length of this melt migration pathway, the more effective the enrichment in precious metals. Ultimately, very precious metal rich sulfosalt melt accumulations can form by this mechanism. When such a sulfosalt melt fractionates as it migrates, a spectrum of PGM would result.

Noble gases in the sediment pore water as proxies for physical transport processes and past environmental conditions in Lake Van?

Y. TOMONAGA[1]*, M.S. BRENNWALD[1] AND R. KIPFER[1,2]

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, CH-8600 Dübendorf, Switzerland (*correspondence: tomonaga@eawag.ch)

[2]Institute of Geochemistry and Petrology, Swiss Federal Institute of Technology (ETH), CH-8092 Zurich, Switzerland

Since many decades unconsolidated sediments in lakes and oceans have been proposed as a potential archive for noble-gas records to reconstruct past environmental conditions in lakes and oceans. In addition, the accumulation of non-atmospheric noble-gas isotopes allows tracing the geochemical origin and transport processes of the pore fluids. For instance, the abundance of terrigenic He isotopes reflects the residence time and transport dynamics of the pore fluids in the sediment. The $^{3}He/^{4}He$ ratio of terrigenic He can be used to constrain the geochemical origin of the pore fluids. However, methods for reliable noble-gas analysis in sediment pore water have been developed only recently.

Lake Van (Turkey) is one of the largest terminal lakes and the largest soda lake on Earth. The physical conditions of the lake are known to react sensitively to changes in the hydrological cycle and the environmental conditions of the lake catchment. Therefore the noble-gas records in the sediments of Lake Van have a great potential as an archive for palaeoenvironmental research. Also, the basin of Lake Van is situated in a tectonically active region characterized by the presence of major faults and volcanos. The lake is known to accumulate mantle fluids. Noble-gas isotopes are therefore useful to study the origin and transport processes of terrigenic fluids in the sediment pore space and their release into the water body.

In this study we present noble-gas data measured in the pore water of sediment samples collected in Lake Van. On the one hand, data from short cores taken at different sites throughout the lake basin will be discussed. Furthermore, we intend to present first results from the noble-gas samples taken from a 220 m long core during the 2010 ICDP drilling operations of the PALEOVAN project.

Iron microbial mat formation from deep continental brines

BRANDY M. TONER[1]*, LINDSEY J. BRISCOE[1], F. MARC MICHEL[2], SCOTT C. ALEXANDER[3], E. CALVIN ALEXANDER JR.[3] AND JEFFREY A. GRALNICK[4]

[1]Department of Soil, Water and Climate, University of Minnesota, St. Paul, MN, USA (*correspondence: toner@umn.edu)
[2]Geological and Environmental Sciences, Stanford University, Stanford, CA, USA
[3]Department of Earth Sciences, University of Minnesota, Minneapolis, MN, USA
[4]Department of Microbiology, BioTechnology Institute, University of Minnesota, St. Paul, MN, USA

Iron oxidizing microorganisms are distributed globally and have been identified as major contributors to iron cycling and mineral formation from diverse geochemical settings – freshwater seeps to deep-sea vents – where ever opposing iron(II)-oxygen gradients prevail. A study of iron microbial mat formation from deep continental groundwaters along anoxic-oxic boundaries has been undertaken. The goals of the research are to define microbial niches created at acute geochemical gradients, and determine how microbial activity alters the mineralogy of mat deposits.

Iron microbial mat processes occur at 700 m depth where anoxic brines emerge from exploratory boreholes into an oxic, mined environment (Soudan Underground Mine State Park, Soudan, MN, USA) within a 2.7 Ga Banded Iron Formation. These sodium-calcium chloride brines are characterized by 100 mS conductivity, pH 6+, -650 mV oxidation-reduction (redox) potential, and total dissolved iron concentrations of 100 mg/L. As the brines equilibrate with the atmosphere in shallow flow channels over ~100 m distance, the pH decreases to 2.8, redox potential increases to +50 mV, and total dissolved iron decreases to less than 40 mg/L. Along these gradients, iron mat formations with diverse facies characteristics and mineralogy are observed.

For minerals from the first 100 m of the channels, iron 1s extended X-ray absorption fine structure spectroscopy and X-ray scattering measurements reveal the presence of akaganeite in all samples, as well as a transition from a biogenic iron oxyhydroxide to ferrihydrite/goethite. Scanning electron microscopy of critical point dried samples shows that microbial biomass is a substantial component of the mat at 0.3 m from the borehole where low redox potential is observed. From this low redox area, cultured isolates from the genus *Marinobacter* and genus *Idiomarina* were obtained. In seeps having lower conductivity, different cultivars and minerals are observed. These results point to salinity as an important factor in the geomicrobiology of the iron mats.

Late Cretaceous hydrocarbon seep carbonates from Kardoi village, Tibet, China

HONGPENG TONG[1,2], YOUYAN BIAN[1,2], DONG FENG[1] AND DUOFU CHEN[1]*

[1]Key Laboratory of Marginal Sea Geology, Guangzhou Institute of Geochemistry, CAS, Guangzhou 510640, China (*correspondence: cdf@gig.ac.cn)
[2]Graduate University of the Chinese Academy of Sciences, Beijing 100049, China

One of the most common signs of the hydrocarbon seeps is the precipitation of carbonates close to the seafloor. Ancient hydrocarbon seeps are increasingly recognized, and occur in a variety of different marine settings and on different regional scales. However, such hydrocarbon seeps are rarely found in ancient strata of the mainland China. Here, we report two isolated carbonate bodies that have been interpreted to represent hydrocarbon-seep deposits. These deposits are in the upper Cretaceous strata at the southern and the northern Kardoi village of Xigaze, Tibet, China. The upper Cretaceous strata here consist of turbidites of a forearc basin, which has been uplifted into Yarlung Zangbo suture zone. The seep carbonates at the southern Kardoi section are about 30 vol% of the strata, occurring as nodules and chimneys while the seep carbonates at the northern Kardoi section mainly occur as nodules and account for about 10 vol% of the turbidite strata. Carbonate rocks from both sections are mainly composed of calcite, in sharp contrast to the host rocks which primarily are felsic minerals. The matrix of the carbonates mainly consists of micritic calcite. Framboid pyrites are frequently observed in the matrix. The carbonates exhibit $\delta^{13}C$ values as low as -32‰ relative to the V-PDB standard, suggesting that they are predominantly hydrocarbon derived, probably thermogenic methane. Overall, the carbonate fabrics and isotope signatures provide unequivocal evidences for a seep origin of the Xigaze deposits. Additional geochemical, mineralogical and petrographic studies of all micritic carbonates are underway. The obtained results will be used for constraining the controlling processes of the two geographically separated southern and northern sections.

We thank Prof. Chi-yue Huang (GIG) for helpful discussion. This work was partially supported by the NSFC (40872079 and 40725011) and Guangzhou Institute of Geochemistry of CAS (GIGCX-07-13).

Topographic confocal Raman microscopy. Established methods – Novel concepts – New possibilities

J. TOPORSKI AND T. DIEING

(jan.toporski@witec.de, thomas.dieing@witec.de)

Confocal Raman microscopy has found increasing relevance over the past years in various field of application in geo- and/or geobiology research. The benefit of obtaining molecular, compositional information on the submicron-scale in three dimensions is of tremendous use yet thus far slightly alleviated by that “large” topography in the range of hundreds of micron or millimeters could not be analyzed without sample pretreatment, i.e. cutting or polishing to obtain a sufficiently flat surface. The new technique of Topographic Confocal Raman Imaging now allows analysis of rough surfaces or tilted samples.

The core element of this imaging mode is an integrated sensor for optical profilometry. Large-area topographic coordinates from the profilometer measurement are correlated with the large-area confocal Raman imaging data. This allows confocal Raman imaging along inclined or rough samples with the true surface held in constant focus while maintaining high level of confocality. The profilometry capabilities of True Surface Imaging mode allows scan ranges of up to 50x100 mm with a spatial resolution on the order of 100 nm vertically and 10 μm laterally. Measuring distances of 10 mm and more provide flexibility for variable sample size requirements. In combination with AFM, the profilometer can even be used as a pre-inspection tool to determine topographic features of interest for high-resolution AFM investigations on large samples.

The potential and examples for Geoscience applications will be shown.

Revisiting the influence of particle size on the equilibrium composition

D. TOPPING[1,2]* AND G. MCFIGGANS[1]

[1]Centre for Atmospheric Science, University of Manchester, UK (*correspondence: david.topping@manchester.ac.uk)
[2]National Centre for Atmospheric Science, University of Manchester, UK

Introduction

Atmospheric aerosol particles can comprise many thousands of largely unidentified compounds with a wide range of properties. The size of an aerosol particle influences the equilibrium composition and phase state for a given set of ambient conditions and availability of semi-volatile material. Incorporating the influence of curvature in theoretical constructs can be complex. Unfortunately, basic absorptive equilibrium partitioning models largely neglect the influence of curvature, leading to errors in predicted composition and volatility for conditions in which size is likely to play an important role: new particle formation in the atmosphere or unseeded experiments in smog chambers.

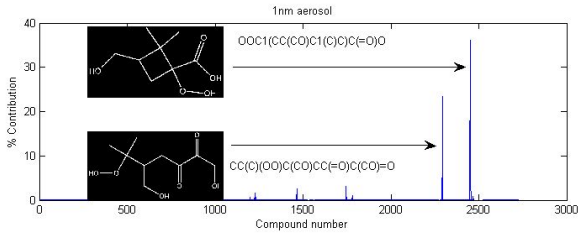

Figure 1: Example of identification of top two compounds contributing to the condensed phase abundance for a 2nm diameter aerosol.

Discussion of Results

In this study we present application of a partitioning model that explicitly accounts for impact of curvature on the equilibrium position for particles of any size and comprised of an unlimited number of compounds. Using results from state-of-the-art gas phase degradation models and property predictive techniques, we are able to explore generalised relationships between, for example, expected aerosol functionality and particle size (e.g. Figure 1). A discussion of the caveats behind this approach is given, along with pitfalls of not explictly accounting for aerosol size in previously applied predictive frameworks with potential impacts of subsequent aerosol properties.

Provenance and grain size effects of siliciclastic sediments in the Dead Sea basin from Pb-Sr-Nd isotopes and trace chemistry

A. TORFSTEIN[1], S.L GOLDSTEIN[1,2] AND M. STEIN[3]

[1]Lamont-Doherty Earth Observatory, Columbia University (adi.torf@ldeo.columbia.edu)
[2]Department of Earth and Environmental Sciences, Columbia University (steveg@ldeo.columbia.edu)
[3]Geological Survey of Israel, Israel (motis@vms.huji.ac.il)

The history of the late Quaternary Dead Sea basin (DSB) hypersaline lakes is closely coupled with orbital and millenial scale climate change in the Northern Hemisphere. In addition, these water bodies were the terminal sink for proximal Cenozoic carbonate bedrock and eolian material originating from the Sahara, suggesting that the deconvolution of the sediment source end members can provide quantitative constraints on the flux of pluvial and eolian material to the DSB during different climate stages.

We present Pb-Sr-Nd isotopic compositions combined with trace and minor element concentrations of siliciclastic sediments deposited over the last 70 ka in Lake Lisan, the last glacial Dead Sea. For each sample, analyses were performed on three grain size fractions of carbonate free material (>20um, 20-5um, <5um).

Significant differences are observed between the composition of the grain size fractions, whereby relative to the two coarse grain size populations, the <5um fraction displays more radiogenic values of $^{87}Sr/^{86}Sr$ (0.7106-0.7125, compared to 0.7087-0.7096 in the coarse fractions) and $^{206}Pb/^{204}Pb$ (18.26-18.93, consistantly higher than coeval coarse fractions), while $^{143}Nd/^{144}Nd$ values in all grain sizes overlap within a range of ~0.5120-0.5123. In addition, the <5um fraction is relatively enriched in lithophilic elements such as Zr, Nb, Pb, and Be.

While the range of lead isotopic compositions corresponds to values measured in proximal bedrock and thus monitors local sources, $^{87}Sr/^{86}Sr$ compositions deviate toward the composition of eolian end member sources, providing distinct constraints on the flux of airbone particles to this area during the late Quaternary. We will present a record of temporal and long term variations in the sediment end member fluxes and compare them to regional climate records. These will further be considered in the context of the grain size distribution and its effect on the chemical and isotopic composition of the samples.

Biogenic supergene galena-rich ore in the Las Cruces deposit, Spain

FERNANDO TORNOS[1], NIEVES G. MIGUELEZ[1], FRANCISCO VELASCO[2] AND JUAN CARLOS VIDEIRA[3]

[1]Instituto Geológico y Minero de España. Rios Rosas 23, 28003 Madrid (Spain) (*correspondence: f.tornos@igme.es)
[2]Universidad del Pais Vasco, Leioa, Spain (francisco.velasco@ehu.es)
[3]Cobre Las Cruces SA (juancarlos.videira@cobrelascruces.com)

The Las Cruces deposit, within the Iberian Pyrite Belt, is one of the richest copper deposits worldwide, shows a well developed supergene alteration zone developed on a steeply dipping primary volcanic-hosted massive sulfide deposit of late Devonian age. The supergene alteration zone formed in the interphase between the basement, including the massive sulfides, and a 150 m thick sequence of Tertiary marl, which hosts a confined aquifer; this gossan probably replaces a former subaerial goethite-rich one that was similar to the other ones found in the IPB. It has several horizons including an upper siderite-hematite zone (red gossan), an intermediate galena-siderite-iron sulfide zone (black rock), a barren coarse pyrite zone and a deep chalcocite zone. The black rock includes skeletal crystals of galena intergrown with siderite and fine grained greigite. Galena shows a mat-like distribution and both the sulfur and carbon isotopes are consistent with a biogenic derivation. The rock shows abundant textures indicative of microbial activity, including forms that resemble fossil microbes and a distribution of the galena controlled by possible microbial mats. Galena shows widespread skeletal growth and both the sulfur and carbon isotopes are consistent with a biogenic derivation; sulfur isotopes values in galena are remarkably high (>19‰) and different from the near 0‰ values of the bulk of the mineralization while $\delta^{13}C$ isotopes in siderite are between -33 and -42‰. Finally, the rock shows abundant textures indicative of microbial activity.

Our interpretation is that the former subaerial gossan hosted during burial major heterotrophic microbial activity that coupled reduction of sulfate carried by the aquifer with oxidation of hydrocarbons or methane accumulated below the sedimentary cap, a process that was enhanced by the heat advected by deep circulating fluids.

Sediment diagenesis modelling in a AMD contaminated reservoir

E. TORRES[1]*, R.M. COUTURE[2], B. SHAFEI[3], C.R. CÁNOVAS[4], P. VAN CAPELLEN[2] AND C. AYORA[1]

[1]IDAEA-CSIC, Jordi Girona 18-26, 08034, Barcelona, Spain (*correpondence: ester.torres@idaea.csic.es)
[2]Earth and Environmental Sciences, University of Waterloo, 200 University Ave. West, Waterloo, ON, Canada
[3]School of Earth and Athmospheric Sciences, GA, Institute of Technology, 311 First Drive, Atlanta, Georgia, USA
[4]Department of Geodynamics, University of Huelva, Avda Fuerzas Armadas s/n 21071 Huelva, Spain

The Sancho water reservoir is located in the Odiel Basin, Huelva (SW Spain) in the Iberian Pyrite Belt. The Basin has been mined intensively during the last century. While the mines are now abandoned, the Basin is still heavily contaminated by acid mine drainage (AMD).

The reservoir has a pH of ~4, with high SO_4 (200 ppm) and heavy metal concentrations in the water column. A monomictic behaviour forces the reservoir to mix in winter, which oxigenates the bottom waters. Solid and aqueous phases analyses show that the sediment acts as a sink of trace elements (e.g. As, Cd, Pb) during oxic conditions and as a source for them during anoxic conditions at the bottom.

Quantitative transport-reaction modelling of sediment diagenesis has been performed by improving on the apporoach outlined in Couture *et al*. [1]. The model has been modified by including: $FeCO_3$ as a new phase, pH and porosity functions with depth, and two organic matter (OM) pools. Due to the monomictic behaviour of the reservoir non-steady-state boundary conditions were imposed as a function of time for O_2, as an error function, and for the Fe $(OH)_3$ (s) flux, because of its dependence on the O_2 concentration. The reaction network includes three primary reactions discribing the degradation of OM via oxic respiration, iron and SO_4 reduction. The secondary reactions considered are the oxidation of pore water Fe(II) by O_2, and of H_2S by O_2 and Fe $(OH)_3$ (s).

The Fe $(OH)_3$ (s) and SO_4 are reduced in the upper few cm, releasing Fe^{2+} and H_2S which precipitate as FeS and pyrite. Excess of Fe^{2+} precipitates as $FeCO_3$. Under anoxic conditions solute concentrations on sediment pore water increase due to the absence of oxygen. Owing to the time-dependent O_2 function implemented in the model, we obtain a periodic response for the years simulated which allow us to reproduce the complex features of the measured sedimentary profiles.

Hydrogeochemical analysis of the Sahl-Abad playa brines (East of Iran)

H.A. TORSHIZIAN*, M.JAVANBAKHT, H. MOLLAIE AND M.R. KETABDARI

Islamic Azad University, Mashhad Branch (*correspondence: h.torshizian@yahoo.com)

The Iranian playas are one of the important playa zones in the world. The study area is located in the North of Birjand in the East of Iran. From hydrogeochemical point of view, the brines of this playa is of the Na- Ca- Mg- K-Cl- SO4 series, with the PH ranging from neutral to slightly alkaline. The concentration of some the above ions are very high in these brines, which is due to the composition of parent rocks in the surrounded area. The evaporate minerals within the brines are NaCl and CaSO4. On the basis of chemical composition of the brines especially their trace element (concentration of Br less than 27ml and ratio of Cl to Br which is more than 290) and concentration of Gypsum and Halite in sediments, a meteoric origin (meteoric water of first order of neutral group) is suggested for these brines.

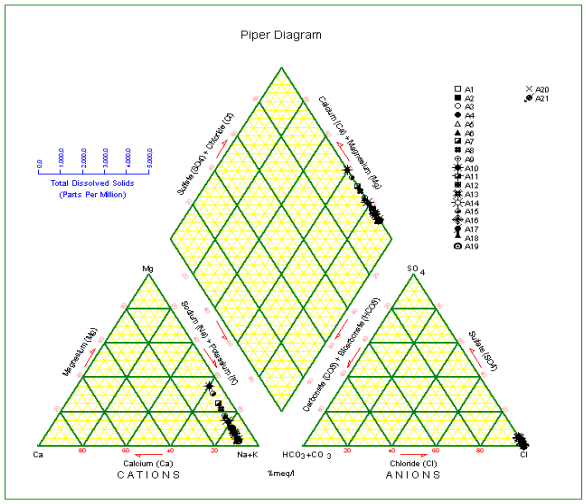

Figure 1: Piper diagram of the Sahl Abad playa brines

Oxygen isotope modification through assimilatory sulfur cycling

ROSALIE TOSTEVIN[1], ALEXANDRA V. TURCHYN[1]*, ALISON G. SMITH[2], MARIA ZORI[2], CHRISTOPHER J. HOWE[3] AND DAVID J. LEA-SMITH[3]

[1]Department of Earth Sciences, Downing Street, University of Cambridge (*correspondence avt25@cam.ac.uk)
[2]Department of Plant Sciences, Downing Street, University of Cambridge
[3]Department of Biochemistry, Tennis Court Road, University of Cambridge

Isotope modification of oxygen isotopes in sulphate in natural environments is widely understood to be dominated by microbially mediated exchange with water during dissimilatory sulphate reduction, and possible abiotic exchange with water at high temperatures and pressures in hydrothermal systems. Here we show a separate mechanism that can also modify the oxygen isotope composition of sulphate ($\delta^{18}O_{SO4}$) in natural environments, through *assimilatory sulphur cycling*. We define this as the assimilation of sulphur into proteins and biomolecules during cellular growth and its return to the extracellular sulphur pool during cellular turnover. Oxygen isotopes in sulphate are replaced during this cycling and thus this process might be an important, and as yet unconstrained factor in understanding the variability of the $\delta^{18}O_{SO4}$ in natural environments. The cyanobacterium *Synechococcus* sp. PCC7002 and the diatom *Phaeodactylum tricornutum* were grown separately in pure culture and the sulphate in the media was monitored for changes in oxygen isotopes relative to a sterile control flask. The media used contained 3mM sulphate and water with $\delta^{18}O_{H2O}$ of 40‰. The $\delta^{18}O_{SO4}$ increased significantly over the period of cell growth (3 weeks). Replicate experiments in media with sulphate concentrations of 30mM (similar to marine environments) show smaller but analytically resolvable changes in the $\delta^{18}O_{SO4}$ over the period of cell growth. Our results suggest that the $\delta^{18}O_{SO4}$ of marine sulphate could be significantly modified by assimilatory sulphur cycling in regions of high biological productivity, and may be a novel proxy for constraining total carbon turnover in an ecosystem.

Tungsten isotopic anomalies in Archean komatiites

M. TOUBOUL*, I.S. PUCHTEL AND R.J. WALKER

Dept. of Geol. Univ. of MD, College Park, MD 20742, USA (*correspondence: mtouboul@umd.edu)

Late or heterogeneous accretion, early mantle differentiation, and/or core-mantle interaction are processes that could have created subtle ^{182}W isotopic heterogeneities within Earth's mantle (where $^{182}Hf \rightarrow {}^{182}W + \beta^-$; $t_{½} = 9$ Myr). To facilitate the search for such effects, we have developed a new ultra-high precision measurement protocol using a *Triton* thermal ionization mass spectrometer, allowing us to resolve ^{182}W anomalies at a ±6 ppm level. Here, we present ultra-high precision W isotopic compositions and W abundances of Archean komatiites from Komati, Weltevreden, Belingwe, Kostomuksha and Vetreny.

Within each komatiite sequence, W abundances are generally correlated with proxies for lava differentiation. In some samples, however, W clearly shows open system behaviour, indicated by large enrichments that are accompanied by enrichments in U and Re. This is likely due to post-eruption alteration and highlights the care that must be taken when examining W isotopes in altered rocks. Of greatest note, Kostomuksha samples exhibit ^{182}W excesses relative to the modern upper mantle, ranging from +12 to +35 ppm. A plot of $\varepsilon^{182}W$ *vs.* 1/W defines a binary mixing line that extrapolates to an ambient terrestrial composition ($\mu^{182}W = 0$), as would be expected due to the variable open-system behaviour of W identified in some samples.

The positive ^{182}W anomaly in the mantle source of the Kostomuksha komatiites is inconsistent with incorporation of a core component, as was initially suggested to explain the $^{186, 187}Os$ enrichments that are also present in the system. Our results, therefore, indicate that the Kostomuksha source included a primordial component characterized by high Hf/W, Re/Os and Pt/Os. The short half-life of ^{182}Hf requires that this reservoir was created within the first ~50 Ma of the Solar System. We speculate that this reservoir represents a product of metal-silicate partitioning at the base of a deep magma ocean and is consistent with reduced metal-silicate D values observed at high P/T for Pt and Re. This component would have contributed highly radiogenic ^{182}W, ^{187}Os and ^{186}Os, but its low elemental abundances would have been largely eliminated by mixing with mantle re-enriched in moderately and highly siderophile elements via late accretion. The generation of these komatiites at 2.8 Ga attests to the long-lived nature of the reservoir, and highlights the evident sluggish mixing of the mantle, even during the Hadean.

A hydrogen rich Early Earth?

H. TOULHOAT[1]*, V. BEAUMONT[1]*, V. ZGONNICK[2], N. LARIN[3] AND V.N. LARIN[3]

[1]IFP New Energy, 1 & 4 Avenue de Bois Préau, 92852 Rueil-Malmaison Cedex, France. (*correspondence: valerie.beaumont@ifpen.fr)
[2]Ukrainian Association for Hydrogen Energy, Nogina St. 14/23, Krivoy Rog, 50014, Ukraine
[3]Russian Academy of Science, Schmidt Institute of Physics of the Earth, B.Gruzinskaya St. 10, 123995, Moscow, Russia
[4]Lomonosov Moscow State University, Leninskiye Gory, 119991, Moscow, Russia

V.N. Larin (1993) [1] proposed that the chemical differentiation in the solar system was driven by the magnetic field of the Protosun, which induced a magnetic zoning of the ionized solar nebula matter. This hypothesis is geochemically supported by a correlation between the Log of the chemical element abundances of the Earth outer geospheres relative to the Sun, and the first ionization potential of these elements.

The observed correlation is theoretically reappraised in the present paper and is interpreted as a Boltzmann distribution, which is proportional to the distance to the Protosun. The model is succesfully tested for the observed solar normalized chemical compositions of the Earth, Mars and chondrites; poorly convincing results are obtained for Venus in absence of reliable data for low abundance elements.

The comparison of the abundance of a given element in the Earth's crust with the average abundance predicted from the proposed model is further interpreted as reflecting the geochemical radial differentiation of the Earth. Using a simple thermochemical model, we propose that the radial distribution of hydrogen on Earth is a function of the chemical affinities of major Earth forming elements with hydrogen.

This model provides insights for hydrogen abundance on Earth. Notably, the inner Earth would have been and still could be hydrogen rich. Although most of this hydrogen have escaped to atmosphere and space through the thorough degassing of the mantle, it is reasonable to suggest, in the perspective given by our model, that very large amounts still reside in the core.

Anions in clay materials: A case study for multi-scale modeling approaches

C. TOURNASSAT

BRGM, French Geological Survey, 45060, Orléans, France

Swelling property in water endows clay materials with a very low hydraulic conductivity and transport of water and solutes in these media is mainly diffusive, with diffusion coefficients that are much smaller than in bulk water. As a consequence, clay materials are recognized as efficient barriers for waste confinements. For instance, bentonites are already used by solid-waste-disposal operators in the form of compact and/or geosynthetic clay liners while engineered bentonite barriers and natural clay formations are foreseen for radioactive waste confinement in deep geological repositories. Clay material physical and chemical properties result from their small size (typically $< 2\mu$m) and structural specificities. Recent developments of computationnal and spectrometric techniques enabled to probe these properties down to the molecular scale, providing accurate descriptions of processes taking place at the solid/water interface. However, for engineering applications, clay properties must be characterised at a large spatial scale (1m-100m) using macroscopic descriptions and often empirical parameters enabling predictive modelling on extended timescales (typically 100 000 years for radwaste repositories). Making the link between these spatial and temporal scales is of paramount importance to assess the robustness of long term predictive modelling results through a detailed justification for the necessary modelling simplifications.

The present talk will focus on anions distribution and mobility in montmorillonite and illite clay materials that are representative of natural clay formation mineralogy. Illite and montmorillonite structures have an excess of negative charge that is compensated by cations adsorption in their interlayer space and on their outer surface. Conversely, anions undergo weak or no specific adsorption and are repelled from the negative surface, a phenomenon called anion exclusion. While this process can be adequately predicted by theoretical models on simple static systems (e.g. clay suspension in 1:1 electrolytes), its quantitive prediction on complex systems (compact clay material, multispecies electrolytes) remains problematic as well as its impact on macroscopic anion diffusion parameters. We will review models available from the nano- to the macroscopic scale in order to (i) highlights recent improvements in our understanding of anion distribution and mobility in clay materials and (ii) to identify remaining gaps to be elucidated.

Halogen compositions in kimberlites and their constituent minerals

C. TOYAMA[1]*, Y. MURAMATSU[1], J. YAMAMOTO[2], H. SUMINO[3], S. NAKAI[3] AND I. KANEOKA[3]

[1]Gakushuin University, Tokyo, 171-8588, Japan (*correspondence: 09242003@gakushuin.ac.jp, yasuyuki.muramatsu@gakushuin.ac.jp)
[2]Kyoto University, Oita, 874-0903, Japan
[3]University of Tokyo, Tokyo, 113-0032, Japan

Introduction

Studies on the isotope and element compositions in kimberlites will provide important information to estimate chemical environment of the Earth's mantle. We had analyzed major and trace elements in kimberlites from South Africa and China. However, some kind of data about chemical compositions of kimberlites are still lacking. Especially, data of halogen elements are very limited. In this study, we analyzed concentrations of halogen elements (Cl, Br, I) in kimberlites and their constituent minerals from six regions, and considered the characteristics and their origin of each area.

Samples and method

Samples analyzed are 34 kimberlites collected from South Africa, China, Greenland, Brazil, Canada and Russia. For the determination of halogen, we used the pyrohydrolysis method combined with ICP-MS [1].

Results and Discussion

The results show that concentrations of Cl, Br and I in kimberlite samples are higher than those in common ultra-mafic rocks. Markedly high Br concentrations (>10ppm) are found in some kimberlite samples from China and Russia, while iodine concentrations in some samples from South Africa, Greenland, Canada and Brazil are relatively high (>0.1ppm). The I/Br ratios (about 1×10^{-1}) in kimberlites obtained for South Africa, Greenland, Canada and Brazil are very similar and relatively high, and they are similar to those in chondrite (CI), peridotite and basalt. The I/Br in kimberlites possibly shows the characteristics of halogen in the mantle where kimberlite magmas were formed. In case of Chinese and Russian kimberlite samples, the I/Br ratios (about 2×10^{-3}) are significantly low suggesting that they are associated with materials having low I/Br ratio, which might have been influenced by seawater (I/Br ratio: 1×10^{-3}).

Introduction

The sea-surface microlayer (SML) covers the ocean surface, and SML has been operationally defined as roughly the top 1 to 1000 micrometer of the ocean surface. SML controls transfer of chemical substances between the ocean and atmosphere, influencing the chemical compositions of atmospheric aerosols that occur in breaking waves. Since solar radiation reaching the ocean surface is relatively strong, compared to the underlying bulk seawater, photochemical reactions on the ocean surface could induce significant chemical changes which in turn change chemical compositions of atmospheric aerosols. This study tries to elucidate the photochemical properties of SML by measuring the UV-VIS absorbance, fluorescence and concentration of dissolved organic carbon (DOC).

Discussion of Results

We collected coastal SML samples around Okinawa Island, Japan. Okinawa Island is located in semi-tropical region and parts of the island coast are covered with coral reefs and parts of the island are heavily affected by human activities. We selected 10 sampling sites represending different environmental conditions, i.e. close to residence area or relatively remote area. We used a glass plate method to collect SML samples, and at the same location and time bulk seawater samples were collected about 10-cm below the surface with high density polyethylene bottles.

Results showed that enrichment factors (EF), defined as ratio between SML and bulk seawater, of absorbance (at 300 nm) and DOC were ca 1.0 to 2.4 and 1.0 to 1.8, respectively. Based on the fluorescence measurements, it is suggested that humic acid-like compounds and aromatic amines were concentrated in the SML, compared to the bulk seawater. We further discuss impacts of human activities on photochemical properties of SML around Okinawa Island.

Dating of submarine hydrothermal deposits by ESR and U-series methods

S. TOYODA[1]*, F. SATO[1], S. NAKAI[2], A. TAKAMASA[2] AND J. ISHIBASHI[3]

[1]Department of Applied Physics, Okayama University of Science, Japan (*correspondence: toyoda@dap.ous.ac.jp)

[3]Graduate School of Earth and Planetary Science, Kyushu University, Japan (ishi@geo.kyushu-u.ac.jp)

As interests in submarine massive sulfides as mineral resources increase, geochronological study of submarine ore deposits becomes more important. Formation of a large ore body requires long-time duration of hydrothermal activity. Moreover, a systematic geochronological study to reveal mineralization stages and sequences would provide an important key to explore submarine ore deposits. We focused on a chronological study of barite ($BaSO_4$) and developed an application of electron spin resonance (ESR) dating of barites. Barite is a sulfate mineral commonly occurred in submarine ore deposits, sometimes including substantial amount of radium that substitutes barium.

As a sample, we used a massive ore deposit collected from a submarine active hydrothermal field (in the southern Mariana backarc basin). This deposit grew rather horizontally to a few meters in length and about 15 cm in a diameter. A piece of slice with thicknees of about 5 cm was taken from the middle part of the deposit and cut into 13 pieces. Each piece was crushed and barite and spharelite were extracted by chemical and magnetic methods.

The ESR signal due to SO_3^- radical was observed in barite. The signal intensity increased with gamma ray dose. By extrapolating the dose response to the zero ordinate, the accumulated natural doses were obtained. The concentration of radium was obtained by the low background gamma ray spectroscopy using a gemanium semiconductor detector. The natural dose rates were calculated from the value. The ESR ages were obtained by dividing the accumulated natural doses by dose rates.

U-series ages were also obtained for these pieces using sulfide mineral mainly composed of sparelite and pyrite by mass spectroscopy. The ages were calculated from the disequiliburium between ^{234}U and ^{230}Th.

The ages obtained by these two methods were consistent within 30 %. The ages for these 13 pieces were grouped into two, one about 2500 years and the other about 1300 years.

The oxidation state of Hadean melts and implications for the composition of Earth's early atmosphere

DUSTIN TRAIL*, E. BRUCE WATSON AND NICHOLAS D. TAILBY

Department of Earth & Environmental Sciences and New York Center for Astrobiology, Rensselaer Polytechnic Institute, Troy, NY 12180, USA (*correspondence: traild@rpi.edu)

Zircon is an exceptionally durable mineral that retains primary chemistry for most elements from the time of igneous crystallization. Zircons are the only known terrestrial solids dating from the first 500 Ma of Earth history, and thus present a unique opportunity to constrain intensive petrological variables from Hadean (i.e. >3.85 Ga) melts that would otherwise be inaccessible. We report an experimental calibration that makes it possible to evaluate the oxygen fugacity of terrestrial melts prior to the Archean based on the incorporation of heterovalent Ce into zircon. Zircons were grown in a piston cylinder apparatus at 1 GPa and 900 to 1300ºC from hydrous silicate melts (~72 wt% SiO_2) doped with La, Ce and Pr (±P). The melt Ce^{4+}/Ce^{3+} ratio was controlled throughout the duration of the experiments by buffering the oxygen fugacity at values broadly covering the range observed in terrestrial and lunar magmas.

Application of this calibration to zircons from the Bishop Tuff magma chamber, mid-ocean ridge basalt residuals, and lunar grains yields average calculated oxygen fugacities broadly consistent with independent estimates. Furthermore, our results show that Hadean zircons crystallized in melts having average oxygen fugacities within error of the fayalite-magnetite-quartz buffer, including zircons with chemical characteristics consistent with an origin from a mantle-derived melt. The oxidation state of Hadean magmas may yield critical constraints on the speciation of volatile gases entering the atmosphere in the Hadean; results of our calibration are most consistent with H_2O, CO_2, SO_2, and N_2 gaseous species as early as 200 Ma after solar system formation.

Geochemistry and PGE mineralogy of chromitite seams of the eastern Bushveld complex, South Africa

M. TREDOUX[1]*, F. ZACCARINI[2], G. GARUTI[2], J. KOTKE-LEVIN[1] AND C. GAUERT[1]

[1]Geology Dept, Univ. of the Free State, PO Box 339, Bloemfontein, 9300 South Africa (*correspondence: mtredoux@ufs.ac.za)
[2]Department of Applied Geosciences and Geophysics, University of Leoben, A - 8700 Leoben, Austria

With the increasing interest in chromitites of the Bushveld complex as platinum-group element (PGE) ores, the need to characterize these layers and their PGE mineralization has grown. This is particularly true for the eastern limb, which in general has been under-explored relative to the western limb.

The whole-rock PGE geochemistry of the eastern limb chromitites was investigated in the 1980s [1, 2]. These studies indicated that the PGE concentrations in the chromitites increased with continued fractional crystallisation. It was also found [2] that the Pt/Pd ratio remains constant right up to, and including, the Merensky reef.

This geochemical investigation was based on borehole core samples, comprising a complete section through the Middle Group (MG) chromitite layers in the central part of the eastern limb [3]. The mineralogical study was supplemented by data from Lower Group (LG) and MG chromitite xenoliths which were associated with the Onverwacht and Tweefontein dunite pipes [4]. The whole rock PGE patterns of all the layers show the same positive Rh anomaly which typically is displayed by the UG2 chromitite. The MG layers display an increase of the HT-PGE (Os, Ir and Ru) relative to the LT-PGE (Pt, Pd and Rh) with stratigraphic height. The individual groups both correlate positively with the Cr_2O_3 concentration.

High magnification ore microscopy and back-scattered electron imaging indicate that very fine-grained (generally ≤10 μm) laurite is by far the major PGE mineral. The laurite composition does not vary significantly from the bottom of the LG to the top of the MG layers, indicating constant S fucacity. This is in contrast with the Upper Group (UG) layers, in which a great variation of PGE minerals is found. A peculiarity of the MG layers is that laurite is often associated with rutile.

Trace element mobility during spheroidal weathering of dolerite dykes from central Portugal

M.J. TRINDADE[1,3], F. ROCHA[2,3]*, M.I. PRUDÊNCIO[1,3] AND M.I. DIAS[1,3]

[1]Technological and Nuclear Institute, EN 10, 2686-953 Sacavém, Portugal
[2]Geoscience Dept., Aveiro University, 3810-193 Aveiro, Portugal (*correspondence: tavares.rocha@ua.pt)
[3]GeoBioTec Research Center, Aveiro University, Portugal

This study focused in an outcrop of central Portugal where several dolerite dykes, intercalated in granite, show a characteristically well developed spheroidal weathering pattern, forming concentric shells of decayed rock. The trace element mobility during weathering of four rounded boulders of decomposition, from three dolerite dykes, is analyzed. Each of them was separated in a clay-rich external shell, two intermediate shells and a core. Their chemical and mineralogical composition was obtained by neutron activation analysis and X-ray diffraction, respectively.

Primary minerals (Ca-plagioclase, augite and biotite) predominate over secundary phases (chlorite, smectite, kaolinite and talc) in the inner parts of the boulders. The more external shells present abundant clay minerals, especially smectite, being the primary minerals accessory or inexistent.

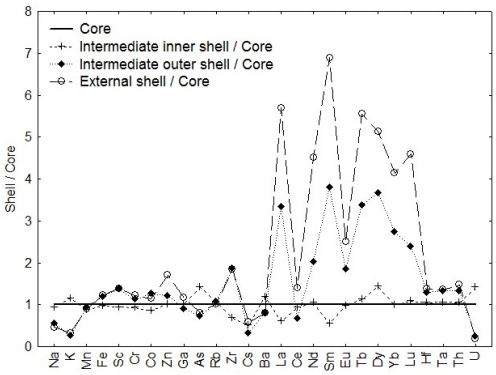

Figure 1: Chemical variability in one rounded boulder.

Weathering promoted the release of REE^{3+} from primary phases, mobilization by meteoric waters, and incorporation in secondary phases, especially smectite, the most abundant clay mineral. Ce and minor Eu were retained, causing negative anomalies. Hf, Ta, Th, Zr, Fe, Sc and Zn were also mobilized into secundary phases. The impoverishment of the outer shells in Na, K, Cs, Ba and U shows they were mobilized out of the system during alteration.

Re-Os isotopes and redox-sensitive elements of the Himalayan black shales: Implications to marine anoxia near the Pc-C boundary

GYANA RANJAN TRIPATHY* AND SUNIL KUMAR SINGH

Physical Research Laboratory, Ahmedabad-380009, India (*correspondence: gyana@prl.res.in, sunil@prl.res.in)

Present study attempts to determine the timing and its implications related to changes in the redox state of seawater at around the Pc-C boundary using Re-Os isotopes and redox-sensitive elements of black shales sampled from a underground phosphrite mine (Maldeota, Dehradun) just overlying the Pc-C bounadry in the Lower Tal formation of the Lesser Himalaya, India. The measured $^{187}Re/^{188}Os$ ratios of these shales vary widely (51 to 137), but linearly with that of $^{187}Os/^{188}Os$ (1.363 to 2.116). Following the bivariate approach that used by Singh *et al*. [1], the $^{187}Re/^{188}Os$-$^{187}Os/^{188}Os$ systematics of these shales provided a depositional age of 541±8 (2σ) Ma with an initial $^{187}Os/^{188}Os$ value of 0.90±0.02 (2σ). The Re-Os age of black shales obtained in this study is quite consistent with the reported radiometric ages for Pc-C boundary at other locations of the world.

Geochemical compositions of black shales deposited near the Pc-C boundary is observed to be different than that of the overlying sequences of black shales. The average Al-normalizied values of organic carbon (C_{org}/Al) and redox-sensitive elements (Re/Al, Os/Al, V/Al, Cr/Al, Cu/Al) of these shales are found to be significantly higher compared to that of black shales [1] overlying ~3 m above [2], but separated by a phosphrite sequence from these shales. This enrichment of C_{org} and trace elemental ratios in the black shales deposited at 541 Ma indicates a highly euxinic seawater near the Pc-C boundary. The inferences from this study of reducing seawater chemistry at the Pc-C boundary can find application in understanding the causative factors of the Cambrian explosion of life. For example, the highly euxinic state of seawater could have imposed a mass extinction [3], which subsequently led to large diverfication in biology resulting into Cambrian explosion of life.

Non-isothermal dehydroxylation kinetics of common sheet-like phases and their informational value

R. TRITTSCHACK* AND B. GROBÉTY

Dept. of Geosciences, Univ. of Fribourg, 1700 Fribourg, Switzerland (*correspondence: roy.trittschack@unifr.ch)

Studying the decomposition kinetics by thermal analyses (e.g. Thermogravimetry, Differential Thermal Analysis, Differential Scanning Calorimetry) of rock forming minerals have a long tradition in Earth Sciences. Often observed rate laws have been used for mechanistic interpretation of the reactions. Classical approaches (Avrami, Time to a Given Fraction TGF) focus on model fitting techniques to extract single values of the apparent activation energy E_a and the 'rate determing step' is derived from the value of the exponent in the Avrami equation. From the physico-chemical point of view such interpretations are for most reactions commonly wrong and have often been critisised especially in the chemistry literature [1-3].

Isoconversional treatment of model-free non-isothermal datasets give, in contrast to the classical methods, E_a as a function of α. Variation of E_a with α are a clear sign that the reaction rate is determined by more than one parallel or sequential step and that classical treatment is not feasible. In such a case, mechanistic interpretation of the kinetic experiments is only possible in combination with information gained from simulations (Density-functional-theory (DFT) models [4, 5]) or *in situ* diffraction and spectroscopic methods.

Here, the dehydroxylation kinetics of two natural occuring phases, lizardite and brucite, are taken as examples for contrasting behaviour of the rate determining reaction step. Lizardite dehydroxylation illustrates a highly dynamic and predominantly increasing evolution of E_a with α [6] indicating that several different steps become rate determining, whereas brucite dehydration evolves with a nearly constant E_a indicating that only one step is rate determining over the entire reaction progress. The possible rate determining steps will be discussed.

Crustal CO_2 liberation at Merapi, Indonesia: An earthquake trigger?

V.R. TROLL[1], D.R. HILTON[2], J.P. CHADWICK[3], E.M. JOLIS[1], L.M. SCHWARZ-KOPF[4], M. ZIMMER[5], L.S. BLYTHE[1] AND F.M. DEEGAN[1]

[1]Dept. Earth Sci (CEMPEG), Uppsala University, Sweden (valentin.troll@geo.uu.se)

[3]Dept. Petrol (FALW), The Netherlands
[4]GeoDocCon, Konradsreuth, Germany
[5]GeoForschungsZentrum, Potsdam, Germany

On May 26th, 2006, the magnitude 6.4 Yogyakarta earthquake occurred along a splay of the Opak River Fault system, with hypocentres at 10-15km depth [1]. Prior to 2006, variation of fumarole carbon isotope ratios was limited ($\triangle\delta^{13}C_{2001\text{-}2004}$ = 0.5‰ ± 0.3l) with an average baseline value of -4.1‰ ±0.2 (vs, PDB). This value is typical of subduction zones [2]. Carbon dioxide collected after the earthquake showed a dramatic increase from the baseline to $\delta^{13}C$ = –2.4‰. In 2007 and 2008, $\delta^{13}C$ values returned to background levels. This rise coincided with an increase in eruptive intensity and volcano seismicity by a factor of 3-5 for several weeks after the earthquake [1]. High carbon isotope gas values, such as those observed in 2006, are not produced by decompression- or fractionation induced degassing in either open or closed system mode [3], suggesting an addition of CO_2 from a non-magmatic, high-$\delta^{13}C$ source. The increase in $\delta^{13}C$ in 2006, its transient duration, the crustal depth of the earthquake hypocentres, and the link with eruptive and seismic intensity are all consistent with addition of CO_2 from mid- to upper-crustal depths. Such additions of crustal CO_2 to subduction zone baseline fluxes may modify volatile budgets of ascending magmas at Merapi considerably [4]. Therefore, CO_2 liberation from long-term crustal storage reservoirs, such as the thick limestone basement underneath Merapi, may be a process that is triggered and/or amplified by external mechanisms such as seismic events. We thus envisage a chain of events whereby earthquake and volcano interact in a positive feedback loop. We conclude that crustal volatiles intensify ongoing eruptions and that late-stage volatile addition may potentially trigger explosive eruptions independently of magmatic recharge and fractionation processes and may even be a key factor in promoting regional seismic activity.

Noble gases as tracers to determine the effective diffusivity in the sediment porewater of Lake Hallwil

M.TRÖSCH[1], Y. TOMONAGA[1]*, C.P. HOLZNER[1] AND R. KIPFER[1,2]

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, CH-8600 Dübendorf, Switzerland (*correspondence: tomonaga@eawag.ch)
[2]Institute of Geochemistry and Petrology, Swiss Federal Institute of Technology (ETH), CH-8092 Zurich, Switzerland

Noble-gas concentrations in surface waters and sediment porewater are often found at atmospheric equilibrium according to the local temperature and salinity conditions prevailing in water body during gas partitioning with the atmosphere. As noble gases are chemically inert, deviations of the measured noble-gas concentrations from the expected solubility equilibrium concentrations can be interpreted in terms of physical transport processess.

Since 1985 an artificial aeration system is installed at the bottom of Lake Hallwil, a medium-sized eutrophic lake in Switzerland, to foster the water circulation and to prevent anoxic conditions in its hypolimnion. Starting from 2002 the aeration system has been enhanced in order to inject oxygen-enriched gas into the water body during the summer period. The enrichment in oxygen is achieved by pumping atmospheric air through large volumes of molecular sieves. The same process is also responsible for a significant enrichment in light noble-gas species (i. e, He, Ne, and Ar) in the injected gas phase.

The small bubbles injected at low pumping rates during summer completely dissolve into the water column producing a characteristical noble-gas excess pattern. This noble-gas excess is expected to diffuse from the water column into the sediments. Therefore, noble gases have the potential to be used directly as tracers to determine the effective diffusivity of solutes in the sediment pore space under quasi-natural conditions and to allow to quantify the overall injected gas / O_2 mass over large time scales.

In this work we present noble-gas concentrations measured in the water column and in the sediment porewater of Lake Hallwil over the last five years. Based on these data we modelled the diffusive transport of He, Ne, and Ar in the sediment column to quantify diffusive transport and the O_2 injection into Lake Hallwil.

[6]Huinay Scientific Field Station, Casilla 1150, Puerto Montt, Chile

Cold-water corals are thought to be especially vulnerable to CO_2-driven climate change and ocean acidification because they live close to the aragonite saturation horizon, which is now rapidly shoaling as anthropogenic CO_2 penetrates into the deep oceans. Due to the sensitivity of calcification to saturation state, this may not only lead to decreased calcification rates but also dissolution of deep-sea calcifiers.

Here we report boron isotopic measurements of cold-water corals representing a wide range of deep-sea and shallow-water environments. These zooxanthellate aragonite corals are all found to have relatively high $\delta^{11}B$ compositions, lying significantly above the seawater borate equilibrium curve. The internal pH of the solitary coral *Desmophyllum dianthus*, determined from the measured $\delta^{11}B_{carb}$ compositions, defines a highly correlated linear array with seawater pH. This relationship, indicative of internal (extracellular) up-regulation of pH at the site of calcification [1], corresponds to a differential pH (ΔpH) of ~0.7 to 0.8 units above ambient seawater. As a consequence the aragonite saturation state of the calcifying fluid is increased approximately two to five-fold, facilitating calcification in low pH environments. This contrasts with the hyper-calcifying tropical zooxanthanlate corals that operate within a significantly lower range of ΔpH values from 0.3 to 0.4 units [1], indicating the importance of temperature on the kinetics of inorganic calcification. These new observations suggest that the effect of declining carbonate saturation state in the deep-oceans may be partially offset by the combined effects of biological up-regulation of internal pH and enhanced rates of calcification from higher ocean temperatures.

Origin and composition of LLSVPs in the lowermost mantle

REIDAR G. TRØNNES

Natural History Museum, Univ. Oslo, Norway (*correspondence: r.g.tronnes@nhm.uio.no)

The structure of the lowermost mantle (D") is dominated by spherical harmonics degree-2 variation with two anti-podal Large Low Shear-Velocity Provinces (LLSVPs) [1]. Their locally steep margins may be favourable sites for the generation of mantle plumes, giving rise to large igneous provinces, and even kimberlites, with ages covering the last 540 Ma [2-4]. The LLSVPs are probably thermochemical piles with sufficient density to resist thermal buoyancy and destruction. Steep margins could be promoted by elevated bulk modulus of the pile material [2].

The piles may be enriched in meta-basaltic material with high density caused by high Fe/Mg ratio in perovskite and high bulk modulus associated with the presence of stiff silica minerals and absence of soft ferropericlase [5, 6]. Peridotite or komatiite with elevated Fe/Mg may be alternative materials in the piles. The origin and age of the LLSVPs are probably linked to the nature of the material. Accumulation of basaltic rocks from subducted slabs could occur slowly in the plume generation zones near the LLSVP-margins over 3-4 Ga [7]. Emplacement of komatiitic or peridotitic material with elevated Fe/Mg, however, could have occurred early, either during the final solidification of a lowermost mantle magma ocean [8, 9] or by sinking of solidified material from a melt accumulation zone (by buoyancy) at 400 km depth [10]. Melting in hot Hadean or Archean plumes may have been widespread at 20-25 GPa where the peridotite solidus is at relatively low T [11, 12]. The psedo-invariant melt compositions at $p > 15$ GPa are poorly constrained and may be relatively silica-rich at 23-30 GPa, where ferropericlase is the liquidus phase [11-13]. A systematic melting study of a range of simplified compositions will provide further insights.

Sulphate reduction induced by hydrogen under hydrothermal conditions

L. TRUCHE[1]*, G. BERGER[2] AND P. CARTIGNY[3]

[1]G2R, Univ. de Lorraine, Vandoeuvre-Lès-Nancy, France (*correspondance: laurent.truche@g2r.uhp-nancy.fr)
[2]CNRS, IRAP, 14 av. E. Belin, 31400 Toulouse, France
[3]IPGP, Univ. Paris Diderot, France

Abiotic redox reactions induced by hydrogen are of prior importance in numerous fields of investigation in geoscience where hydrogen is produced either naturally or indirectly via industrial activities: e.g. nuclear waste storage [1], underground storage of hydrogen [2], hydrogen generation during serpentinization and related redox reaction [3], early earth, termochemical sulphate reduction (TSR) [4].

In this experimental study we focus on sulphate reduction induced by hydrogen under hydrothermal conditions. We provide kinetic data as a function of temperature (125°C-300°C), pH, hydrogen pressure, sulphate speciation (HSO_4^-, $MgSO_4°$, $CaSO_4°$), surface catalysts or additional electron donor (Hastelloy C273, Ni (0), Fe (0), magnetite). This parametric approach on simplified systems allow us to probe the reaction mecanism and to discriminate electron donors: i.e. native metal, mixte oxide, atomic hydrogen or H_2. In addition, we provide kinetic data that can be apply in numerical simulations. In presence of these catalysts, the reaction rate is one to two order of magnitute higher than in diphasique systems [4] i. e: aqueous sulphate + dissolved hydrogen. However, low pH are required in presence of Hastelloy or Ni (0) to reduced sulphate within hours in the temperature range 250-300°C. Under these conditions hydrogen is not necessary but the reaction rate is enhanced in its presence. We suppose that hydrogen radicals generated by alloy or metal corrosion are the main electron donors. In presence of magnetite, the reaction occurs at low temperature (125°C) but only under restricted conditions: low sulfate concentration, pH around magnetite PZC and hydrogen partial pressure. We further reveale that sulphide reaction initiation is not a necessary condition providing that these catalytic surfaces are present in the system.

The results of this study are discussed in the light of kinetic data and reaction pathways obtained in previous studies using hydrocarbons as electron donor instead of H_2.

Platinum-group elements in basaltic rocks from the Etendeka province in N.W. Namibia

R.B. TRUMBULL*, J.K. KEIDING AND K. HAHNE

GeoForschungsZentrum Potsdam, Telegrafenberg, D-14473 Potsdam, Germany (*correspondence: bobby@gfz-potsdam.de)

The continental flood basalts and intrusive rocks of the Paraná – Etendeka Large Igneous Province have been reasonably well studied, giving a good foundation for more specific questions. One aspect of special interest in LIPs and their mantle source (s) concerns the behavior of platinum group elements (PGE). These elements and their isotopes can help distinguish mantle components (lithospheric, asthenospheric, deep-mantle) and they have obvious economic significance. Some Phanerozoic flood basalt provinces are associated with important Cu-Ni-PGE ore deposits (Emeishan, Siberia), whereas others appear to lack them (Karoo, Deccan and Paraná-Etendeka). Whether this difference relates to conditions in the magma source region or to the nature of crustal assimilation is debated, but sulfur is seen to play a critical role.

We present new PGE concentration data for lavas, dolerite dikes and gabbroic intrusions from the southern Etendeka region of Namibia. The rocks represent the low-Ti magma series, with examples from both tholeiitic and alkaline groups. MgO contents range from 5 to 18 wt.%. PGE concentrations were measured on 5g samples by Ni-sulphide fire assay followed by ICPMS. The results give very low values compared with basalts from other LIPs, with 1 to 6 ppb total PGE, but in agreement with a previous study of Karoo and Etendeka rocks [1]. Primitive mantle-normalized PGE concentrations are below 1 and PGE abundance patterns show moderate to high fractionation (Pt/Ir = 5-30). Ratios of Cu/Pd are high (10^4 to 10^5). There appear to be no systematic differences in abundance or PGE patterns in the tholeiitic vs. alkaline magma series.

The low PGE contents in these rocks may relate to retention of sulphides in the mantle source as argued by [1] or to removal by sulphide saturation of the magma during ascent and evolution. Bulk-rock ratios of chalcophile-lithophile trace elements (e.g. Cu-Zr) in the samples suggest the latter but additional evidence will come from analyses of S and trace elements in olivine-hosted melt inclusions.

Sea floor methane emissions in continental shelves and the role of anaerobic methane oxidation

IANA TSANDEV[1], PIERRE REGNIER[1,2], ANDREW DALE[3] AND ANDY RIDGWELL[4]

[1]Faculty of Geosciences, Utrecht University, Utrecht, the Netherlands
[2]Department of Earth and Environmental Sciences, Unversité Libre de Buxelles, Brussels, Belgium

[4]School of Geographical Sciences, University of Bristol, Bristol, UK

Fluxes of methane from sea floor gas hydrates are a key forcing of Earth's climate. If this methane is oxidized aerobically, such as in a ventilated water column or the oxic part of the sediment, it results in loss of seawater dissolved inorganic carbon (DIC) and alkalinity (ALK) and $CaCO_3$ dissolution. The effect can be opposite if anaerobic oxidation of methane takes place, eg. throughout the reduced part of the sediment column, releasing alkalinity and inducing carbonate precipitation. In this study we identify shelf environments known for high methane hydrate concentrations and model the sediment column with a 1-D biogeochemical reaction network simulator (BRNS) of sedimentary dynamics. Upper boundary conditions on the sediment are extracted from an Earth system model of intermediate complexity – GENIE – through steady state fields of the relevant tracers (organic matter flux to the seafloor, bottom water oxygen content, etc.). We further impose bottom boundary upward advective fluxes of methane on the sediment column based on hydrate dissolution estimates. We identify the pathways of methane transformation – aerobic vs. anaerobic. We find that upon methane hydrate destabilization, anaerobic methane oxidation (AOM) can significantly reduce the efflux of methane to the overlying water and build up DIC and ALK inventories in the sediment porewaters, pushing the system toward carbonate precipitation. This results in increased effluxes of DIC and ALK to the overlying seawater. The magnitude of the AOM effect is, however very sensitive to the assumed rate of anaerobic methane oxidation in the sediment.

Biogeochemical impact of long-range transported dust over Northern South China Sea

S.-C. TSAY[1]*, S.-H. WANG[1,2] AND N.C. HSU[1]

[1]Goddard Space Flight Center, NASA, Greenbelt, Maryland, USA (*correspondence: si-chee.tsay@nasa.gov, christina.hsu@nasa.gov)
[2]Oak Ridge Associated Universities, Oak Ridge, Tennessee, USA (sheng-hsiang.wang-1@nasa.gov)

Transpacific transport and impact of Asian dust aerosols have been well documented (e.g. results from ACE-Asia and regional follow-on campaigns), but little is known about dust invasion to the South China Sea (SCS). On 19-21 March 2010, a fierce Asian dust storm affected large areas from the Gobi deserts to the West Pacific, including Taiwan and Hong Kong. As a pilot study of the 7-SEAS (Seven South East Asian Studies) in the northern SCS, detailed characteristics of long-range transported dust aerosols were first observed by a comprehensive set of ground-based instruments deployed at the Dongsha islands (20°42′52″ N, 116°43′51″ E). Aerosol measurements such as particle mass concentrations, size distribution, optical properties, hygroscopicity, and vertical profiles help illustrate the evolution of this dust outbreak. Our results indicate that these dust particles were mixed with anthropogenic and marine aerosols, and transported near the surface. Satellite assessment of biogeochemical impact of dust deposition into open oceans is hindered by our current inability in retrieving areal dust properties and ocean colors over an extensive period of time, particularly under the influence of cloudy conditions. In this paper, we analyze the changes of retrieved Chlorophyll-a (Chl-a) concentration over the northern SCS, considered as oligotophic waters in the spring, from long-term SeaWiFS measurements since 1997. Over the past decade, six long-range transported dust events are identified based on spatiotemporal evolutions of PM_{10} measurements from regional monitoring stations, with the aid of trajectory analysis. Multi-year composites of Chl-a imagery for dust event and non-dust background during March-April are applied to overcome insufficient retrievals of Chl-a due to cloudy environment. Due to anthropogenic modification within a shallow boundary layer off the densely populated and industrial southeast coast of China, the iron ion activation of deliquescent dust particles enhances the efficiency of fertilization for biological productivity. Compared to the West Pacific, the marine ecosystem in the northern SCS is much more susceptible to the biogeochemical impact of long-range transported Asian dust.

Multimegabar phase relations of major Earth and planetary materials

TAKU TSUCHIYA*, H. DEKURA, A. METSUE AND Y. KUWAYAMA

Geodynamics Research Center, Ehime Univ. Matsuyama 790-8577, Japan

Recent improvements in detection methods have allowed for the discovery of terrestrial exoplanets with 1–10 times Earth's mass, so-called 'super-Earths'. However, their interior is currently highly unclear, because understanding of the ultrahigh-pressure phase relations of major Earth and planetary materials is still quite limited. Those should be clarified before developing models of the internal structures of such objects. In this study, we tried to establish the ultrahigh-pressure and temperature phase relations of some silicates by means of *ab initio* techniques.

It has been known that silica (SiO_2) shows a sequential phase evolution from quartz, coesite, stishovite, $CaCl_2$, α-PbO_2 and pyrite (modified fluorite) with elevating pressure. However, further denser phases are still underdetermined, although studies on some low-pressure analogs have suggested an orthorhombic cotunnite phase as the final high-pressure phase. After examining several dense structure types with AX_2 compound, we successfully discovered a new phase transformation of pyrite type SiO_2 at multi-megabar condition to an unexpected hexagonal structure, which possesses high and relatively regular nine-fold coordinated Si. Similar phase transitions were also predicted in other dioxide compounds, and we finally succeeded in identifying one of them experimentally.

Then, we investigated high-pressure stabilities of some important silicate compounds ($MgSiO_3$ and $CaSiO_3$) and elucidated that the new phase change in silica could initiate breakdown of these silicates to oxide mixtures in the conditions relevant to the mantle of super-Earths and the core of giant planets. Thsy would lead to various complexities in their internal structures. Our calculations show that relatively large density jump is expected associated with the breakdown of $MgSiO_3$ post-perovskite, while the breakdown of $CaSiO_3$ yields an metallic oxide phase. Based on the results, we try to make a standard internal structure model of terrestrial exoplanets.

Subduction cycling of C-O-H volatiles from sediment melting

K. TSUNO[1]*, R. DASGUPTA[1], L. DANIELSON[2] AND K. RIGHTER[2]

[1]Department of Earth Science, Rice University, Houston, TX, 77005, USA (*correspondence: Kyusei.Tsuno@rice.edu)
[2]NASA-Johnson Space Center, Houston, TX, 77058, USA

Sediment subduction is a key mechanism of crustal recycling and mantle-exosphere exchange of C-O-H fluids. Thus high pressure melting systematics of C-O-H bearing pelite is important. While experimental data on the melting relations of alumina-rich pelites became recently available to 23.5 GPa [1, 2], those of alumina-poor pelites are limited to 3 GPa [3, 4]. To completely understand the deep cycling of water and carbon dioxide via sediment subduction, we performed new melting experiments on a silica and alumina-poor, water-undersaturated and carbonate-saturated pelite up to 7 GPa.

Piston cylinder and multi-anvil experiments are performed at 3-7 GPa and 800-1150 °C using a model pelite composition containing 1 wt.% H_2O and 5 wt.% CO_2 in Au capsules. We bracketed the solidus temperatures, at 800-850 °C at 3 GPa, at 900-1000 °C at 5 GPa, and <1100 °C at 7 GPa. Cpx, garnet, and coesite are present in all the experiments, and subsolidus phases also include rutile, phengite, and $calcite_{ss}$ at 3 GPa and 800 °C and joined by kyanite at 5 GPa and 900 °C. The near-solidus melts at 3 GPa, 850 °C are hydrous rhyolite, whereas those at 5 GPa, 1000 °C and 7 GPa, 1100 °C are K-rich carbonatitic. At 5 GPa and 1100 °C, both silicate and carbonatite melts were present. The phengite-out boundary is located between 850 and 900 °C at 3 GPa and 1000 and 1100 °C at 5 GPa, and phengite was not present at 7 GPa and 1100 °C. The solidus constrained in our study is 50-100 °C lower than the previous experiments on pelitic compositions [1, 2].

Comparison of our melting boundaries with thermal models of slab surface temperatures suggests that water-undersaturated, carbonated pelite solidus is located near the *P-T* trajectories of warm subduction zones. Hence subducting pelite in cold to intermediate subducting zones likely survives melting-induced devolatilization up to ~200 km. Hot subduction, on the other hand, may lead to supply of K-rich carbonatitic melt flux to deep sub-arc mantle wedge.

Accumulation of trace elements in paddy soil and dry land under different geological background

C.L. TU[1], T.B. HE[2]*, C-Q. LIU[1] AND Y.C. LANG[1]

[1]State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China

[2]Agricultural college, Guizhou University, Guiyang 550025, China (*correspondence: hetengbing@163.com)

To establish a rational farming mechanism, it is essential to know the relative contributions of both natural and anthropogenic sources to the trace elements in agricultural soil. Our results indicate that the difference of physicochemical properties in natural soils derived from three types of geological parent material is significant ($p<0.01$), but there are no significant differences between trace element contents. Trace element concentrations in most agricultural soils are far beyond natural soils and most of paddy soils have higher trace element contents than dry land soils, which indicates that anthropogenic input strongly influenced trace elements in agricultural soil and more seriously the paddy soil. In dry land, the basic physicochemical properties of soils are similar to those of natural soils derived from same geological parent material. Trace element contents exhibit high relationships with soil pH, C/N and physical clay (<0.01mm) ($p<0.05$). The soil derived from carbonate rock has relative high contents of trace elements and alkaline condition of the soil make the significant enrichments of Cd, Cr and Hg in dry land. The soil derived from red residua has the highest values of Pb and As contents in dry land, partly because the type of soil has amount of physical clay which could weaken the mobility of trace elements. In the paddy field, the differences of paddy soils derived from different parent materials are fading slowly due to numerous times of irrigation and drainage. The key difference is that most of paddy soils derived from carbonate rocks show neutral to alkaline, others show neutral to acidic in paddy fields. Traced element contents have just a pronounced relationship with cation exchange capacity (CEC) ($p<0.05$). With exception of Cr and Hg in paddy soil derived from carbonate rock, different geological background didn't significantly influence the trace element contents.

Transport and aggregation behavior of quantum dots and model nanoparticles in soil environments: Role of soil chemistry and biofilms

NATHALIE TUFENKJI[1]*, IVAN R. QUEVEDO[1] AND SHWETA TRIPATHI[1]

Department of Chemical Engineering, McGill University, 3610 University Street, Montreal, Quebec, H3A 2B2 Canada (*correspondence: nathalie.tufenkji@mcgill.ca)

Recent reports underline the potential environmental risks linked to the 'nano' revolution, yet little is known regarding the fate and impacts of engineered nanomaterials following their release in natural soils and groundwaters. To better understand the transport and fate of these materials in natural environments, a growing number of experimental studies are being conducted. Studies of nanoparticle transport in soils commonly involve laboratory-scale packed column experiments and more recently, deposition experiments using a quartz crystal microbalance (QCM). Such experimental investigations of nanoparticle transport and deposition provide valuable insights into their migration behavior and, hence, potential risks linked with the release of these materials in the natural environment.

Ongoing studies in our laboratory are aimed at examining the transport and aggregation behavior of commercial quantum dots (QDs) and model polystyrene latex nanoparticles in natural and model soil environments. Well-controlled experiments are conducted over a wide range of soil porewater chemistries to understand the role of salt concentration, ion valence and dissolved macromolecules on nanoparticle transport and stability. Moreover, the mobility of the nanoparticles in the presence of soil biofilms is evaluated using laboratory-scale column studies. Transport and deposition studies are complemented with physicochemical characterization of the nanoparticles and collector surfaces using several techniques (e.g. Kelvin probe force microscopy (KPFM), dynamic light scattering (DLS), transmission electron microscopy (TEM), confocal laser scanning microscopy (CLSM) and laser Doppler velocimetry (LDV)). Taken together, this data is used to interpret the stability of the quantum dots and model nanomaterials in soil environments.

Primary and secondary water content heterogeneity in volcanic glasses

H. TUFFEN[1], J.M. CASTRO[2], J. OWEN[1] AND J.S. DENTON[3]

[1]Lancaster Environment Centre, Lancaster University, UK (h.tuffen@lancaster.ac.uk, j.owen2@lancaster.ac.uk)
[2]Institut für Geowissenschaften, Johannes Gutenberg University Mainz, Germany (castroj@uni-mainz.de)
[3]Los Alamos National Laboratory (jo.denton@yahoo.com)

Spatial heterogeneities in the dissolved water content within volcanic glasses are generated by diffusive degassing and crystallization of melts, as well as subsequent post-eruptive hydration of quenched glasses. Characterization of the resultant water diffusion gradients using micro-analytical techniques such as SIMS or synchrotron FTIR allows us to model the timescale of water diffusion and thus key pre-, syn- and post-eruptive processes. We present a variety of micro-analytical data to illustrate three sources of water content heterogeneity within rhyolitic glasses.

Firstly, enrichment of water in glass surrounding spherulites reflects its expulsion during growth of anhydrous mineral phases. Our diffusion models have placed new constraints on spherulite growth rates within obsidian flows [1]. Secondly, we have found strong water enrichment adjacent to perlitic fractures in subglacially erupted obsidian lavas [2]. Diffusion and cooling models show that perlitisation starts at ~400 °C and occurs over timescale of days [3]. Finally, we have used SIMS analysis to overcome the hydration problem and successfully measure the dissolved magmatic water content of pumices [4]. This provides new insight into magma storage and degassing prior to an exceptionally violent eruption.

Studies of near surface redox transitions in crystalline rocks in Sweden and Greenland

E.-L. TULLBORG[1]*, H. DRAKE[2], J. SUKSI[3] AND J. SMELLIE[4]

[1]Terralogica AB, P.O. Box 4140, SE-443 14 Gråbo, Sweden (*correspondence: evalena@terralogica.se)
[2]School of Natural Science, Linnaeus University, SE-391 82 Kalmar, Sweden
[3]Laboratory of Radiochemistry, Department of Chemistry, P.O. Box 55, FIN-00014 University of Helsinki
[4]Conterra AB, P.O. Box 8180, SE 104 20 Stockholm

Oxidising groundwater conditions in the near surface of crystalline rock usually change to reducing in the upper 100 m of the bedrock. To detect the depth of this redox transition zone only from groundwater considerations may be difficult because of flow changes and mixing with time. More useful is to use a combination of different geochemical analyses of redox sensitive elements (e.g. Ce, U) in fracture coating samples. These data, together with mapped changes in fracture mineralogy with depth (especially the presence or absence of minerals like Fe-oxyhydroxides and Fe-sulphides), have been shown to mirror the switch from oxidising to reducing conditions [1, 2, 3]. In addition, U-series isotopes can provide time constraints on redox changes contributing to mobilisation and deposition of uranium.

The present study compares new results from close to the ice margin in Greenland (Greenland Analogue Project [4].) with results from two coastal Swedish sites (Äspö and Laxemar) [2, 3]. One of the key questions for the long term safety of a repository for spent nuclear fuel is whether the intrusion of glacial meltwater can maintain its oxidising character to repository depth (~500 m). If that is the case, mineralogical and geochemical evidence should be observed, especially in fracture material from the Greenland drill cores.

The comparison of results shows that although evidence of oxidation (e.g. breakdown of pyrite and formation of Fe-oxyhydroxide) are documented to greater depth in the Greenland drill cores than at Äspö and Laxemar, it does not exceed 100 m. Also, positive Ce anomalies (indicating Ce^{4+}) are recorded to greater depth in the Greenland drill cores (~ 40 m) compared with Äspö and Laxemar (10-15 m), although still not very deep. Uranium isotopes indicate a transition from mobilisation to deposition in accordance with the other redox indicators, albeit the patterns are complex and the uranium content in the Greenland samples is very low.

Wetting of mineral surfaces – Molecular dynamics simulation

DANIEL TUNEGA[1,2], ROLAND ŠOLC[1], HASAN PAŠALIĆ[2], MARTIN H. GERZABEK[1] AND HANS LISCHKA[2]

[1]Institute of Soil Research, University of Natural Resources and Life Sciences, Vienna, Peter-Jordan-Strasse 82, A-1190 Vienna, Austria (*correspondence: daniel.tunega@boku.ac.at) (rsolc@boku.ac.at, martin.gerzabek@boku.ac.at)

[2]Institute for Theoretical Chemistry, University of Vienna, Währinger-Strasse 17, A-1090 Vienna, Austria (hans.lischka@univie.ac.at, hasan.pasalic@univie.ac.at)

Wettability of minerals is primarily related to an energetic characteristic of surfaces affecting processes as adhesion, friction, detergency, biofilm growth, etc. The wetting ability of a solid surface is mainly determined by its chemical composition, structure and topography [1]. The solid-liquid contact angle method is often used to characterize wettability of surfaces and to determine its surface free energy.

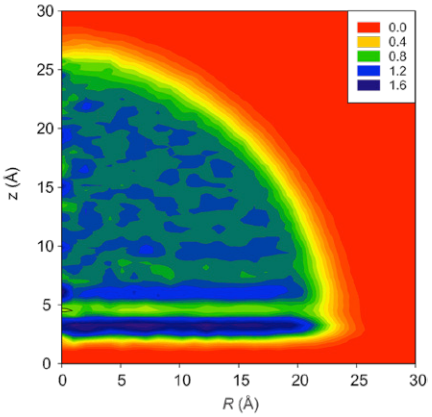

Figure 1: Visualization of water density profile (in g/cm3) of water droplet on the (001) tetrahedral kaolinite surface calculated for last 2 ns of MD simulation.

In order to elucidate structural and compositional factors affecting hydrophilic/hydrophobic character of minerals, interactions of water nanodroplets with basal surfaces of selected minerals (particularly kaolinite, goethite and lepidocrocite) were investigated by means of classical molecular dynamics simulations at room temperature. From the evolution and shape of the nanodroplet on the surfaces it was possible to characterize hydrophobic/hydrophilic character of studied surfaces.

Single particle ICP-MS for detection of engineered nanoparticles in environmental samples

JANI TUORINIEMI[1]*, GEERT CORNELIS[1], STEFAN GUSTAFSSON[2] AND MARTIN HASSELLÖV[1]

[1]Department of chemistry, University of Gothenburg. Kemivägen 10 412 96 Gothenburg, Sweden (jani.tuoriniemi@chem.gu.se, geert.cornelis@chem.gu.se, martin.hassellov@chem.gu.se)

[2]Department of Applied Physics, Chalmers University of Technology, 412 96 Gothenburg, Sweden (stefan.gustafsson@chalmers.se)

Nanoparticles are used in increasing quantities in a vast number of products and concerns have been raised about possible harmful effects on health and environment. In order to study their fate and transport in different environmental compartments, methods that are sensitive, selective and capable of detecting extremely low concentrations of engineered nanoparticles among a high background concentration of natural nanoparticles need to be developed.

The established methods in trace metal analysis fail to distinguish between different types of particles, and other techniques (e.g. electron microscopy) can not provide quantitative information on a routine basis.

Single particle ICP-MS has showed promising potential for element-specific particle detection, by detecting particles as single intense spikes [1]. In this study, the technique is developed for complex environmental matrices and the capabilities and limitations of the technique for analysis and size estimation are explored.

Au and Ag standard nanoparticle suspensions have been used to show that an optimal dwell time exists between 1 and 10 ms for a specific nanoparticle size - background concentration combination where the spread in spike intensities is minimized, the sensitivity with respect to concentration is maximized while the (spike) signal-to-noise-ratio is kept high enough to detect the smallest particles in the sample. It was also possible to simultaneously measure the size and number concentrations of e.g. Ag nanoparticles, and the background concentration of dissolved silver, because nanoparticle spike intensities are independent from the dissolved signal.

Finally, application of the method to spiked natural waters and real treated waste water as well as road runoff is presented.

Isotopic composition of the Early Precambrian crust of the South-Western Siberian Craton: Implications for crustal growth and mantle-crustal interaction through time

OLGA TURKINA

Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (turkina@igm.nsc.ru)

Isotopic Sm-Nd whole-rock and Lu-Hf zicon analysis is a powerful approach for tracing crustal growth and evolution through time. New isotopic data on Early Precambrian metamorphic complexes and granitoids from the south-western Siberian Craton are used to constrain main stages of crustal growth via magmatism and to trace mantle-crustal interaction during lithosphere evolution.

The oldest crust of the south-western Siberian Craton consists of Paleoarchaean (3.3-3.4 Ga) TTG and felsic granulite complexes. The isotopic signatures (ε_{Nd} from +3.1 to -1.0 and ε_{Hf}=2.1-3.3) suggest involvement of pre-3.3 Ga crust in their formation. Felsic metamagmatic and granitoid complexes were formed through a time interval from 2.9 to 1.85 Ga and are mostly characterized by negative ε_{Nd} values suggesting their crustal-derived genesis. The ε_{Nd} values decrease through time but deviate from the isotopic evolution trend of the Paleoarchaean crust. The higher ε_{Nd} values are indicative of mantle contribution to the genesis of the felsic rocks. Both, the T_{Hf} (DM) of 3.0-3.2 Ga and ε_{Hf} from -1.6 to +2.4 of the 2.7 Ga felsic metavolcanics, confirm involvement of older crustal and mantle sources in their formation. The studied mafic metamagmatic associations vary in age from ca. 3.4 to 2.6 Ga. The Paleo- and Mesoarchaean amphibolites compositionally correspond to tholeiitic basalts. Their flat REE patterns $(La/Yb)_n$=0.6-1.4) and ε_{Nd} values (1.1-4.4) suggest derivation from depleted mantle. On the contrary, the Neoarchean (2.6-2.7 Ga) mafic granulites, which protoliths correspond to subduction-related basalts, are mostly enriched in LREE and possess variable ε_{Nd} (+3.9 to -0.2) and ε_{Hf} (7.2-2.2). These features suggest contamination of their mantle sources by crustal material probably via sediment subduction. Thus, the available isotopic data provide evidence of mantle-crustal interaction during the Early Precambrian evolution of the south-western Siberian Craton. Contribution of mantle sources in the formation of felsic rocks is traced during the whole Early Precambrian, while the reverse proccess of recycling of crustal material into the mantle are marked in the Neoarchaean mafic rocks only.

Rapid assembly of an 'S-type' batholith in New Zealand: The plutonic equivalent of a supereruption?

R. TURNBULL[1]*, A. TULLOCH[1] AND J. RAMEZANI[2]

[1]GNS Science, Private Bag 1930, Dunedin, New Zealand (*correspondence r.turnbull@gns.cri.nz)

[2]Dept. Earth, Atmospheric and Planetary Sciences, MIT, USA

Plutonic bodies are an integral part of most orogenic belts and reflect the plumbing system by which mantle and lower crustal melts are fractionated and crust is formed. A critical step in understanding the formation of the Earth's crust is investigating the physical and chemical processes that lead to the formation of large-volume silicic caldera-forming magmatic systems.

Recent research has suggested that some plutons were produced by incremental growth and solidification over several millions of years and therefore do not retain large volumes of eruptible magma at any stage in their construction. In contrast, caldera-forming eruptions require rapid accumulation of large volumes of silicic magma.

We present preliminary high-precision U-Pb ID-TIMS geochronology from the Devonian Karamea Suite in western New Zealand that suggest the entire suite of 'S-type' granites was emplaced within ~2.1 Ma The Karamea magma flux rates (~85-125km^3/km arc/Ma)[1] are comparable to, or in excess of, those estimated for volcanic 'flare-up' events (supereruptions) which are typically associated with large volumes of silicic magma. We hypothesise that the Karamea high magma production rates required intimate interaction between voluminous hot asthenospheric magma and the lowermost sialic crust, necessitating emplacement within an extensional intra-arc setting similar to that observed in the active Taupo Volcanic Zone of New Zealand. Detailed O- and Hf-isotopic studies in zircon, and geochemical characterisation of mafic end members of the suite will allow us to test these hypotheses, and also to determine the relative contributions of juvenile and recycled continental crust to magma generation.

Dissolved metals and As from metal mine waste - Laboratory vs. field determination

A.J.M. TURNER*, C.B. BRAUNGARDT AND J.S. RIEUWERTS

University of Plymouth, Drake Circus, Plymouth. PL4 8AA (*correspondence: alison.turner@plymouth.ac.uk)

Leachates from aged mine waste tips at two abandoned metal mines in south west England were investigated in order to determine the scale and mechanisms of ecotoxic element release and assess the advantages and limitations of field and laboratory methods. Tip drainage waters were sampled in streams and shallow groundwater and master variables were determined *in situ*. In the laboratory, mine waste samples were extracted in batch experiments (acetic acid, MilliQ H_2O and $MgCl_2$) and the European dynamic up-flow percolation test (CEN TS14405). A range of metals, metalliods and anions was analysed in water samples and mineralogy (XRD, SEM-EDX) and particle size of mine waste was determined.

Waste tip material contained a small proportion (<5%) of primary sulphide ore minerals, and Pb, Cu, Zn, Mn and As were associated with abundant secondary Fe phases and clays. Fractional release of elements from the mine waste was generally observed in column and field leachates. At low concentrations (<5 μmol L^{-1}), selective metal adsorption onto secondary Fe phases was implied in the order of affinity of Pb>Cu>Mn>Zn>Cd> Ni.

Under oxic conditions, element release from the waste material was controlled by the interplay of dissolution and sorption processes. Column and batch extractions with MilliQ H_2O provided a good approximation of metal concentrations observed in the field when the L:S ratio was representative of field conditions, i.e. low and high L:S ratio for perched water tables within tips and shallow groundwaters, respectively. However, metal and As behaviour at the solid-solution interface was very sensitive to pH change. Leachate As concentrations were higher in the field (up to 380 μmol L^{-1}, pH 5.0-5.3) than in the laboratory experiments (up to 41 μmol L^{-1}, pH 4.0-4.5), reflecting the greater mobility of oxyanions at higher pH values. Conversely, Pb concentrations were lower in the field (up to 2.8 μmol L^{-1} pH 3.2-5.6) compared to laboratory leachates (up to 81 μmol L^{-1}, pH 1.9-2.6). Batch extractants that amend the eluent pH also resulted in descrepancies between field and batch leachates. This highlighted the importance of maintaining pH conditions representative of field pore waters in column and batch extractions. Nevertheless, when applied to representative samples, carefully constrained laboratory experiments can aid the prediction of pollutant fluxes in the field.

Fluoride removal from solution by calcite — pCO_2 sorption kinetics

B.D. TURNER*, S.B. SLEAP, K. KRABBENHOFT AND S.W. SLOAN

Centre for Geotechnical and Materials Modelling, The University of Newcastle, 2308, NSW Australia (*correspondence: brett.turner@newcastle.edu.au) (Scott.Sleap@ newcastle.edu.au, Kristian.**Krabbenhoft**@newcastle.edu.au, Scott.Sloan@newcastle.edu.au)

Effective remediation modeling and design depends on the ability to predict the rate at which a pollutant will be removed from a system. It is important therefore, to model the sorption *rate* rather than equilibrium sorption. Here we establish the time dependence of F sorption under various conditions.

The kinetics of fluoride removal by calcite as a function of pCO2 (mol%), initial fluoride concentration and calcite surface area were analysed according to pseudo- first and second order reaction kinetics. If pseudo-second order kinetics are applicable, a plot of t/q_t against t should be a linear relationship, from which the initial sorption rate constant (h), can be determined from the slope and intercept of the plot.

Free drift experiments were carried out in a constant temperature room utilizing a gas glovebox connected to commercially prepared CO_2/N_2 mixtures. Solutions of F (as KF) were equilibrated in the CO_2/N_2 atmosphere prior to the addition of calcite of known mass and size (<150 μm & +1.18-2.36mm). pH and F^- ion selective electrodes were used to follow the reaction in at one minute intervals.

It was found that the pseudo-second order reaction kinetic model provided the best correlation to the data in all cases (r^2>0.99). Plots of the sorption rate constant (log (h)) vs pCO_2 show that for the same initial [F], the <150μm fraction (larger SA) has a larger rate constant as larger SA dissolves quicker. Particles with the same SA however show a significant difference in the sorption rate with changes in initial [F]. The fact that h increases with increasing [F]. is surprising given that previous findings[1] show the larger the initial concentration the slower the reaction rate as it takes longer to reach equilibrium

The major advantage of these results is the possibility of obtaining generalized predictive expressions which can be used directly to derive the amount of fluoride removed at any given concentration, pCO_2 and reaction time without the necesstity of developing complicated theoretical models.

Subduction delivers sediment and hydrated oceanic lithosphere into the convecting mantle. Some of these materials are involved in magma generation and returned to the surface as arc volcanism. The remainder continues into the deeper mantle contributing to long-term heterogeneity that may be later sampled by mantle plumes. In order to understand the global cycling of volatiles in subduction zones it is essential to understand the physical and chemical processes of fluid release and melting. Unique upper mantle samples from Batan Island (Philippines) have incompatible trace element and radiogenic isotope characteristics typical of their host lavas. Here we show that they also preserve extreme U-Th-Ra disequilibria. These do not result from either host magma contamination, steady-state diffusion in the mantle or subsequent crustal level processes. Rather, they provide the first direct evidence that such signatures in arc lavas originate in the mantle and that contributions from both wet sediment melts (between 8 kyr and 10's kyr ago) and aqueous fluids (<< 8 kyr) were separately delivered from the slab. The samples also us to estimate the amounts of water (≥ 625 ppm) that may be returned to the asthenosphere, perhaps to be stored at the seismic transition zone.

Life as the catalyst of mineral weathering in acidic forest ecosystem

M-P. TURPAULT[1]*, S. UROZ[1,2], C. CALVARUSO[1,2], C. COLLIGNON[1,2], L. MARESCHAL[1], P. FREY-KLETT[2] AND C. LEPLEUX[1,2] .

[1]INRA-BEF 54280 Champenoux, France (*correspondence: turpault@nancy.inra.fr)
[2]IAM –INRA-Univ. Nancy, 54280 Champenoux, France (uroz@nancy.inra.fr)

In our temperate regions, forests ecosystems developed on acidic soils are characterized by a low nutrient-content and an absence of fertilization. In this context, the life (plant, fungi, bacteria) is strongly dependent on the nutrients input coming from soil mineral weathering and atmospheric deposits. However, what do we know about the relative contribution of biotic and abiotic reactions on the mineral weathering process? What is the stability of soil mineral in time? Are there mineral weathering hot spots into the soil? Who are the actors involved in mineral weathering? Our present knowledge highlights that mineral dissolution is increased in the upper soil horizons where life is intense and the organic matter mineralised. Preliminary analyses also show that a large proportion of fine-size minerals evolves during the seasons in relation with the environmental conditions. Notably, the soil under the influence of the tree root systems (ie rhizosphere) appears as an important mineral weathering hot spot due to intense biological activities (root and associated microbes), which take place in. Despite its small size (ca. 1% of soil), it contributes up to half of the weathering flux. Recent results showed an enrichment of efficient mineral weathering bacteria in the rhizosphere, suggesting a functional complementation between the trees and their associated microbes. Future challenges will be to identify the abiotic and biotic parameters impacting weathering reactions, and to develop models integrating life. Multidisciplinary approaches combining isotopic and genetic tools as well as biogeochemistry and ecology are needed.

Single crystal Sr-isotope data of Ferrar lavas and sills determined by LA-MC-ICPMS

JAN F. TYMPEL[1], MICHAEL ABRATIS[1], AXEL GERDES[2] AND LOTHAR VIERECK-GOETTE[1]

[1]Institute of Geosciences, Friedrich-Schiller-Universitaet Jena, Germany

[2]Institute of Geosciences, Goethe-Universitaet Frankfurt am Main, Germany

The emergence of the Mid-Jurassic Ferrar Large Igneous Province (LIP) in North Victoria Land (NVL), East-Antarctica, which preceded the Mesozoic disintegration of the supercontinent Gondwana, constitutes an apposite example of rapidly emplaced large-scale in- and extrusive magmatic successions within the continental lithosphere. The emplacement commenced with shallow sill intrusions into partly unconsolidated epi- and volcaniclastic sediments of a preexisting sedimentary basin (Transantarctic Basin) chiefly composed of Triassic to Jurassic fluvial strata, forming a potent and up to several hundred meters thick continuous igneous succession that is capped by the Kirkpatrick flood basaltic andesite series.

Strontium isotope ratios ($^{87}Sr/^{86}Sr$) determined by *in situ* Laser Ablation Multi Collector Inductively Coupled Mass Spectrometry (LA-MC-ICP-MS) on single plagioclase phenocrysts show characteristically radiogenic (crustal) values between 0.7094 and 0.7117 as is characteristic of the Ferar LIP and distinguishing from the Karoo LIP. Within this range, lithologically and geochemically distinct rock units display systematically different isotope ratios: shallowly intruded andesite sills and associated cross-cutting dykes show the most radiogenic values ($^{87}Sr/^{86}Sr$ = 0.7112 - 0.7117), local pillow lavas of basaltic andesite composition and flows show intermediate ratios ($^{87}Sr/^{86}Sr$ = 0.7103 - 0.7106) and orthopyroxene rich lava flows feature the lowest ratios ($^{87}Sr/^{86}Sr$ = 0.7094 - 0.7097). Moreover, stratigraphically young high-Ti Kirkpatrick andesite lavas exhibit significantly lower Sr isotope ratios than underlying low-Ti flow counterparts. These systematic variations in isotope ratios could indicate different degrees of crustal assimilation of the respective magmas.

Measured isotope ratios of Sr and Rb ($^{87}Sr/^{86}Sr$ vs. $^{87}Rb/^{86}Sr$) from most rock samples allow for plotting well defined isochrones, which are in fair agreement with previously published crystallization ages averaging around 180 Ma. Method-related dating uncertainties, however, complicate chronologic interrelations between the petrographically distinct units.

Heinrich events on the Irish Atlantic margin: Insights from the Pb isotopic composition of ice-rafted feldspar

S. TYRRELL[1]*, L.T. TOMS[1,2] AND P.D.W. HAUGHTON[1]

[1]UCD School of Geological Sciences, University College Dublin, Belfield, Dublin 4, Ireland (*correspondence: shane.tyrrell@ucd.ie)

[2]PetroStrat Ltd., Tan-y-Graig, Conwy, Wales, LL32 8FA, United Kingdom (lee.toms@petrostrat.com)

Understanding the provenance of ice-rafted debris (IRD) constrains the delivery of material from the ice margin into the marine environment and provides insight into the coupling between ice sheet instability, ocean circulation and the climate system. Six distinct IRD-rich horizons from the Last Glacial are recognized in the North Atlantic deep marine record. These horizons, termed 'Heinrich layers', are linked with binge-purge ice-cycles of the Laurentide (LIS) ice-sheet and associated with Bond-Cycle (~10ka) rapid cooling. These layers bracket other, less-significant, ice-rafting events which are potentially coupled with millennial-paced Dansgaard-Oeschger oscillations.

The Pb isotopic composition of K-feldspar, measured *in situ* using LA-MC-ICPMS, provides a powerful means of linking ice-rafted debris back to its basement source/s. In the North Atlantic region, Pb isotopes in basement rocks have been shown to vary at a scale appropriate to distinguishing ice sheet sources. Specifically, unradiogenic Pb K-feldspar compositions are indicative of derivation from the LIS or Greenland ice-sheet (GIS), whereas more radiogenic compositions suggest sourcing from the British-Irish ice sheet (BIIS).

K-feldspar Pb analyses have been obtained from IRD-bearing horizons in two well-characterised gravity cores on the eastern margins of the Rockall Basin, offshore western Ireland. These include data from 'Grey Bands', a lithologically distinct facies and likely 'Heinrich layer' equivalent. The results show that LIS/GIS sources dominate the 'Grey Bands' whereas BIIS sources mainly contributed the non-'Grey Band' IRD, supporting correlation of 'Grey Bands' with Heinrich events. The data also illustrate that the Bond-Cycle paced forcing, which may have led to increased ice calving on the LIS, had little or no apparent impact on the stability of the BIIS. Furthermore, this approach has allowed for the identification of a Heinrich-like layer in the older (~250ka; MIS 8) glacio-marine record west of Ireland.

Lead sources in Lower Silesia (S.W. Poland): Isotopic study of soils, basement rocks and anthropogenic materials

R. TYSZKA[1]*, A. PIETRANIK[2], J. KIERCZAK[2], V. ETTLER[3] AND M. MIHALJEVIČ

[1]**Wroclaw University of Environmental And Life Sciences**, C.K. Norwida 25/27, 50-375 Wroclaw, Poland (*correspondence: rafal.tyszka@up.wroc.pl)

[2]University of Wroclaw, Cybulskiego 30, 50-205 Wroclaw, Poland

[3]Charles University, Albertov 6, 128 43, Prague 2, Czech Republic

At present, water and atmosphere is contaminated by heavy metals derived from different sources. The main challenge is to identify these sources and estimate their contributions. In environmental studies isotopic ratios of $^{206}Pb/^{207}Pb$ and $^{208}Pb/^{206}Pb$ are routinely used to track Pb contamination in these sources, because at the first approach, the anthropogenic Pb has lower $^{206}Pb/^{207}Pb$ and higher $^{208}Pb/^{206}Pb$ than the lithogenic one.

In this study we characterize Pb isotopic ratios of various lithogenic backgrounds and anthropogenic materials in Lower Silesia, SW Poland. The area comprises several important mining and smelting sites, mainly of Cu ores, and coal mines. We also provide isotopic data for soil profiles developed on different geological units, in contaminated and uncontaminated sites, in order to characterize interactions between anthropogenic and lithogenic materials in the area.

Samples of basement rock, ore, coal, slag, fly ash and soil were collected from different parts of Lower Silesia. Anthropogenic materials from Lower Silesia have uniform $^{206}Pb/^{207}Pb$ of ca. 1.18 with Pb concentrations varying from 3 to over 10000 ppm. On the other hand, $^{206}Pb/^{207}Pb$ in natural rocks varies from 1.17 to 1.38 and the Pb concentration is generally low, below 30 ppm.

The soil profiles formed on natural bedrock are characterized by increase in Pb concentration from the bottom to the top of each profile, which is correlated with decrease in $^{206}Pb/^{207}Pb$ and are good records of contamination by antropogenic airborne material. The uppermost soil horizons (A and O) contain from 40 to 70% of anthropogenic Pb and deeper horizons may contain up to 10% of anthropogenic Pb. The source of this Pb is best approximated by coal burning.

Lead, zinc and antimony leaching from glass-works fly ash in simple organic acids

M. UDATNY[1]*, M. MIHALJEVIC[1] AND L. STRNAD[2]

[1]Institute of Geochemistry, Mineralogy and Mineral Resources, Faculty of Science, Charles University, Albertov 6, 128 43 Prague, Czech Republic (*correspondence: martinudatny@seznam.cz)

[2]Laboratories of Geological institutes, Faculty of Science, Charles University, Albertov 6, 128 43 Prague, Czech Republic

The release of hazardous elements from anomalous geomaterials represent risk for the environment. In our research, we focused on exogenic alteration of fly ash (FA) originating from glass-works in Svetla nad Sazavou (Czech Republic). This factory produces glass with high amounts of PbO. FA from electrostatic filter contains elevated concentrations of Pb, Zn and Sb. The main mineral phases of this material detected by X-ray diffraction are calcite $CaCO_3$ (79%), witherite $BaCO_3$ (10%), quartz SiO_2 (6%) and senarmontite Sb_2O_3 (5%). Small amount of FA may be emitted from factory and can settle in the surrounding environment (soil).

Low-molecular-weight organic acids (citric, acetic and oxalic in concentration of 0.5 mmol/L), simulating soil-like environments and deionised water, were used to test possible mobilization of risk elements from the FA. The leaching experiments were carried out at liquid-to-solid (L/S) ratio of 10 (1 g of FA in 10 ml of leaching medium). The solutions were shaked in ten different times (0.5 to 1440 hours). Leachates were analyzed by inductively coupled plasma mass spectrometry (ICP-MS).

Lead, Zn and Sb exhibit different kinetic leaching curves corresponding to different behaviour of cations (Zn, Pb) and anion (Sb). The concentration of Zn in leachate initially increased, then rapidly decreased and subsequently wery slowly increased. The Pb concentration increased rapidly at the beginning and then very slowly decreased due to possible sorption on present and newly formed phases. Concentration of Sb in leachate increased during all the experiment, which can be attributed to the slow dissolution of senarmontite. Large differences between four leaching solutions were not observed. The leaching is fastest in the citric acid solution. The initial pH were about 3.3–4.0 for organic acids and about 5.6 for deionised water). All the leachates reached the pH value about 10, which corresponds to the equilibrium with calcite present in the FA.

Newly discovered MIL 090030, MIL 090032, and MIL 090136 nakhlites: Paired with MIL 03346?

A. UDRY AND H.Y. MCSWEEN, JR.

Department of Earth and Planetary Sciences, University of Tennessee, Knoxville, TN, 37996, US

Here we present the petrology of newly discovered (2009-2010) meteorites: MIL 090030, MIL 090032 and MIL 090136 from Miller Range, Antarctica. Our aim is to test the hypothesis [1, 2] that these meteorites are paired with nakhlite MIL 03346, which underwent less equilibration and faster cooling that the other nakhlites, and so originate from the top of the nakhlite cumulate pile [3].

The mineralogy of these nakhlites is dominated by cumulus euhedral augite and less-abundant cumulus olivine. They also display a fine-grained albitic intercumulus matrix composition, which exhibits fayalite-magnetite filaments, and skeletal ilmenite. Pyroxene displays a 10 μm Fe-rich rim, suggesting reequilibration with intercumulus matrix. Iddingsite has been observed, representing the aqueous alteration product of olivine. Pyroxene cores have a composition of Wo_{40} and En_{36}, and pyroxene rims have an average composition of $Wo_{32\text{-}40}$ and $En_{8\text{-}12}$. Olivine has a composition of $Fo_{35\text{-}42}$, and interstitial olivine has a composition $>Fa_{90}$, which are similar to those of MIL 03346 [3].

Similarities in mineral compositions, abundances, and textures infer that these nakhlites are paired with MIL 03346. Major and trace elements combined with CSD analyses, will determine the location of these three nakhlites within the cumulate pile and further assess the possibility of a pairing with nakhlite MIL 03346. This enables the petrologic variability to be constrained within a much larger sample of MIL 03346.

'Hidden' metals and minerals: How to detect nanocompounds

S.S. UDUBASA[1]*, G. UDUBASA[1], S. CONSTANTINESCU[2] AND N. POPESCU-POGRION[2]

[1]Univ. of Bucharest, Fac. of Geology & Geophysics, Bucharest, Romania (*correspondence: sorin.udubasa@gmail.com)

[2]National Institute of Materials Physics, Magurele-Bucharest, Romania

Mining waste dumps provide materials suitable to investigate the fate of some metals and minerals during processing/alteration by meteoric waters. Such materials contain commonly all the minerals of the primary ores. It has been proven that, in addition, some minerals or compounds at nanometric scale can form within the waste dumps. Such minerals we can call 'hidden', as they escape the routine investigation by mineralogical methods. Their identification relies on structural techniques such as TEM/SAED, NGR (Mössbauer), XRD etc.

A waste dump in the Leaota Mts., South Carpathians, Romania, has been selected for detailed investigations. The material was produced by exploration of several types of ores, i.e. a combination of pentametallic ores (Ag-Co-Ni-Bi-U) and gold + Cu-Pb-Zn ores. Note that the waste dump is about 50-60 years old.

Attempts were made for the uptake of metals by using *Zea mays* and *Trifolium repens* planted on waste dump materials and neutral soils artificially enriched in metals (Au, U, Cu, As). Good results were obtained in both experiments. Significant enrichment factors of metals (plants vs. starting substratum) were obtained in both cases and both plants, plus surprisingly by analysing also *Alnus incana*, a spontaneously grown tree on the waste dump [2].

The 'hidden' compounds of nanometric size were identified in all the samples analysed: Au, Au-Ag alloys, Ag_2CO_3 (probably the first occurrence under natural conditions), maghemite, wüstite, pseudobrookite, lavendulan, and an amorphous phase, on which the silver carbonate develops. Such nanocompounds are likely to facilitate the metals uptake by plants as the nano-sized compounds show a greater bioavailability as compared to the crystalline (larger size) equivalents [1, 3].

The search for nanocompounds in plants and a deeper investigation of the amorphous phase are in progress.

Ultraviolet Spectra of $^{32/33/34/36}SO_2$; implications for the Archaean atmosphere

YUICHIRO UENO[1], SEBASTIAN DANIELACHE[2], SHOHEI HATTORI[2], MATTHEW JOHNSON[3] AND NAOHIRO YOSHIDA[2]

[1]Tokyo Institute of Technology, Meguro, Tokyo 152-8551, Japan (ueno.y.ac@m.titech.ac.jp)

[2]Tokyo Institute of Technology, Midori-ku, Yokoyama, 226-8502, Japan

[3]University of Copenhagen, DK-2100, Denmark.

Photodissociation of SO_2 is known to yield mass independent fractionation of sulfur isotopes (S-MIF). The MIF recored in the Archaean sedimentary rocks can be an important tracer for the atmospheric chemistry at that time, though wavelength dependency of the MIF by SO_2 photolysis is still poorly understood. We newly determined the ultraviolet absorption cross sections of not only $^{32}SO_2$, $^{33}SO_2$ and $^{34}SO_2$ but also $^{36}SO_2$ from 190 to 220 nm with a resolution of 4 cm^{-1}. The spectra of the ^{32}S, ^{33}S and ^{34}S samples are in agreement with our previously published spectra [1]. The cross sections of the isotopically enriched species (>98% for all the four isotopologues) were corrected based on the isotopic composition of the samples used for the measurements. The absorption spectra show rich vibrational structure and the positions and widths of the peaks change with isotopic substitution in a complex fashion.

The results show that the mass independent fractionation observed during broadband photolysis is product of the change in the amount of red shifting of the heavier isotopologues as suggested by our previous analyses [1, 2].

We will discuss the implications for the chemical composition of the Archaean atmosphere and its evolution based on our calculated wavelength dependency of mass independent fractionation factors for ^{33}S and ^{36}S.

A novel application of (U-Th)/He geochronology to constrain the age of small, young meteorite impact craters: A case study of Monturaqui crater, Chile

I. UKSTINS PEATE[1], M.C. VAN SOEST[2] AND J.-A. WARTHO[2]

[1]Geoscience, 121 Trowbridge Hall, Univ. Iowa, Iowa City IA 52242 (Ingrid-Peate@uiowa.edu)

[2]Noble Gas Geochem. & Geochron. Labs, School of Earth and Space Exploration, Arizona State University, Tempe AZ 85287

Small and young impact structures have been commonly dated by methods such as thermoluminescence, ^{14}C, short-lived extinct radionucleide and cosmogenic techniques. However, (U-Th)/He dating is a low temperature radiometric technique that could potentially bridge the gap between the previously mentioned methods and common geochronological techniques employed on larger impact structures to yield precise impact formation ages. Here we report (U-Th)/He apatite and zircon single crystal ages from the small and young Monturaqui impact structure. The very small size of this crater will act as an ultimate test for the applicability of the low temperature (U-Th)/He technique for dating very small, young impact structures.

We selected two samples of impactite from the Monturaqui crater, representing different lateral sampling areas from the ejected material. A total of 10 zircons and 22 apatite grains were analyzed, and yielded a total of 10 successful zircon ages, and 12 successful apatite ages. The zircon (U-Th)/He ages range from 0.662 to 197.3 Ma and the apatite (U-Th)/He ages range from 0.616 to 61.5 Ma. This age fits well with the previous age range estimates for Monturaqui, and the range is interpreted to reflect a set of partially to completely reset (U-Th)/He ages, which yielded 2 reset apatite ages and 1 reset zircon age, which give a mean age of 663 ± 90 ka.

The results of this study show that the (U-Th)/He dating method has the potential to yield accurate ages for even very small impact structures, like Monturaqui: 663 ± 90 ka. Many of the grains are only partially reset, requiring analysis of a large number of grains to obtain an accurate age, similar to detrital dating studies.

Calorimetry in soil sciences: An unique approach

HAMEED ULLAH*, JOSE A. SIMONI AND CLÁUDIO AIROLDI

Instituto de Quimica, Universidade Estadual de Campinas, Campinas, São Paulo, Brazil (*correspondance: hameedchemist@yahoo.com)

All physical, chemical and biological processes are accompanied by changes in energy which means, heat. This makes calorimetry one of the most suitable techniques to study all these process [1]. In Soil study, microorganism, microbial biomass and organic matter are the most important parameter of soil quality [2] and they could be evaluated, at the same time, using Calorimetry, more generally by ITC and DSC.

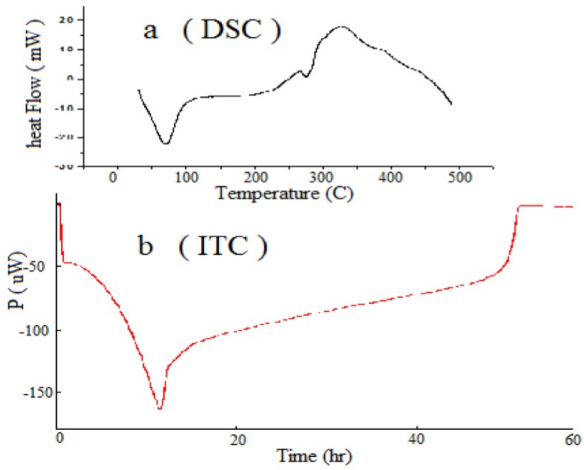

Figure 1: DSC (a) and ITC (b) curves of soil sample

In this study we have evaluated the use of Isothermal microcalorimetry (ITC) to study the effects of soil aging and influence of different experimental conditions on the glucose degradation of Brazilian soil. We also study the influence of the green house effect on the soil metabolism using ITC (Fig.1b). Differential Scanning Calorimetry used to study various properties (organic matter etc) of the soil understudy (Fig.1a). Oxygen and carbon isotope signatures of high-latitude Permian to Jurassic calcitic fossils from southern hemisphere

C.V. ULLMANN[1]*, H.J. CAMPBELL[2] AND C. KORTE[1]

[1]Københavns Universitet, Øster Voldgade 10, 1350 København K, Denmark (*correspondence: cu@geo.ku.dk)
[2]GNS Science, 1 Fairway Drive, Avalon 5010, New Zealand

Oxygen and carbon isotope values of calcitic fossils have been frequently used for characterization of palaeo-environments and for attempts to estimate temperature of past seawater. Fossil shell and skeletal remains of low-Mg-calcite are most suitable for this purpose because of their resistance to diagenesis and to resetting of their primary geochemical signals. Studies of samples from high palaeolatitudes are of particular interest of their potential to quantify past palaeotemperature gradients.

In the present study, brachiopods, bivalves and belemnites were sampled from Permian to Jurassic successions in New Zealand and New Caledonia that were deposited at palaeolatitudes higher than 60°S in marine forearc environments with sedimentation dominated by volcanogenic siliciclastics. The good temporal resolution, based on New Zealand stages, minimizes errors in stratigraphic correlation to low latitudes. The quality of samples was checked by scanning electron microscopy (SEM) with complementary trace element evaluation (ICP-OES) currently in progress. These screening techniques are used for evaluation of postdepositional alteration of samples as well as for detection of potential vital effects and ecological impacts.

A preliminary evaluation of about 1200 $\delta^{18}O$ and $\delta^{13}C$ values shows distinct temporal fluctuations based on the upper envelopes of the trends [cf. 1]. The overall carbon isotope trend is in good agreement with the low-latitude datasets, including its rapid increase of ~4 ‰ during the early Late Triassic [2] that is therefore likely of global nature. The early and middle Permian and the late Jurassic high-latitude $\delta^{18}O$ values are heavier if compared to their low-latitudes counterpart. The Triassic values, on the other hand, do not show any clear difference between high- and low-latitudes, indicating a diminished pole-to-equator sea surface temperature gradient at these times.

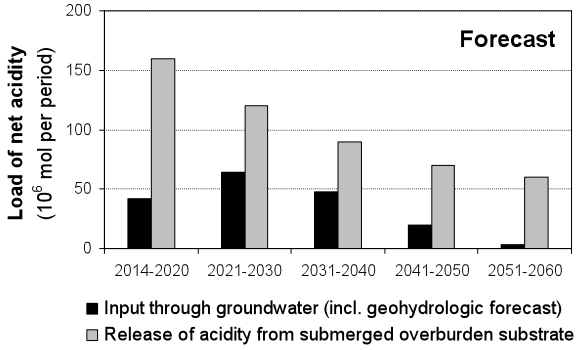
Long-term forecast of acidity load from overburden substrate into a mining pit lake: An integrated approach

K.-U. ULRICH[1]*, I. GUDERITZ[1], B. HEINRICH[1], L. WEBER[2], K.-H. POKRANDT[2] AND C. NITSCHE[1]

[1]BGD Soil & Groundwater Laboratory, 01219 Dresden, Germany (*correspondence: kulrich@bgd-gmbh.de)
[2]LMBV Lausitzer & Mitteldeutsche Bergbauverwaltungs-gesellschaft mbH, 04356 Leipzig, Germany

Open-cast lignite mining in Germany left behind hundreds of lakes most of which are strongly acidic and do not meet water quality standards set for recreational use and water management purposes. To estimate future expenses and develop appropriate reclamation technologies, the authority in charge (LMBV) needs a reliable prediction of the lake water chemistry including the loads of acidity and alkalinity. By combining field and bench experiments with appropriate models, the most relevant physicochemical processes were identified and reliable data collected to determine crucial model parameters that enable a long-term forecast of net acidity load from the lake bed into the water of Lake Zwenkau, a pit lake of $176 \cdot 10^6$ m^3 currently being filled. The results demonstrate that the release of acidity is mainly by molecular diffusion of protons following ion exchange within the submerged overburden substrate (~5 km^2). Similar release rates were found in both a 10-month field test and bench experiments under controlled conditions. While during the five-year period of lake filling the overburden substrate contributes by only ten percent to the overall load of net acidity, this source of acidity will dominate over other sources like groundwater recharge beyond the filling period.



Without technical treatments, the discharge of net alkalinity from natural groundwater may not balance the net acidity of the pit lake before the 2051-60 decade.

[3]Chrono-Environnement, Université de Franche Comté, Besançon, France

Since its complete obduction (at ~34 Ma), the New Caledonia ophiolite has experienced strong weathering due to tropical conditions. This alteration is expressed as laterization affecting the serpentinized peridotites located at the upper part of the massif. This weathering does not macroscopically affect the serpentinites located in the lower part of the ophiolite, but previous studies showed that these serpentinites display anomalous chemical composition relative to the others (silica enrichment, strong Ce negative anomaly).

Our study focuses on the determination of the processes responsible of (a) the chemical variability of the serpentinites and (b) the formation of new mineral phases in the different parts of the ophiolitic sequence. First, mineral phases (including the polymorphs of serpentine) were identified by Raman spectrometry. Second, the relationship between mineral phases in finely-divided assemblages were characterized using an original method, based on micro-beam X-ray fluorescence mapping of cm-scale samples. Third, the chemical exchanges between the different parts of the ophiolitic sequence were estimated from the compositions of major elements and REE in serpentinites, peridotites and laterites.

Our results demonstrate that the chemical and mineralogical transformations of the basal serpentinite are directly linked to the laterization process occurring at the top of the ophiolite. Laterization leads to leaching of silica, magnesia (~80g/100g of protolith) and REE. Only the cerium, which is immobile in oxidyzing conditions, remains immobile in the laterites. Leached elements are transported by percolation of meteoric fluids to the bottom of the ophiolitic sequence where they accumulate and precipitate by supersaturation. New phases such as magnesite and amorphous silica are formed. In the laterites located at the top of the sequence, the leaching process leads to the concentration of transition metals of economical interests such as iron and nickel.

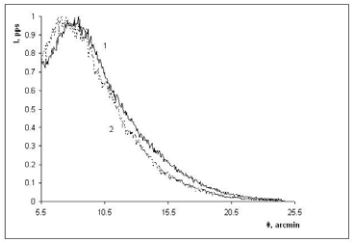
Determining the porosity of analcime by X-ray reflectometry

VASILY ULYASHEV

Institute of Geology Komi SC UB RAS, Syktyvkar, Russia, 54 Pervomayskaya st (*correspondence: vaskom77@mail.ru)

X-ray reflectometry represents the method of research based on measurement of reflective ability in x-ray range of lengths of waves and using the phenomenon of full external reflexion of X-rays. The given technique last years is used in chemistry, the physicist and materials technology for definition of physical and geometrical properties of surfaces, thin films and multilayered structures.

In the presented work as a method x-ray reflectometry porosity of a mineral - analcime Na_2 $[Al_2Si_4O_{12}]$ (H_2O) $_2$ is investigated. Reflectogram the given mineral is on fig. 1.



On reflectogram we find a critical angle for each curve *($\theta_{exp.\,cur.}$)* which corresponds to a point with the intensity equal to half of the maximum size (I = 0.5). From fig. it is visible that a critical angle initial mineral: *$\theta_{exp.\,cur}$ = 11, 9 argmin*. For this purpose, what to define porosity it would be necessary to know still a critical angle calculated theoretically under the formula of Frenelja *$\theta_{theor.\,cur}$ = 13, 37 argmin*.

Knowing experimental and theoretical critical calculate angles porosity under the formula $P = 1–(\theta_{exp.cur}/\theta_{the.cur.})^2$ [1].

Porosity of the initial sample has made *21 %* (an error *of 1 %)*.

Let's consider reflectogram annealed analcime (a curve 2). In drawing distinctions of curves 1 and 2 are well visible. Annealing has led to displacement critical angle towards smaller corners (*$\theta_{exp.\,cur}$ = 11, 5 argmin)*. Porosity annealed a mineral has made *27 %*.. Thus, annealed has led to porosity increase. At present while there is no strict explanation of this effect. It is possible to assume that during time annealed there was a partial phase transition in surface mineral areas. It can be assumed that during annealing occurred partial phase transition in the surface region of the mineral.

Transboundary problems of water resources quality in the Selenga river basin

I.D. ULZETUEVA*, D.TS.-D. ZHAMYANOV, B.O. GOMBOEV AND V.V. KHAKHINOV

Baikal Institute of Nature Management SB RAS, 8, Sakhyanova Str., Ulan-Ude, 670047, Russia (*correspondence: idulz@mail.ru, dabaj18@yahoo.com)

The Selenga river basin is occupies the territory of 447060 km^2 and it is devided by two countries – Russia and Mongolia. 67 % of territory is situated in Mongolia, 33 % - in Russia [1].

From 2007 to 2009 years the Baikal Institute of Nature Management together with Korea Environment Institute, Institute of Geoecology of Mongolian Academy of Sciences have carry outed 3 scientific expeditions in the territory of Selenga river basin (in territory of Russia and Mongolia) within the scope of the International project 'Integrated water management model on the Selenge river basin' for social and economic information collection and water sampling.

We studied the identification of the general content of 15 microcomponents (Fe, Cu, Mn, Zn, As, Mo, Al, Pb, U, Cd, Ni, Co, Cr, Ag, Au) in 30 samples in water objects of the Selenga river basin: 16 from which are selected in territory of Mongolia, on river Selenga inflows – Orkhon, Tuul, Kharaa, 14 in Republic of Buryatia (Russian Federation) – in waters the river Selenga, and on its inflows – Uda, Dzhida, Modonkul.

The investigated waters of the Selenga river basin are alkalescent and low-mineralized, concerning to hydracarbonate class of calcium group and have a favorable oxygen mode. Reduction of concentration of the main ions downstream the river is connected with effect of dilution by waters of inflows which have a smaller mineralization.

Results of researches of the Selenga river basin water quality have shown that the basic pollutants are metals: copper, iron, zinc, arsenic, aluminium, manganese, molybdenum, uranium.

Almost all water objects do not correspond to the requirements of water objects quality of fishery purpose (in Russia the rivers of fishery purpose have the highest standards on water quality, the river Selenga in the territory of Russia is the water object of fishery purpose). The Most polluted rivers are Tuul, Kharaa, Modonkul which basins are the most influenced by industrial regions, and also mining enterprises.

Release mechanisms of Sr and Cs from the weathered Hanford sediments

W. UM[1,2]* AND H-S CHANG[3]

[1]Pacific Northwest National Laboratory, Richland, WA, USA (*correspondence: wooyong.um@pnl.gov)
[2]Pohang University of Science and Technology, South Korea
[3]Savannah River Ecology Laboratory, Aiken, SC, USA

Introduction

Various aspects of the acute effects of the released high level radioactive waste on sediments, including mineral weathering and contaminant transport have been extensively investigated at the Hanford Site. However, the long-term behavior of radionuclides in the contaminated sediment after the removal of the caustic source is not as well studied. Sediment pore water is expected to return to conditions of circumneutral pH and low ionic strength after long times, but the possibility exists that radioactive contaminants sequestered in the impacted sediments might be remobilized by the change in subsurface geochemical conditions.

Results and Discussion

The leaching behavior and release mechanisms for Sr and Cs from the unsaturated columns packed with the two weathered Hanford sediments was modeled using the CrunchFlow code, which represented the reaction network as a combination of mineral dissolution/precipitation and ion exchange reactions. The leach tests were conducted using background Hanford pore water with focus on the first 200 pore volumes. The weathered sediments were prepared by reaction for 6 months with a synthetic Hanford tank waste leachate containing stable Sr and Cs (10^{-5} and 10^{-3} molal representative of LOW- and HIGH-weathered sediments, respectively) as surrogates for ^{90}Sr and ^{137}Cs. The mineral composition of the weathered sediments shows that zeolite (chabazite-type) and feldspathoid (sodalite and cancrinite) are the major byproducts. However, the amount of secondary minerals in the sediments varied depending on the weathering conditions. Reactive transport modeling indicated that the leaching behavior of Cs was controlled by ion exchange, while Sr release was affected primarily by dissolution of the secondary minerals. The release of K, Al, and Si at later times in the leaching experiment using the HIGH-weathered sediment indicates additional dissolution of a more crystalline mineral (cancrinite-type). A two-site ion-exchange model successfully simulated the behavior of Cs release in the LOW-weathered sediment column. However, a three-site ion-exchange model was needed to describe Cs release in the HIGH-weathered sediment column.

Petrological implications of temporal and spatial variations in magma chemistry of the Quaternary Tendurek shield volcano, Eastern Anatolian Collision Zone, Turkey

E. UNAL[1]*, M. KESKIN[2], V.A. LEBEDEV[3], E.V. SHARKOV[3], M. LUSTRINO[4] AND M. MATTIOLI[5]

[1]YYU, Dept. of Geol. Engineering, Zeve Campus, Van, Turkey (*correspondence: esinunal@yyu.edu.tr)

[5]Università degli Studi di Urbino 'Carlo Bo', Dipartimento di Scienze Geologiche, Italy

The Quaternary Tendürek Volcano is one of the largest eruption centers of the Eastern Anatolia with a summit elevation of 3538 m and a footprint area of 650 km^2. It is a shield volcano consisting of lavas ranging in composition from tephrites through benmoreites/phonolites to trachytes. The young volcanism of the region is thought to be related to the continent-continent collision taken place after the closure of the Neo-Tethys Ocean. The Tendürek volcano is of special importance, because it is one of the rare places in Eastern Anatolia where calc-alkaline and potassic alkaline volcanism coexisted.

Lavas of the Tendürek volcano are classified on the SiO_2 versus K_2O diagram as medium K / high K and shoshonitic series. Medium to high potassic basalts, trachy-basalts, tephrites and basaltic-trachyandesites basically follow a partial melting trend on La vs. La/Yb diagram in contrast to the trachy-andesites, phonotephrites, tephriphonolites, phonolites, and trachytes of the shoshonitic series aligning along a fractional crystallization trend. The high-SiO_2 shoshonitic rocks (i.e. phonolites) uniformly contain lower concentrations of TiO_2 (0.52-1.17 %), MgO (0.46-1.05 %) and CaO (1.01-2.93 %) and high values of K_2O (3.95-5.16 %). The high-SiO_2 phonolitic lavas have a more pronounced enrichment in incompatible elements, such as Rb, Th, La and Nb, in comparison to those in the other shoshonitic rocks. The aforementioned differences in the chemical compositions of these two groups of shoshonitic rocks may reflect variations in the fractional crystallization process which involved clinopyroxene and plagioclase during the petrogenesis of the potassic rocks.

The global climate impact of civil aviation

NADINE UNGER

School of Forestry and Environmental Studies, Yale University, New Haven, CT 06511, USA (nadine.unger@yale.edu)

Aircraft emissions affect climate change through increasing carbon dioxide (CO_2) but also a host of other short-lived non-CO_2 effects that are complex, involve impacts that are both warming and cooling and are unique to this sector. Previous assessments of aviation climatic impacts have used a segmented approach whereby each effect was calculated separately and the effects summed. Integrated approaches using newly available Earth System models that allow simulation of more realistic interactions between effects are now possible and give different results. Here, we apply the NASA GISS Earth System Model to reassess the net radiative forcing on 20- and 100-year timescales due to year 2006 emissions from civil aviation including the effects on ozone, methane, sulfate, black carbon, water vapor and CO_2. A new hourly resolution aviation emissions inventory that was developed using the Federal Aviation Administration's Aviation Environmental Design Tool is applied. The model includes interactive tropospheric and stratospheric chemistry, full coupling between gas-phase chemistry and aerosols in the exhaust and background atmosphere. The sensitivity of the ozone climate impact to altitude of emission injection is examined for aircraft emissions and compared to other major anthropogenic surface sources of precursors. The climate impact of global desulfurization of jet fuel is examined. Global mean temperature response to aviation emissions is compared relative to the impacts of other major economic sectors.

Metasedimentary rocks as indicators of crustal growth

L.N. URMANTSEVA* AND O.M. TURKINA

Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia (*correspondence: urmantseva@gmail.com)

Results of Sm-Nd isotopic analyses and U-Pb dating on metasedimentary rocks of two main basement uplifts of western part of the Siberian Craton (illustrated by paragneisses of Angara-Kan granulite-gneiss block of the Yenisey Ridge and Irkut granulite-gneiss block of the Sharyzhalgai Uplift) were summarized to constrain provenance of metasediments, time of sedimentation and finally to determine stages of crustal growth.

Sm-Nd model ages of rocks under consideration (T_{Nd} (DM)=2.4-3.1 Ga for the Sharyzhalgay Uplift and 2.4-2.8 Ga for Angara-Kan block) indicate presence of the Archean and Paleoproterozoic sources in the provenance [1, 2]. As regarding U-Pb data on zircons there are three detrital core age groups (≥2.7, 2.3, 1.95-2.0 Ga) in rocks of the Sharyzhalgai Uplift and cores varying in age from ~2.6 to ~1.9 Ga in rocks of the Angara-Kan block [3, 4]. The age of metamorphic rims of ca. 1.85-1.86 Ga in both cases determines the upper boundary of sedimentation and together with the youngest core ages brackets sedimentation time between 1.85 and 1.95 Ga for the Irkut block and 2.0-1.9 and 1.86 Ga for Angara-Kan block.

Potential source areas for ancient mainly Neoarchean material might be rocks of the exposed basement of south-west margin of the Siberian Craton. Presence of juvenile Paleoproterozoic crust in source area is indicated by minimal values of model Nd ages of paragneisses in common with prevail Paleoproterozoic detrital zircon cores. These Paleoproterozoic juvenile crustal sources may have been presented by buried basement of western part of the Craton, where model Nd ages of 2.3-2.4 Ga for granites and 2.8-3.4 Ga for gneisses were determined by Kovach *et al*. [5].

Finally, examined Sm-Nd and U-Pb isotopic data allow to identify derivation of detritus from buried and exposed basement of the Siberian Craton and determine the Archean and Paleoproterozoic stages of crustal growth within the Siberian Craton.

Nanoscale observations of dolomite dissolution

M. UROSEVIC[1]*, E. RUIZ-AGUDO[1], C.V. PUTNIS[2], C. CARDELL[1], A. PUTNIS[2] AND C. RODRIGUEZ-NAVARRO[1]

[1]Dept. Mineralogy and Petrology, University of Granada, Fuentenueva s/n, 18071 Granada, Spain (*correspondence: maja@ugr.es)

[2]Institut für Mineralogie, Universität Münster, Corrensstrasse 24. D-48149, Münster, Germany

The dissolution of carbonate minerals plays a fundamental role in a large spectrum of geological and biological processes as e.g. the global carbon cycle, and biomineralization. Moreover the understanding of carbonate dissolution is essential in the preservation of the Cultural Heritage and building stone. Among other carbonates, calcite ($CaCO_3$) and magnesite ($MgCO_3$) dissolution has been thoroughly investigated over a range of environmental conditions and solution compositions. In contrast, there is a significant lack of understanding of the molecular-scale reaction mechanisms of dolomite ($CaMg(CO_3)_2$) [1]. In this work we present a systematic *in situ* Atomic Force Microscopy (AFM) study of dolomite dissolution in the pH range 3 to 10 aimed to unravel the nanoscale processes governing dolomite-fluid interactions. Dolomite dissolution under neutral to alkaline pH seems to be controlled by the removal of dolomite layers by spreading and coalescence of shallow etch pits, nucleated at point defects or in defect-free areas. Overall dolomite dissolution rate (R_{AFM}) values were nearly pH-independent in the range 5 to 10 (7-$9 \cdot 10^{-13}$ mol·cm^{-2}·s^{-1}), while a slight increase in R_{AFM} values was observed at pH < 5 (10-$17 \cdot 10^{-13}$ mol·cm^{-2}·s^{-1}). At all pHs (and particularly at pH < 5) the formation of a Mg-rich surface precipitate (most probably nesquehonite) was detected. Our results suggest that the mechanism of dolomite dissolution inferred solely from measurements of the solution chemistry could be misestimated as a consequence of the precipitation of such a secondary phase, particularly at acidic pHs.

Enhancing the bioavailability of subbituminous coal

M.A. URYNOWICZ[1]* AND Z. HUANG[2]

[1]Coalbed Natural Gas Center of Excellence, University of Wyoming, Laramie, WY 82071, USA (*correspondence: murynowi@uwyo.edu)
[2]University of Wyoming, Laramie, WY 82071, USA

Recent scientific discoveries suggest that much of the coal bed natural gas (CBNG) within the Powder River Basin, located in Wyoming and Montana, was generated by anaerobic microbial systems within the coal seams long after the initial process of coalification. This type of natural gas, referred to as secondary biogenic natural gas, relies on the active biological conversion of coal-derived constituents into methane. Secondary biogenic CBNG can also be found in numerous other coal fields located throughout the world. Interest in secondary biogenic natural gas has grown significantly in recent years with the realization of its vast potential and the significant benefits that this energy source has over fossil fuels.

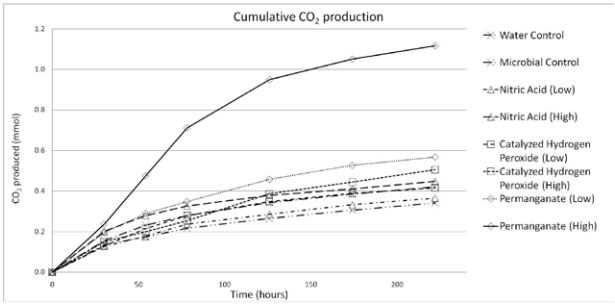

Figure 1: Cumulative CO_2 production.

The aim of this study was to evaluate several conventional groundwater remediation technologies including *in situ* chemical oxidation with permanganate and catalyzed hydrogen peroxide, and acid treatments for enhancing the biodegradability of coal. Although dissolved organic carbon was increased with each method, only the permanganate treatment resulted in a significant increase in coal bioavailability (Figure 1).

Enhanced shelf sediment weathering during glacial periods damps pCO_2 reduction: A negative feedback

H. USHIE[1]* AND K. MATSUMOTO[2]

[1]AORI, University of Tokyo, Chiba 277-8564, Japan (*correspondence: ushie@aori.u-tokyo.ac.jp)
[2]Geology and Geophysics, University of Minnesota, Minneapolis, MN 55455, USA (katsumi@umn.edu)

In the past 800 thousand years and before industrialization, the largest variations in atmospheric CO_2 concentration (pCO_2) occurred in connection with the glacial cycles that characterized Earth's climate over this period [1]. The mechanisms responsible for the glacial-interglacial pCO_2 changes have remained unresolved. One curious feature of at least the last four glacial-interglacial cycles is that pCO_2 reached about the same upper limit of 280 ppm during peak interglacial periods and about the same lower limit of 180 ppm during peak glacial periods. Here, we show using a numerical model of earth system [2] that enhanced shelf sediment weathering during glacial sea-level low stand will tend to raise pCO_2 and thus stabilize it from further reduction. This is contrary to the so-called shelf nutrient hypothesis [3], which proposed that increased weathering of nutrients (e.g. phosphate) would enhance the organic carbon pump of the ocean and thus reduce pCO_2. We demonstrate that weathering of exposed continental shelves would in fact raise pCO_2 because not all nutrients from weathering will be utilized by biology but more importantly because the spatial distributions of carbon and phosphate from weathering become decoupled in such a way that carbon is preferentially stored in the upper ocean and phosphate in the deep ocean. An extension of this finding suggests that the preferential dissolution of phosphate in shelf sediments during interglacial high stand would tend to enhance biological production and thus stabilize pCO_2 from further increase. The impact of sea level-driven continental shelf exposure and submersion on CO_2 is therefore a negative feedback that helps explain both the upper and lower limits of pCO_2 over the Pleistocene.

Experimental and numerical investigations of the formation of felsic asteroidal crust

T. USUI[1]*, J.H. JONES[1] AND H. SENSHU[2]

[1]KR, NASA/JSC, Houston, TX 77058, USA
(*correspondence: tomohiro.usui@nasa.gov)
[2]PERC, Chiba Institute of Technology, Chiba, Japan

Achondrites exhibit a diverse set of petrographical and geochemical features that individually reflect distinct environments during differentiation processes on their parent asteroids. Our study reports on experimental and numerical investigations that constrain the formation of felsic asteroidal crust recorded in paired achondrites GRA 06128 and GRA 06129 (GRAs).

GRAs are characterized by high abundances of sodic plagioclase, resulting in alkali-rich, felsic, whole-rock compositions. Geochemical studies suggest that the GRAs originate from a partial melt from a volatile-rich asteroid that did not segregate metallic core. We performed partial melting experiments on a synthetic, alkali-bearing, H-chondrite composition under a wide range of fO_2 conditions (IW-1 to IW+2). The experiments suggest that fO_2 conditions significantly influence the compositions of partial melts. Partial melts at IW-1 are distinctly enriched in SiO_2 (up to 70 wt%) and depleted in FeO contents relative to those of >IW melts (~39-47 wt% SiO_2). The silica-enriched, reduced (IW-1) melts are characterized by high alkali contents, resulting in silica-oversaturated compositions. In contrast, the silica-depleted, oxidized (>IW) melts, which are also enriched in alkali contents, have distinclty silica-undersaturated compositions. These experimental results suggest that alkali-rich, felsic, asteroidal crusts as represented by GRAs should originate from a low-degree (F = <15 %, T = <1050 °C), relatively reduced (~IW-1) partial melt from a parent body having near-chondritic compositions.

We also perfomed numerical simulations for the thermal evolution of a GRAs parent body by assuming ^{26}Al and ^{60}Fe with the CAI canonical values as dominant heat sources. The numerical investigations suggest that a GRAs parent body should have accreted 0.7-1.2 Myr after CAI and reached a size of 18–50 km in radius in order to satisfy both chronological and experimental constraints of GRAs. This implies that a planetesimal that possesses a felsisc crust produced by low-degree partial melting would have intermediate characteristics regarding the size and/or timing of accretion between chondrite and highly differentiated achondrite parent bodies.

Thermodynamic consequences of the injection of CO_2-H_2S gas mixtures in sulfur-rich hydrocarbon reservoirs

RAKHIM UTEYEV[1], LAURENT RICHARD[2]*, AURÉLIEN RANDI[1] AND JACQUES PIRONON[1]

[1]Nancy-Université, G2R, 54506 Vandoeuvre-lès.Nancy cedex, France (rakhim.uteyev@g2r.uhp-nancy.fr, aurelien.randi@g2r.uhp-nancy.fr, jacques.pironon@g2r.uhp-nancy.fr)
[2]Amphos21, Passeig. de García i Fària 49-51, 08019 Barcelona, Spain
(*correspondence: laurent.richard@amphos21.com)

Many petroleum basins around the world, among which the recently discovered giant oil and gas fields of the Northern Caspian Sea, are characterized by very high H_2S contents. In order to overcome the tremendous environmental challenge associated with the exploitation of these petroleum and natural gas reserves, the capture on the platforms and reinjection inside the reservoirs of CO_2-H_2S gas mixtures has been proposed. If these gas mixtures are out of chemical equilibrium with the water-rock-gas-hydrocarbon systems at depth, predicting the occurrence of such reactions as the formation and destruction of organic sulfur compounds, or the precipitation of elemental sulfur in the reservoirs is of major importance for the oil industry.

Activity diagrams and temperature – log $f\,H_2S_{(g)}$ diagrams have been constructed to determine the relative stabilities of H_2S, hydrocarbons, organic sulfur compounds, and elemental sulfur at temperatures and pressures typical of petroleum reservoirs. The diagrams suggest that thiacycloalkanes and thiophenes may react with H_2S to produce hydrocarbons and elemental sulfur, while benzo- and dibenzothiophenes should not react with H_2S due to their higher stability.

Experiments have been conducted at 150°C and 500 bar in sealed autoclaves, in which various classes of organic sulfur compounds were reacted with H_2S in the presence of water. In accord with the thermodynamic predictions, thiacycloalkanes and thiophenes reacted with H_2S, while benzo- and dibenzothiophenes did not. Elemental sulfur was formed only in the reactions involving the thiophenes, which we interpret in terms of the potential for reduction (electron transfer) which is higher in the case of the thiophenes. In contrast, no hydrocarbons were detected at the end of the experiments. Dithiacycloalkanes were produced instead. Group additivity estimates of the thermodynamic properties of dithiacycloalkanes suggest that these compounds may be stable under the conditions of the experiments.

Podiform chromitites from the Turkish ophiolites: An overview to the mineralogy of Platinum-group elements

İ. UYSAL[1]*, F. ZACCARINI[2], G. GARUTI[2], M. KALIWODA[3], R. HOCHLEITNER[3], R.M. AKMAZ[4] AND S. SAKA[1]

[1]Karadeniz Technical University, Dept. Geol. Eng. Trabzon, Turkey (*correspondence: iuysal@ktu.edu.tr)
[2]University of Leoben, Dept. Appl. Geol. Sci. Geophysics, Leoben, Austria
[3]Ludwig Maximillian University, Mineralogische Staatssammlung, Münich, Germany
[4]Zonguldak Karaelmas University, Dept. Geol. Eng., Zonguldak, Turkey

Podiform chromitites of Mesozoic ophiolites of the Western Mediterranean Tethys represent a major source of chromium, and are considered a potential target for platinum group elements (PGE) exploration. Turkey is one of the major chromite producers in the world, ranking 4th in exports. Most of the Turkish chromitites occur in the mantle tectonite unit of supra-subduction zone ophiolites. In this contribution we have summarized the results of investigation obtained on several Turkish Cr- and Al-rich podiform chromitites [Muğla (SW Turkey), Eskişehir, Bursa (NW Turkey), Kop Mountains (NE Turkey), Kahramanmaraş, Malatya, and Gaziantep (SE Turkey)] with special regard to their mineralogy of platinum group elements (PGE). About 450 PGM grains, generally less than 15 μm in size, have been identified in all the investigated chromitites. They occur in fresh (84%) and altered chromite crystals (6%), along cracks and fissures (8%) of the chromite and, rarely, in the silicate matrix (2%) generally composed of secondary silicates, such as chlorite and serpentine. The PGM form single phase crystals or they are part of polyphasic grains composed of other PGM, base metals sulphides and silicates. The PGM containing IPGE (Os, Ir, Ru) are the most abundant phases (96% of all PGM) compared to the PPGE (Rh, Pd, Pt) bearing PGM (4%). The IPGE bearing PGM are composed of laurite-erlichmanite serie (74%), native osmium (8%), unidentified Ru-Fe phases (6%), native iridium (4%), irarsite (3%), unidentified Ir phases (2%) and native ruthenium (1%). Very rare (up to 2%) kashinite, cuproiridsite, ruarsite, and unidentified Os phase have also been identified. A total of 20 grains of PPGE phases have been found in all the localities, and most of them are Pt-Fe alloys (40%), accompanied by platinum (20%), hollingworthite (20%) and unidentified Pt (10%), Rh (5%) and Pd (5%) phases. These results confirm a strong predominance of PGM containing IPGE over PPGE, as typical for mantle hosted ophiolitic chromitites.

Arsenate precipitation: An alternative fate of As in soils contaminated with mine-related wastes

K. VACA-ESCOBAR[1] AND M. VILLALOBOS[1,2]*

[1]Environmental Bio-Geochemistry Group, Chemistry School
[2]Earth Sciences Graduate Program, Geology Institute, UNAM, Coyoacan, CU, Mexico 04510, D.F
(*correspondence: mariov@geologia.unam.mx)

Introduction

Arsenic and heavy metals are highly abundant elements in soils contaminated with mining and metallurgical wastes [1]. The final fate of arsenic in aerated environments is usually reported as As(V) bound to iron oxide surfaces [2]. However, we have found evidence of an alternative mechanism as insoluble heavy metal arsenates [3]. In this work we investigate the conditions that favor one mechanism over the other by both modeling and experimental methods. We applied a triple layer surface complexation modeling scheme [4] simultaneously with arsenate precipitation equilibra to predict the speciation expected as a function of total As/Fe ratios, and pH in a simple goethite /Pb(II)/ carbonate system, and compared the results with experimental data under selected conditions.

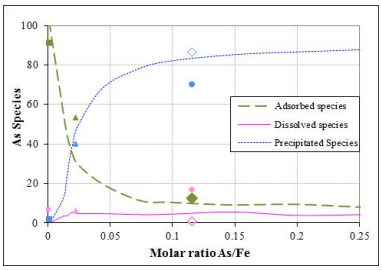

Figure 1: As(V) species distribution in goethite/Pb(II)/ carbonate systems. Model and experimental results at pH 7.

Discussion of Results

Adsorption processes only prevail at very low As/Fe ratios, and precipitation as Pb(II) arsenate quickly becomes predominant (Fig. 1). Modeling results as a function of pH will also be presented.

Microbial and photochemical mineralization of dissolved organic carbon from big rivers

A.V. VÄHÄTALO[1,2] AND H. AARNOS[2]

[1]Coastal Zone Research Tem, Aronia Research and Development Institute, Novia University of Applied Sciences and Åbo Akademi University (anssi.vahatalo@helsinki.fi)
[2]Department of Environmental Sciences, University of Helsinki (hanna.aarnos@helsinki.fi)

We addressed the potential for microbial and photochemical mineralization of dissolved organic carbon (DOC) from ten big rivers. In order to quantify the direct photochemical mineralization of DOC to CO_2, the sterile-filtered river waters were irradiated with an artificial solar radiation until photochemical reactions photobleached chromphoric dissolved organic matter (CDOM) completely. For the assessment of biological mineralization of DOC, irradiated waters and their dark controls received nutrients and indigenous microbes from rivers. The concentration of DOC was followed over one year to quantify the amount of DOC consumed by microbes. Photochemical reactions mineralized DOC directly to CO_2 and also produced biologically available photoproducts. The magnitude of photoreactive DOC depended on the magnitude of CDOM. A part of DOC was resistant to photoreactions but was decomposed with low rate by microbes.

The first data about the concentrations REEs in waters from weathering zone of Berezitovoe gold deposit (Priamurye, Russia)

ELENA A.VAKH, ALEKSANDR S. VAKH AND NATALIA A. KHARITONOVA

Far East Geological Institute FEB RAS, Russia, Adasea@mail.ru

The Beresitovy gold deposit located in the northeastern Amur gold province in the downstream basin of the Khaikta River. In 2007, two mining companies: Berezitovy Mine Ltd. and High River Gold Mines Ltd., started to mine this deposit. Geologically, the deposit is localized in a southeast part of the North Asian craton, in a zone of its joint with formations of northern frame Tukuringra-Dzhagdinsky terrein Mongolo-Ohotsky zone. Two formations of sediments (granites and ore–metasomatic rocks) occur in the deposit. Main minerals bearing REEs are allanit, monatsit - (Ce), chervandonit - (Ce).

In this study we present the preliminarily results of investigation the content and distribution of REEs in the bedrock and water from weathering zone of deposit. Our data indicate that the content of REEs in bedrock of Berezitovoe deposit can reach up to 230 ppm and the content of LREEs is at about 90% of total REEs. All types of bedrock display of strong negative Eu amonalies.

The surface water of area is enriched in total REEs (1, 4 ppm), although the content of LREEs is higher in 8-10 times then HREEs. Drainage water is yellow, dark -yellow color with TDS up to 10 g/l and pH varies from 3, 0 to 4, 5. This water belongs to Mg-K-SO_4 type and content a huge amount of REEs (up to 16, 1 ppm). The concentration LREEs is higher then HREEs as well. It is established that drainage water is a selective accumulation of middle REEs.

Comparison of REEs content in bedrocks, ore and surface water is appeared the similarity of their profiles.

Speleothem record of permafrost in Siberia and aridity in Mongolia during the last 450 kyr

A. VAKS[1]*, O.S. GUTAREVA[2], S.F.M. BREITENBACH[3], E. AVIRMED[4], A.M. KONONOV[2], A.V. OSINZEV,[5] AND G.M. HENDERSON[1]

[1]Department of Earth Sciences, University of Oxford, Oxford, United Kingdom (*correspondence: Anton.Vaks@earth.ox.ac.uk)

[2]Institute of Earth's Crust, Russian Academy of Science, Siberian Branch, Irkutsk, Russia

[3]Swiss Federal Institute of Technology Zurich, Geological Institute, Zurich, Switzerland

[4]Institute of Geography, Mongolian Academy of Sciences, Ulaanbaatar, Mongolia

[5]Arabica Speleological Club, Irkutsk, Russia

We have used speleothems from six caves along a north-south transect in Eastern Siberia and the Mongolian Gobi Desert (60°22′N - 42°50′N) to track the evolution of permafrost and desert aridity. The studied caves are located in various climate zones: from the southern boundary of continuous permafrost, through the discontinuous/island permafrost, to the dry Gobi Desert.

More than 90 horizons of 22 speleothems were dated by U-Th method. The youngest speleothem age in the northernmost cave was 404 ± 32 kyr, corresponding to interglacial Marine Isotopic Stage (MIS) 11, while eleven other horizons in six speleothems from this cave were older than the ~500 kyr U-Th dating limit. These results suggest that MIS-11 in Eastern Siberia was warmer than today, causing brief permafrost degradation at 60°N, followed by re-establishment and continuous permafrost since then. Between 56°N and 52°N speleothem ages clustered into the warmest intervals of interglacial MIS-11, 9, 7, 5 and 1, showing intermittent melting of the permafrost. This data provides constraints on glacial-interglacial migrations of the southern boundary of continuous permafrost in Eastern Siberia during the last 450 kyr. No speleothem deposition younger than 500 kyr was found in the Gobi Desert, showing that arid conditions prevailed during this entire period.

The year-round monitoring of $\delta^{18}O$ and δD values of cave water and atmospheric precipitation in the city of Irkutsk and nearby cave shows that $\delta^{18}O$ and δD values of rain and snow are in direct relationship with temperature throughout the year, and $\delta^{18}O$ and δD values of the cave water reflect the weighted annual average of precipitation. Ongoing work is making use of these observations to create stable isotope records of the Siberian speleothems.

Mantle source components of the Early Cretaceous to Paleogene mafic tholeiitic and alkaline magmatism in Rio and related mantle metassomatism processes

S.C. VALENTE

Geosciences Dept., UFRuralRJ, Seropédica, RJ, 23890-00, Brazil (sergio@ufrrj.br)

The Early Cretaceous (*c*. 132 Ma) to Paleogene (*c*. 55 Ma) mafic magmatism in Rio is mostly represented by tholeiitic dolerites and ultramafic and alkaline lamprophyres, respectively [1]. The tholeiites are often regular, long, tens of metres-thick, vertical, ENE-trending intrusions with remarkably uniform textures and structures. In contrast, the ultramafic and alkaline lamprophyre dykes are generally less than one metre thick and display variable textures, structures and morphologies. Litogeochemical and Sr-Nd-O isotopic data show that the least evolved tholeiitic dolerites seem not to represent contaminated melts and are likely to be related to a predominantly asthenospheric, plume source similar in composition to Tristan da Cunha lavas. Small contributions (~10%) from the overlying subcontinental lithospheric mantle may have imprinted lithospheric signatures in the least evolved dolerites such as negative Nb anomalies. The Paleogene alkaline dykes comprise a strongly undersaturated suite including ultramafic and alkaline lamprophyres and sodic agpaitic phonolites. Sr-Nd isotope data point to a contribution of asthenospheric mantle sources for the generation of the alkaline dykes likely to be related to the Trindade plume. Heat conduction and advection from the plume triggered the melting of the readly fusible, volatile-rich, mafic potassic parts of the overlying subcontinental lithospheric mantle beneath Rio, leading to the generation of the most primitive ultramafic ultrapotassic lamprophyres. Major and trace element characteristics of the ultrapotassic ultramafic lamprohyres (*e.g*. CaO/Al_2O_3 <1; $(La/Nb)_N$~0.9) and their Sm-Nd model DM ages (496-660 Ma) indicate that the Late Proterozoic enrichment process of the subcontinental lithospheric mantle seems to have been unrelated to subduction processes but largely controlled by the migration of high H_2O/CO_2 silicate melts from the underlying asthenosphere.

Lunar zircon: Primitive $\delta^{18}O$ of dry evolved and mafic magmas

J.W. VALLEY*, M.J. SPICUZZA AND T. USHIKUBO

WiscSIMS, Dept. of Geoscience, Univ. Wisconsin, Madison, WI, 53706, USA
(*correspondence: valley@geology.wisc.edu)

Oxygen isotope ratios of zircons from the Moon have been measured *in situ* by SIMS [1], including grains from: quartz monzodiorite (n=4; 4, 294 Ma [2]), impact melt (n=1), breccia and shocked norite (n=2), and Apollo 12 (n=6) and 14 (n=3) regolith. Zircons from regolith may represent lithologies not found at Apollo landing sites. Some zircons have K-feldspar ± silica as inclusions or infilling cracks, suggesting they represent extreme differentiates of mafic magmas, similar to zircons in lunar granophyre [2]. The average $\delta^{18}O$ for lunar zircons ranges from 5.19 to 5.82 ‰ (ave. = 5.59 ±0.33‰, 2SD). Trace element concentrations of these zircons, also measured by SIMS, are: Ti 37-170 ppm; P 425-1120 ppm; Y 780-2850 ppm; total REE 485-1780; Hf 10, 500-12, 750 ppm; Th 4-38 ppm; and U 12-108 ppm [1].

The $\delta^{18}O$ (whole rock) values of mare basalts range from 5.33 to 5.81: 5.69 ±0.17 (2SD, n=23) for low-Ti and 5.54 ± 0.26‰ (n=15) for high-Ti basalts [3, 4]. The low variability allows comparison with zircons from other samples. The average basalt has the same $\delta^{18}O$ as igneous zircons: $\Delta^{18}O$ (WR-Zrc) ~ 0. This WR-Zrc fractionation contrasts with samples from Earth, where $\Delta^{18}O$ (WR-Zrc) ~ 0.0612 (wt.% SiO_2) –2.50‰ [5]. For instance, unaltered MORB $\delta^{18}O$ (WR) values average ~ 5.6-5.7, while $\delta^{18}O$ (Zrc) values average 5.2 ±0.5 (n=197) for gabbro and plagiogranite from ocean crust: $\Delta^{18}O$ (WR-Zrc) ~0.5 [6]. Thus $\Delta^{18}O$ (WR-Zrc) values on the Moon deviate significantly from relations on Earth.

In general, values of $\delta^{18}O$ (Zrc) vary negligibly during closed system magmatic differentiation because $\Delta^{18}O$ (WR-Zrc) correlates to $\delta^{18}O$ (WR); both increase for siliceous rocks with high $\delta^{18}O$ minerals (Qt, Flds). However, in detail, variable T will change this relation and the best explanation of the lunar results is that magmatic T's were significantly higher due to low water content. High crystallization T for lunar zircons is supported by values of [Ti] in lunar zircons (37-170 ppm) that are significantly higher than in terrestrial igneous zircons (0.2-30 ppm) [7]. We thus infer a low water content of these highly evolved lunar melts and that mafic parent magmas on the Moon were significantly drier.

The role and effect of boron during the crystallization of $CaCO_3$

B. VALLINA-ANTUÑA[1,2], J.D. RODRIGUEZ-BLANCO[1], J.A. BLANCO[2] AND L.G. BENNING[1]

[1]School of Earth and Environment, University of Leeds, LS2 9JT, United Kingdom (beatrizvallina@gmail.com)
[2]Departamento de Fisica, Universidad de Oviedo, E-33007 Oviedo, Spain

Boron (B) is a crucial element in carbonate biominerals and its isotopic signature is used as a paleo-acidity proxy and to reconstruct atmospheric CO_2 levels through time [1, 2]. Most studies however, focused on compositional or isotopic analyses of natural marine carbonates, but the mechanisms of boron incorporation or the role and effect that $[B]_{aq}$ plays during the nucleation and growth of the various calcium carbonate polymorphs is still unknown. Therefore the aim of this research was to quantitatively assess the crystallization pathways of $CaCO_3$ polymorph in the presence of $[B]_{aq}$ and to mimic B/Ca ratios in modern seawater.

The experiments were performed at 10-30°C in stirred reactors by mixing equimolar solutions of $CaCl_2$ and Na_2CO_3 doped with 0-25mM of $[B]_{aq}$. Reactions were followed for between ten minutes and eight hours, while simultaneously recording changes in pH as a direct proxy for the crystallization reactions. At regular time intervals solid and solution aliquots were collected and characterized by XRD, SEM, FTIR or wet-chemical analysis.

The results show that in the presence of $[B]_{aq}$ the initial amorphous calcium carbonate (ACC) remained stable for up to 5 minutes, while at equivalent conditions with no $[B]_{aq}$ the transformation to vaterite begins after ~1 minute [4]. However, after the full ACC breakdown, the crystallization pathways vary dramatically as a function of temperature and $[B]_{aq}$, concentration compared to the pure system [2]. For example, at 30°C and 10mM $[B]_{aq}$, the ACC to calcite transformation via vaterite was ~ 25% faster compared to the pure system. Furthermore, when 25mM of $[B]_{aq}$ were added, the initial ACC transformed directly to calcite in less than 10 minutes with no vaterite intermediate. Overall our experiments revealed that the effect of temperature was inverse to that of the B/Ca ratio in solution. The effects were also reflected in the variations in polymorph distribution as a function of time and in the changes in morphologies of the various $CaCO_3$ polymorphs at the conditions tested.

New characterization of uranium mineralogy in Ukrainian ores

A.A. VALTER[1] AND K.B. KNIGHT[2]

[1]Institute of Applied Physics, Nat. Acad. Sci. Ukraine, Sumy, 40030, Ukraine (avalter@iop.kiev.ua)
[2]Lawrence Livermore National. Lab., (knight29@llnl.gov)

The economically significant uranium ores of Ukraine form one of the largest uranium ore reserves in Europe. Concentrated in the central Ukrainian shield, these ore bodies (~1, 8 Ga, inferred from U-Pb analyses [1]), are associated with albitites in granites. Carbonates, iron oxides and Ca-Fe garnets are found genetically associated with uranium minerals, while albite and other alkali silicates formed during earlier stage metasomatic processes. Albite has been altered at the margins adjacent to the uranium minerals from low to high albite. We present preliminary work characterizing primary uranium ores in Ukraine, as part of a larger effort to develop a database of nuclear materials for Ukraine.

We have studied uranium minerals from representative samples of the Severinskoje (I), Michurinskoje(II), and Vatutinskoje (III) deposits, as well as from the Adabash fracture zone mineralization (IV), using mineralogy and gamma spectrometry [2]. This study presents new X-ray diffraction (powder and single grains), SEM and TEM characterizations, and microprobe study of the principal U-minerals present:

Uraninite (IV), a_0=0, 542 nm, forming cubic crystals up to 0, 5 mm. Average composition is Na_2O 5, 6%; SiO_2 0, 8%; CaO 1, 74%; PbO 23%; U_3O_8 72, 4%. U, Ca, Pb appear to be associated with the host crystal matrix, while Na, Si and trace elements are concentrated in solid inclusions (up to 0, 5 mm). *Coffinite (I, II, III)* forms elongated crystals up to 0, 1 mm. Average composition is Al_2O_3 0, 9%; SiO_2 15%; CaO 2, 5%; Fe_2O_3 1, 4%; U_2O_3 65%. *Brannerite (II, III)* forms elongated, needle-like crystals up to 0, 1 mm. Average composition is PbO 6, 17%; UO_2 39, 18%; CaO 3, 15%; SiO_2 2, 31%; TiO_2 24, 49%; FeO 2, 08%. This mineral occurs intergrown with an unknown silicate mineral (mixture) with composition ~ (Ca, Pb, U)(Ti, Fe)$_2$Si$_3$O$_{11}$. *Ca-Uraninite (I)* ~CaU_2O_6, is cubic, a_0 = 5, 37 nm. This is possibly a new mineral variety. It forms in thin veins (~20 um thick) and globules (~1 um). *Ca-boltwoodite (I)* occurs as thin veins of plate-like crystals up to 20 um in diameter. The boltwoodite powder XRD pattern suggests a disordered layered structure, possibly representing a new mineral variety. The relative composition is U:Si:(Na+K+$Ca_{0,5}$) ≈ 1:1:1.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Re-Os in pyrite as a constraint on the timing of HP metamorphism during the Tianshan orogeny (NW China)

D. VAN ACKEN[1], R.A. CREASER[1], W. SU[2] AND J. GAO[2]

[1]University of Alberta (vanacken@ualberta.ca, rcreaser@ualberta.ca)

[2]Chinese Academy of Sciences (suwen@mail.igcas.ac.cn, gaojun@mail.igcas.ac.cn)

The Tianshan mountain belt in Central Asia is situated between the Junggar and Tarim basins. Because of its large extension of over 2500 km of length and complex geological history, it is a key piece to understand the tectonic evolution of Eurasia. Paleozoic collision resulted in the closeure of the Paleo-Asia ocean and amalgamation of small continental fragments. Dating of metamorphic units within the Tianshan is important to understand the timing of its tectonic evolution throughout the Phanerozoic.

Collision between the Yili-Central Tianshan and Tarim-Karakum plates in the southwestern Tianshan is recorded by eclogites embedded in greenschist and blueschist-facies metapelites, in the high-pressure, low-temperature belt in the Southern Tianshan, NW China. The majority of ages obtained with Sm-Nd, Ar-Ar, and U-Pb time the peak of metamorphism in the Late Carboniferous around 345 Ma, while younger Ar-Ar and Rb-Sr ages around 310 Ma are interpreted as mica cooling ages or recrystallization due to fluid flow. Younger U-Pb ages of about 225 – 230 Ma suggest later peak metamorphism, and thus a later continental collision, or resetting of the U-Pb system during the Triassic.

New Re-Os data, obtained on pyrite mineral separates from eclogites from the western Tianshan HP-LT belt, confirm the older Carboniferous ages. Sulfides from three eclogite samples yield ages between 310 and 380 Ma, with large uncertainties up to 100 Ma resulting from the few data points per sample available. These ages likely represent sulfide formation or recrystallization during eclogite-facies metamorphism, and provide independent evidence for Carboniferous ages of eclogite formation.

The similar ages yielded by isotope systems hosted in silicates and sulfides from Tianshan eclogite confirm a) Carboniferous ages for the eclogite-facies metamophism during the Tianshan orogeny and b) the potential of the Re-Os system to date sulfide formation in metamorphic rocks. However, ages obtained in this manner may represent ages of sulfide formation by fluid flow or remobilization during later stages of metamorphism, and thus needs to be compared with independent, silicate mineral-hosted isotope chronometers.

Metal pollution assessment in sediment of the Talar River, N. Iran

M. VANAEI, A. MAGHSOUDI, A.S. SAEEDI AND M. NAJJARAN

In the Ghaemshahr Area the Lenth of the Tallar River Separated to 8 sample site and 112 Samples Collected from Sediment and For the Distingoition of Geogenic Pollution for each sample, 1 gr of sample was digested with the solution of $HF+HC_lO_4+HNO_3$ but in the Antropogenic Pollution the sample was digested with the solution Acetic Acid, hydroxileamine, Hydrocloride and hydrogenproxide and then Analized with Atomic Abasorbtion Method

The Enrichment Ratio and Geo-accumulation Index has been Calculated and Evalutated the Degree of Contamination Metals (Zn, V, Sn, Pb, Ni, Cu, Cr, Co, Cd, Ag, Fe) In the Sediment of the Talar River.

According to the contamination categories, the Ag has been Enriched and show very high absorption and Cd in the 1, 2, 4, 5, 7 Site and Sn in the 2, 4, 6, 7 Site Shows Intense to Very High Absorption.

Degree of Geo-accumolation Index Show that the Ag in the 1, 2, 3, 4, 5, 7, 6 Sites has been Enriched and Show Heavily Contaminated and Cd in the 1 Site and Sn in the 2, 5 Site Shows Heavily Contaminated.

In the Dogol Railway Station to Orim Village the Cd, Ag and Sn Contain of High Level of Antropogenic Contamination and Fe Contain of Low Level of Antropogenic Contamination and in the Babolsar-Bahmanir site Cd, Ag and V Contain of High Level of Antropogenic Contamination and Fe Contain of Low Level of Antropogenic Contamination

Activity Minning (Coal and Fluorite) and Depo of Coal in the Upper part of River Very Affected the Absorption and Contamination but in the Downstream, Realize of Industry and Urban Sewage very Affected the Absorption and Contamination

Causes and consequences of isotopically heavy dissolved molybdenum in rivers

DEREK VANCE[1]*, ANDREW R. KEECH[1], ALAN MATTHEWS[2] AND COREY ARCHER[1]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Wills Memorial Building, Bristol, BS8 1RJ, UK (*correspondence: d.vance@bristol.ac.uk)

[2]Institute of Earth Sciences, Hebrew University of Jerusalem, 91904 Israel

The molybdenum (Mo) isotopic composition of the dissolved load of rivers is isotopically heavy relative to likely average continental crust. Two key aspects of this finding are not understood. The first is the origin of this isotopic fractionation. The second is the degree to which the riverine dissolved load reflects the delivery of Mo isotopes from the continents to the oceans. Both of these issues are crucial to the intrepretation of oceanic Mo isotope records, and to their use as redox indicators. Here we address both these issues, the first using new data from soil profiles that constrain processes by which Mo and its isotopes are released during weathering, and the second through data and models that have implications for the release of Mo from riverine particulate material in estuaries and shallow seas.

We have studied Mo isotope systematics in a range of soil chronosequences, and the data suggest that the behaviour of Mo and its isotopes in the weathering environment is dependent on an array of controls. In one key chronosequence from Scotland, however, there is a previously un-heralded role implied for biological processes. In these soils, there is pronounced retention of Mo in organic material at the top of the profile, that becomes more pronounced as the soil ages. In these soils Mo isotope retention/release in/from soils is controlled by both Fe-Mn oxides and organic material. These data are consistent with recent findings that Mo is limiting in many terrestrial ecosystems and that soil bacteria take up the light isotope.

A key issue for oceanic Mo isotope records is the isotopic composition of the input from the continents. The heavy dissolved load of rivers presents some severe problems for models of the Mo isotope mass balance in the modern oceans. Recent data from continental margin settings, however, particularly those that are marginally sub-oxic, suggests that diagenetic reactions could release the light particulate Mo washed into the oceans as the counterpart of the heavy dissolved load. The implications of this suggestion for the oceanic Mo isotope budget will be explored.

GEOTRACES intercalibration results for Nd isotopes and REE on seawater and particulate samples

TINA VAN DE FLIERDT[1], KATHARINA PAHNKE[2] AND GEOTRACES INTERCALIBRATION PARTICIPANTS

[1]Department of Earth Science and Engineering, Imperial College London, South Kensington Campus, London, SW7 2AZ, UK

[2]Department of Geology and Geophyscis, University of Hawaii, Honolulu, HI 96822, USA

One of the key activities during the initial phase of the international GEOTRACES program was an extensive international intercalibration effort for all trace elements and isotopes (TEIs) targeted by the program, to ensure that results from different cruises and from different labs can be compared in a meaningful way. Two intercalibration cruises sailed in 2008 and 2009 to enable systematic testing of sampling equipment and methods, and to collect large amounts of homogenous seawater samples to check whether results for dissolved and particulate TEIs obtained by different laboratories are accurate and reproducible.

Here we present the results from the intercalibration efforts on neodymium isotopes and rare earth elements in seawater and marine particulates. For seawater, we obtained Nd isotope results from 11 different laboratories on duplicate seawater samples from two different water depths (2000m and 15m) at the Bermuda Atlantic time series study site (BATS). Average ε_{Nd} values are -13.1 ± 0.6 and -9.1 ± 0.6. This is a very satisfactory result for the community, as individual labs typically achieve external reprodibilities of $^{143}Nd/^{144}Nd$ measurements between 0.2 and 0.4 ε units (2 σ standard deviation). In an attempt to test whether the spread in reported isotope ratios is due to differenct protocols used for pre-concentration and ion chromatography, or rather due to different methods applied on the mass spectrometry end, we distributed an isotopic standard of unknown composition to all labs. Averaged results from all laboratories reveal a very similar external reproducibility of 60 ppm (2σ SD) on $^{143}Nd/^{144}Nd$, indicating that mass spectrometry is the main variable in achieving accurate and precise Nd isotope ratios.

We will furthermore present Nd isotope results on systematic shipboard filtration tests, a comparison of different sampling systems, as well as intercalibration results for Nd isotopes in marine particulates and REE patterns in seawater and particulates. While the community is definitely ready for Nd isotope measurements in seawater, the analyses of marine particulates seems to require a common methodology to provide comparable results.

Crystallization of low-K calc-alkaline igneous rocks at lower crustal pressures

G. VAN DEN BLEEKEN[1]*, O. MÜNTENER[1] AND P. ULMER[2]

[1]Institute of Mineralogy and Geochemistry, University of Lausanne, Switzerland (*correspondence: g.vandenbleeken@opgc.univ-bpclermont.fr, othmar.muntener@unil.ch)

[2]Institute for Mineralogy and Petrology, ETH Zürich, Switzerland (peter.ulmer@erdw.ethz.ch)

We will present phase relations and compositions from high-pressure equilibrium crystallization experiments on low-K calc-alkaline rocks saturated in H_2O. The wider rationale of this study is to advocate the role of crystal fractionation in the lower crust of subduction-related magmatic arcs, as an alternative to the more conventional partial melting of amphibolites [1]. Furthermore, we aim to clarify the role of epidote (+Na-mica) during igneous crystallization near the solidus, and its potential effect on derivative granitic rock compositions by comparing our results with studies on natural sodium-rich granitoids [2].

As starting materials, we use a powdered natural paragonite+epidote+garnet-bearing mafic rock derived from the lower crust of the Kohistan paleo-island arc, and a trace-element-doped gel of similar composition. Experimental pressure and temperature were varied in the near-solidus domain (1.0-1.6 GPa; 650-800 °C), representing conditions relevant for deep arc crust formation. All experimental runs were buffered at NNO.

First results show that amphibole occurs in all runs, garnet is present at pressures above 1.0 GPa, and plagioclase is present in all runs except where epidote is present. As minor phases, rutile or ilmenite, and quartz are observed. In accordance with the addition of ~15 wt% water, coexisting liquids were saturated in H_2O, as indicated by the occurrence of 'bubbles'. Close to the solidus at 1.2 GPa, plagioclase disappears and an amphibole+garnet+rutile+ epidote+quartz assemblage coexists with vapour and hydrous melt. On a water-free basis (EMP analyses recalculated to 100 wt%), the glasses have high silica contents (~70-76 wt%) and low amounts of total alkali (~1.1-1.5 wt%), placing them into the dacite and rhyolite fields on the TAS diagram.

More experimental and analytical work is underway, and we will present a comprehensive set of data on phase relations, major-element compositions and element partitioning at the Conference.

How deep is deep? Plant biogeochemistry for detecting deep mineralisation

B.G. VAN DER HOEK*, S.M. HILL AND ROBERT C. DART

Deep Exploration Technologies Cooperative Research Centre, School of Earth & Environmental Sciences, University of Adelaide, Australia, 5005 (*correspondence: benjamin.vanderhoek@adelaide.edu.au)

Transported and potentially deep regolith extends across much of Australia, presenting a challenge for mineral explorers using traditional surface geochemical exploration techniques. Plant biogeochemistry is emerging as a valuable supplementary tool in exploration programs within these environments.

The application of plant biogeochemistry involves the chemical analysis of plant material (subaerial), where the elements are sourced from the regolith via the roots. Accumulation of elements in plant material is dependant on the element and its bioavailability. Element concentrations in plants are typically orders of magnitude lower than in geochemical material and exhibit different element associations.

Plant material has been analysed from the Tunkillia Au-prospect in the Gawler Craton, South Australia. Extensive exploration drilling has defined a biomodal distribution of Au – low concentrations at near-surface, a depletion zone, and primary mineralisation at depths exceeding 40 m. Gold concentrations in a variety of plant species have been up to 20 times background levels of plants in the region.

At Tunkillia, a large plant biogeochemistry and down-hole geochemistry dataset is integrated with isotope and soil biota analysis. This assists modelling of the vertical transportation of elements and limitations of plant root systems that access deep into the regolith profile.

Carbonation of steel slag II

SIEGER R. VAN DER LAAN[1]*, CHRISTIAN LIEBSKE[1], HANS KOBESEN[2], ELEANOR J. BERRYMAN[3], ANTHONY E. WILLIAMS-JONES[3] AND ARTACHES A. MIGDISOV[3]

[12]TATA Steel RD&T, Ceramics Research Centre, TATA Steel Europe OSF2, IJmuiden, The Netherlands (*correspondence: sieger.van-der-laan@tatasteel.com)
[3]Department of Earth and Planetary Sciences, McGill University, Montreal, Quebec, Canada

One of the options that the steel undustry has to mitigate some of its CO2 emissions is mineral carbonation of steel slag, a by-product of the steel refining process. Our study investigates reactions taking place during dissolution and carbonation of steel slag, with the aim of determining optimal conditions for conversion. A H_2O-CO_2 fluid is pumped through slag grains (2 – 3 mm) in a flow-through reactor at elevated pressure, and temperatures of 125 to 200°C, as described in a companion abstract [1]

The starting steel slag contains ~50 wt% CaO in larnite (Ca_2SiO_4), srebrodolskite ($Ca_2Fe_2O_5$) and free lime. In addition, there is an inert phase, Mg-wuestite ((Fe, Mg)O)). After an experiment, entire cross sections of slag grains were analysed by SEM-EDS spectral imaging. Based on the information in the images, the volume proportions and distribution of reactant and product minerals were quantified using in-house developed PARC (PhAse Recognition & Characterization) software. This method reliably reproduces bulk compositions of solids as confirmed with XRF analysis [2]. The PARC results were used to calculate the mass balance between starting material, reacted slag and fluid and, in conjunction with the fluid chemistry, helped reconstruct the reaction path.

δD of alkenones as proxy for paleo sea surface salinity

M.T.J. VAN DER MEER[1]*, S. KASPER[1], A. BENTHIEN[2], J. BIJMA[2], R. ZAHN[3], J.S. SINNINGHE DAMSTÉ[1] AND S. SCHOUTEN[1]

[1]NIOZ, BGC, PO Box 59, 1790 AB Den Burg, The Netherlands (*correspondence: Marcel.van.der.Meer@nioz.nl)
[2]AWI, PO Box 12 01 61, D-27515 Bremerhaven, Germany
[3]ICREA and UAB, E-08193 Bellaterra (Cerdanyola), Spain

Culture studies of haptophyte algae showed that there is a strong correlation between the fractionation factor $\alpha_{alkenones\text{-}growth}$ water and salinity [1]. with less fractionation at higher salinities. Based on these results, paleosalinities of the Black Sea and the Eastern Mediterranean have been reconstructed using the δD of alkenones [2, 3].

However, there has been some debate about whether analyzing the C_{37} alkenones together is appropriate for reconstructing paleosalinity since there is a relatively large difference in the δD of the $C_{37:2}$ and $C_{37:3}$ alkenones, respectively [4-6]. To examine this potential problem we analyzed the $C_{37:2}$ and $C_{37:3}$ alkenones of the original Schouten *et al*. [1] *E. huxleyi* samples separately and found an increasing difference in δD between the $C_{37:2}$ and $C_{37:3}$ alkenone with decreasing temperature and, therefore, decreasing relative abundance of the $C_{37:2}$ alkenone. These results suggested that for the purpose of reconstructing paleo SSS it might be better to analyze the C_{37} alkenones together rather than the separate isomers.

To test this δD paleo sea surface salinity proxy in open marine settings it was applied to assess Agulhas current variability during the transition from Marine Isotope Stage (MIS) 6 to 5 and MIS 2 to 1. The reconstructed paleo SSS show a substantial shift to lower salinities during both deglaciations in agreement with reconstructions based on oxygen isotopes and Mg/Ca of planktonic foraminfera. These results indicate the potential of this proxy in open marine settings where salinity shift are relatively small.

The age and origin of the Limpopo sub-continental lithospheric mantle

Q.H.A. VAN DER MEER[1], M. KLAVER[1], L. REISBERG[2], B. DAVIDHEISER[1] AND G.R. DAVIES[1]*

[1]VU Amsterdam, De Boelelaan 1085, 1081HV Amsterdam, The Netherlands (*correspondence: gareth.davies@falw.vu.nl)
[2]CRPG, 15 rue Notre-Dame de Pauvres, B.P. 20, 54501 Vandoeuvre-lès-Nancy, France

The Limpopo Mobile Belt (LMB) represents the suture zone between the Kaapvaal and Zimbabwe cratons, but the timing of the collision is still highly debated. Mantle tomography indicates a clear continuation of subcratonic mantle beneath LMB and the adjacent cratons. The origin of both the crust and lithospheric mantle of the LMB is also the subject of controversy and a Zimbabwean, Kaapvaal and allochtonous origin have all been proposed.

The Venetia kimberlite cluster is located within the central zone of the mobile belt and mantle xenoliths from the diamond mine provide an excellent opportunity to address the origin of LMB. We present an extensive petrology-geochemical dataset on a selection of Venetia peridotitic xenoliths, including 24 Re-Os isotope analyses.

Whole rock and mineral major element analyses of garnet-harzburgites and lherzolites indicate that the Venetian lithospheric mantle underwent up to 50% melt depletion, at least partially in the absence of garnet and by implication <70km. The depleted residue was subsequently re-enriched in silica and incompatible elements by subduction-related and asthenospheric melts. The mode of whole rock rhenium depletion ages is 2.6 Ga, which is significantly younger than both the Zimbabwe and Kaapvaal cratons.

Based on combined Os-Nd-Hf isotope systematics of the xenoliths we argue that the majority of the SCLM beneath LMB stabilised at ~2.6 Ga in a separate terrain, which is coeval with major crust forming recorded by zircon Hf and U-Pb model ages

Patterns of cosmogenic age distributions for Late Quaternary moraines in Tibet

Uncertainties in moraine exposure ages have been recognized as a difficulty when trying to reconstruct past climate changes or comparing moraine exposure ages with known paleo-climate proxys such as $\delta^{18}O$ variations. Many moraines have been dated although the number of samples on each moraine vary widely and may often be too small to assess the true geological scatter of the dated landform. Here we present cosmogenic age distributions for moraines of Tibet and present various explanations to explain the shape of the distributions for moraines dated with large numbers of samples. While it is true that the more samples are dated the more complexity may arise just by adding more information to the data set, it is also true that by targeting to few samples complex depositional or post-depositional processes may be completely overlooked. We focus on moraines deposited in comparable glacial setting from the last glacial maximum and before, and will show that similar geomorphologies are not necessarily correlated with age but most probably to similar glacier ice dynamics. Distributions of ages need to be explained by some independent assessment of depositional or post-depositional model, that can be further tested by the addition of observations, such as, for instance, the relative ages of inset moraines, or the amount of cumulated tectonic offset when available. True and independent moraine age assessments are preferable whenever possible, but it is noticeable that some patterns of ages can be recognized over large sets of data covering large areas of Tibet that argue for at least some synchronous glacial advances and moraine retreats, that with no surprise do correlate with global climate variations.

[8]Health Effects Institute, Boston, MA, USA (acohen@healtheffects.org)

Acute exposure to high levels of fine particulate matter ($PM_{2.5}$), such as emitted by the Moscow wildfires in summer 2010, are associated with serious adverse health effects, yet the location and scale of such events often make *in situ* monitoring difficult. Recent satellite retrieval developments have the potential to monitor surface pollution during these events. We estimate daily $PM_{2.5}$ concentrations using satellite observations during the Moscow fires. We increase the coverage of aerosol optical depth (AOD) retrieved from the Moderate Resolution Imaging Spectroradiometer (MODIS) by relaxing the operational cloud screening criteria which can mistake extreme aerosol events for cloud. This relaxed product shows excellent agreement with coincident operational retrievals (r^2=0.994; slope = 1.010) and increases coverage during the fires by 21.3%. We relate MODIS AOD to $PM_{2.5}$ using a chemical transport model (GEOS-Chem) and find good agreement with $PM_{2.5}$ values estimated from *in situ* PM_{10}. We find that the relationship between AOD and $PM_{2.5}$ is insensitive to uncertainties in biomass burning emissions. Satellite-derived and *in situ* values both indicate peak daily mean $PM_{2.5}$ of ~600 μg/m^3 on August 7, 2010 around Moscow, with a potential ~400 excess deaths during the fires.

Growth rate of giant gypsum crystals

A.E.S. VAN DRIESSCHE[1], J.M. GARCÍA-RUÍZ[1], K. TSUKAMOTO[2], L.D. PATIÑO[1] AND H. SATOH[2]

[1]LEC, IACT, CSIC - U.Granada, 18100 Granada, Spain
[2]Department of Mineralogy, Petrology and Economic Geology, Tohoku University, Sendai 980-8578, Japan

Mineralogical processes taking place close to equilibrium, or with very slow kinetics, are difficult to quantify precisely. The determination of ultra slow precipitation rates should reveal characteristic timing associated to processes that are important at geological scale. We designed a high-resolution phase-shift interferometer to measure growth rates of crystals at very low supersaturation values. To test this technique, we selected the giant crystals of gypsum of Naica ore mines

(Mexico), a challenging subject in mineral formation. They are formed by a self-feeding mechanism driven by solution-mediated anhydrite-gypsum phase transition, and are the result of an extremely slow crystallization process close to equilibrium [1]. To calculate the formation time of these crystals we measured the growth rates of the {010} face of gypsum growing from current waters from Naica at different temperatures. The slowest measurable growth rate was found at 55 °C, being 1.4±0.2x10^{-5} nm/s, the slowest value measured for a crystal growth process. At higher temperatures growth rates increase exponentially due to decreasing gypsum solubility and higher kinetic coefficient [2]. At 50 °C neither growth nor dissolution was observed indicating that growth of giant crystals of gypsum occurred at Naica between 58 °C and current temperature of Naica waters, confirming formation temperatures determined from fluid inclusion studies. Our results demonstrate the usefulness of applying advanced optical techniques in laboratory experiments to gain a better understanding of crystal growth processes occurring at a geological time scale.

Effect of low-molecular-weight organic acids on thallium mobility in soil – A model rhizosphere solution approach

A. VANĚK*, I. GALUŠKOVÁ AND M. KOMÁREK

Czech University of Life Sciences Prague, 16521 Prague, Czech Republic (*correspondence: vaneka@af.czu.cz)

The kinetic batch leaching of Tl-bearing mineral soil in 500 μM solutions of citric, oxalic and acetic acid was performed to simulate the release of Tl in the rhizosphere-like environment. The obtained data demonstrate that low-molecular-weight organic acids significantly contribute to soil alteration accompanied by the release of lithogenic Tl (if present). The highest mobilization rates for Tl were observed after 0.5 h of leaching (with maximal values obtained for oxalate) followed by a substantial decrease. Thallium extractability in the organic acid solutions was up to 2.8-fold higher compared to water. Based on the experimental and speciation modeling data, Tl release is mainly pH-driven and can be attributed to acid ion exchange and/or acid leaching, as the formation of Tl-LMWOA complexes is negligible. The main Tl solubility-controlling phases predicted include illite and the identified Mn (III, IV) oxide due to their ability to efficiently sorb Tl^+ on the mineral surfaces from which Tl can be potentially mobilized. The role of primary silicates (i.e. orthoclase and muscovite) in the total process of Tl mobilization seems to be of lesser importance because the supposed alteration/dissolution of these phases during LWMOA leaching was limited.

A geochemical reference (baseline) for the natural geogenic variation in Pb isotope ratios in sedimentary soils

P.F.M. VAN GAANS[1]*, N. WALRAVEN[2], G. VAN DER VEER[3], S.P. VRIEND[3], B.J.H. VAN OS[4] AND G.TH. KLAVER[1]

[1]Deltares, Utrecht, the Netherlands (*correspondence: pauline.vangaans@deltares.nl, gerard.klaver@deltares.nl)

[3]Universiteit Utrecht, Utrecht, the Netherlands
[4]Rijksdienst voor het Cultureel Erfgoed, Amersfoort, the Netherlands (b.van.os@cultureelerfgoed. nl)

Given the wide historic to recent use of lead, enhanced Pb concentrations in soils may pose serious problems. The Pb isotopic composition (Pb-ic) can be used to distinguish natural from anthropogenic Pb and to appoint anthropogenic Pb sources. Often, a local reference is used to establish the natural geogenic Pb-ic, with which to compare the observed ratios in contaminated soils. However, Pb-ic is known to depend on soil type and show high spatial variability. Here we go for a regional approach, using as reference a set of 342 samples of sand and clay subsoils in the Netherlands. The combined geogenic Pb isotope ratios ($^{206}Pb/^{207}Pb$, $^{208}Pb/^{207}Pb$ and $^{206}Pb/^{208}Pb$) are empirically modelled, through regression with geochemical proxies as predictors.

Total concentrations of Al and Zr, as measured by XRF, were found to be suitable, mutually independent predictors of the geogenic Pb isotope variability. To eliminate the effects of outliers and high variability, we used a robust trimmed least squares regression, based on a core dataset containing the 70% of the data having the smallest absolute regression residuals. For this core dataset, the percentage of variance explained is about 70%. The model grasps the main trends displayed in the measured data: a) an apparent age range within both sands and clays, tending towards higher ^{208}Pb with increasing apparent age, and b) a clear shift towards lower ^{207}Pb from sands to clays. The Zr content is hypothesized to represent the proportion of U-Th containing 'parent' minerals to Pb containing 'daughter' minerals; the Al content represents the proportion of secondary minerals.

The regional reference allows prediction of the baseline Pb-ic where no local reference is avaialble, e.g. in topsoils that differ in lithology from their subsoil or where subsoil Pb contamination is suspected. Otherwise the regional reference is as suitable as a local subsoil reference.

Characterization of Fe(0) electro-coagulation reaction products using synchrotron-based techniques

C.M. VAN GENUCHTEN[1]*, J. PEÑA[2], S.E.A. ADDY[1], G. SPOSITO[1,2] AND A.J. GADGIL[1,2]

[1]University of California, Berkeley, Berkeley, CA (*correspondence: cmvangenuchten@berkeley.edu)
[2]Lawrence Berkeley National Laboratory, Berkeley, CA

Electrocoagulation (EC) using Fe (0) electrodes is a promising technology capable of cheaply and efficiently removing arsenic from drinking water. In EC, an electric current is applied to Fe (0) electrodes inserted into pumped groundwater contaminated with arsenic. Electrolysis of the Fe (0) anode leads to the *in situ* formation of iron (oxyhydr)oxides, which form surface complexes with arsenic. Of concern in such systems are common groundwater constituents (PO_4^{3-}, SiO_2, Ca^{2+}, Mg^{2+}), which can influence the structure of the generated precipitates in both subtle and complex ways. To assess the influence of these ions, synchrotron-based techniques were used to characterize EC precipitates generated in chemically varying electrolytes. Electrolytes were chosen to clarify the individual effect of strongly-adsorbed ions (0.5mM Na_2HPO_4, 0.75mM SiO_2) and weakly-adsorbed ions (1mM $CaCl_2$, 1mM $MgCl_2$, 2mM NaCl) on the removal of 1μM As(V) at pH 7.5. The As K-edge XANES and EXAFS spectra of precipitates generated in the Na_2HPO_4 electrolyte differed in both phase and line shape from those of precipitates generated in the NaCl and $CaCl_2$ electrolytes. These differences likely reflect a change in the adsorbent structure due to sorption of the surface-poisoning PO_4^{3-} oxyanion. The Fe K-edge EXAFS spectra and PDFs of similar samples will be presented to provide complementary views of the adsorbent structure (phase, crystallite size, and degree of FeO_6 octahedral polymerization) in instances where variations in the As K-edge spectra were observed. These results provide an important molecular-scale understanding of arsenic removal during EC.

On the way to medical diagnosis based on the isotopic analyis of metabolically relevant transition metals

L. VAN HEGHE[1]*, E. ENGSTRÖM[2], I. RODUSHKIN[2], A. VERSTRAETE[3], H. VAN VLIERBERGHE[4], C. CLOQUET[5] AND F. VANHAECKE[1]

[4]Department of Gastroenterology and Hepatology, Ghent University, De Pintelaan 185, Ghent, Belgium
[5]CRPG/CNRS, BP 20, 54501, Vandoeuvre-Nancy, France

Although modern medicine already has many sophisticated tools for the diagnosis of a large variety of diseases, there are still diseases for which diagnosis is difficult or can only be accomplished at a later stage of progression. New diagnostic tools are therefore highly needed for drawing unequivocal conclusions or start medicating people at an earlier stage.

A promising approach for diagnosis is the isotopic analysis of elements the metabolism of which is affected by the disease (e.g. Fe)[1]. Next to Fe, also Zn and Cu are important transition metals because of their great catalytic, structural and regulating importance in the human body [2].

These non-radiogenic elements show natural variations in isotopic composition due to isotope fractionation. As a result, we aim at developing a minimally invasive method, based on isotopic analysis using MC-ICPMS. In the method developed for this purpose Cu, Fe and Zn were isolated from blood within the same chromatographic separation with quantitative recovery, thus avoiding the effect of on-column isotope fractionation. External precisions for this method are 0.02; 0.05 and 0.03 ‰ (2s) for δ^{56}Fe, δ^{66}Zn and δ^{65}Cu, respectively. A first sample set comes from supposedly healthy human volunteers (reference population, including vegetarians and 'omnivorous) to investigate the dependence of isotope composition and nutrition. Whole blood from patient populations will be investigated at a later phase.

Towards a quantitative record of Archaean ocean water chemistry: An element partitioning approach

VINCENT J. VAN HINSBERG[1]*, KRISTOFFER SZILAS[2] AND BERNARD J. WOOD[1]

[1]Department of Earth Sciences, University of Oxford, United Kingdom (*correspondence: V.J.vanHinsberg@gmx.net)
[2]Geological Survey of Denmark and Greenland - GEUS, Copenhagen, Denmark

The composition of the Archaean ocean is of interest for two reasons in particular: 1. Ocean water is the reaction product of processes operating on the surface of the early Earth and in its interior, and its composition thus allows for insights into, and constraints on these processes, including the nature of Archaean plate tectonics; and 2. Ocean water is the likely medium in which life originated and developed, and knowledge of its composition, and changes therein over time provides insights into the inorganic forcing on life's evolution.

Qualitative information on the composition of the early Earth ocean has been obtained from the mineralogy and compositions of marine sediments preserved in the geological rock record. Banded Iron Formations, in particular, appear a viable source of information on changes in (trace) element abundance [1]. At present, it is not possible to translate this qualitative record into actual concentrations, and information is furthermore restricted to a small suite of elements, which severely limits the information that can be gained.

In this contribution, we present an approach that uses the lattice-strain theory systematics in element partitioning to reconstruct *quantitative* information on water chemistry from the composition of minerals. Although this approach can be applied to marine sediments, we use it here on samples of altered ridge basalts (greenstones), which are an indirect source of information on ocean water chemistry, because the interaction between ocean water and fresh oceanic crust at the ridges has a dominant control on the composition of the ocean. Combining experimentally determined mineral - fluid partition coefficients for chlorite and plagioclase at appropriate conditions, with the compositions of these minerals in well-preserved Archaean greenstones, we are able to track the evolving composition of the early Earth ocean.

Innovative low kV X-ray microanalysis of submicron particles using PARC algorithms

CORRIE J.G. VAN HOEK* AND SIEGER R. VAN DER LAAN

TATA Steel RD&T, Ceramics Research Centre, IJmuiden, The Netherlands
(*correspondence: corrie.van-hoek@tatasteel.com)

One of the challenges in microanalysis is to get accurate qualitative and quantitative analysis on the smallest phases present in a sample. Using PARC (**P**h**A**se **R**ecognition and **C**haracterization) algorithms as developed at CRC, we can arrive at the theoretical resolution using a FEG-SEM equipped with X-ray microanalysis equipment as will be shown in this paper.

The analytical spatial resolution for microanalysis is dictated by the SEM acceleration voltage, and the average atomic number of the phases present in the specimen. The challenge is finding the proper spot in a sample where the best analysis (without contaminated signal from the surrounding), can be obtained of the smallest phase for a given analytical condition.

The PARC approach simply circumvents manual selection of spots by including ALL pixels of an image field in the spectral image (SI) dataset. PARC software sorts all pixels of the SI dataset according to the phases they represent. The pixel populations can than be automatically cleaned from contaminant signals, leaving pure spectra for ZAF corrected quantification. The quality of analysis subsequently can be assessed from the resulting phase stoichiometry. In addition, phase area proportions and phase chemistry can be combined to reproduce the bulk composition of the sample material. We will show that using PARC in combination with FEG-SEM-EDS good stoichiometric analysis can be obtained on samples with crystals of less than 500 nm, even for trace phases.

Several PARC applications will be presented during this conference.

H_2O and CO_2 devolatilization in subduction zones: Implications for the global water and carbon cycles

PETER VAN KEKEN[1]*, BRAD HACKER[2], ELLEN SYRACUSE[3] AND GEOFF ABERS[4]

[1]University of Michigan, Ann Arbor, MI, USA (*correspondence: keken@umich.edu)
[2]University of California, Santa Barbara, CA, USA
[3]University of Wisconsin, Madison, WI, USA
[4]Columbia University, Palisades, NY, USA

Subduction of sediments and altered oceanic crust functions as a major water and carbon sink. Upon subduction the water and carbon may be released by progressive metamorphic reactions. Quantification of the volatile release from subducting slabs is important to determine the provenance of volatiles that is released by the volcanic arc and to constrain the flux of water and carbon to the deeper mantle. In recent work we used a global set of high resolution thermal models of subduction zones to predict the flux of H_2O from the subducting slab [1] which provides a new estimate of the dehydration efficiency of the global subducting system. It is found that mineralogically bound water can pass efficiently through old and fast subduction zones (such as in the western Pacific) but that warm subduction zones (such as Cascadia) see nearly complete dehydration of the subducting slab. The top of the slab is sufficiently hot in all subduction zones that the upper crust dehydrates significantly. The degree and depth of dehydration is highly diverse and strongly depends on (p, T) and bulk rock composition. On average about one third of subducted H_2O reaches 240 km depth, carried principally and roughly equally in the gabbro and peridotite sections. The present-day global flux of H_2O to the deep mantle translates to an addition of about one ocean mass over the age of the Earth. We extend the slab devolatilization work to carbon by providing an update to Gorman *et al*. [2], who quantified the effects of free fluids on CO_2 release. We use the new high resolution and global set of models to provide higher resolution predictions for the provenance of CO_2 release to the mantle wedge.

Geology, age and origin of the oldest terrestrial rocks and minerals

MARTIN J. VAN KRANENDONK

Geological Survey of Western Australia, 100 Plain St., East Perth, WA 6004 Australia (martin.vankranendonk@dmp.wa.gov.au)
School of Earth and Environment, The University of Western Australia, Crawley WA 6009 Australia

Earth's mineral and rock record extends back to an astonishing 4.4 Ga. The earliest history (4.4–4.03 Ga, 'The Hadean') is represented by zircon crystals and isotopic evidence from younger rocks of buried and/or vanished sources of this age [1, 2]. In the Archean, increasing amounts of crust are preserved from 4.03–3.5 Ga, but only as high-grade gneiss terrains with little primary sedimentary or volcanic material. Strangely, these rocks contain little or no evidence for meteorite bombardment at this time. Nevertheless, these remnants contain important clues to crust-forming processes and tantalising hints of the earliest biosphere. After 3.5 Ga, better-preserved crustal remnants yield more robust clues to early Earth processes and biosphere components.

Debate continues on the nature of early crust formation processes, specifically whether plate tectonics (of any kind) operated in early (or even middle) Earth history. Hadean crust may have been thick and basaltic, crystallised from a magma ocean and locally intrenally differentiated to form tonalite [3]. The early Archean was characterised by two types of crustal growth mechanisms, as on modern Earth [4]: 1) plateau formation over zones of upwelling mantle, forming thick welts of autochthonous crust affected by internal differentiation (e.g. East Pilbara Terrane, Pilbara Craton); 2) subduction-accretion in zones with voluminous arc-like magmatism and crustal imbrication (e.g. Western Greenland). By 3.1 Ga, modern-style (i.e. steep) subduction had commenced locally [5], and a significant proportion of the continental crust may have formed by 3.0 Ga, starting the supercontinent cycle.

Freeze-fry cycles in the Paleoproterozoic Turee Creek Group, Western Australia

MARTIN J. VAN KRANENDONK[1]*, AIVO LEPLAND[2] AND KOSEI E. YAMAGUCHI[3,4]

[1]Geological Survey of Western Australia, 100 Plain St., East Perth WA, 6004 Australia (*correspondence: martin.vankranendonk@dmp.wa.gov.au)

[4]NASA Astrobiology Institute

Previous research has suggested a Paleoproterozoic Snowball Earth consisted of up to three glaciations from 2.42–2.22 Ga, coincident with the timing of the inferred rise in atmospheric oxygen [1, 2]. Supporting geological and isotopic data from North America, Fennoscandia, and South Africa are supported by the occurrence of glacial rocks in the Turee Creek Group (TCG), Australia, and their geochemical characteristics [3, 4].

New $\delta^{13}C$ and $\delta^{18}O$ isotope data on bedded and stromatolitic dolomites, combined with previously available results [5] - recast in the light of corrected stratigraphic assignation - suggest that three freeze-fry cycles are recorded in the TCG. The first cycle is preserved in the lowest Kungarra Formation, reflected by a decrease and subsequent increase in $\delta^{13}C$ upsection, from 0-2‰→-6‰→0‰, associated with a decrease in $\delta^{18}O$ from 0→-4‰. Part of a second cycle is recorded in rocks of the glaciomarine Meteorite Bore Member and immediately overlying rocks of the upper Kungarra Formation ($\delta^{13}C$ from -2.5 to -6‰→-1‰, and $\delta^{18}O$ from 0 to -3→-12‰), whereas a third cycle is recorded in rocks of the overlying Kazput Formation ($\delta^{13}C$ from -3→1‰, and $\delta^{18}O$ from 0→-16→5‰).

The low-grade TCG carbonates are considered to have escaped significant post-depositional resetting. $\delta^{18}O$ variability and trends are interpreted to reflect changes in the temperature of basinal diagenetic fluids across cooling and warming periods, while mantle-like $\delta^{13}C$ values support periodic global collapse of the biosphere.

Ion diffusion in argillaceous materials

L.R. VAN LOON

Paul Scherrer Institut, 5232 Villigen PSI, Switzerland

Molecular diffusion is the dominant transport process of radionuclides which needs to be considered when evaluating the safety of radioactive waste repositories in argillaceous host rocks. The diffusive behaviour of radionuclides depends both on the properties of the porous medium and on the diffusing species.

Clay minerals (notably montmorillonite and illite) have a permanent negative surface charge which attracts cations and repulses anions leading to the formation of a diffuse double layer (DDL). The net positive charge of the DDL compensates the negative charge of the clay surface [1]. In the case of the diffusion of neutral species, no interaction between the electrostatic field and the species occurs and diffusion can be described by Fick's law [2]. The concentration gradient in the pore water is the driving force for diffusion of neutral species. In this case, only geometrical factors such as constrictivity and tortuosity are important. In the case of charged species, the situation is different. Because cations are attracted by the negative surface charge, the concentration gradients in the DDL and in the interlayers of the clay grains are larger than in the free pore water and consequently the diffusive flux is also larger. The electrostatic field thus enhances cation diffusion. Unlike cations, anions are repulsed from the surface leading to anion exclusion from the interlayers and the DDL. Anion exclusion leads to a lower accessible porosity for the anions, resulting in lower diffusive fluxes. All factors directly influencing the DDL thus also affect the diffusive behaviour of cations and anions.

This study gives an overview of the state-of-the art of knowledge on diffusion processes in dense argillaceous materials. Focus will be on tracer diffusion of ion exchanging cations, anions and neutral species in a constant electrolyte background and in different argillaceous materials [3]. The diffusive behaviour of cations which.. sorb via surface complexation is expected to be different and a brief outlook on current activities will be discussed.

A predictive model for cation diffusion in periclase

JAMES A. VAN ORMAN AND KATHERINE L. CRISPIN

[1]Department of Geological Sciences, Case Western Reserve University (james.vanorman@case.edu, klc24@case.edu)

Understanding rates of diffusion in periclase is essential for understanding chemical transport in Earth's lower mantle. Cation diffusion through periclase is faster than through any other major crystalline phase in the lower mantle, and thus provides an upper limit on the bulk diffusive transport that is possible in the absence of fluids.

The variation in diffusivity among different cations is controlled by their ionic properties, including size, charge, polarizability and electron configurations. No clear relationships among ionic properties and diffusivity have previously been recognized in periclase, despite the existence of a large diffusion database. The trends are obscured by variations in diffusivity that are likely due to the variable chemical purity of the MgO crystals used in the experiments. Here we take advantage of constraints provided by diffusion and ionic conductivity studies on doped MgO crystals to compare the cation diffusion data at a common vacancy concentration. Clear trends emerge between diffusivity and ionic size, charge, polarizability and crystal field stabilization energy. These trends are parameterized to provide a predictive expression for cation diffusion rates in periclase over a broad range of conditions relevant to Earth's lower mantle.

^{40}Ar-^{39}Ar geochronology and PT estimations on garnet-hornblende-muscovite-plagioclase schists from the Kheis Belt, South Africa

V. VAN SCHIJNDEL* AND D.H. CORNELL

Department of Earth Sciences, The University of Gothenburg, SE-40530, Sweden
(*correspondence: valby.van.schijndel@gvc.gu.se)

The Kheis Belt on the western margin of the Kaapvaal Craton, South Africa, is often referred to as a thin-skinned fold and thrust belt. However, Humphreys *et al*. [1] indicated that the schists of the Palaeoproterozoic Groblershoop Formation within the Kheis Belt reached equilibrium conditions between 600-700°C and 8-11 kBar. The schists of this study contain a main mineral assemblage of grt+hbl+plag+musc+epi+qtz with accessory chlorite, biotite, ilmenite and rutile. The peak metamorphic mineral assemblage is represented by grt+hbl+musc and the plagioclase has an Ab content of 0.83. The garnet and hornblende have inclusions of quartz, epidote and ilmenite, indicating a greenschist facies mineralogy assemblage. This is oldest assemblage preserved in the sample. Preliminary modeled results, obtained by equilibrium phase diagrams based on bulk composition were calculated for the NaCaKFMASH system with the program Theriak/Domino [2, 3]. These diagrams indicate that the garnet and hornblende growth started at 520°C and 9.5-10 kBar. An increase in Mg in the rims of the garnets points to a prograde reaction. PT conditions went up during garnet growth and reached a possible maximum at 660°C and 12.5 kBar. At higher temperatures kyanite becomes stable and this is not present in the samples. It is unlikely that the temperature reached above 660°C. Retrograde chlorite postdates all other minerals. 40Ar-39Ar dating on both muscovite and hornblende gave 1147±4 Ma and 1141±3 Ma. These ages are related to the Namaqua Orogeny and the agreement between the cooling ages of muscovite and hornblende arguments for a rapid uplift. Therefore are these ages thought to represent cooling ages that can be directly correlated with the peak metamorphic conditions.

Monitoring nutrients cycles at catchment scale

T.P. VAN TOL[1] AND B. VAN DER GRIFT[2]*

[1]Alterra, Wageningen University and Research Centre, P.O. Box 47, NL-6700 AA Wageningen, The Netherlands (dorothee.vantol-leenders@wur.nl)
[2]Deltares, P.O. Box 85467, NL-3508 TA Utrecht, The Netherlands (*correspondence: bas.vandergrift@deltares.nl)

In The Netherlands, the high concentration of nitrogen and phosphorus has an adverse affect on the quality of our surface water. The abundant growth of algae, water plants and reed is a recurring problem in Summer. Furthermore, the discharge of nutrient-rich water into the sea is a real threat to the marine ecosystem. Unfortunately, the origin and fate of all these nutrients often remains unclear.

The total nutrient concentration in surface water is determined by a range of sources, transport routes and chemical or biological processes. Nutrient cycles at a watershed scale are therefore very complex. To come up with solutions to improve the water quality it is very important to gain insight into the origin of the sources, their transportation time and what happens en route. In four typical watersheds in the Nederland's we studied the biogeochemical cycling of nitrogen en phosphorus at regional scale. The main goal of the project is to understand the relationship between long term changes in nutrient surplus and the quality of the surface water. The four watersheds are: a sandy with high loads of nutrients due to intensive cattle breeding, a more natural sandy area, a clay polder and a polder with peat soil. Each area has it own characteristics regarding the sources and transport route for nutrients. For this study we analysed soil, groundwater, sediment and surface water quality on several locations. The surface water quality and quantities were monitored continuously in the period 2004-2010. Combined with data collected on nutrient loads this resulted in an extensive dataset to study biogeochemical cycling of nitrogen and phosphorus in the soil-groundwater-surface water system at regional scale. A combined soil-groundwater-surface water model is used to predict the effectiveness of different source or transport route oriented measures to improve the quality of the surface water.

One of the major findings is the importance of sediments in the binding and relase of phosphorus when transported form groudnwater to surface water and the rol of sulfate in this proces.

Uranyl coordination chemistry on magnesite and brucite surfaces: Polarisation dependent EXAFS

A. VAN VEELEN[1]*, G.T.W. LAW[1], A.J. SMITH[1], J.R. BARGAR[2], J. ROGERS[2] AND R.A. WOGELIUS[1]

[1]University of Manchester, School of Earth, Atmospheric and Environmental Sciences, Oxford Road, Manchester, M13 9PL, United Kingdom (*correspondence: arjen.vanveelen@postgrad.manchester.ac.uk)
[2]Stanford Synchrotron Radiation Laboratory, PO Box 4349, Stanford, CA 94309, USA

Previous studies have examined uranium uptake by calcium carbonate minerals (calcite and aragonite) under conditions pertinent to both natural and anthropogenically perturbed systems. However, research on uranyl uptake by magnesium-rich minerals such as magnesite [$MgCO_3$], brucite [$Mg(OH)_2$], nesquehonite [$MgCO_3 \cdot 3H_2O$] and hydromagnesite [$Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O$] has not, to the best of our knowledge, been previously conducted. Such experiments will improve our understanding of the mobility of uranium and other actinides in natural lithologies such as dolomitic limestones or mafic igneous emplacements, as well as provide key information applicable to nuclear waste repository strategies involving Mg-rich phases. Thus, experiments with minerals powders were used to determine the partition coefficients and coordination of UO_2^{2+} during adsorption and coprecipitation with magnesite, brucite nesquehonite and hydromagnesite. A second set of experiments used single crystal magnesite (10.4) cleavage surfaces and MgO(111) surfaces engineered and hydroxylated to be equivalent to the $Mg(OH)_2$(00.1). Here EXAFS measurements were made at $\chi = 0^o$ and $\chi = 90^o$ in order to use the polarisation of the incident beam to unequivocally determine adsorbate and coprecipitate structures. The selected minerals were reacted with uranyl chloride at three different concentrations (500, 50 and 5 ppm) above and below solubility boundaries of schoepite ($UO_2(OH)_2 \cdot H_2O$) at pH 8 and $PCO_2 = 10^{-3.5}$ atm. K_d values for Mg carbonate phases were comparable to or exceeded those published for calcium carbonates. EXAFS results showed clear polarisation dependence of surface uranyl. The spectra demonstrated consistently that the uranyl molecule is preferentially oriented with the axial oxygens perpendicular to the mineral surface. This implies the creation of local rutherfordine-like regions which may polymerise at high uranyl activities into a thin film.

Nanoscale structural variation in pyrobitumen of the 2.0 Ga Zaonega Formation, Karelia, Russia

M.A. VAN ZUILEN[1]*, D. FLIEGEL[2], R. WIRTH[3], A. LEPLAND[4], Y. QU[5], A. SCHREIBER[3], A.E. ROMASHKIN[6] AND P. PHILIPPOT[1]

Alteration and especially remobilization of organic material and carbonic fluids in Archean rocks has led to many controversies regarding early life. It is therefore important to establish the detailed changes that occur when carbonaceous materials are affected by metamorphism. A case study is presented here of carbonaceous matter that occurs in sediments of the 2.0 Ga old Zaonega Formation, Karelia, Russia. Petroleum generation and contact-metamorphism caused by intersecting magmatic bodies, regional greenschist-facies metamorphism, and circulation of silicate-saturated fluids, led to complex mixtures of silicious and bituminous materials. Raman spectroscopy and transmission electron microscopy on pyrobitumen-rich samples revealed two significantly distinct carbon allotropes; 1) graphitic films representing highly ordered carbon, and 2) variously oriented nm-scale crystallites representing strongly disordered carbon that comprises the bulk pyrobitumen matrix. This clear bimodal distribution in structural order cannot be related to a simple temperature- or pressure-induced graphitization process, and requires additional effects that caused annealing of sp2-bound carbon crystallites. Potential effects include variations in graphitizing precursor materials, local stress and strain caused by mineral authigenesis or gas bubble growth, and reorganization of graphitic clusters by hydrothermal fluid circulation. The details of these effects and their implications for the general alteration and remobilization process of organic structures in the Archean rock record will be discussed.

Evaluation of chromium reductive immobilization and oxidative re-mobilization in flow-through aquifer sediment columns

CHARULEKA VARADHARAJAN*, PETER S. NICO, LI YANG, MATTHEW A. MARCUS, RUYANG HAN, MARKUS BILL, JOERN LARSEN, APRIL VAN HISE, SERGI MOLINS, CARL STEEFEL, MARK CONRAD, EOIN L. BRODIE AND HARRY R. BELLER

Earth Sciences Division, Lawrence Berkeley National Laboratory, 1 Cyclotron Road, Berkeley, CA (*correspondence: cvaradharajan@lbl.gov)

Remediation of chromium contamination typically involves reducing the toxic and soluble hexavalent form, Cr(VI), to the relatively harmless and mostly immobile trivalent state, Cr(III). The objective of the overall project is to identify the biogeochemical mechanisms that control *in situ* chromium reduction and oxidation.

In the initial phase of the experiment, reduction under anaerobic conditions was observed for over 12 months by subjecting flow-through columns containing homogenized sediments from the Hanford 100H site to different dominant electron acceptors, i.e. NO_3^-, Fe(III), and SO_4^{2-}, in the presence of Cr(VI) and lactate. Cr(VI) was depleted in the effluent solutions of the nitrate-treated columns, all of which exhibited denitrifying conditions, as well as in some of the sulfate-amended columns where fermentative conditions were dominant. However, only a small amount of Cr(VI) was removed under other electron-accepting conditions. Spectroscopic analysis of the column sediments showed that most of the chromium was precipitated as mixed phase Cr-Fe hydroxides.

In the second phase of the study, the denitrifying and fermentative columns were subjected to oxidizing conditions that are expected to be prevalent once the bioremediation is completed (with nitrate and O_2 present). Preliminary results show that the chromium precipitated in the denitrifying columns was more readily mobilized under the oxidizing conditions, suggesting that fermentative conditions promote more sustained Cr(VI) remediation.

LA-ICPMS U-Pb ages of Paleo- and Mesoproterozoic granites in Bolivia

G.L. VARGAS-MATOS[1], M.C. GERALDES[1], R. MATOS[2] AND W. TEIXEIRA[3]

[1]UERJ, Faculdade de Geologia. Rua Sao Francisco Xavier 524, Rio de Janeiro (RJ), 22241-000, Brazil
[2]UMCLA. Universidad Mayor San Andreas. La Paz, Bolivia
[3]USP. Universidade de Sao Paulo. Sao Paulo (SP) Brazil

Proterozoic granites of Bolivia new U-Pb zircon ages indicate an important change in chronostratigraphy of Bolivian Precambrian. The age of the Correreca Granite (1894 ± 13 Ma and 1925 ± 32 Ma) suggest an important magmatic event which spatial distribution is bounded on the north by the San Diablo shear zone, defining the oldest terrain with distinct geological story from other areas of the Bolivian pre-Cambrian. The San Pablo granite (ascribed as the Lomas Manechi magmatic event) yielded 1617 ± 14 Ma, in agreement with the ages of the literature (1.67-1.62 Ga). The results of isotopic granitoids of Cachuela, Motacusal and Talcoso (San Ignacio orogeny), present U/Pb age between 1307 and 1333 Ma, suggesting an important period of generation of granitoids in the Bolivian pre-Cambrian.

The Sunsas magmatism presents predominantly crustal sources and presents temporal variation between 1071 Ma and 1047 Ma (Granites Naranjito, Taperas, Primavera and El Carmen).

The data here reported suggest a geological evolution for the Bolivian pre-Cambrian composed of four episodes of magmatism represented by the Correreca event, followed by San Pablo event. The younger San Ignacio event is represented by magmatic arc with important participation of older continental crust. Finally, the magmatism Sunsas is comprised of anarogenic (type A) and crustal rocks (S-type) representing an important collisional period in the SW Amazonian craton.

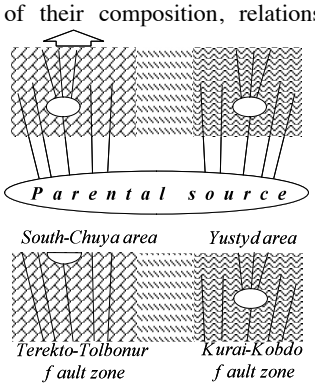
Petrology of lamprophyres as a result of the study of minerals

ELENA VASYUKOVA

IGM SB RAS, av. ak. Koptyuga, 3, Novosibirsk, Russia (lenav@inbox.ru)

Lamprophyres of the Chuya complex are one of the biggest displays of the alkali high potassium early mezozoic magatism of the Gorny Altay. Within this region dikes distributed unevenly, according to the fault zones and fractures. We have studied two largest and most saturated dikes local areas – South Chuya and Yustyd. The choice of these two areas is linked to the fact, that they are con fined to two distinct fault systems, located in the different host rocks and associated with the different ore disttricts. In addition, rocks of different areas vary in the degree of carbonatization, phenocrysts and structural-textural features.

Petro- and geocemical characteristics of rocks from different local habitats were so similar, that alowed to assert a single maternal source. Phenocrysts of pyroxen, phogopite, containing cromium and possibly olivine suggest, that the parental melt was high-Mg and its geochemical characteristics indicate the involvement of enriched mantle. Trends in harker variation diagrams, morphology (type 'dike-in-dike') – all this dose not in contradict the hypothesis on the formation of the dikes as a result of fractionation. Studies of minerals have confirmed this suggestion. Most informative for petrological studies in this rocks are phlogopites and apatites. The composition of plogopites reflects changes in the content of major elements, and apatites – of rare elements. In addition, their constituent volatiles significantly influenced the composition of the fluid phase of the rockforming melt. Study of their composition, relationships and restoration of the sequence of crystallization of minerals allowed to assume a model of formation of the Chuya lamprophyre complex, explain the differents between the two dikes areas.



The ultimate hypothesis is that the dikes South Chuya area formed at great depths directly from the source dyke Yustyd area are the result of crystallization of fractionated melt in the hypabyssal parts of the lithosphere, and associating with lamprophyre syenite massif is an intermediate chamber.

Eu(III) interactions with calcium carbonate

AIKATERINI I. VAVOURAKI[1]*, ÁGELES FERNÁNDEZ-GONZÁLEZ[2], MANUEL PRIETO[2] AND PETROS G. KOUTSOUKOS[1]

[1]Department of Chemical Engineering, University of Patras, Greece (*correspondence: kvavouraki@chemeng.upatras.gr)
[2]Department of Geology, Universidad de Oviedo, Spain

Understanding the interactions of radionuclides with mineral phases is important for the long-term storage safety of nuclear waste deposits which depends strongly on their interactions with the minerals. Calcite is a candidate mineral for use in nuclear waste repositories. Model studies involve nonradioactive trivalent lanthanides. In the present work Eu(III) interactions with calcite were investigated using two crystallization techniques which could yield complementary information. Counter-diffusion of (Ca^{2+}, Eu^{3+}) and (Na^{+}, CO_3^{2-}) ions was achieved through a porous silica hydrogel [1] in a U-shaped tube and aqueous solutions supersaturated with respect to calcite were prepared by mixing equimolar $CaCl_2$ and Na_2CO_3 solutions. The range of Eu(III) concentration was 10^{-2} – 50 mM. In the case of gels, Eu(III) was introduced into the sodium silicate solution used for the preparation of the silica gel to avoid formation of Eu(III) oxides. Crystals of calcium carbonate polymorphs in the presence of Eu(III) were formed in less than a month in the silica gel. Crystal growth proceeded and was finalized past a time period of one year. Additional crystallization experiments were carried out by vapor diffusion using the sitting drop crystallization method on a 'crystallization mushroom' [2]. Calcium carbonate precipitated in droplets containing $CaCl_2$: $(NH_4)_2CO_3$ ratio of 2.5 in the presence of Eu(III) concentration of 4 – 10 mM. The calcium carbonate polymorphs formed in the presence of Eu(III) were examined by Scanning Electron Microscope (SEM-EDS) and with electron microprobe (EMP) analysis. The extent of incorporation of Eu(III) into the calcium carbonate crystal structure is discussed in the perspective of using this mineral as a host for radionuclide disposal.

Bacterial and fungal communities colonizing mercury sulfide surfaces

A.I. VAZQUEZ-RODRIGUEZ[1]*, C.M. SANTELLI[2], S.C. BROOKS[3] AND C.M. HANSEL[1]

[1]School of Engineering and Applied Sciences, Harvard University, Cambridge, MA USA (*correspondence: avazquez@fas.harvard.edu)
[2]Department of Mineral Sciences, Smithsonian Institution, Washington, DC USA
[3]Environmental Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN USA

Soils and sediments, where mercury (Hg) can exist as Hg sulfide minerals (HgS), represent major reservoirs of Hg in aquatic environments. Due to their low solubility, primary and authigenic HgS (e.g. cinnabar and metacinnabar) have historically been considered insignificant sources of soluble Hg(II) to the environment. Recently however, the solubility of HgS was shown to be greatly enhanced in the presence of a natural microbial consortium [1]. The mechanisms for this enhanced solubility have yet to be assessed. Moreover, bacteria and fungi capable of colonizing HgS surfaces in the environment have not been identified, yet their proximity and association with the mineral makes them likely key players in effecting chemical changes that can impact dissolution.

To this end, we assessed the microbial diversity on HgS surfaces in the Hg-contaminated sediments and floodplain soils of the East Fork Poplar Creek in Oak Ridge, TN. Cinnabar and metacinnabar mineral sections were incubated at various depths, and hence redox conditions, in the creek channel, bank, and floodplain. Other metal sulfides, namely pyrite (FeS_2) and sphalerite (ZnS), were also incubated to distinguish the host metal effects on the colonizing community composition. Composition and diveristy were determined after 6 weeks of incubation, via pyrosequencing using bacterial (16S rRNA) and fungal (ITS) primers.

Our results reveal a high diversity of microorganisms colonizing all the metal sulfide surfaces. The microbial community composition and phylogenetic diversity vary as a function of the host metal within the sulfide, as well as between the HgS polymophs, cinnabar and metacinnabar. Oxidation rinds are observed on metacinnabar surfaces, the extent of which decreases with depth within the sediment. These communities have been cultivated and are being investigated for their ability to solubilize HgS. The results from this study will have large implications on the role that microbial communities play in the dissolution of HgS phases and hence mobility of Hg within the environment.

On the origins of prebiotic carbon containing rocks in the early Earth

ARON VECHT

Aron Vecht and Associates, London NW4 2AG, England (phosphors@vecht.com)

In 2007, we suggested that a paradigm shift was required to alter the generally accepted view of the organic origin of the carbon in earliest rocks [1]. To explain the distribution of deposits of methane (as hydrates), natural gas, oil, oil-tars, carbonatites as well as carbonates, we proposed the existence of stable minerals at depth which reacted when exposed to water and/or oxygen nearer the surface. We termed such rocks 'reactive minerals'. We chose carbides as examples e.g. Calcium Carbide or Aluminium Carbide. These would yield acetylene and methane respectively when exposed to water. These would in turn form carbonates under oxidizing conditions, or hydrocarbons and even graphite when exposed to a reducing environment. Under high temperatures carbonates would yield oxides while hydrocarbons would form carbon dioxide. We suggested that the existence of a considerable range of carbon containing compounds found in prebiotic rocks was not consistent with their organic origin.

More recently, evidence has been presented to support our suggestions.

1. The existence of a range of carbonate magma intrusions [2].
2. More detailed studies of ^{13}C to ^{12}C ratio. This was originally assumed to be evidence for the organic origin of carbonate deposits [3], however, more recently this conclusion has been questioned.

The oldest carbon containing rocks showing the existence of living systems is based on Stomatoporoids and Prokarryotic cell structures. These are based on Chlorophyll and DNA systems respectively. Clearly such complicated organic structures must have developed from other organic synthetic systems. Thus Miller-Urey type systems [4] or Fischer-Tropsh catalytic reaction [5] have been proposed. Such complicated processes are unlikely to explain the large carbon containing deposits found with wide distribution. The simple carbon compounds we propose are much more likely to result in the variety and distribution of the range and extent of carbon compounds found on Earth.

The relationship between the earliest organic species and the earliest carbon containing rocks need considerable further study. Many assumptions are made without detailed information. Unfortunately, although detailed isotopic studies of the oldest rocks have been reported, the extent of carbon present (or absent) has so far been overlooked [6].

Power law behavior in continental crustal heat production and its implications to the thermal regime of the continents

NIMISHA VEDANTI, RAVI P. SRIVASTAVA, O.P. PANDEY AND V.P. DIMRI

National Geophysical Research Institute, Council of Scientific and Industrial Research, Hyderabad- 500606, India (nimisha@ngri.res.in)

The nature and distribution of radiogenic crustal heat production is directly related to the temperature-depth regime in the continental lithosphere. It depends upon the amount of Uranium, Thorium and Potassium present in the rock. It is a primary source of heat flow and contributes to as much as 50% to the observed heat flow at the surface. In the absence of direct sub-surface measurements, number of heat production models have been proposed, which includes widely used exponential model in which heat production diminishes exponentially with depth [1, 2], however this has not been the case. Our detailed study of the fractal behavior in the deep crustal heat production data from some of the prominent continental crustal section across the globe like Kaapvaal craton (south Africa), Baltic shield (Russia) and Dharwar craton (India) etc. exhibits inherent power law behavior in the deep continental heat production data, rather than exponential as has hitherto been believed [3]. This would mean that in case of power law distribution model, decay of heat production with depth within the crust will be slower. Consequently, more heat flow would be generated by heat producing elements within the crust and thus heat flow input from the mantle would be comparatively lower. This would affect rheological behavior of the crust. In comparison to exponential model, power law distribution conforms much better with geological observations and rock types, where metamorphic grade gradually increases with depth till Moho is reached and corresponding lithologies changes from felsic, to mafic. Thus, fractal models can be considered more realistic in defining the decay of heat producing elements with depth within the differentiated crust. Present findings will have significant impact in the estimation of lithospheric temperature-depth distribution.

Discovering environmentally-critical nanomineralogy: Highly reactive Mn-oxyhydroxide nanofiber nucleation and growth catalyzed by nanohematite

HARISH VEERAMANI[1]*, URS DIPPON[2], MITSUHIRO MURAYAMA[1], RACHEL HENDERSON[1], ANDREAS KAPPLER[2] AND MICHAEL F. HOCHELLA, JR.[1]

[1]Department of Geosciences, Virginia Tech, Blacksburg, VA 24061, USA (*correspondence: harish@vt.edu)
[2]Geomicrobiology, Center for Applied Geoscience (ZAG) Eberhard-Karls-University of Tübingen, Germany

Manganese oxides typically form by the oxidation of aqueous Mn(II) catalyzed by mineral surfaces and are non-specific but potent redox-active mineral components commonly found in the environment. They therefore participate in a wide array of reactions with organic and inorganic compounds. They often exhibit high sorptive reactivities and capacities exceeding those exhibited by iron oxides. When present, they can play a key role in the mobility and bioavailability of important aqueous ions.

The present study investigates abiotic Mn(II) oxidation catalyzed by nanoparticulate hematite in the presence of molecular oxygen in batch reactors. The kinetics of the reaction is studied as a function of the hematite particle size and the presence of organic ligands. The effect of organic ligands on the morphology of Mn-oxides is also studied.

Surface-area normalized rate constants suggest differences in reactivity of hematite depending on its particle size. The end product of Mn(II) oxidation, a higher valent manganese oxyhydroxide identified as the mineral hausmannite, has been characterized by employing a suite of analytical techniques including high-resolution TEM, EELS mapping, SAED and SEM. The resultant Mn-oxyhydroxides have a unique nanosized, fiber-like morphology. SEM analyses were used to describe the formation and growth of Mn-oxyhydroxides fibers over time. Mössbauer analysis on nanoparticulate hematite after complete Mn(II) oxidation indicate small detectable amounts of Fe(II) suggesting hematite reduction and resorption of ferrous iron.

These findings suggest that the formation of Mn-oxides can be influenced by the bulk mineralogical and geochemical composition of the surrounding environment, as well as by the interfacial solute–solid nanochemistry of the solid-phase oxidant. This study further signifies the relevance of low-temperature interfacial geochemistry in the formation and the transformation of environmentally pertinent nanominerals.

Arsenic partition in redox gradients systems with iron and sulfur presence

A.S. VEGA, S.E. ACEVEDO, E. LEIVA, P. RÍOS, G.E. PIZARRO AND P.A. PASTEN*

Department of Hydraulic and Environmental Engineering Pontificia Universidad Catolica de Chile Santiago Chile (*correspondence: ppasten@ing.puc.cl)

In many cases the fate of arsenic (As) is controlled by its interaction with iron (Fe) and sulfur (S) species at the mineral-water interface. Although redox gradients are ubiquitous in aqueous systems, fewer controlled experimental studies have been performed on As-Fe-S systems. The interaction between diffusion-limited transport and the kinetics/equilibrium of chemical reactions was studied using redox gradient columns and batch sorption/coprecipitation experiments. The column was filled with a glass porous media, 1 mM $FeCl_2$ and 0.1 mM As(III) or As(V). Boundary redox conditions were controlled at each end (oxygen saturated water and 3 mM sulfide). Batch experiments used ferrihydrite and mackinawite as models for Fe and Fe/S precipitation under oxic and anoxic environments, respectively. A PHREEQC model was calibrated with the results from the batch experiments and it was used to assess As especiation scenarios in the column. Arsenic (0.1 mM) is effectively removed from solution by reaction with ferrihydrite (As(V): 99% As(III): 98%) and mackinawite (As(V): 45% As(III):93%) at oxic and anoxic conditions, respectively. Similar As removal from solution was observed when mackinawite and ferrihydrite were formed before and after As was added to the solution. The only exception was when mackinawite reacted with As(V). In the redox gradient column As is immobilized at oxic (pe = 0.3) and anoxic (pe = -3) conditions, whereas at intermediate redox potentials As is mobile (see Figure 1), showing that Fe and S have a buffer effect on the fate of As. The PHREEQC model shows that equilibrium conditions are not attained in the column.

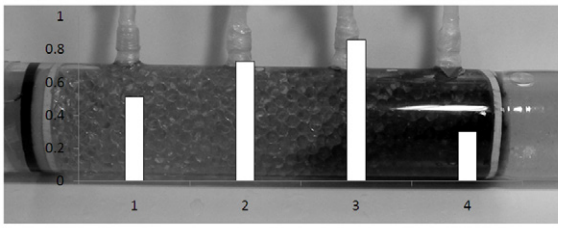

Figure 1: Redox gradient column. At the oxic boundary As immobilization on Fe oxides was favoured while As immobilization on Fe-S minerals was favoured at the anoxic boundary. Bars depict the As concentration in solution.

Exploration of interactions involving human tooth enamel and dental composites using vertical scanning interferometry

MANUEL VEGA-ARROYO[1,2], S. RAY TAYLOR[2], ROLF S. ARVIDSON[1]*, HEIDI B. KAPLAN[3], GENA D. TRIBBLE[2] AND ANDREAS LUTTGE[1]

[1]Department of Earth Science MS-126, Rice University, Houston TX 77005, USA (*correspondence: rsa4046@rice.edu)
[2]University of Texas Health Science Center at Houston – Dental Branch, Houston, TX 77030, USA
[3]Department of Microbiology and Molecular Genetics, University of Texas Medical School, Houston, TX 77030, USA

Although methacrylate resin-based dental composites are now used in the restoration of ~70% of the 120 million cavities (carious lesions) treated every year in the US, these materials have a limited service-life, requiring replacement after less than ~6 years (40% of a conventional amalgam). This replacement is most commonly necessitated because of secondary caries. Although the origin of these lesions at resin composite restoration sites is as yet unclear, they may be localized by leakage via microgaps between the cavosurface wall and the restoration. These microgaps result from shrinkage accompanying acrylate polymerization, thus yielding a protected microenvironment for growth of oral flora and subsequent chemical attack of the tooth (hydroxyapatite dissolution), and possibly the resin as well.

We present preliminary experimental results using restored teeth analyzed by vertical scanning interferometry (VSI, Fig. 1). VSI allows precise quantification of the geometry of the microgap environment and changes developing therein. Although the distribution of microgap volume is heterogeneous, the data clearly reveal the potential for micro-environments. Ongoing experiments include analysis of the chemical and mechanical response of these materials to imposed thermal and mechanical stresses, and *in vitro* analysis of microbial populations and attendant biofilm development.

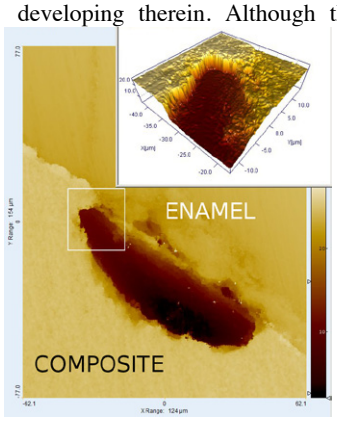

Figure 1: Microgap development at tooth-composite boundary.

Grain-supported flow at magma transfer zones

N. VEGAS[1]*, J. RODRIGUEZ[2], J.M. TUBIA[1], J.J. ESTEBAN[1] AND J. CUEVAS[1]

[1]Dpt. Geodinamica, Univ. Pais Vasco, UPV/EHU, E48940, Spain (*correspondence: nestor.vegas@ehu.es)
[2]Dpt. Mineralogía-Petrología, Univ. País Vasco, UPV/EHU, E48940, Spain

Before extruding in volcanic systems, magma suffers a continued evolution during ascent from its source. Fingerprints of this magma transfer through the lithosphere are recorded by microstructures and textures in plutonic rocks.

At the most internal parts of the Variscan chain, high-K plutonic suites were emplaced following the roots of the orogen [1]. This singular high-K and Mg association of rocks (vaugnerites, appinites, redwitzites or durbachites) is related with vertical extrusion of lithosferic-mantle derived, high-K and Na melts [2, 3].

A widespread feature of these high-K suites is the development of sphene-centred ocellar textures in some synplutonic intrusions affected by mingling processes. The structural and petrological study of these textures indicates that they formed as an effect of Reynolds dilatancy in highly crystallised crystal mushes affected by grain-supported flow [4]. Fabrics deduced from field and ASM studies indicate oblate strain and compressive regime. These conditions favoured the vertical movement of hyperdense crystal mushes with non-newtonian behaviour. The strain partitioning in these magma transfer zones will promote melt migration to upper structural levels. Moreover, it will enhance the mingling process, fauvoring the large lithological variation observed in these suites.

Intracratonic carboniferous granites in the Paleoproterozoic crust of Lithuania: New SHRIMP U-Pb zircon ages

I. VEJELYTE[1]*, K. YI[2], M. CHO[3] N. KIM[2] AND T. LEE[2]

[1]Vilnius Univ., D. of Hydrogeology and Engineering Geology (*correspondence:irma.vejelyte@gf.vu.lt), Lithuania
[2]Korean Basic Science Institute, Ochang, South Korea
[3]Seoul National University, Seoul, South Korea

Employing a Sensitive High-Resolution Ion Microprobe at Korea Basic Science Institute, we found Carboniferous granite previously unknown in the Paleoproterozoic crust of western Lithuania. The granite sample was recovered from a deep drill hole, Girkaliai-2, which is situated 3 km to the east of the Baltic Sea, within the Telsiai deformation zone. In the drill core, the analyzed granite forms a 10-cm wide dyke intruding the Paleoproterozoic charnockitic rocks. It is medium to fine-grained and consists of K-feldspar, plagioclase, biotite, and quartz. Accessory phases include monazite, zircon and opaque minerals. The contact between the granite and the host charnockite is straight and sharp. Two groups of zircon grains have been recognized in the granite. Zircons of major group are prismatic in shape and show concentric and oscillatory zoning characteristic of magmatic growth. Their U/Pb ratios are 0.81-2.15, and the U contents are 57-156 ppm. A weighted mean $^{206}Pb/^{238}U$ age of 349.1±5.7 Ma (MSWD=3.2) was obtained from 12 spots. The second group of zircons yielded concordant U-Pb ages of 2042, 1880, 1846, 1726, 1630, and 1455 Ma. These grains represent xenocrysts entrapped from various country rocks during the granite emplacement. Our U-Pb zircon ages demonstrate that the Paleoproterozoic crust in western Lithuania has been affected by Early Carboniferous magmatism. The Girkaliai granitic dyke is similar to the 355 Ma diabase dykes in the eastern Baltic offshore [1], and the ca. 350 Ma alkaline-carbonatite intrusions in Poland such as Elk, Pisz and Tajno. Thus, all of these Carboniferous ages are attributed to the intracratonic magmatism associated with Paleozoic rifting in the East European craton [2]. This is a contribution to the project 'Precambrian rock provinces and active tectonic boundaries across the Baltic Sea and in adjacent areas' of the Visby Programme (the Swedish Institute).

Microbial sulphur isotope fractionation in a Mars analogue environment at Rio Tinto, SW Spain

ESTHER VELASCO[1,2]*, PAUL MASON[2], PIETER VROON[1], WILFRED RÖLING, RICARDO AMILS[3,4] AND GARETH DAVIES[1]

[1]Faculty of Life and Earth Sciences, VU University of Amsterdam, The Netherlands (*correspondence: esther.velasco@falw.vu.nl)

[3]Centro de Astrobiologia, Madrid, Spain
[4]CBM-SO, Autonoma University of Madrid, Spain

Sulphur isotopes are likely to be a key in future tool for the detection of past or present life on Mars, where abundant sulphate minerals are present. To investigate the link between the activity of sulphate reducing microorganisms and sulphur isotope fractionation, we incubated sediment from a modern hyper-acidic, Fe-rich subareal environment at Rio Tinto, SW Spain. This site has been frequently used as a geochemical analogue of Mars.

Sediments were sampled from the upper part of the Rio Tinto (Marismilla) as wel as the estuary (Moguer). Laboratory incubation were carried out at 30°C using an artificial input solution with sulphate in excess and following techniques developed by Stam *et al*. [1]. The experiments were performed with an input solution at pH 7 and pH 3 and electron donors were provided by the natural substrate. Duplicate reactors were incubated for a total of 10 weeks. Initial data indicate moderate sulphate reduction rates of between 5 and 90 nmol cm^{-3} h^{-1} in Marismilla and between 5 and 45 nmol cm^{-3} h^{-1} in Moguer, independently of pH. Outflow solutions showed pH close to 7, regardless of inflow pH of 7 or 3, suggesting buffering within the sediment. Sulphur isotope fractionation was extreme in the Moguer estuary, extending beyond the maximun of 47‰ as predicted by the standard Rees model [2] of microbial sulphur isotope fractionation, suggesting that additional fractionation is possible [3] or indicating multiple cycles of reduction and oxidation of sulphate within the reactors. And inverse correlation between sulphate reducing rates and isotope fractionation was observed.

Mineral metastability and effective bulk composition: The effect of grain sizes and modal mineral amounts

S.O. VERDECCHIA[1]*, J. RECHE[2], E.G. BALDO[1], E. SEGOVIA-DIAZ[3] AND F.J. MARTINEZ[2]

[1]CICTERRA (CONICET-UNC). Av. Veléz Sarsfield 1611, X5016CGA Córdoba, Argentina (*correspondence: sverdecchia@gmail.com)

[2]Departament de Geologia, Universitat Autónoma de Barcelona, 08193 Bellaterra, Spain

[3]Dpto. de Petrología y Geoquímica, CSIC-Universidad Complutense, 28040 Madrid, Spain

Large staurolite porphyroblasts (up to 2 cm) were recognized in quartz-mica schist of the Sierra de Ancasti (west-central Argentina) [1] with the mineral association: Crd-And-St-Grt-Bt-Ms-Pl-Qtz-Chl-Op. Textural relations suggest that the assemblage St-Grt-Bt was present in the metamorphic peak. Growth of late And or Crd porphyroblast is recognized as well. Two post-peak textural domains were indentified: a) St being replaced by And without Crd, and b) Crd rich domains lacking And. A P-T pseudosection in the MnNCKFMASH system using XRF bulk composition allowed to estimate conditions of 590°C and 5.2kb for the St-Grt-Bt assemblge but post-peak textures and mineral compositions where not predictable. We assumed that the original XRF bulk composition was not valid during post-peak conditions not only because the cores of metastable porphyroblasts such as staurolite could have been isolated and excluded of the effective bulk composition [2] (EBC), but also, because heterogeneous distribution of staurolite could have affected the local EBC. Accordingly, post-peak textural relations (~580°C-3.5kb) developed during decompression were modeled using two bulk compositional domains defined on the basis of observed differences in staurolite mode. Two extreme cases were modelled: a) St poor - Crd rich domains lacking And; b) And + St rich domains lacking Crd. Results approximate real compositions and modal amounts observed in both post-peak textural domains. Thus, variation of EBC and generation of EBC domains through the PT path is a critical factor to consider for correct interpretation of metamorphic mineral and textural evolution and particularly for discrimination between polymetamorphic and single metamorphic episodes.

Evaluation of contaminant transport parameters at Leningrad Atomic Power Plant drain area

E.A. VERESCHAGINA

SpbSU, Saint-Petersburg, 199178 (ea.grigorieva@gmail.com)

The Leningrad Atomic Power Plant (Leningrad APP) drain area was studied. A hydrological study has been performed to demonstrate how contaminant transport proceeds in case of hypothetical disasters.

Gridded Surface Subsurface Hydrologic Analysis (GSSHA) model was chosen for the simulation of radionuclide and chemical transport. GSSHA is a physics based, fully distributed, hydrologic and sediment transport model. The distributed nature of the model confers significant potential advantages for the analysis of non-point source pollutant fate and control.

Precipitations falling on the watershed contain specified concentrations of contaminants for hypothetical disasters at Leningrad APP. As rainfall accumulates on the land surface, ponded surface water infiltrates, providing a source of contaminants into the soil column, and move as surface runoff to adjacent territory. Concentrations of contaminant are affected by decay and transformations.

The most part of the water ponded on the land surface infiltrates, removing contaminants. Water that infiltrates is assumed to contain the same concentration of dissolved contaminants as the ponded water. Infiltration was simulated using traditional Hortonian Green and Ampt (GA) approach.

Additionally, field experiments for testing the values of the Green and Ampt infiltration equation parameters were done for prevailing at the drain area soil types. The determined parameters were the effective capillary suction and the effective hydraulic conductivity.

Comparison of the model outputs with the experimental data indicates that the model can successfully describe cumulative infiltration in different soil types and contaminant transport.

Using rare earth elements (REE) for tracing water masses

MARC VERHEUL[1] AND GERARD KLAVER[2]

[1]Deltares, Utrecht, The Netherlands (marc.verheul@deltares.nl)
[2]BRGM, Orleans, France (G.klaver@brgm.fr)

Rare earth elements are a group of elements consisting of scandium, yttrium and the lanthanides. The concentrations in Dutch ground and surface water are low, at sub ppb (μg/kg) level, but measurable with an optimised ICP-MS. The lanthanides show chemically nearly identical behaviour, which results in concentrations with a constant ratio between the different elements, although the absolute concentrations can vary by more than two orders of magnitude. The measured concentrations need to be divided by the levels in a reference clay mineral, yielding a flat line for samples with a clayey signature. Water with a calciferous influence is enriched with the heavier REE compared to the lighter REE. The slope can be expressed by the quotient of the sum of the normalised ytterbium and lutetium values and the sum of the normalised lanthanum and praseodymium values. The gadolinium anomaly (an enrichment) is caused by the application of gadolinium as a contrast agent during medical MRI-scans. This last anomaly is a clear indication of anthropogenically influenced (ground) water.

Due to absence of topography and constant water substraction in the polderareas of the Netherlands, the hydrological system can be extremely complex locally. With REE-profiles and by combining all the characteristics of these REE-profiles, it is possible to make a water balance in these complex hydrological systems.

A simple method for *in situ* zircon U-Th-He dating

PIETER VERMEESCH AND ANDY CARTER

Department of Earth and Planetary Sciences, Birkbeck, University of London (p.vermeesch@ucl.ac.uk)

In situ U-Th-He dating of zircon by laser ablation offers significant advantages over the current practice of whole grain degassing and dissolution:

1. It dramatically increases sample throughput. Grains of zircon are notoriously hard to dissolve. Measuring their U and Th content requires dissolution in hydrofluoric acid at high temperature and pressure using a Parr bomb for up to 72 hours. In contrast, measuring the U and Th content by LA-ICP-MS can be done in a matter of minutes.
2. The process of in-situ measurements of U and Th content of grains yields U-Th-Pb ages as a by-product. Thus, in-situ dated zircon crystals are double-dated by default, offering exciting new research opportunities for detrital geochronology.

We here propose a simple four step procedure to measure *in situ* U-Th-He ages without the need to know any absolute concentrations or ablation pit volumes:

1. Polish and mount two sets of grains in indium: a standard of known U-Th-He age, and the sample of interest, whose age is unknown.
2. Ablate the grains with a UV laser and measure the raw helium signal (e.g., in units of mV or Hz) of the unknown sample along with helium measurements of the age standard.
3. Measure the U and Th signals of the standard and the unknown by EMPA, SIMS, or LA-ICP-MS in the same order as the helium measurements.
4. Given the known age of the standard and its raw U and Th signals, calculate the expected He signal of the standard. Dividing the measured by the expected He signal yields a 'gain factor' K. The U-Th-He age of the unknown is then obtained by applying this same gain factor to its raw He signal.

This new method eliminates the need for interferometric microscopy to measure ablation pit volume, largely avoids the challenges of measuring absolute U and Th concentrations by ICP-MS, and has relatively few sources of analytical uncertainty, potentially resulting in improved precision and accuracy over alternative analytical procedures.

Modelling Li isotope signatures of waters altering a basaltic glass in under-saturated conditions

A. VERNEY-CARRON[1], N. VIGIER[1] AND R. MILLOT[2]

[1]CRPG-CNRS, Vandœuvre lès Nancy, France
[2]BRGM, Orléans, France

In order to use lithium isotopes as tracers of silicate weathering, it is necessary to constrain the Li isotope fractionation caused by weathering processes (especially, mineral dissolution and secondary phase formation) as a function of environmental parameters.

Preferential uptake of ^{6}Li during the formation of clay minerals was quantified by several studies (e.g. [1]). Concerning leaching, experiments with a Li-rich basaltic glass in under-saturated conditions have shown that the δ^7Li values of the leachates are lower than the fresh basaltic glass value during the early stages [2]. This was explained by a 2-step model: (1) Li is released in solution by diffusion, which leads to the formation of a leached layer. As ^{6}Li is lighter than ^{7}Li, the ratio of the diffusion coefficients of both isotopes (a=D_7/D_6) is lower than 1. Thus, the solution is enriched in ^{6}Li and the leached layer in ^{7}Li. (2) The dissolution of the leached layer tends to increase the solution δ^7Li value. D_7/D_6 is also found to correlate with temperature.

In order to model natural data, D_7/D_6, but also the relative contribution of diffusion and dissolution rates has to be estimated. At T < 20°C, D_7/D_6 is nil. However, it can be significant for hydrothermal fluids. Using diffusion and dissolution rates at high T°, the model shows that the high dissolution rate masks the kinetic effect due to diffusion. In any case, the only way to produce δ^7Li values in solution greater than that of the fresh mineral is to preferentially incorporate ^{6}Li into the secondary phases formed during the alteration.

The Pb age of the Earth from Neoarchean galenas

J. VERVOORT[1]*, J. BLICHERT-TOFT[2] AND F. ALBARÈDE[2]

[1]School of Earth and Environmental Sciences, Washington State University, Pullman, WA, USA 99164 (*correspondence: vervoort@wsu.edu)
[2]Ecole Normale Supérieure, 69007 Lyon, France

Pb isotopes have provided the earliest estimates for the age of the Earth [1-3] and still provide important absolute age constraints on Earth's formation. Recent age determinations using the Pb isotope composition of the bulk silicate Earth range from 50 to 150 Ma after solar system formation [4-8]. Variation in present-day Pb isotope compositions in the silicate Earth, however, contribute to the uncertainty in these age determinations. Here we use the Pb isotope composition of galenas in volcanogenic massive sulfide (VMS) deposits in the Superior Province, Canada to determine the Pb age of the Earth. All deposits are Neoarchean (~2.7 Ga) and are derived from juvenile, mantle-derived volcanic rocks, as evidenced by their Nd and Hf isotopic compositions. Pb isotopes in the galenas are time invariant and thus provide a snapshot of the Neoarchean mantle from which they are ultimately derived.

A plausible scenario for Earth's Pb evolution is that it began with a low μ in the solar nebula and increased progressively during accretion to the current value of ~ 8 for the silicate Earth [4-8]. Using a low average μ from 4.56 to 4.52 Ga (< 0.7) with an increase to its current high μ at 4.52 Ga, the galena Pb trend is nearly coincident with the 2.7 Ga Geochron. With these parameters there is no Pb paradox at 2.7 Ga. The timing of this process, however, is dependent on the early stage of Pb evolution on Earth: If μ was lower during Earth's formation, the bulk of Pb loss occurred earlier; if μ was higher, integrated Pb loss occurred later, but with maximum of ~4.48 Ga. Our estimate for the Pb age of the Earth of ~4.52 Ga is older than the range of ages based on the present-day silicate Earth. This age most likely dates Pb loss to the core [4-8] or to space during accretion [9], and may have been finally punctuated by a moon forming impact.

Arsenic mobility in coal-combustion ashes mixed with agricultural soil

V. VESELSKÁ[1]*, K. PEŤKOVÁ[1], R.M. BOLANZ[2], J. MAJZLAN[2], Ľ. JURKOVIČ[1], B. LALINSKÁ[3], E. HILLER[1] AND O. ĎURŽA[1]

[1]Department of Geochemistry, Comenius University, Bratislava, 842 15 Bratislava, Slovakia (*correspondence: veselska@fns.uniba.sk)
[2]Institute of Geosciences, Friedrich-Schiller University, Jena, Germany
[3]Department of Mineralogy and Petrology, Comenius University, Bratislava, 842 15 Bratislava, Slovakia

In this study, we focus on the influence of coal combustion residues (ashes) on soils. Ashes with elevated As content were buried in soils when a dam of an ash impoundment of the Nováky power plant (Slovakia) failed in 1965; subsequently, the ashes were covered by agricultural soil. In order to assess the arsenic mobility, we performed leaching studies with distilled water, ammonium nitrate, and acid ammonium oxalate solutions on ash-soil samples collected in three various depths intervals (0-30, 20-60 and 40-100 cm) at various locations in the 1965 ash spill.

Mild extractions with H_2O and 1 M NH_4NO_3 show that there is a potential to contaminate the surrounding environment with As due to relatively high concentrations of As measured in the leachates. However, in both extractions, the released As concentrations represent only a small percentage of the As_{TOT} (5.3% and 0.3%, respectively).

Oxalate-extractable As fraction (73% of the As_{TOT}) should be associated with the poorly crystalline Fe, Al, and Mn oxide phases, which represent 17%, 14%, and 63% of the total element concentrations in the samples, respectively. It could be assumed that released amounts of Si_{OX} (484- 21, 319 mg/kg) and Al_{OX} (10.04-22, 984 mg/kg) support a possibility of silicate leaching from amorphous glasses in this extraction step.

Single extractions were complemented with magnetic separation of heavy fraction, X-ray diffraction and electron microprobe analyses of ash-soil mixture. These studies show, that the magnetic fraction of the soils contains an average value of 0.15 wt% As and 0.08 wt% As in the non-magnetic fraction. In depths of > 40 cm, there were significant positive correlations between As and total Fe (r=0.71), as well as As and total Al (r=0.78). Positive correlation of r=0.94 was also found for As-Ca, indicating that Fe, Al, and Ca-rich minerals control the distribution of As and retain this element in the soils.

This study was supported by the project VEGA No. VEGA 1/1034/11.

From compositional to P-T-deformation-t(relative age)-redox maps at the thin section scale

OLIVIER VIDAL, PIERRE LANARI, BENOIT DUBACQ, MANUEL MUNOZ AND ERIC LEWIN

Linking deformation with metamorphic conditions requires spatially continuous estimates of pressure (P) and temperature (T) conditions at least in two dimensions (P–T maps) that can be superposed to the observed structures of deformation at different scales.

We have developed an approach and a package of matlab scripts to produce EMP quantitative X-ray maps of composition at the thin section scale. These maps of mineral composition can be combined with a multi-equilibrium approach involving phyllosilicates to calculate P–T-deformation-t (relative age)-Fe^{2+}/Fe^{3+} maps, even for samples free of low variance parageneses. Various application examples show that in metapelites metamorphosed at < 550 °C, the composition of phyllosilicates does not change significantly by lattice diffusion with varying P and T. Different compositions of phyllosilicate grains coexisting metastably in the same thin section are therefore indicative of different P-T conditions of crystallization that were achieved at different times. The nucleation of new phyllosilicate grains with different compositions during P–T variation is activated by deformation, so that the location of the different phyllosilicate generations characteristic of different P–T conditions is correlated to the microstructures. In addition to historical information about the P–T and deformation history, the P–T-deformation-t-Fe^{2+}/Fe^{3+} maps highlight the evolution of redox condition and the heterogeneity of rheology at the thin section scale.

Interaction of Se(IV)/Se(VI) species with granitic rock: Understanding of retention processes

K. VIDENSKA[1]*, V. HAVLOVA[2], M. GALIOVA[3] AND V. HAVRANEK[4]

[1]ICT Prague, Technická 5, 166 28 Prague 6, Czech Rep. (*corespondence: katerina.videnska@vscht.cz)

[4]INP CAS, Husinec-Rez 130, 250 68 Rez, Czech Rep

Introduction

The fission product ^{79}Se belongs between radionuclides considered in safety assessment of radioactive waste geological repository, namely due to relative long half life ($3.56 \cdot 10^5$ yrs), anionic form in solution and biogenic character.

Modelling

According to modelling (the Geochemist´s Workbench) Se can be present at –II, 0, +IV and +VI oxidation states under granitic water conditions. Se (0) stability field would increase with increasing concentration of Se.

Experimental

Se(IV) and Se(VI) as anionic species are not usually supposed to be strongly bound on mineral surfaces [1]. Series of batch sorption experiments with crushed granitic rock revealed different sorption properties of selenite Se(IV) and selenate Se(VI), with favourable attraction of Se(IV). The higher oxidation state of selenium and large grain size significantly decreased K_D–values.

Discussion

In order to identify potential retention mechanisms, LA-ICP-MS and PIXE measurement were performed on surface of granitic samples after contact with Se(IV) or Se(VI) solution. Surface maps revealed trend of Se increased concentration in presence of Fe.

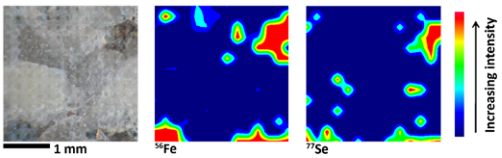

Figure 1: LA-ICP-MS surface map of granite sample after contact with 2.10^{-5} M Se(IV) solution.

Seawater-derived REY and HFSE systematics in Archean BIFs

S.VIEHMANN[1,4]*, J.E. HOFFMANN[1,2], C. MÜNKER[2], B.W. ALEXANDER[3,4] AND M. BAU[4]

[1]Steinmann Institut, Universität Bonn, Germany (*correspondence: fumi@uni-bonn.de)
[2]Geologisch-Mineralogisches Institut, Universität zu Köln, Germany
[3]Inorganic Ventures Inc., Christiansburg, VA, USA
[4]Jacobs Universität Bremen, School of Engineering & Science, Bremen, Germany

The HFSE and REE-Y patterns of Banded Iron Formations (BIFs) can be used to place constraints on the trace element composition of Archean seawater [e.g. 1]. Here we report the first high-precision HFSE (Nb, Ta, Zr, Hf) and REE (Lu, Sm, Nd) concentration data for separated chert and magnetite mesobands of ca. 3.7 Ga old BIFs from Isua (SW Greenland) and ca. 2.7 Ga old BIFs from the Temagami Formation (Superior Province, Canada), all obtained by isotope dilution. Other trace element measurements were performed using Quadrupole ICP-MS.

PAAS-normalized REY signatures of both Archean BIFs are comparable to modern and other Archean seawater patterns (e.g. [2]) and show seawater-like positive La, Y, Gd anomalies. Positive Eu anomalies suggest an enhanced hydrothermal input in Archean oceans, and the constant lack of negative Ce anomalies indicates anoxic seawater conditions [3].

Superchondritic ratios of Nb/Ta and Zr/Hf in magnetite bands of the Isua BIFs (40.2 - 59.2; 44.9 - 53.7) point toward lower Nb/Ta and Zr/Hf ratios of Isua cherts (19.2 - 32.5; 31.3 - 46.1). Temagami BIFs display the same characteristic with superchondritic Zr/Hf ratios in magnetite samples (38.1 - 47.1) contrary to subchondritic Zr/Hf ratios in cherts (18.9 - 28.5). By contrast magnetite and chert layers of Temagami BIFs exhibit uniform Nb/Ta ratios (14.1 - 27.0). Compared to compositions of modern aqueous [e.g. 4] and hydrothermal reservoirs, HFSE ratios of the Archean BIFs lie between those fields. Therefore different depositional environments for Isua and Temagami BIFs are favoured and also a different behaviour of both geochemical twins (Nb-Ta and Zr-Hf) in different water depths and water masses of Archean seawater is suggested.

[4]Departamento de Geologia, Campus do Morro do Cruzeiro, Universidade Federal de Ouro Preto, 35400-000 Ouro Preto-MG, Brazil

The iron cycle study provides important insights into the early Earth System evolution history. The Precambrian record is marked by Banded Iron Formation (BIF) occurrences, which are the product of chemical precipitation from seawater, which were subsequently affected by diagenetic and metamorphic processes.

In Central Brazil, the Quadrilátero Ferrífero region comprises a large occurrence of Paleoproterozoic BIF with approximately 7000 km^2, which hosts one of the largest iron ore deposits in the world. Some samples of the Quadrilátero Ferrífero's BIF were used in a preliminary investigation on the iron isotope signature recorded by these deposits.

We have analyzed a suite of samples by MC-ICP-MS using the nickel doping technique. Thirty three analyses of the Milhas hematite standard gave a δ^{57}Fe value of 0.766±0.088‰ (2SD), relative to the IRMM-14 standard. On the USGS BIF reference rock we obtained δ^{57}Fe = 0.903±0.042 (2SE, n=6). Both values agree within uncertainties with previously published values. Our results on the Quadrilatero Ferrifero show large δ^{57}Fe variations, between -1.493± 0.034‰ and -0.061±0.12‰. These different δ^{57}Fe values were obtained for BIF samples which have different mineralogical associations. Samples with the lightests δ^{57}Fe correspond to siliceous BIF whereas all other samples, are BIFs intermingled with carbonates. Such an isotopic range extending towards very light δ^{57}Fe values have only been found in 2.5-2.7 Ga age BIFs, like those of the Quadrilátero Ferrífero.

Biogeochemical characterization of geothermal fluids

ANDREA VIETH-HILLEBRAND, ALEXANDRA VETTER, ANKE SACHSE, STEFANIE HENNE, SIMONA REGENSPURG AND KAI MANGELSDORF

GFZ German Research Centre for Geosciences, Telegrafen-berg, D-14473 Potsdam (vieth@gfz-potsdam.de)

Biogeochemical investigations on deep geothermal fluids are relatively rare, but are of great importance to characterize the geochemical origin of the fluid as well as the potential that biological processes will effect the working reliability of geothermal plants.

To characterize the natural variability in the inventory of dissolved organic carbon (DOC) compounds in geothermal fluids, samples from different geothermal plants in numerous geothermal regions of the world have been screened for the qualitative and quantitative composition of the DOC using size-exclusion chromatography. The characterization of the DOC as well as inorganic anions are valuable to evaluate if microbial processes will be relevant in the geothermal system as the DOC and several inorganic anions like nitrate and sulfate represent potential nutrients for the microbial ecosystem. The changes in composition of the microbial ecosystem in geothermal plants and heat storage systems were also characterized by bacterial membrane phospholipid fatty acids (PLFA) composition.

Here, we will present recent results on the screening of the DOC in selected geothermal fluids from a variety of geothermal plants and heat storage systems as well as the monitoring of fluid chemistry and PLFA composition in heat storage systems present in the North German Basin.

Samples from a solar assisted heat storage located in a quaternary freshwater aquifer in 15 to 30 m depth clearly show that the composition of the microbial ecosystem changes with respect to the seasonal changes of charge and discharge of heat. In wintertime, the PLFA composition of the indigenous microbial community showed an adaptation of the cell membrane during the discharge mode, when temperature decreases from 50 to 13.7°C during time of heat extraction.

One deep heat storage in the North German Basin (1250 m depth) where surplus heat from a gas and steam cogeneration plant is stored in summertime and which is used in wintertime for district heating shows changing PLFA patterns that clearly indicate different composition of the microbial communities on the warm and cold side.

Isotopic tracing of lithium sources in the Seine River, Paris (France)

N. VIGIER[1], J. GAILLARDET[2], P. LOUVAT[2] AND J. CHEN[2]

[1]CRPG-CNRS, Nancy Université, 15 rue Notre-Dame-des-Pauvres B.P. 20 F-54501 Vandœuvre lès Nancy
[2]IPGP, CNRS, 75252 Paris, France

Li isotopes have recently been used for tracing chemical erosion of silicate lithologies in present-day river basins and in the past, through oceanic records. Silicate weathering is a significant sink of atmospheric CO_2, but classical methods are insufficient for determining alteration rates and control laws with sufficient precision to be used in modeling of geochemical cycles and climate at large scale.

Most of the published studies show that dissolved lithium mainly come from silicate lithologies, even in mixed lithology basins (e.g. Kisakurek *et al*. 2005). However, recently a couple of sudies have also shown that anthropogenic input might impact the Li isotopic composition of natural waters. Indeed, some rain waters display unusually high δ^7Li and fertilizers may also be highly enriched in ^{7}Li (Millot *et al*. 2010). Analyses of commercial solutions show that their δ^7Li are particularly high relative to the range estimated for natural systems (Tomascak, 2004).

In order to estimate the order of magnitude of Li contamination of natural waters from anthropogenic sources, the Seine River in Paris, the largest urban area in France, has been sampled at various seasons. Li isotopes were measured in the filtered fractions (<0.2µm) by MC-ICP-MS, after the Li separation procedure described in Vigier *et al*. (2009).

The δ^7Li measured in the dissolved fractions of the Seine River range between 8.6‰ and 14.2‰. This range is within that determined for rivers located far from human activity. However, these values are low when compared to the published values for carbonate and evaporite lithologies (~30‰). This may mean that, even in a basin dominated by this kind of lithology, dissolved Li mainly comes from minor silicate phases. This is consistent with the low Li levels in carbonates. Another possibility is that anthropogenic inputs are significant and have on average a low δ^7Li in the Paris area. Some streams draining rooves and roads display a wide range of δ^7Li (from 25‰ to -17‰), with an average of 7‰. A positive correlation between δ^7Li and discharge in the Seine waters does suggest a role of anthropogenic components, such as for Zn (Chen *et al*. 2008). More investigation is needed in order to better determine the isotope composition of each potential endmember.

FTIR study of OH-OD exchange in Fe-free ringwoodite-wadsleyite samples

E. VIGOUROUX[1], J. INGRIN[1], N. BOLFAN-CASANOVA[2] AND D. FROST[3]

[1]UMET - UMR CNRS 8207 - Université Lille 1 – Cité Scientifique, 59655 Villeneuve d'Ascq, France (eric.vigouroux@ed.univ-lille1.fr, jannick.ingrin@univ-lille1.fr)
[2]LMV - UMR CNRS 6524 - Université Blaise Pascal – 5 rue Kessler, 63038 Clermont-Ferrand, France
[3]BGI – Bayreuth University– Universitatsstrasse, 95447 Bayreuth, Germany

Mantle ringwoodite and wadsleyite may incorporate large amount of H in their structure (up to several wt % H_2O). A good knowledge of hydrogen diffusion in these mineral phases and its relationship with their electrical conductivity is critical to estimate the real amount of water present in the transition zone. We synthesized ringwoodite and wadsleyite in multi-anvil presses up to 21 GPa and 1100 °C from forsterite powder surrounded by a small amount of brucite. The grain size of the ringwoodite samples ranged between 30 and 70 μm, while wadsleyite samples had grains sizes smaller than 20 μm. The samples incorporated moderate amount of water in the range of 0.1 to 0.2 wt% H_2O as confirmed by FTIR analyses performed on double face polished thin slices of few hundred microns.

In order to measure H diffusion rate in ringwoodite, we annealed a 106 μm thick slice for up to 80 hours in a OD enriched atmosphere at 400°C and we followed step by step the OH-OD exchange by FTIR. The main OH band in ringwoodite, the OH broad band at 3120 cm^{-1}, decreased rapidly but no equivalent OD band was produced. It suggests that, in ringwoodite, the mobility of H linked to this defect, is high and the removing of hydrogen from the crystals are not limited by D self-diffusion (ringwoodite was not destabilized even after 80 hours annealing, as confirmed by Raman and FTIR analyses). The effective diffusion coefficient through the thin section is of the order of 2 10^{-14} m^2s^{-1}, and the corresponding intra-crystalline diffusion coefficient is around 3 10^{-15} m^2s^{-1} assuming an average grain size of 40 μm. These results are ten times faster than the diffusion coefficient in wadsleyite extrapolated at 400°C from the experiments of Hae *et al*. 2006 performed in wadsleyite [1].

Estimation of mass discrimination in MC-ICP-MS Nd isotope analysis using generalized power law

B. VIJAYA GOPAL, B. SREENIVAS AND Y.J. BHASKAR RAO

National Geophysical Research Institute (CSIR), Hyderabad 500007, India (bvijayagopal@ngri.res.in)

The multi collector Inductively Coupled Plasma Mass Spectrometer (MC-ICP-MS) is known for large mass discrimination when compared to Thermal Ionization Mass Spectrometer (TIMS), but remains time-independent. An exponential law is routinely used to correct for this mass discrimination in MC-ICP-MS analysis. Although, this resulted in precisions of < 50 ppm when compared to TIMS analysis, the fringe isotope ratios, eg. $^{150}Nd/^{144}Nd$ seems to deviate by > 500 ppm. Thus, a generalized power law (GPL; [1]) was introduced. Applying GPL for Nd isotope analysis of JMC Nd, it was shown that an exponent variable (n) of -0.23 is more effective in correcting the measured Nd isotope ratios using Nu Plasma MC-ICP-MS [2]. Also it was observed that variable n for various instruments generally ranges between -0.2 and -0.5. In this work, we estimated the n value for Nd isotope compositions of JNd_i measured on Nu HR MC-ICP-MS and found that GPL with a n value of -0.19 is more effective (Fig. 1). This value of n appears similar to the one obtained by Wombacher and Rehkamper [2].

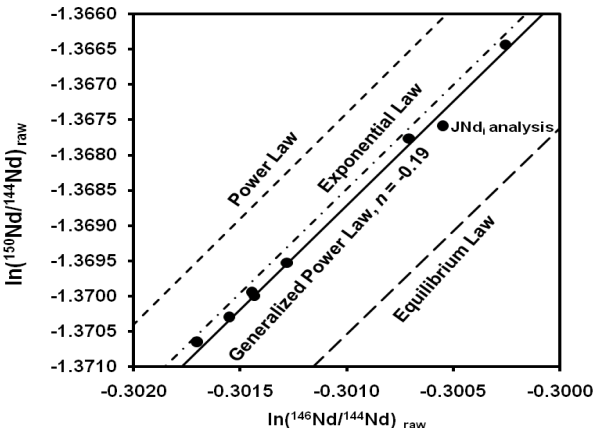

Figure 1: Analysis of JNd_i with various laws for correction

[1] Maréchal, C.N. Télouk, M & Alberède, F. (1999) *Chem. Geol.* **156**, 251–253. [2] Wombacher, F & Rehkämper, M. (2003) JAAS, **18**, 1371–1375.

REE distribution for the Arkachan large intrusion-related Gold deposit: Evidence for fluid origin

O.V. VIKENT'EVA*, G.N. GAMYANIN AND N.S. BORTNIKOV

IGEM RAS, Moscow 119017, Russia (*correspondence: ovikenteva@rambler.ru)

The Arkachan gold deposit is located in the tin metallogenic zone of Mesozoic Verkhoyansk belt (400 km to the North of Yakutsk) and hosted by sandstones and siltstones $C_{2\text{-}3}$-P_1. There is granite intrusion 2 km beneath the deposit. REE were determined by ICP-MS for unaltered and altered host rock, for quartz and carbonate and for fluid inclusions.

The REE total content increases from unaltered to altered host rocks from 90 to 200 ppm and from 170 to 830 ppm for sandstones and siltstones, respectively. All studied host rocks, ore carbonate and quartz are enriched in LREE, but carbonates from altered terrigenous rocks has La/Yb<1. Host rock alteration produced by acidic high temperature fluids and REE distribution were controlled by the sorption. Role of the complexation is increased at ore quartz and carbonate precipitation. Values of tetrad effect, more pronounced for the third tetrad are 1.2-1.5. Distinct negative Eu anomaly (Eu/Eu*=0.4-0.7) prevails in the rocks and minerals (Fig.1).

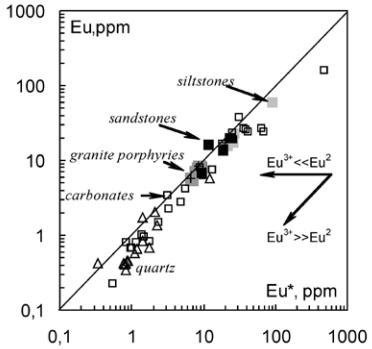

Figure 1: Plot of chondrite-normalized Eu concentrations versus calculated Eu^*_n values, where $Eu^*_n=(Sm_n(Tb_n \cdot Eu_n)^{½})^{½}$.

Fluids with deficient of Eu derived from granitic plutons. The Eu/Eu* values for the some samples, e.g. for late quartz, are 1-1.4, specified by a relatively reduced hydrothermal fluid with $Eu^{3+}<<Eu^{2+}$. The inverse relationship of ∑REE and of Eu/Eu* indicates a substantial role of magmatic fluid in the formation of the altered rocks. The hydrothermal fluids of the Arkachan deposis are known to be a mixture of H_2O+CO_2+NaCl with salinity of 3.7 to 26.3 wt % NaCl-equv. leaving chloride as the most likely candidate for the REE-transporting agent. LREE depletion of the siderite might be a result of the mineralogical control.

Ore-magmatic hydrothermal systems of massive sulphide deposits of Southern Urals: Melt and fluid inclusion data

I.V.VIKENTYEV[1]*, V.S.KARPUKHINA[2], V.B.NAUMOV[2] AND A.Y. BORISOVA[3,4]

[1]IGEM RAS, Moscow 119017, Russia (*correspondence: viken@igem.ru)
[2]GEOKHI RAS, Moscow 119991, Russia (naumov@geokhi.ru)
[3]GET-OMP, Toulouse 31400, France (borisova@lmtg.obs-mip.fr)
[4]Geological Department, MSU, Moscow 119899, Russia

According to existing models [1], the formation of the volcanogenic massive sulphide (VMS) deposits of the Urals is related to shallow chambers of acidic magma. The ore bodies are hosted by locally altered felsic rocks. All economic VMS deposits are located at some lithostratigraphic levels corresponding to two major and a few local stages of Lower Silurian and Middle Devonian volcanism. Melt inclusions (MI) and high density fluid inclusions (FI) in quartz phenocrysts were studied in 200 samples of dacite, rhyodacite and rhyolite.

Two main types of MI have been discovered: the most widespread devitrified inclusions, and rarely found glasses, some of them contain the ore globules of magnetite and also sulphides, represented by pyrrhotite, pentlandite, chalcopyrite and bornite, defined by electron microprobe. Melting of glasses occurred at 600-720°C, homogenization at 850-1130°C, whereas devitrified inclusions at 750-820°C and 950-1210°C accordingly. MI were analyzed for major elements and F, Cl by electron microprobe and H_2O by secondary ion microprobe. The concentrations of volatiles in the MI are (in wt%) are H_2O up to 6.5, Cl up to 0.28, F up to 0.42 contents; the average content of sulfur is 0.025 wt%.

FI in quartz phenocrysts are round to negative crystal shaped, from 25 to 100 μm, with gas bubbles from 8 to 40 μm. The homogenization of the FI occurred at 124-250°C in liquid phase. The freezing temperatures of FI range from -14 to -37°C. Salinities are from 1.2 to 6.2 wt% NaCl, density of aqueous fluids from 0.80 to 0.94 g/cm^3, calculated pressure from 680 to 850 MPa. Micro-Raman investigation demonstrated a presence of liquid H_2O only. Evaluated by LA-ICP-QMS at GET [2] contents in the magmatic fluid are**:** Cu 0.03-2.1 wt%, Zn 0.008-1.7 wt%, K 0.08-2.0 wt%, Fe 0.1-1.3 wt%, B 40-1600 ppm, Ba 20-2200 ppm, Sn 4-1600, Pb 14-740 ppm, Ag 4-200 ppm, Au 4-8 ppm.

Alterations to nanoparticle associated proteins

P.J. VIKESLAND, M.S. HULL, M. CHAN, R. KENT AND P. PATI

Virginia Tech, Blacksburg, VA 24061, USA (pvikes@vt.edu, mahull@vt.edu, mychan@vt.edu, ronkent40@gmail.com, param@vt.edu)

Engineered nanoparticles are often either purposely stabilized with proteins or acquire a protein 'halo' while in geologic or biologic media. The presence of this protein coat is generally thought to stabilize nanoparticles and make them resistant to aggregation and deposition phenomena. Our work has systematically examined the gold nanoparticle/protein interface in an effort to quantify the strength and stability of these interactions and to define the chemical and morphological transformations of the protein coat. Bovine serum albumin (BSA) was chosen as a representative protein and gold nanoparticles serve as a model nanoparticle system. Gold is an ideal model nanoparticle since it can be readily produced as monodisperse suspensions of varying size and variable surface functionality. Furthermore, gold is amenable to a number of surface plasmon enabled spectroscopies that facilitate quantitative evaluation of the protein/gold interface.

This presentation will highlight studies conducted to 1) quantify BSA binding to gold nanoparticle surfaces, 2) evaluate how BSA conformation changes in response to variations in solution chemistry, 3) determine the stability of the BSA coating under flow conditions, and 4) elucidate the chemical and biological reactivity of the BSA coating. These experiments collectively rely upon UV-Vis measurements of changes in the surface plasmon band location and intensity, surface enhanced Raman spectroscopy to evalate changes in BSA conformation and chemistry, and deposition and flow-cell AFM studies that define the stability of the BSA-gold nanoparticle interaction.

The current work has led to an improved understanding of protein/nanoparticle interactions and has helped define the chemical and morphological transformations that surface associated proteins are subject to. The collected results have important implications on the ultimate fate, transport, and toxicity of nanoscale particles released to aquatic environments.

Optimizing the use of magnetite from an iron mine for reduction of aqueous Cr(VI)

M. VILLACÍS-GARCÍA[1] AND M. VILLALOBOS[1,2]*

[1]Environmental Bio-Geochemistry Group, Chemistry School
[2]Earth Sciences Graduate Program, Geology Institute, UNAM, Coyoacan, C. U., Mexico 04510, D.F
(*correspondence: mariov@geologia.unam.mx)

Introduction

Magnetite is an inverse spinel ferrite that contains in its structure both Fe^{3+} and Fe^{2+} [1], and may therefore act as a reducing agent. This behavior has been applied in remediation of contaminated water with oxydized metal species that upon chemical reduction become immobile [2]. In this paper we present an investigation using natural samples of this mineral from an Fe mine deposit in Mexico towards the reduction of Cr(VI) to Cr(III), with the final aim to understand the geochemical conditions of optimal performance for applying it to real pollution scenarios. The most important problem to solve for optimal implementation, is the rapid surface passivation of the mineral due to complete oxidation of superficial Fe^{2+}, which results in very low Cr(VI) reduction yields.

Methodology

Investigations were performed with magnetite of various particle sizes, both natural and synthetic. Batch experiments were performed with a solid concentration of 6 g L^{-1} and concentrations of Cr(VI) of 5-10 mg L^{-1} and up to 50 mg L^{-1}. Mixtures of magnetites with low amounts of Fe (0) were also investigated, which presumably replenish superficial magnetite Fe(II) [3].

Discussion of Results

The reduction capacity of magnetite increased with decreasing particle size, but the overall reduction rates and yields were relatively low. Small weight percentages of Fe (0) (1-5%) mixed with magnetite, which in the absence of magnetite showed no reduction capacity, significantly increased both rates and yields. We report the optimization of the magnetite/Fe (0) ratio as a function of particle size, and pH, and confirmed the surface-mediated reduction mechanism.

Introduction

Ferrihydrite (FH) is a common hydrous ferric oxide nanomineral of 'young' formation in aqueous geochemical environments. Its small particle sizes (1.5-5 nm) [1, 2] expose a very high specific surface area at the mineral/water interface, and this may have considerable influence on the transport and fate of a variety of trace and major elements through diverse sorption processes. In particular, arsenate anions show a very high affinity for FH, and their fate in contaminated environments is almost invariably associated to Fe(III) oxide surfaces [3, 4]. The extremely small FH nanoparticles, which show high particle aggregation when dried, preclude experimental determination of important surface parameters for the thermodynamic description of its adsorption behavior. In the present work we have compiled eight sets of published acid-base surface titration data for synthetic preparations of FH across a wide range of particle sizes, and two sets of arsenate adsorption data, and unified their description through a face-distribution site-density model developed previously for goethite.

Discussion of Results

We show that the surface proton charge behavior of FH in conjunction with its As(V) adsorption behavior may be adequately described using the affinity constants derived for goethite, by assuming the FH surface to be composed predominantly of a surface site configuration equal to that of the (010) goethite face (*Pnma* space group). Also, through the applied model the available specific surface area of each FH preparation in aqueous suspension may be successfully derived, showing values between 330 and 1120 m^2/g. The implications of the results reported here are highly relevant for predictive purposes of FH surface reactivity in general.

In this work we present preliminary results about the abundance and species richness of diatom in sediments related with the chemistry of pore water. The oceanographic cruise (WAG-02) was done at the end of July 2010 in the Wagner and Consag basins of the Northern part of Gulf of California. The study area is characterized by pockmarks, mud volcanoes and gas vents at depths of 65 to 150 m approximately [1].

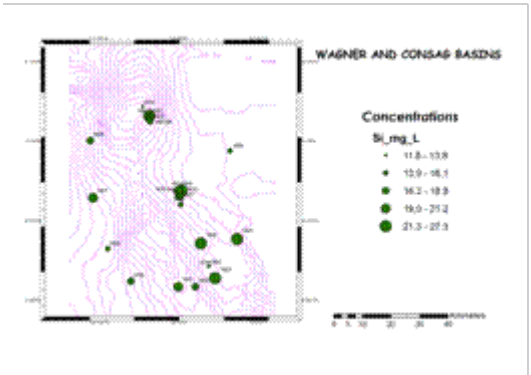

Figure 1: Spatial distribution of silica concentrations in pore water.

Discussion of Results

The presence of silica in the Wagner Fault could be high productivity waters in the zone, dissolution of minerals and the hydrothermal activity.

Os isotopes in sulfides from xenoliths of the Campos de Calatrava Volcanic Field, Central Spain

C. VILLASECA[1], J.M GONZÁLEZ-JIMÉNEZ[2], W.L. GRIFFIN[2], E. ANCOCHEA[1], F. GERVILLA[3], S.Y O´REILLY[2], N.J. PEARSON[2] AND E. BELOUSOVA[2]

[1]Dpt. Petrology and Geochemistry, UCM-CSIC, Madrid, Spain (granito@geo.ucm.es, eancochea@geo.ucm.es)
[2]GEMOC ARC National Key Centre, Sydney, Australia (jose.gonzalez@mq.edu.au., bill.griffin@mq.edu.au, sue.oreilly@mq.edu.au, npearson@mq.edu.au, elena.belousova@mq.edu.au)
[3]Dpt. Mineralogy & Petrology, University of Granada, Spain (gervilla@ugr.es)

The Campos de Calatrava Volcanic Field (CCVF) comprises more than 200 volcanic centers with ultra-potassic to more Na-rich alkaline magmas that intruded the easternmost branch of the Hercynian Iberian Massif, in central-south Spain, ca. 8.7-0.7 Ma ago. Small lherzolite-wherlite xenoliths are embedded in pyroclastic deposits of volcanic centers. These xenoliths are spinel-bearing varieties; garnet is absent in the lherzolite suite. The presence of interstitial volatile-rich minerals (i.e. amphibole and phlogopite) and the distribution of trace elements in them suggest mantle metasomatism by subduction-related melts [1].

Fe-rich monosulphide solid solution (Fe-rich Mss) (<16.67 at% Ni) is the only sulphide present in the xenoliths. *In situ* LA-MC-ICPMS analyses reveal that sulfides included in primary silicates are Os-poor (<15 p. p. m.), making it difficult to obtain precise Re-Os isotope data. In contrast, sulfides sitting in open fractures or included in metasomatic silicates have higher Os contents (up to 89 p. p. m.). The Re-Os data show large variations in $^{187}Os/^{188}Os$ (0.1142-0.1241) and $^{187}Re/^{188}Os$ (0.02-0.12). T_{MA} and T_{RD} (Re depletion) model ages, compared with PUM at the present day, range from 1.0 to 2.3 Ga and from 0.75 to 2.1 Ga respectively. One grain has $^{187}Os/^{188}Os$ = 0.1270 and $^{187}Re/^{188}Os$ = 0.05; T_{MA} and T_{RD} are 0.4 and 0.35 Ga.

The differences in Re-Os systematics of sulfides reflect a probable metasomatism at 1 Ga ago. This metasomatic event is also recognised in Nd T_{DM} ages from spatially associated gabbros of the Hercynian orogen in central Spain (Fernández-Suárez *et al*. 2011).

Novel insights into the ion sorption properties of calcite in aqueous solutions using cavity ring-down spectroscopy

A. VILLEGAS-JIMÉNEZ[1]*, R.M. HAZEN, [1] AND D.A. SVERJENSKY[2]

[1]Carnegie Institution of Washington, Geophysical Laboratory, Washington, D.C. 20015, USA (*correspondence: adriano@gl.ciw.edu)
[2]Johns Hopkins University, Earth and Planetary Sciences, Baltimore, MD 21218, USA

Despite significant advances on the elucidation of the structure of the calcite-water interface, much controversy still surrounds some of its most fundamental physical-chemical properties [e.g. the pH of the isoelectric point, the point of zero net surface charge, the proton and lattice-derived ion sorption properties]. This is largely due to the lack of suitable experimental approaches allowing a rigorous characterization of calcite surface equilibria over expanded compositional ranges. Electrokinetic techniques do not allow direct probing of surface reactions whereas conventional wet-chemical approaches (batch and titration) fail to control or monitor $CO_{2\ (g)}$ exchange across the air-water interface which leads to large uncertainties in the computed (ad)sorption data. Recently, a novel titraton protocol that addreses this difficulty was developed and tested over a relatively wide range of chemical conditions [1]. The new data was interpreted in terms of the following $2H^+/Ca^{2+}$ ion exchange equilibrium:

$$(\equiv CaCO_3)_{2(exc)} + 2\ H^+ \Leftrightarrow \equiv Ca(HCO_3)_{2(exc)} + Ca^{2+}$$

If true, this mechanism may impact the aqueous speciation of carbonate-rock systems with restricted $CO_{2\ (g)}$ ventilation via the buffering of pH and calcite dissolution. It follows that a careful verification of this reaction is warranted. To this end, and to gain further insight into the ion sorption properties of $CaCO_{s3\ (s)}$ in aqueous solutions, we are conducting new titrations of high-purity, additive-free, synthetic calcite and aragonite powders over a broader range of conditions using a novel titration approach that allows, for the first time, a reliable monitoring of the chemistry of the $CaCO_{3\ (s)}$-$H_2O_{\ (l)}$-$CO_{2\ (g)}$ system. Accurate pCO_2 measurements are obtained via a gas-recirculation device and a last-generation cavity ring-down laser spectrometer which avoids interferences from water vapor with negligible sample perturbation, a notable advantage over IR spectrometer-based strategies. Our approach yields very high-quality data suitable for the calibration of ion sorption models for $CaCO_{3\ (s)}$ surfaces.

Molybdenum isotopes in the altered oceanic crust, a novel proxy for recycling?

F. VILS[1]*, T. ELLIOTT[1], M. WILLBOLD[1], M. HARRIS[2], C. SMITH-DUQUE[2], R. COGGON[3] AND D. TEAGLE[2]

[1]University of Bristol, BS8 1RJ Bristol, United Kingdom (*correspondence: flurin.vils@bristol.ac.uk)
[2]National Oceanography Centre Southampton, University of Southampton, SO14 3ZH Southampton, United Kingdom
[3]Imperial College London, SW7 2AZ, United Kingdom

During movement of the oceanic crust away from mid-ocean ridges, hydrothermal alteration of the oceanic crust results in a distinct elemental and isotopic signal. The change in isotopic composition compared to unaltered MORB is an important tracer for the involvement of fluids released from the altered oceanic crust at the base of arc volcanoes during subduction. Any isotopic system not fractionated during dehydration reaction and inert to diffusion is therefore a valuable tracer to shallow or deep recycling of subducted material. Recent studies showed that Mo isotopes could be such a novel proxy [1, 2, 3] as measured Mo isotope values in arc and ocean island basalts differ significantly from mantle values (estimated to be similar to continental crust 0‰ $\delta^{97/95}$Mo). This study investigates the change in Mo isotopes through the altered oceanic crust to better constrain the input into the subduction zone.

Samples of the altered oceanic crust across the Pacific Ocean have been measured for Mo isotopes and Mo concentrations (ODP Sites 1179, 1301, 1256). Combined the studied samples show a decreasing down-hole trend varying over 1‰ $\delta^{97/95}$Mo. The heavier isotope ratio in the upper part of the crust might be the source region for the heavy isotope ratio seen in the Mariana arc [2] and the lighter isotope ratio further down-hole might be the source for the light isotope ratio seen in ocean islands basalts [1, 3]. To further constrain this down-hole trend over a complete section of the altered oceanic crust (through pillow basalts, sheeted dyke complex, and gabbros), additional Mo isotope and concentration measurements on the deepest ODP hole (Site 1256) are currently in process.

Heavy metals and arsenic in the soils in the area of Narva power plants: Distribution and controlling factors

L.-E. VINNE*, L. BITYUKOVA AND H. SCHVEDE

Institute of Geology at Tallinn University of Technology, Tallinn, Estonia
(*correspondence: liis-erliken.vinne@gi.ee)

Two world's largest oil shale-fired thermal power plants located in the North-eastern Estonia are the main sources of air pollution in Estonia. Up to 50 ths tonnes of combustion ashes are emitted to the atmosphere annually.

Oil shale contains most of the naturally occurring chemical elements at least in trace amounts. Trace species may be realised during combustion and can pose an environmental and human risk. Soils have been considered as one of the main recipients of pollutants.

To evaluate potential hazard of contamination in the area influenced by the Narva Power Plants the geochemical mapping was carried out. Geochemical maps created basing on the ICP-MS data for major and trace elements allow illustrating spatial distribution of elements studied and outline the areas with uncommon concentrations in the soils. Well-defined areas with the highest values of elements are observed generally along the seacoast zone and to the east of the Narva region that reflect the incorporation of the Lower Ordovician shale bedrock naturally enriched in potentially toxic elements.

Mobility and availability of arsenic and heavy metals in soils was evaluated by the two-steps (milliQ water and sodium acetate) sequential extraction. The results showed that heavy metals and arsenic are leached in low quantities and attributed generally to mineral phase in the soils. The water soluble fractions are negligible (<1%). The Na-acetate extractable concentrations of Cd, Co, Cr, Pb and Zn are much higher than those obtained using water extraction. Extractability of elements depending on pH, grain size composition and soil types also as elements contribution from very various parent materials will be discussed in the presentation.

Thermodynamics of solid solutions of carbonates with non-isostructural end-members: The prediction of solubility limits with the single defect method

V.L. VINOGRAD[1], M.I. LUCHITSKAIA[2] AND B. WINKLER[2]

[1]Institute of Energy and Climate Research (IEK6), Forschungszentrum Jülich, 52425, Germany (v.vinograd@fz-juelich.de)
[2]Institute of Geosciences, University of Frankfurt, Frankfurt a.M., 60438, Germany

Carbonates are considered as sorbents for various contaminants dissolved in aqueous solutions. Numerous studies suggested that carbonates can retain significant amounts (up to thousands of ppm) of SO_4^{2-}, SeO_4^{2-}, $HAsO_3^{2-}$, HPO_4^{2-}, CrO_4^{2-}, while concurrent spectroscopic and surface diffraction studies have shown that these anions, indeed, replace CO_3^{2-} units of the carbonates. The question is, can these experimental results be considered as a proof for the formation of thermodynamically stable solid solutions? Our approach to the problem is based on the assumption that the solute components obey Henry's law. This is equivalent to assuming that the enthalpy of mixing of a diluted solid solution can be approximated as a linear function of the mole fraction of the solute. The extrapolation of this line to 100% of the solute component allows defining the enthalpy of the virtual (solute) end-member, which within the same assumption forms a perfectly ideal solution with the host. We have been able to calculate the total energies of virtual end-members from the total energy of the host (carbonate) and the energies of supercells of the host with a single CO_3^{2-} unit replaced by an anion of the solute end-member. The energies were calculated from first principles. The standard enthalpies of the virtual end-members were then calculated relative to reference compounds with the same composition, whose standard thermodynamic properties are well defined. Our calculations predict vanishingly small concentrations of SO_4^{2}, SeO_4^{2-}, $HAsO_3^{2-}$ and HPO_4^{2-}. This suggests that carbonate 'solid solutions' formed by co-precipitation with these components are not stable in the thermodynamic sense. Experimental approaches to testing this hypothesis are discussed.

Recent progress in analytical techniques sensitive to ppm-range concentrations attracted the interest of petrologists to geothermobarometry based on trace element partitioning between various minerals [1]. Current approaches for the calibration of such geothermobarometers are purely phenomenological. Indeed, the thermodynamic mixing properties of solid solutions, whose concentration ranges do not exceed 1000 ppm, cannot be easily measured and thus typically are not known. We propose to use atomistic model simulations for the calibration and extrapolation of such geothermobarometers. In this report we will present the results of density functional theory based simulations of TiO_2-SiO_2 and TiO_2-ZrO_2 solid solutions with rutile and a-PbO_2-type structures obtained using the double-defect method [2]. The results will be discussed in relation to Zr-in-rutile thermometry and Si-in-rutile barometry. The pressure effects of Ti-in-quartz and Ti-in-zircon thermometers have also been modeled.

[4]Finnish Meteorological Institute, P.O. Box 503, 00101 Helsinki, Finland

SOA formation and properties are widely studied to clarify the role of SOA in radiative forcing and climate. However, very limited information is available on the morphology and phase state of SOA particles. Verifying the physical phase state of SOA particles gives new and important insight into their formation and growth process and essential information on their implications in the atmosphere [1, 2].

According to our recent results [3], pine derived SOA particles in chamber conditions as well as atmospheric SOA particles formed in boreal forest can be amorphous solid in their physical state at least several hours after their formation. However, it is not known yet how general the observation is and what the atmospheric implications are.

In this study we have investigated the physical phase state of SOA particles formed in Boston College flow tube from various precursor VOCs representing both biogenic and anthropogenic sources. In addition, the phase change was investigated as a function of particle oxidation level (O:C) and flow tube SO_2 concentrations.

According to our results the solid phase is the dominating phase state of formed SOA in the case of both biogenic and anthropogenic precursors at least up to relative humidity (RH) values of 55-70%. At higher RH values the humidity induced phase transition takes place and particles liquefy. We find that the O:C ratio of particles as well as chamber SO_2 concentration have an effect on the phase of SOA particles.

[4]Dept. of Physics and Astronomy, Denison University, Granville, OH 43023, USA

The solar nebula, in which the Earth and all other solar-system bodies were formed, was a complex chemical mixture of gas and dust. In order to fully understand the nebula's chemical composition at the time the solid bodies were formed, one has to go back in time and retrace the chemistry to the molecular cloud that collapsed to form the solar nebula. Here we present recent astrochemical observations and models that aim to do just that [1, 2, 3]. The main focus is on water and on simple organic compounds like methanol (CH_3OH) and dimethyl ether (CH_3OCH_3), which are tracers of the organic complexity that likely aided the eventual formation of life. The models predict that water and simple organics were already formed abundantly at an early time. As the parent molecular cloud collapsed and evolved into the early solar system, changes in density, temperature and radiation led to further chemical processing. The abundances of several key species in this simulated solar nebula match those observed in comets [4], but others are off by orders of magnitude. We discuss what both the good and the poor matches mean for the delivery of organic material to the Earth and elsewhere.

[4]Museo Nacional de Ciencias Naturales, CSIC, c/ Serrano 115 dpdo., 28006 Madrid, Spain

Geobiological systems with emphasis on halite and gypsum crusts from the Atacama Desert, one of the driest places on Earth, were studied. Raman spectroscopic analysis revealed variations in pigment composition within various endolithic colonies, allowing in some cases suggestions to be made about survival strategies.

Scytonemin, an effective extracellular UV-protectant, was found in cyanobacterial colonies within halite and gypsum crust from the hyperarid core of the Atacama Desert using Raman spectroscopy. The amount of scytonemin present differed depending on the particular microhabitat. Substantial differences are proposposed to reflect a variable biosynthesis due to the amount of light available inside the halite and gypsum crust.

Raman spectroscopic analyses of the endoevaporitic colonies from Ca-sulphate exhibited systematic variations in carotenoid composition together with the presence/absence of a phycobiliprotein signal (indicative for cyanobacteria). The cyanobacterial signal was accompanied by two clearly distinguishable ν(C=C) carotenoid bands at ~1516 and 1498 cm^{-1}, pointing to carotenoids of different chain length. Within the colonies living closer to the surface, scytonemin was also identified. The Raman signal of algal colonies from near the rock surface exhibited a ν(C=C) carotenoid band at ~1525 cm^{-1} accompanied by chlorophyll, whereas the same carotenoid band obtained from red algae is shifted towards lower wavenumbers with the spectra lacking chlorophyll.

Fast Raman mapping of the green algal colonies exhibited great potential of the method for the study of endolithic communities in their original habitats.

Readily available acidity in schwertmannite

CHAMINDRA VITHANA[1,2]*, LEIGH SULLIVAN[1,2], RICHARD BUSH[1,2] AND ED BURTON[1,2]

[1]Southern Cross GeoScience, Southern Cross University, Australia (*correspondence: c.vithana.10@scu.edu.au)
[2]CRC CARE, Building X, University of South Australia, Mawson Lakes SA 5095, Australia

Introduction

Schwertmannite and jarosite are considered as less soluble ironhydroxy sulfate minerals which are present in highly acidic environments (pH < 3). These minerals release acidity in the long run as they weather by hydrolysis [1]. However, 1M KCl extraction of soil samples (Clarence and Quartz) spiked with those two minerals showed that schwertmannite has some acidity that may be readily available.

Results and Discussion

Unlike jarosite, schwertmannite released acidity during 1M KCl extraction. It was found that the measured acidity in schwertmannite added samples was ~1/3 of the expected total inherent acidity (Figure 1). This acidity release was also associated with the release of surface bound sulfate from schwertmannite. It was found that ~30% of sulfate in schwertmannite was able to be release by 1M KCl, an amount that matches other observations [2].

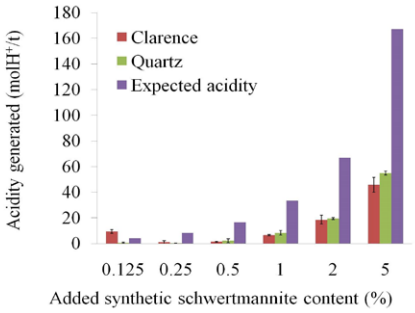

Figure 1: Acidity generated vs expected acidity

Smelting activities in the Copperbelt Province (Zambia) have produced huge amounts of various wastes. Dust particles emitted during the ore and slag processing pose high risk of environmental pollution in this area [1, 2]. Three types of dusts identified as possible sources of contamination were studied: (A1) dust from slag crushers, (A2) fly ash trapped by filters originating from processing of the slags and (B) electrostatic precipitator dust from smelting of Cu and Co-rich ores. Bulk chemical analyses and mineralogical investigation using XRD, SEM/EDS and TEM were performed. The samples were enriched with various levels of metals and metalloids. Maximum concentrations of 256 g Cu/kg (B), 8.9 g Co/kg (A1), 4.7 g Pb/kg (A2) and 19.8 g Zn/kg (A2) were determined. Based on XRD analysis, the composition of dust A1 generally corresponds to silicate slags [3] with dominating Ca-Fe pyroxenes, quartz (SiO_2), fayalite (Fe_2SiO_4) and cuprospinel ($CuFe_2O_4$). Calcite ($CaCO_3$), Ca-Fe pyroxenes and quartz represented the main phases of fly ash A2 with minor ZnS and elemental Cu and a significant portion of amorphous/glassy fraction. Chalcanthite ($CuSO_4 \cdot 5H_2O$), magnetite (Fe_3O_4) and delafossite ($CuFeO_2$) dominated in dust B. Detailed mineralogical investigations revealed the presence of Cu sulphides in the studied samples and possible substitutions of metals in the pyroxene structure. Elevated concentrations of Cu, Co and Zn were detected in the silicate glass. *In situ* weathering processes may result in the release of contaminants into the environment (e.g. soils) depending on the stability of phases present in the dust.

Sedimentary and chemical weathering fluxes at the outlet of the granitic Strengbach catchment (Vosges massif, Eastern France)

DANIEL VIVILLE*, FRANÇOIS CHABAUX, PETER STILLE, MARIE-CLAIRE PIERRET, SOPHIE GANGLOFF AND SYLVAIN BENARIOUMLIL

EOST-LHYGES (CNRS/Uni. Strasbourg), 1, rue Blessig, F-67084 Strasbourg Cedex, France (*correspondence: dviville@unistra.fr)

Understanding the relationship between chemical weathering and physical erosion rates is an important issue of Surface and Environmental Science. The determination of the relationships and parameters controlling chemical weathering and physical erosion can be achieved, among others, by comparing weathering and erosion fluxes measured at the outlet of small experimental watersheds. Astonishing is the fact, that numerous studies of chemical weathering fluxes exist and that only a few focused on erosion fluxes. This is for instance the case for the Strengbach catchment, for which geochemical budgets have been established since the mid 80ties but physical erosion rates only since very recently.

The aim of this study is to assess the physical erosion rate of the granitic Strengbach catchment (0.8 km^2, Vosges Massif, Eastern France) with the dissolved flux carried by the streamlet.

The results show that the erosion rate (about 5 T. km^{-2}. yr^{-1}) is at least equivalent to the chemical weathering rate and could be twice depending on the weathering rate retained corrections (atmospherical, biological). They also indicate that the erosion rate based on the lonely suspended matters calculation induces an underestimation of about 30%.

On the basis of this work, it appears that the weathering and erosion budgets determined on the Strengbach catchment do not differ significantly from other granitoids catchments studied previously.

Marine Mo isotope inventory: The role of igneous rock weathering

A.R. VOEGELIN[1]*, TH.F. NÄGLER[1], N. NEUBERT[2], T. PETTKE[1], M. STEINMANN[3] AND O. POURRET[4]

[1]Institut für Geologie, Universität Bern, Switzerland (*correspondence: voegelin@geo.unibe.ch)
[2]Institut für Mineralogie, Leibniz Universität Hannover, Germany
[3]UMR 6249 Chrono-Environment, Université de Franche-Compté, France
[4]HydrISE, LaSalle Beauvais, 60026 Beauvais cedex, France

The marine isotope inventory strongly depends on fractionation processes during continental rock weathering and subsequent river transport. Concerning molybdenum (Mo), the riverine contribution accounts for the largest part of the marine budget (e.g. [1]). Models of oceanic Mo cycling thus strongly depend on understanding continental processes causing Mo isotope fractionation.

This study investigates the effect of igneous crustal rock weathering on aquatic $\delta^{98/95}$Mo signals by comparing stream water and bedrock (basalt, granite, gneiss) Mo isotope data to results of laboratory leach experiments. Stream waters analyzed here are enriched in the heavy isotopes, a result in line with findings of previous studies [2-4]. To date, weathering of magmatic rocks has not been associated with resolvable Mo fractionation, as their $\delta^{98/95}$Mo show little variability ($\delta^{98/95}$Mo = -0.1 to 0.3‰, [5]). Incongruent mineral weathering and/or adsorption/resorption processes are the most likely factors to have caused the observed signals, while soil retention and adsorption of light Mo to the particulate load play a secondary role. This interpretation, based on water and bedrock samples, is supported by data of bedrock leach experiments, where leach solutions show a moderate fluctuation in $\delta^{98/95}$Mo between 0.5 and 1‰. This is nearly identical to the variability found in the stream waters (0.6-1.1‰). Sulfide oxidation was proposed to be an important factor controlling stream water Mo isotopic composition in a catchment underlain by sedimentary rocks [4]. Considering that silicate rocks may contain sulfides with variable isotope signatures, their incongruent dissolution could generate the observed aqueous $\delta^{98/95}$Mo signals.

Nanoparticulate Fe(III)-precipitates forming by Fe(II) oxidation in water

A. VOEGELIN*, S. SCHWARZ, S.J. HUG AND R. KAEGI

Eawag, Swiss Federal Institute of Aquatic Science and Technology, CH-8600 Duebendorf, Switzerland (*correspondence: andreas.voegelin@eawag.ch)

The oxidation of dissolved Fe(II) at oxic/anoxic boundaries leads to the precipitation of nanoparticulate Fe(III)-phases that profoundly impact the biogeochemical cycling of Fe and the fate of other major and trace elements in environmental systems. Despite the importance of Fe(III)-precipitates as immobilizing sorbents or colloidal carriers for contaminants and nutrients, numerous questions relating to their formation, their structural diversity and resulting differences in reactivity remain to be resolved.

Own recent work on Fe(III)-precipitates formed in aerated Fe(II)-containing aqueous solutions at pH 7 indicated the importance of Fe(III)-phosphates [1, 2]: At molar dissolved P/Fe (II) ratios >0.5, we observed exclusive formation of amorphous Fe(III)-phosphates that also incorporated substantial amounts of Ca. At P/Fe(II) <0.5, we concluded from X-ray absorption spectroscopy data that Fe(III)-phosphate formed until P was depleted, followed by the formation of other F(III)-phases (Si-rich hydrous ferric oxide at Si/Fe > 0.5, 2-line ferrihydrite at Si/Fe ~0.2-0.5, or lepidocrocite at Si/Fe <0.2) [1]. Electron microscopy data suggested that the different Fe(III)-phases became mixed in nanoparticles with diameters of a few 10-100 nm [2].

In continuing work, we aim (i) to resolve the composition and structure of Fe(III)-phosphates and the mode of cation and anion incorporation (Ca versus Mg, phosphate versus arsenate), (ii) to evaluate the transformation of different types of fresh precipitates during aging, and (iii) to assess how the different types of fresh Fe(III)-precipitates and their aging products affect other major and trace elements in aquatic systems. This work is based on controlled laboratory experiments in synthetic aqueous solutions, complemented by studies on real systems such as diagenetic Fe accumulations in lake sediments or As-removal units for drinking water treatment.

The partitioning of volatile elements between metal and silicate at high pressures and temperatures

A.K. VOGEL[1]*, D.C. RUBIE[1], D.J. FROST[1] AND H. PALME[2]

[1]Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany (*correspondence: antje-kathrin.vogel@uni-bayreuth.de)

[2]Forschungsinstitut und Naturmuseum Senckenberg, D-60325 Frankfurt, Germany

Volatile elements are depleted in the Earth´s mantle and in nearly all other solid objects of the inner solar system (Moon, Mars, meteorites), most probably because they failed to condense at high temperatures. In some cases evaporation before or during accretion may also have occurred. Many of these elements were additionally affected by core formation. To disentangle primary depletion and depletion by core formation and to provide additional clues for the processes of core formation we studied the metal - silicate partitioning behaviour of the volatile siderophile elements Sn, Pb P, Cu and Ge, covering a range of 650 K in condensation temperatures.

Experiments were performed over a pressure and temperature range of 10.5 GPa to 23 GPa and 2273 K to 2673 K respectively using a multianvil apparatus. The oxygen fugacity varied from -2.0 to -2.4 log units relative to the iron-wüstite-buffer. The starting materials consisted of 3 parts (by weight) silicate (peridotitic composition) and 1 part (by weight) metal, with the latter consisting of 95 wt% Fe, and 1 wt% of P_2O_5, Cu, GeO_2, SnO and Pb_3O_4 respectively. To consider the effect of S one experiment was performed with 10wt% S added as FeS to the metal phase of the starting material. Analyses of the metal phases were performed with an EPMA, the compositions of the silicate phases were analyzed by LA-ICP-MS.

The volatile elements Sn and Pb are similarly depleted in the Earth´s mantle, which requires similar effective partition coefficients ($D^{met/sil}$) during core formation. However, at low pressures the partition coefficients of Sn and Pb differ by up to two orders of magnitude. Our results show that the liquid metal – liquid silicate partition coefficients of Sn and Pb converge with increasing pressure, indicating that equilibration pressures of at least 30 GPa were necessary to avoid fractionating them in the Earth´s mantle.

We found that 10 wt.% S in the metal phase has hardly any influende on the $D^{met/sil}$ of Pb but lowers the value for Sn by about 0.6 orders of magnitude.

Isotope reference materials for present and future isotope research

JOCHEN VOGL* AND WOLFGANG PRITZKOW

BAM Federal Institute for Materials Research and Testing, Berlin, Germany (*correspondence: jochen.vogl@bam.de)

The variation of isotope abundance ratios is increasingly used to unravell natural and technical questions. In the past the investigation and interpretation of such variations was the field of a limited number of experts. With new upcoming techniques and research topics in the last decades, such as provenance and authenticity of food, the number of published isotope data strongly increased. The development of inductively coupled plasma mass spectrometers (ICPMS) from an instrument for simple quantitative analysis to highly sophisticated isotope abundance ratio machines influenced this process significantly. While in former times only experts in mass spectrometry were able to produce reproducible isotope data, nowadays many laboratories, never been in touch with mass spectrometry before, produce isotope data with an ICPMS. Especially for such user isotope reference materials (IRM) are indispensible to enable a reliable method validation. The fast development and the broad availability of ICPMS also lead to an expansion of the classical research areas and new elements are under investigation. Here all users require IRM to correct for mass fractionation or mass discrimination or at least to enable isotope data related to a common accepted basis. Despite this growing interest suitable IRM are still lacking for a number of isotope systems such as magnesium.

For all isotope abundance ratio applications reference materials are necessary either for correction of mass fractionation/mass discrimination, for method validation or to provide a common accepted basis. The production of these urgently needed IRM, however, has stagnated within the past decades. Reasons might be that the scientific relevance often has not been realized; time and effort seemed not in balance with the scientific gain. Recently the situation has changed slightly, as researcher at NIST resumed their work and BAM and NRC started working on IRM.

The needs for present research on isotope variations are being considered and are compared to the limitations of current isotope reference materials within this presentation. The resulting disagreement between both is being discussed and solutions will be provided.

Geochemical consequences of thermomechanical processes in subduction zones. Implications for crustal making processes

KATHARINA VOGT[1], TARAS GERYA[1,2] AND ANTONIO CASTRO[3]

[1]Swiss Federal Institute of Technology (ETH-Zurich), 8092 Zurich, Switzerland
[2]Moscow State University, 119899 Moscow, Russia
[3]University of Huelva, 21071 Huelva, Spain

We have analyzed the dynamics of crustal growth processes at active continental margins based on a 2D coupled petrological-thermomechanical numerical model of an oceanic-continental subduction zone. The model includes spontaneous slab retreat and bending, dehydration of subducted crust, aqueous fluid transport, partial melting, melt extraction and melt emplacement in form of both extrusive volcanics and intrusive plutons.

Our results show that the rate of crust formation and the composition of newly formed crust are strongly depended on the degree of rheological weakening induced by fluids percolating from the subducting slab and upwards propagating melts. Subsequently we could identify the following geodynamic regimes: (i) stable arcs (ii) compressional arcs with plume development and (iii) extensional arcs.

Crust formation in stable arc settings is characterized by flattened intrusions and low crustal growth rates. At first dacitic melts are produced due to partial melting of the slab nose, followed by flux melting of wet peridotite. In compressional arcs the emplacement of hybrid plumes adds additional material to the continantal crust. Partially molten rock melanges composed of basalts and sediments accumulate at asthenospheric depth forming plumes, which rise through the mantle prior to emplacement. We have calculated the isotopic initial ratios of Sr and Nd in the plume during the simulations, showing that the geochemical signature varies strongly with the basalt/(basalt+sediment) fraction in the plume. These signatures are transferred to andesitic magmas and finally confirm the geochemical signatures of the continental crust.

Crustal growth in extensional arc settings is accomplished by decompression melting of dry peridotite, leading to elevated crustal growth rates.

Experimental weathering of micas in acid soils conditions: Contribution of boron isotopes

A. VOINOT[1,2] *, D. LEMARCHAND[1], M-P. TURPAULT[2] AND F. CHABAUX[1]

[1]LHYGES, CNRS-UDS, Strasbourg, France (*correspondence: alexandre.voinot@etu.unistra.fr)
[2]BEF, INRA, Champenoux, France

Soil minerals evolve by contact with weathering agents (protons, organic acids and ligands) supplied by atmospheric inputs or produced by coexisting living organisms. Determination of their relative contribution and seeing if they interact with soil minerals through different mechanisms is a key step toward identification of the pedogenic processes in action and soil sustainability.

In order to test if different weathering agents can induce specific and traceable mechanisms (dissolution vs. transformation), we lead a series of laboratory experiments intended to investigate the behavior of phyllosilicate minerals in contact with 3 different chemical reactants: HCl (protons), citric acid (organic acids) and siderophores (ligands). These experiments were performed at 2 different pH conditions (pH3 and pH4.5) for 37 days at 20°C in a continuous flow system. Biotite was selected as test mineral because it is a common and reactive mineral in soils. To trace weathering reactions, we monitored the boron chemical and isotopic compositions in the outflowing solutions. The choice of B as weathering proxy is based on its balanced distribution between minerals sites (interlayers and tetrahedral sites). Moreover, each of these sites have distinct B isotopic signatures [1], in line with the large isotopic fractionation generated by weathering reactions [2].

Comparison of B and major elements in solution reveals that all experiments conducted at pH3 and citric acid at pH4.5 lead to predominant dissolution reactions. By contrast, reactions conducted at pH4.5 with HCl and siderophores show a large removal of isotopically fractionnated boron, indicating a predominant contribution of interlayer sites and a large transformation (vermiculitization) of the biotite.

Proterozoic magmatism

O. VOLCAN

oasisvolcan@yahoo.com

Proterozoic magmatism along the margin of the Yangtze Block is extensive and provides important evidence in the plate tectonic reconstructions for the Proterozoic.The wangcang area on the northwestern margin of the Yangtze Block consists of complex Archean to early Proterozoic crystalline basement and a suite of high-grade metamorphic rocks surrounded by late Neoproterozoic to Phanerozoic sedimentary covers.In the the northwestern margin of the Yangtze craton there were found many bodies as tectonic blocks of greenshist rocks, which were named Hekou Formation. Single- grains zircon U–Pb TIMS dating of andesite-dacite indicates that the Hekou Formation erupted at 882 ± 69 Ma. This is a new time for volcanics rocks found along the margin of the Yangtze Block.

Spatial pollution gradients in Central Europe after 25 years of decreasing industrial emissions

P. VOLDRICHOVA[1,2]*, M. NOVAK[1], L. ERBANOVA[1], E. PRECHOVA[1], F. VESELOVSKY AND V. BLAHA[1]

[1]Department of Geochemistry, Czech Geological Survey, Geologicka 5, 152 00 Prague 5, Czech Republic (*correspondence: petra.voldrichova@geology.cz)

[2]Department of Analytical Chemistry, Faculty of Science, Charles University in Prague, Albertov 6, 128 43 Prague 2, Czech Republic

Industrial pollution in the Czech Republic (Central Europe) peaked in the mid-1980s. Soft coal combustion in the north of the country was one of the largest sources of many trace elements for the atmosphere and ecosystems. Introduction of more advanced technology in the 1990s led to a steep decrease in nationwide industrial emission rates of pollutants. In the mid-1980s, the Northern Czech Republic was 4 to 10 times more polluted than the Southern Czech Republic, which is less industrialized. In 2009, we established a new network of 10 monitoring stations near the borders between the Czech Republic, Germany, Austria and Poland. Samples of vertical and horizontal atmospheric deposition (snow and ice accretions, respectively) are collected each winter (Oct. 15- April 15). Monitoring sites are situated on mountaintops at an elevation of 1000 m. All samples are treated in a clean laboratory (class 7). Concentration of 19 elements (Al, As, Bi, Be, Cu, Co, Cr, Cd, Fe, Mn, Ni, Pb, Sb, Sc, Ti, Th, U, V, and Zn) is determined using SF ICP MS. Preliminary data from 2009 suggest that, for most of the environmentally relevant elements, spatial pollution gradients differ from previous decades. For example, for arsenic (As) and lead (Pb), the eastern part of the country (Jeseniky and Beskydy Mts.) exhibits the highest pollution loads. At the same time, the northern and southern part of the country show lower pollution loads. The northern part of the country, situated near a cluster of coal-burning power plants, experienced a faster decrease in pollution rates over the past 25 years than the south; its current atmospheric deposition is not significantly higher than in the south. For antimony (Sb), all 10 sites have similar atmospheric inputs. For zinc (Zn), the highest concentrations in atmospheric input were found in the northwest. Novohradske Mts. (south) have similar Zn inputs as Jizerske Mts. (north). Overall, pollution levels are up to 20 times lower compared to the late 1980s. They are more site-specific, and reflect temporal changes in operation of distant vs. local point sources of pollution.

The Paleozoic $\delta^{88/86}Sr_{seawater}$ record – Quantifying carbonate production rates at mass extinction events

H. VOLLSTAEDT[1]*, A. EISENHAUER[1], F. BÖHM[1], J. FIETZKE[1], A. KRABBENHÖFT[1], V. LIEBETRAU[1], J. FARKAŠ[2] AND J. VÉIZER[3]

[1]Leibniz-Institut für Meereswissenschaften (IFM-GEOMAR), Wischhofstr. 1-3, D-24148 Kiel, Germany (*correspondence: hvollstaedt@ifm-geomar.de)

[2]Czech Geological Survey, Geologicka 6, 152 00 Praha 5, Czech Republic

[3]University of Ottawa, Dept. of Earth Sciences, 140 Louis Pasteur, Ottawa, Canada K1N 6N5

Within the Phanerozoic Eon strata boundaries are often associated with the extinction of marine organisms. The reasons for these events are still discussed and a quantification of observed changes in the marine carbonate system is missing.

Strontium (Sr) is one of the most important divalent cations in calcium carbonate minerals and a carrier of important proxy information. In terms of the Sr output flux of the ocean ($\delta^{88/86}Sr_{seawater}$: ~0.39‰), isotopically light carbonates ($\delta^{88/86}Sr_{carbonates}$: ~0.15 – 0.25‰) represent the major Sr sink. Consequently, variations in Sr/Ca and paired $^{87}Sr/^{86}Sr$-$\delta^{88/86}Sr$ values are a suitable tool to investigate the global carbonate budget throughout Earth's history including the biotic turnover of calcifying organisms at stratigraphic boundaries. Latter processes are expected to have a large influence on Sr geochemistry and isotope composition of seawater.

We measured paired $^{87}Sr/^{86}Sr$-$\delta^{88/86}Sr$ ratios of ~120 modern and Paleozoic marine brachiopod samples which were screened for diagenetic alteration prior to the measurement. Reproducibility of double spike-derived $\delta^{88/86}Sr$ based on an international coral carbonate standard (JCp-1) is 0.019‰ (2SD, n=26).

We observe major drops in $\delta^{88/86}Sr_{seawater}$ of 0.05 – 0.15‰ at mass extinction events which coincide with a decrease of 10-50% in the number of marine genera [1]. This emphasizes the strong coupling of the carbonate system to $\delta^{88/86}Sr$ of seawater. In contrast, $\delta^{44/40}Ca_{seawater}$ changes are much less pronounced at these biotic turnovers. Furthermore, excursions in $\delta^{13}C_{carbonate}$ at strata boundaries are related to changes in the organic carbon production rather than to the carbonate production.

By taking changes in $^{87}Sr/^{86}Sr$, $\delta^{88/86}Sr$ and Sr/Ca into account we are able to make quantitive statements on the Sr input and output fluxes of the ocean at the major Paleozoic mass extinction events, including the Permian/Triassic boundary.

Unconventional matrices prevent novel isotopes turning traditional

F. VON BLANCKENBURG[1], J. BOUCHEZ[1], M. GUELKE-STELLING[2], M. OELZE[1], C. OSTERTAG-HENNING[3], J. SCHUESSLER[1] AND G. STEINHOEFEL[1]

[1]Earth Surface Geochemistry at GFZ German Centre for Geosciences, Potsdam, Germany (fvb@gfz-potsdam.de)
[2]KIT, Mineralogy and Geochemistry, Karlsruhe, Germany
[3]Bundesanst. Geowiss. Rohstoffe BGR, Hannover, Germany

Do 'non'-traditional isotopes still deserve their prefix? It only takes a look at your preferred stable isotope systems compilation to realise that variations are largest in the biosphere and its geologic derivatives. Hence, to move the field into the next decade, and beyond the Geosciences, we need to develop tools to cater for matrices that are by any geological standard non-traditional. Here we review progress on this effort from our laboratories' past years work.

Biomedical

Metal isotopes are superb tools to trace the process and timing humans metabolize nutrients. Each human bears a distinct stable Fe isotope signature in its blood, which is identical to that in muscle tissue and that of blood plasma, suggesting that this characteristic ratio is set when Fe is received by the transferrin molecule during intestinal absorption.

Plant Physiology and human nutrition

Higher plants induce substantial fractionation of Mg, Si, Ca, Fe, and Zn isotopes. Fe isotope fractionation has been shown to differ between grasses and non-grasses, where the former are enriched in light Fe through reduction in soils, and the latter take up unfractionated complexed Fe(III). Plants induce similar fractionation as metals are being moved through their tissue.

Crude oil

First results of various types of crude oil yielded surprisingly heavy Fe isotope compositions, tracing bacterial iron oxidation/reduction processes during oil biodegradation in the reservoirs.

Weathering at the micrometer scale

The large diversity of weathering and biotic products in soils requires detection of their isotope variability at the micro-scale. We have now developed a second-generation UV-femtosecond laser ablation system, and measure novel stable isotopes in bulk soil (as fused glass beads or powder pellets), at the mineral scale in thin sections, individual phytoliths, and by ablating fluids after element separation and evaporation.

The challenge to all these cases is to (1) develop taylor-made matrix-suited methods; (2) demonstrate that the analyses are free of artefacts, requiring reference materials; (3) understand the underlying processes - the ultimate aim.

The ^{10}Be(meteoric)/^{9}Be ratio as a tracer of weathering and erosion

F. VON BLANCKENBURG*, H. WITTMANN AND N. DANNHAUS

Earth Surface Geochemistry at GFZ German Centre for Geosciences, Potsdam, Germany
(*correspondence: fvb@gfz-potsdam.de)

We provide a systematic framework to derive weathering and erosion rates from the ratio of the meteoric cosmogenic nuclide ^{10}Be to stable ^{9}Be, suggested to serve as proxy for weathering and erosion over the late Cenozoic [1].

In a weathering zone some of the ^{9}Be, present in silicate minerals, is released and partitioned between a reactive phase (adsorbed to clay and hydroxide surfaces), given the high partition coefficients at intermediate pH, and to a minor degree into the dissolved phase in pore waters. The combined mass flux of both phases is defined by the soil formation rate times a mineral dissolution rate – and is hence proportional to the chemical weathering rate. The surface of the weathering zone is continuously exposed to fallout of meteoric ^{10}Be. This ^{10}Be percolates into the weathering zone where it mixes with dissolved ^{9}Be. Both isotopes may exchange with the adsorbed Be, given that equilibration rates of Be are fast relative to soil residence times. Hence a ^{10}Be/^{9}Be (reactive) ratio results from which the ^{9}Be weathering flux can be calculated given that the delivery rate of ^{10}Be is now often known. If the loss of ^{10}Be into the dissolved phase is furthermore small, the ratio of ^{10}Be (reactive) to that of the residual mineral-bound ^{9}Be provides a physical erosion rate.

We have tested this approach in sediment of the Amazon and Orinoco basin, and compared it to dissolved Be isotope data [2]. The reactive Be was extracted from sediment by combined hydroxylamine and HCl leaches. In the Amazon trunk stream, the Orinoco, Apure, and La Tigra river ^{10}Be/^{9}Be (dissolved) agrees well with ^{10}Be/^{9}Be (reactive), showing that in most rivers these two phases also equilibrate. ^{10}Be/^{9}Be ratios range from 5×10^{-9} for the Brazilian shield rivers to 2×10^{-10} for the Beni river draining the Andes, corresponding to denudation rates of 0.01mm/yr for the shields and 0.5mm/yr for the Andes, compatible with denudation rates from *in situ*-produced cosmogenic ^{10}Be [3]. 10-50% of the ^{9}Be was mobilised from bedrock.

Once delivered to the ocean, this riverine Be, be it dissolved or reactive, will eventually drive ^{10}Be/^{9}Be ratios of ocean water and disclose global weathering rates.

Apatite composition of Southern Germany volcanoes: Clues to origin and magmatic evolution

A. VON DER HANDT[1] AND M.K. RAHN[2]

[1]Geowissenschaftliches Institut, University of Freiburg 79104 Freiburg, Germany
[2]Swiss Federal Nuclear Safety Inspectorate (ENSI), 5200 Brugg, Switzerland

Volcanic activity in SW Germany has focussed along the Upper Rhine graben (with volcanic centres at Kaiserstuhl and Odin's Forest). In addition, eruptive centres are also found far away from known tectonic lines in the Urach and Hegau areas. Dating of these rocks reveals an extended period of activity along the Upper Rhine graben (60-15 Ma [1]), while activity in isolated centres was relatively short (Kaiserstuhl: 16-19 Ma [1, 2], Hegau: 15-7 Ma [3, 4]), Urach: 17-? Ma [5]).

Apatite is a common mineral in many of the eruptive products, which are mostly of mafic to ultramafic as well as carbonatitic composition. Previous studies on these apatites (e.g. Rahn and Selbekk 2008) have shown that their composition is variable with respect to Si and S (replacing P) as well as OH and Cl (replacing F). Thus the question arises whether apatite could be used as an indicator of magmatic evolution and whether there are clear differences to be found, which allow a distinction between the Kaiserstuhl, Hegau and Urach eruptive centres on the basis of apatite composition.

In order to evaluate the compositional evolution, apatites from the Kaiserstuhl and Hegau were dated using the fission track technique. Dated samples were analysed by means of EPMA and SIMS to obtain major and trace element data and check for sample internal variation. Both, Kaiserstuhl and Hegau volcanics show a large compositional range from F-rich to OH-rich chemistry, with Cl-endmember lower than 5%. Apatites close to OH endmember are restricted to samples from the Hegau. A clear distinction of sources is possible on the basis of Sr, Zr and REE element contents. Hegau apatites show a wider spread in magmatic REE fractionation, together with flatter chrondrite REE patterns. Combination of age and compositional data allows to clearly attribute distant tuff layers to the Hegau, while no such layers show Kaiserstuhl characteristics. Erupted material from the Hegau has faced up to 80 km of westward air transportation.

Chemical speciation of Fe-rich colloids and nanoparticles in the Southern Ocean

B.P. VON DER HEYDEN[1]*, A.N. ROYCHOUDHURY[1] AND S.C.B. MYNENI[2]

[1]Dept. of Earth Sciences, Stellenbosch University, Stellenbosch 7602, South Africa (*correspondence: bvon@sun.ac.za)
[2]Dept. of Geosciences, Princeton University, Princeton, NJ 08544, USA

Iron is an important nutrient and limits the productivity in the Southern Ocean. Previous biogeochemical studies largely focused on the size-dependent Fe-pools in ocean water with little attention to the chemical speciation of iron. As a result, molecular level factors affecting the bioavailability of particle-bound iron are largely unexplained.

Using clean techniques, samples were collected along two transects between Cape Town, Antarctica and the South Georgia Islands. Iron particles were trapped on 0.2μm filters and subsequently analyzed in their pristine state using *in situ* L-edge XANES spectroscopy and high-resolution scanning transmission X-ray microscopy. Chemical speciation of the discreet, quasi-spherical particles was accomplished through a combination of the spectral shape analysis and the quantitave parameterization of the L_3-edge splitting.

From these spectroscopic analyses, particles in Southern Ocean could be classified into five broad categories including ferric oxides, magnetite, other mixed valence species and at least two ferrous species. A distinct spatial variation in iron speciation was also evident with ferric species predominating in the mid-latitudes (32°S- 55°S) and ferrous-rich species more common in the high latitudes. A number of mixed-valence species, including magnetite, made up a significant proportion of the particles found to the north of the Polar Front. Proximal to the African- and South Georgian shelves, Al-substitution, a solubility-depressing effect, was observed to occur in the ferric species. The substituted Al in iron oxides displayed a gibbsite-like structure.

We are currently evaluating the cause of this spatial and chemical variability, which may be attributed to the particle source, and to a range of processes including photochemical response and biological interactions. However, it is clear that such variability in speciation will have a profound impact on Fe solubility and iron-ligand interaction, thereby influencing the Fe-pool that is bioavailable.

Clay mineralogy and chemical environment of an Aptian lacustrine succession in North-Eastern Brazil

W. VORTISCH[1]*, V.H. NEUMANN[2], R. GRATZER[1] AND D. ROCHA[2]

[1]Montanuniversität Leoben, 8700 Leoben, Austria (*correspondence: Walter.Vortisch@unileoben.ac.at, gratzer@unileoben.ac.at)

[2]Universidade Federal de Pernambuco, Dep. de Geologia, Recife, Brazil (neumann@ufpe.br, dunaldson@msn.com)

The studied core was drilled in the Jatobá Basin, which is underlain and surrounded by the crystalline basement of the Borborema Province (NE Brazil).

113 samples were analysed by X-ray diffractometry, 17 of which were selected for clay mineral analysis. Sandstones were also studied by polarising microscopy and scanning electron microscopy.

Petrographically, 5 lithotypes can be defined: (1) generally silty grey shales, (2) grey marly shales to shaly marls, (3) generally fine-grained, argilaceous sandstones (4) micritic limestones, occasionally with a minor content of dolomite, (5) dolostone (dolomite > calcite).

In many of the shales, expandable clay minerals are dominant among the clay mineral suite (predominantly illite-smectite), followed by illite, kaolinite and chlorite.

In contrast to the shales, sandstones can contain considerable amounts of smectite, besides illite and minor proportions of kaolinite and chlorite. Quartz and feldspars are usually main components. Calcite is sometimes present. Some of the sandstones show high contents of unweathered biotite, often marking sedimentary structures like ripple crossbedding as dark layers.

The presence of chlorite and biotite as clastic components, indicate mild regional weathering, and/or fast erosion and transport to the lacustrine basin. Smectite occurring in the sandstones indicates volcanic activity.

The ocurrence of dolomite is uncommon for lacustrine freshwater environments. Freshwater conditions are indicated by oxygen isotopes [1] and ostracods. The occurrence of dolomite together with high organic matter content and intensive bacterial activity may explain lacustrine dolomite formation without evaporitic conditions.

[3]ETH, Zürich 8092, Switzerland

[4]UFV, Abbotsford V2S-7M8, Canada

River systems present a significant challenge to quantification of global elemental fluxes among atmospheric, terrestrial, and marine reservoirs, as aquatic passageways exhibit complex processing and storage of material on timescales driven by local and distant climatic and geophysical cycles [1-3]. The Fraser River basin in southwestern Canada has three important features making it ideal for testing geochemical approaches to tackling these issues: 1) its moderate size and temperate climate are neither exceptional nor insignificant among global rivers; 2) a spectacular diversity of bedrock geology and vegetation allow for discrimination of sources of transported material; and 3) its modest industrial footprint allows for assessment of relatively unperturbed processes. Three recent field campaigns at low, medium, and high water flow have generated a broad dataset of informative geochemical parameters. Dissolved $^{87}Sr/^{86}Sr$ signatures of major tributaries and daily discharge data form the backbone of a preliminary attempt to model the geochemical variability of exported material across the hydrograph. Over one full year of time series sampling near the Fraser mouth has demonstrated that subannual variability in dissolved $^{87}Sr/^{86}Sr$ is significant and mirrors temporal and spatial changes in the hydrology of the basin. Extending this approach to other elemental fluxes of interest and other river basins will vastly improve global biogeochemical budgets and the potential to predict future changes.

Review of geochemical problems and mitigation during the production of geothermal reservoirs

FRANCOIS-D. VUATAZ AND NIELS GIROUD

Laboratory for Geothermics - CREGE, University of Neuchatel, CH-2000 Neuchatel, Switzerland (francois.vuataz@unine.ch)

Introduction

In many geothermal fields worldwide, production and reinjection of hot brines modify the temperature and pressure conditions around the wells. This induces geochemical processes within the reservoir and/or along the well casings and the surface pipelines. Some geothermal fluids are relatively benign even at high temperature, whereas others can cause numerous problems due to either a high salinity or a high content of particular gases or dissolved solids. Permeability decrease, well and pipeline partial plugging or metal corrosion are the main consequences of these chemical processes. If they are not taken seriously into consideration and solved, the outcome can be a production decrease, a high maintenance cost, or even the loss of a well.

Mineral scaling

Due to the high solubility of silica at high temperature, silica scaling is a frequent problem in geothermal plants. Amorphous silica precipitates after flashing or cooling of the fluid in surface pipelines or reinjection wells. Silica can be removed from the fluid and exploited commercially as a by-product. Carbonate scaling occurs in carbonate reservoirs and CO_2-rich fluids. Other minerals can form scales, such as anhydrite, sulphides and oxides.

Metal corrosion

Various types of corrosion are observed on well casings and surface pipelines, due to dissolved H_2S and CO_2, high chloride content or gas exsolution. Numerous laboratory experiments on the corrosion processes have been performed, but the results often differ from on-site monitoring experiments of the corrosion processes.

The Earth mantle is mainly composed of silicates and its carbon contents is very low, of the order of 10 to 500 ppmw [1]. However carbon and its oxidized forms as carbonates and CO_2, likely play a crucial role in the dynamics and chemical differentiation of the mantle. The onset of partial melting at about 300km deep in the mantle, corresponds to the formation of liquid carbonates or carbonatites. In the astenosphere, the observed electrical conductivity anomalies [2] could originate from carbonatitic magmas exhibiting a very large conductivity, about 100 to 100 000 times that of olivine. However the physical and chemical properties of carbonatites at mantle conditions are poorly known and some theoretical guidance could be useful in this context.

We present a First-principles Molecular Dynamics simulation study of liquid $CaCO_3$. Its structural and transport properties have been investigated in the (T, P) range 1000-2000K and 0-6 GPa. Diffusion constants are found in good agreement with available data on viscosity [3]. Surprisingly CO_3^{2-} units diffuse nearly as fast as the Ca^{2+} cations. Because of the fast dynamics into the melt it was also possible to estimate the ionic conductivity. For the investigated thermodynamic conditions, we found an ionic conductivity close to 100 S. m^{-1}, in agreement with the available experimental data [2]. The local structure around the CO_3^{2-} anions has been studied in details and appears to be quite complex, sharing some similarities with the crystalline polymorphs calcite and aragonite. Simulation data on vibrational spectroscopy of liquid $CaCO_3$ will also be presented.

A low sulphur epithermal gold mineralisation in Kisacik-Ayvacik area (Çanakkale-Turkey)

ALAADDIN VURAL[1], DOĞAN AYDAL[2] AND İBRAHIM AKPINAR[1]

[1]Gumushane University, Engineering Faculty, Geological Engineering Department, Baglarbasi, 29100, Gumushane, Turkey (*correspondence: vural@gumushane.edu.tr) (hiakpinar@gumushane.edu.tr)

[2]Ankara University, Engineering Faculty, Geological Engineering Department, 06100, Tandoğan, Ankara, Turkey (aydal@ankara.edu.tr)

Kısacık-Ayvacık area is located in northern part of Küçükkuyu (Çanakkale), town within Biga Peninsula, northwestern Anatolia, Turkey. In general, throughout the area magmatic rocks and ultramafic rocks, sporadically at their contacts, are seen.

The purpose of this work is to investigate the occurrences conditions, types, places of gold enrichment and probing the genetics of gold enrichment in Kısacık-Ayvacık area along with outlining alteration distribution, petrographic and ore mineralogy features of the rocks in the region. In general, Pre-Tertiary rock units of Kazdağı Group and ophiolitic melange, and Tertiary magmatic rocks consisting altered haematitized-silicified andesite, rhyolite, ignimbrite, quartz porphyry and pyroclastic rocks are present. These rocks have subalkaline composition, nevertheless showing a calcalkaline tendency.

The gold mineralizations in Kısacık-Ayvacık area are observed within altered volcanic rocks of dacite, andesite and tuffs. These rocks have galena, pyrite, chalcopyrite, graphite, and haematite minerals and mineralisation of invisible gold enrichment. Gold values in studied volcanic rocks changes between 40 ppb-8500 ppb. Occurences temperatures of gold mineralizations change between 190 °C and 290 °C, salinity 0-7 % NaCl and S isotope values are mostly near zero. Consequently, these values imply a low-sulphidized epithermal type gold mineralization in the study area.

Application of experimental mineralogy to the description of new platinum-group minerals

A. VYMAZALOVÁ[1]*, M. DRÁBEK[1] AND F. ZACCARINI[2]

[1]Czech Geological Survey, Geologicka 6, 152 00 Prague 5, Czech Republic (*correspondence: anna.vymazalova@geology.cz)

[2]University of Leoben, Peter Tunner Str.5, A8700 Leoben, Austria (federica.zaccarini@unileoben.ac.at)

According to [1] there are more that 500 platinum-group (PG) phases termed as unidentified and require complete or clearer identification to be approved as new mineral species, in particular crystallographic characterization is often missing. One of the significant tools enabling the better characterisation of a natural phase can be an application of a synthetic material. The advantage is that the synthetic PG-phases are prepared in a required amount, under controlled chemical and physical parameters, such as chemical composition and temperature. The synthetic PG-phase can be thus applied as a comparative and descriptive material of a natural analogue. Such approach has been used in case of description of milotaite (PdSbSe) [2] or pašavaite ($Pd_3Pb_2Te_2$) [3]. The synthetic material should display the identical optical and physical (microhardness and reflectance) properties and chemical identity with natural sample. Significant role plays the structural identity of natural and synthetic material that has to be also proved. Electron back-scattering diffraction (EBSD) study can be applied to support structural identity. Furthermore the Raman spectroscopy, a nondestructive, structurally sensitive technique, suitable for grains of small mineral size (less than 10 microns) such of those of PGM is a sufficient method to prove structural identity.

Focusing of upward fluid migration due to mineral grain size variation

I. WADA[1]*, M.D. BEHN[1], E.M. PARMENTIER[2] AND A.M. SHAW[1]

[1]Woods Hole Oceanographic Institution, Woods Hole, MA, 102543, USA (*correspondence: iwada@whoi.edu, mbehn@whoi.edu, ashaw@whoi.edu)
[2]Brown University, Providence, RI, 02912, USA (em_parmentier@brown.edu)

In this study, we use numerical models to quantify the effect of mineral grain size on the migration path of aquous fluids in the mantle wedge. Grain size affects grain-scale permeability of the mantle and fluid migration, which is an important factor that controls the location of hydrous melting in the wedge. By coupling a subduction zone thermal model with a laboratory-derived grain size evolution model, we predict that the spatial variation in grain size in the flowing part of the mantle wedge is large; grain size increases from 10–100 μm in the shallowest part of the region beneath the forearc to a few cm in the hottest part of the mantle beneath the arc. Based on our preliminary modeling results, we find that aqueous fluids that migrate into the shallow fine-grain-size region become trapped in the down-going mantle due to low permeability and dragged downdip until permeability becomes high enough for the fluids to migrate upward. Thus, the grain size distribution can play an important role in controlling the location of hydrous melting by focusing the upward fluid migration. We plan to further develop our model by incorporating the effect of dynamic pressure gradients and accounting for the variation in fluid influx at the wedge base. Our modelling results will then be compared with the locations and degrees of hydrous melting inferred from geophysical and geochemical data for various arcs worldwide.

Metal-silicate partitioning of Mo and W at high pressures and temperatures: Applications to core formation on Earth and Mars

J. WADE[1] AND B. J. WOOD[2]

[1]Dept of Earth Sciences, University of Oxford, South Parks Rd, Oxford, OX1 3AN. (*Jon.Wade@earth.ox.ac.uk)
[2]Dept of Earth Sciences, University of Oxford, South Parks Rd, Oxford, OX1 3AN. (Bernie.Wood@earth.ox.ac.uk)

In order to place better constraints on the conditions of core formation on Earth and other terrestrial planetary bodies we have performed experiments to determine the partitioning of Mo and W between liquid Fe-rich metal and liquid silicate at pressures of 1.5-24 GPa and temperatures of 1803-2723K. Experiments performed in MgO capsules at 1.5 GPa/1923 K indicate that Mo is in the +4 oxidation state in the silicate at oxygen fugacities >2 log units below the IW (Fe-FeO) buffer. In contrast W^{6+} is the dominant tungsten oxidation state in the silicate at 1.9-3.2 log units below the IW buffer

Mo metal/silicate partitioning is strongly dependent on pressure and silicate melt composition, but temperature has no detectable effect. In contrast, we find that W partitioning is strongly dependent on silicate melt composition and temperature, but the role of pressure is minor.

Applying these and earlier results to the Earth and Mars indicates that the Mo content of the terrestrial mantle is consistent with core segregation at pressures of 20-40 GPa, in agreement with earlier work on Ni and Co partitioning. The Mo content of silicate Mars is about half that of silicate Earth and is consistent with much lower pressures of core formation (~11 GPa) on the smaller planet. In contrast to these results, the W content of silicate Mars (~50 ppb) is insensitive to conditions of core formation while that of silicate Earth (~12 ppb) is inconsistent with a single stage of core formation at any pressure. Since metal-silicate partitioning of W is strongly influenced by light element (S, Si, O) contents of the metal, we consider it likely that the “light” element in the core is largely responsible for the inconsistency in core-mantle partitioning of this element.

REE and stable isotope constraints on formation of metamorphic quartz veins: A case study from the Rhenish Massif (Germany)

T. WAGNER[1]*, A.J. BOYCE[2], J. ERZINGER[3]

[1]Geochemistry and Petrology, ETH Zurich, Switzerland (*correspondence: thomas.wagner@erdw.ethz.ch)
[2]Scottish Universities Environmental Research Center, Glasgow, UK
[3]GeoForschungsZentrum, Potsdam, Germany

We have investigated fluid-rock reactions during formation of metamorphic quartz veins in the fold-and-thrust belt of the Rhenish Massif (Germany). The veins record two assemblages that were formed in an evolving fluid-rock system, which are (1) massive vein filling (elongate-blocky quartz, chlorite, apatite, albite) and (2) open space filling (euhedral quartz crystals, carbonates, sulfides). We performed a detailed REE and stable isotope study of vein minerals, altered wall rocks and precursor host rock metapelites. The REE and oxygen isotope data of vein quartz and altered wall rocks, combined with mass balance analysis, support that local mobilization of material was dominant during formation of the early massive vein assemblage, but that contributions from advecting fluids were also important. The strong shift in K/Na ratios in altered wall rocks and model fluid temperatures that are higher (350-400 °C) than estimates for the host rocks point to substantial fluid advection. Formation of the veins can be explained by a crack-flow-seal model, with multiple repetition of vein opening, fluid advection and vein sealing events. Each cycle was initiated with vein opening, resulting in enhanced permeability and considerable fluid advection and hydrothermal alteration of wall rocks. Conditions during each cycle evolved towards a decrease in fluid advection, coupled with substantial diffusional leaching of silica and precipitation in the veins. The formation of the later open space filling assemblage records transition from an advection- to a diffusion-dominated regime. This is supported by vein mineral and fluid inclusion textures recording conditions of undisturbed mineral growth, fluid inclusion data that point to a thermally equilibrated state (150-200 °C), and stable isotope data that demonstrate a local source for the vein minerals.

From anoxia to oxic conditions in the aftermath of oceanic anoxic event 2 (Late Cretaceous)

M. WAGREICH

University of Vienna, Center for Earth Sciences, Althanstrasse 14, 1090 Vienna, Austria, (michael.wagreich@univie.ac.at)

Sections in the Ultrahelvetic units of the Eastern Alps (Austria) record oceanic anoxic event 2 (OAE 2) at the distal European continental margin of the western Tethys [1, 2]. Upper Cenomanian marl-limestone cycles are overlain by black, organic-rich (5% TOC, kerogen type II) layers, followed by Lower/Middle Turonian light grey to reddish marly limestones. Carbon isotope values display the well documented positive shift. The appearance of red-colored carbonates (CORB - Cretaceous Oceanic Red Beds) indicates a total time span of about 1.5 my for oxic bottom waters to become dominant. Orbital cycles of 400 kyr and 100 kyr frequencies are identified. Benthic foraminifera associations indicate repeated phases of enhanced organic matter flux and less aerated bottom waters during the transitional interval [3]. Sedimentation of red layers was controlled by periods of well oxygenated bottom waters, reduced sedimentation rates and degradation of organic matter in the underlying sediments. Principal component analysis of carbonate chemical data showed that the development of red coloured pelagic sediments is accompanied by a shift towards highly oligotrophic conditions in the surface ocean as well as a decrease in hydrothermal activity [4].

Higher up in the section, red limestone-marl cycles are present. Enhanced input of nutrient- like trace metals during episodes of higher volcanic activity is inferred, terrigeneous elements (Al, Li, Rb, Be) decrease upwards. Iron speciation data for marl and limestone layers attest to oxic early diagenesis during marl deposition compared to limestone episodes. Low sediment accumulation rates (2.5 mm/ka) are reconstructed. Geochemistry and stable isotope data indicate a highly oligotrophic environment with efficient recycling of organic matter and nutrients in the upper water column. Nutrient availability varied and resulted in periods of higher primary production. Iron oxides cause the red color in CORBs. The main fraction of iron in CORB sediments is fixed in silicate lattices and immobile.

Uniform Os isotopic composition in early-formed planetesimals

R.J. WALKER

Dept. of Geology, University of Maryland, College Park, MD 20742, USA (rjwalker@umd.edu)

The isotopic compositions of some elements, such as W, Ru and Mo, vary among early-formed planetesimals. These variations likely reflect incorporation of different proportions of matter from diverse nucleosynthetic sources, and could be the result of accretion from a poorly mixed nebula, accretionary processes that favored isotopically distinct components, and/or late injection of isotopically diverse matter to the nascent Solar System. Constraints placed on the level of isotopic variability among early-formed planetesimals for additional elements with different chemical characteristics and nucleosynthetic origins may help to elucidate the dominant processes. Osmium is an important element to add to this list as it is one of the most refractory elements, yet is volatile in oxidized forms. Further, separate *s*- and *r*-process enriched components have been shown to exist in low metamorphic grade chondrites. Although, bulk chondrites show no measureable Os isotopic anomalies, early formed iron meteorites are also fertile hunting grounds. Isotopic anomalies for a number of elements are present in irons. For Os, certain irons from groups IAB, IIAB, IIIAB, IVA and IVB also show well resolved anomalies in ε^{190}Os, ε^{189}Os and ε^{186}Os$_i$. These anomalies, however, differ from anomalies observed in components extracted from chondrites, and are attributed to variable exposure of the irons to cosmic rays. Of note, each of the major iron groups contains at least one member with no resolved Os isotopic anomalies. We conclude that Os was homogeneously distributed on the scale of planetesimal accretion within the current level of resolution (~ ±5 ppm for ε^{190}Os). This contrasts with heterogeneity in other siderophile elements, such as W, Ru and Mo. Given that W and Os are similarly refractory, this may indicate that anomalies present for other elements in irons resulted from selective incorporation of mineralogic hosts, rather than large scale nebular heterogeneity.

Nuclear forensic analysis of trinitite at high spatial resolution

C.M. WALLACE*, A. SIMONETTI, AND P.C. BURNS

Department of Civil Engineering and Geological Sciences, University of Notre Dame, Notre Dame, IN 46556, USA (*correspondence: cwallac1@nd.edu)

The world's first atomic bomb, the Trinity "gadget" was detonated on July 16, 1945. The explosion resulted in partial melting of the surrounding desert sand, which subsequently fused into blast-melt glass known as trinitite. Recent investigations of trinitite have been conducted using a variety of analytical techniques, including EMPA, SEM, SIMS, XRF, and light microscopy [1,2]. This study includes preliminary results from optical microscopy, SEM, and laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). Optical microscopy was used in order to "map" thin sections of trinitite and distinguish remnant crystalline grains and inclusions from the surrounding glassy matrix. SEM was conducted on samples prior to thin sectioning in order to image surface morphology. Quantitative spot analyses were subsequently performed via LA-ICP-MS in order to determine the trace element/radionuclide compositions of different phases. The LA-ICP-MS results to date confirm the "supergrade" nature of the plutonium and the presence of a natural uranium tamper in the Trinity device. In addition, plutonium-rich areas are characterized by higher REE abundances and correlate negatively with the fission product ^{137}Cs. Trace element abundances are extremely variable within individual crystal grains (hundreds of microns). The relationship between Pb isotope ratios and Pu abundances is somewhat ambiguous, i.e. they do not correlate positively in all of the trinitite phases. Future work will include isotopic analysis using a LA-multi-collector-ICP-MS instrument configuration.

Incorporation of ^{90}Sr into alkaline altered sediments

S.H. WALLACE[1], S. SHAW[1], K. MORRIS[2], J.S. SMALL[3] AND I.T. BURKE[1]*

[1]School of Earth and Environment, University of Leeds, Leeds, UK (*correspondence: I.T.Burke@leeds.ac.uk)
[2]School of Earth, Atmospheric and Environmental Science, University of Manchester, Manchester, UK
[3]National Nuclear Laboratory, Risley, Warrington, UK

The use of cementitious materials is ubiquitous at nuclear facilities and in radioactive waste packaging. Water in contact with fresh cement produces a highly alkaline solution dominated by K and Na hydroxides causing localised areas of high pH groundwater at the concrete/soil interface. Silicate minerals within sediments and clay barrier materials are known to alter to zeolite and feldspathoid phases under these conditions. The effect of alkaline pore fluid induced weathering reactions on the mobility of radionuclides is not well understood, especially with respect to potentially highly soluble fission products such as ^{90}Sr (as Sr^{2+}).

Here we used 20 $g.L^{-1}$ batch experiments containing sediments representative of the UK Sellafield nuclear site in a pH 13.5 high ionic strength cement-based leachate to investigate Sr^{2+} sorption as a function of time. Experiments initially contained 20 ppm Sr^{2+} (spiked with 30 $Bq.mL^{-1}$ ^{90}Sr tracer) and were sampled from 2 days up to one year (one experiment was aged for one year at 70°C). Change in Sr speciation within sediments was determined using X-ray absorption spectroscopy and sequential extraction techniques.

At 2 days 72.6±8.6% ^{90}Sr was removed from solution, which rose to 93.8±3.3% at 10 days but then decreased to 81.8% after a year. In the 70°C aged sample sorption increased to 98.0±2.5%. This suggests that initial alteration enhances Sr sorption but further recrystallisation releases some sorbed Sr. Sequential extractions show that the majority (65-75%) of ^{90}Sr remains in the $MgCl_2$ exchangeable fraction even after one year. In the 70°C aged sample, 25.2±5.8% ^{90}Sr was found to be residual. EXAFS analysis revealed two Sr-O-Si(Al) bond distances at 3.69 and 3.84 in a 10 day sample and at 3.57 and 3.83 Å in a one year sample, consistent with weak Sr sorption to aluminosilicate phases. EXAFS spectra from a 70°C aged sample contain evidence for a single Sr-O-Si(Al) bond distance at 3.45 Å consistent with Sr incorporation in a neoformed feldspathoid phase such as cancrinite. These results indicate that alkaline altered sediments could be a sink for ^{90}Sr in the environment, however even after alteration ^{90}Sr may remain exchangeable with other ions in solution.

Reactive transport modelling to quantify arsenic mobilization and capture during aquifer storage and recovery of potable water

ILKA WALLIS[1,2], HENNING PROMMER[2,3], THOMAS PICHLER[4], VINCENT POST[1] AND CRAIG SIMMONS[1]

[1]Flinders University / NCGRT, South Australia
[2]CSIRO Land & Water, Australia
[3]University of Western Australia
[4]University of Bremen, Germany

Aquifer storage and recovery (ASR) is an artificial recharge technique which is increasingly used as a water management tool to augment depleted groundwater resources. ASR is a critical component of the long-term water supply plan in various regions, including Florida and Australia. However, under particular, site-specific conditions the viability of ASR as a safe and cost-effective water resource may be impacted by elevated arsenic concentrations that are detected during recovery of the injectant. This study describes a conceptual and process-based reactive transport model of the coupled physical and geochemical mechanisms controlling the fate of arsenic during ASR. The conceptual/numerical model assumes that (i) arsenic is initially released following pyrite oxidation triggered by the injection of oxygenated water (ii) then largely complexed to neo-formed hydrous ferric oxides before (iii) being released again during recovery as a result of both dissolution of hydrous ferric oxides and displacement from sorption sites by competing anions. Multi-cycle hydrochemical data from an affected site where oxic, potable water was injected into a reducing pyrite-containing storage zone were used to evaluate the model. For this site a detailed assessment of the partitioning of arsenic among mineral phases, surface complexes and aqueous phases during injection, storage and recovery is given, together with an evaluation of temporal and areal extent of arsenic mobilization and capture.

Physico-chemical and mineralogical transformations of fluid fine tailings (FFT) associated with the Alberta oil sands end pit lakes

G.E. WALSHE*, M. CHEN, E. CHI FRU AND C.G. WEISENER

GLIER, University of Windsor, Windsor, Ontario, Canada (gwalshe@uwindsor.ca; chen112h@uwindsor.ca; echifru@uwindsor.ca; weisener@uwindsor.ca)

Traditional methods used to extract bitumen involve caustic hot water digestion and flotation, which produce a fine tailing slurry consisting of water, sand, fines residual bitumen and naphtha products [1]. The current practice is to store the tailings in large settling basin to allow the solids to settle out by gravity forming a denser unconsolidated mass termed fluid fine tailings (FFT). To date little information exists on the biogeochemical nature of the newly processed FFT product prior to deposition and the evolution of the material during long term storage in settling basins.

Discussion and Results

During the development of the material significant changes in pore water geochemistry and the associated *in situ* development of AVS are observed, giving rise to the depostion of proto-iron sulfides (Fig. 1). The chemical evolution of porewater and head water was tracked over a period of 6 months. The significance of changes observed will be discussed in terms of the biotic versus physico-chemical processes.

Highly oxidized species in TSR-altered oils

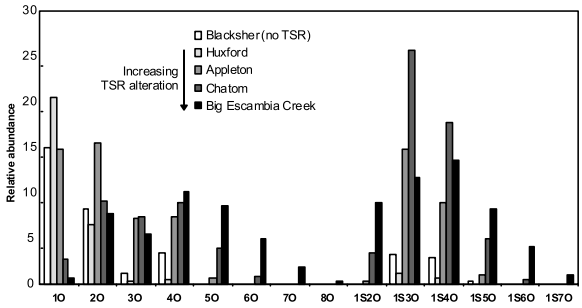
C.C. WALTERS[1]*, K. QIAN[1], C. WU[1], A.S. MENNITO[1], AND Z. WEI[2]

[1]Exxonmobil Research & Engineering, 1544 Route 22 East, Annandale, NJ 08801 (*correspondence: clifford.c.walters@exxonmobil.com)

[2]Exxonmobil Exploration Co., 233 Benmar, Houston TX 77060

Thermochemical sulfate reduction (TSR) involves a complex series of redox reaction that occur typically in hot (>120°C) carbonate reservoirs whereby petroleum is oxidized by sulfate forming H_2S, CO_2, and a sulfur-rich insoluble solid. It is well documented that oils altered by TSR are enriched in organosulfur species, primarily thiophenic, that form as a consequence of the primary sulfate reduction reaction and back reactions with produced H_2S or other low valance state sulfur species. In contrast, enrichment in partially oxidized hydrocarbons has not been reported in TSR-altered oils, which typically have low Total Acid Numbers (TAN < 0.2).

Oils from onshore Alabama were analyzed by negative ion electrospray ionization Fourier transform ion cyclotron resonance mass spectrometry (NESI-FTICR-MS). The suite includes oils at varying extent of TSR-alteration as well as oils of equivalent thermal maturity that have not subjected to TSR-alteration. Although the total amount of oxygen species is low in all samples, their relative distribution varies in a systematic manner. With increasing extent of TSR, 1O and 2O species, which dominate unaltered oils, are replaced with species containing additional oxygen atoms. Hydrocarbons and organosulfur species with 5 to 8 oxygen atoms are detected only in the most TSR-altered oils.



The distributions of the Ox and SOx species appears to accurately reflects the extent of TSR and are particularly useful in deciphering the geohistory of reservoirs where H_2S and light hydrocarbons have migrated in from off-structure.

The evolution dynamics of chemical mantle reservoirs – 3D numerical results

U. WALZER[1]* AND R. HENDEL[2]

[1]Institut für Geowissenschaften, Friedrich-Schiller-Universität Jena, Humboldtstr. 11, 07743 Jena, Germany (*correspondence: u.walzer@uni-jena.de)

[2]Institut für Geowissenschaften, Friedrich-Schiller-Universität Jena, Humboldtstr. 11, 07743 Jena, Germany (roland.hendel@uni-jena.de)

A dynamic 3-D spherical-shell model for the chemical evolution of the Earth's mantle is presented. Chemical differentiation, convection, stirring, and thermal evolution constitute an inseparable dynamic system. Our model is based on the solution of the balance equations of mass, momentum, energy, angular momentum, and four sums of the number of atoms of the pairs ^{238}U-^{206}Pb, ^{235}U-^{207}Pb, ^{232}Th-^{208}Pb, and ^{40}K-^{40}Ar. Similar to the present model, the continental crust of the real Earth was not produced entirely at the start of the evolution but developed episodically in batches. The details of the continental distribution of the model are largely stochastic, but the spectral properties are quite similar to the present real Earth. Some preliminary results have been published in [1]. The modeled present-day mantle has no chemical stratification but we find a marble-cake structure. If we compare the observational results of the present-day proportion of depleted MORB mantle with the model then we find a similar order of magnitude. The MORB source dominates under the lithosphere. In our model, there are nowhere pure unblended reservoirs in the mantle. It is, however, remarkable that, in spite of 4500 Ma of solid-state mantle convection, certain strong concentrations of distributed chemical reservoirs continue to persist in certain volumes, although without sharp abundance boundaries. It is interesting to compare these results with the survival of primitive blobs in the lower mantle proposed by Becker *et al*. [2]. Finally we present results regarding the numerical method, implementation, scalability and performance.

Wettability alteration upon reaction with $scCO_2$: Pore scale visualization and contact angle measurements

JIAMIN WAN*, YONGMAN KIM AND JONGWON JUNG

Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, 94720 USA (jwan@lbl.gov, ymkim@lbl.gov, jjung@lbl.gov)

The interfacial forces among reservoir mineral substrates, brine and supercritical (sc) CO_2 can greatly affect the distribution of $scCO_2$ injected in geological formations for its sequestration. When brine and $scCO_2$ contact with a substrate, the equilibrium configuration among the three interfacial tensions determines the wetting property (contact angle) of the substrate. The contact angle together with the pore size distribution determines the distribution of capillary entry pressures for porous media. Therefore, contact angles in the mineral-brine-$scCO_2$ system control the pore-scale advance of the $scCO_2$-brine interface during injection, structure trapping of CO_2 at reservoir-caprock boundaries, and residual trapping of $scCO_2$ at later stages of geologic sequestration. The wetting behavior of $scCO_2$ in contact with caprocks is especially important because it is a primary factor controlling CO_2 leakage from reservoirs to the land surface and atmosphere. Although CO_2 is commonly assumed to be the non-wetting phase in the current predictive models for CO_2 storage capacity, recent studies have begun to show that the wettability of caprock minerals can be altered in the presence of $scCO_2$ under pressures and temperatures representative of geological storage conditions. Understanding is critically needed on how and to what degrees chemical reactions and physical processes in the deep reservoirs affect the wetting properties of rock surface. Such understanding will enable more reliable estimates of CO_2 residual saturations and capillary threshold pressures needed for predicting larger scale system behavior.

We studied silica wettability alteration within single pores containing brine and $scCO_2$ under flow conditions, using engineered transparent micromodels. The process of $scCO_2$ injection into an initially brine saturated silica porous network (pore throat and body sizes are 30 and 120 μm, respectively) was conducted under controlled P and T. We observed (1) the CO_2 phase entering pores, displacing brine, and leaving initially smooth brine films coating silica pore walls with the contact angle θ close to zero, and (2) over longer times (CO_2 diffused into brine films), the brine films contracted into small brine-droplets as a result of decreased wettability (increased θ). At steady state, the θ values of these brine-droplets are 49° ±10° for the 1.0 M, and 70° ±7° for 5.0 M NaCl. We hypothesize that neutralization of the silica surfaces resulting from brine film acidification by CO_2 is responsible for the observed wettability alteration.

Quantifying electron flow in the sulfidation of lepidocrocite

M. WAN[1], C. SCHRÖDER[1,2] AND S. PEIFFER[1,*]

[1]Department of Hydrology, University of Bayreuth, Bayreuth Germany (moli.wan@uni-bayreuth.de; *correspondence: s.peiffer@uni-bayreuth.de)
[2]Center for Applied Geoscience, Eberhard Karls University, Tübingen, Germany

The interaction between sulfide and ferric (oxyhydr)oxides exerts control on electron flow and ultimately the sulfur cycle in many anoxic groundwater, soil and marine systems. In most situations it leads to pyrite formation, the pathway still being researched [e.g. 1]. To identify the intermediate products and to quantify the electron flow during the reaction we used Mössbauer spectroscopy, TEM, wet chemsitry analyses and a novel technique to determine polysulfides.

We reacted synthetic lepidocrocite enriched in the Mössbauer-sensitive isotope ^{57}Fe and dissolved sulfide at neutral pH in an anoxic glove box. The solid fraction was extraced at different time steps (15 min, 2hrs, 48 hrs, 72 hrs and one week), frozen and analyzed with Mössbauer spectroscopy. Both iron and sulfur species were measured with wet chemistry analysis methods in parallel runs. Polysulfides were derived with Trifluoromethanesulfonate and measured by HPLC with UV-Dector.

Mössbauer spectra showed the formation of pyrite after 48 hrs. Mackinawite and magnetite were identified as intermediate products and confirmed TEM observations by Hellige *et al*. [1]. The spectra also provided evidence for Fe-deficient FeS phases such as pyrrhotite. Wet chemistry analysis shows polysulfides form in the first few minutes, accompanying with the formation of elemental sulfur. Most of them are surface associated. With the knowledge on the distribution of Fe between its oxidation states, mineral phases and dissolved species and the determination of polysulfides we can quantify the electron flow along the reaction path to pyrite formation.

A thermogravimetric study of thermally treated silica nanoparticles

QUAN WAN[1]*, YI XIAO[1] AND GEORGE BARAN[2]*

[1]Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou, 550002, P.R. China (*correspondence: wanquan@vip.gyig.ac.cn, grbaran@temple.edu)

Silica is the most abundant mineral in the earth's crust. The surface chemistry of silica often plays a critical role in many earth processes, for example weathering of rocks. When the size of silica particles approaches the nanoscale or when they contain nanoscale pores, the surface area of the silica particles increases dramatically and this can fundamentally affect several properties of interest. Using a combination of dehydration (heating 2hrs at 200°C), dehydroxylation (heating 2hrs at 400, 600 or 800°C) and rehydroxylation (boiling overnight in water), we thermally treated three different types of silica particles, *i.e*. AA-05 (spherical , diameter ~ 500 nm) synthesized via the Stöber process, N-2329 (spherical , diameter ~ 75 nm) synthesized through water glass route, and V-258 (irregular, median size ~700 nm) ground glass [1]. Samples were characterized by thermogravimetric analysis (TGA), pycnometry, elemental analysis and scanning electron microscopy (SEM). We found that heating 2hrs at 200°C removed physically absorbed water, while heating at higher temperature incrementally removed surface silanol groups. Boiling overnight in water resulted in partial recovery of silanol groups. However dehydroxylation became irreversible for samples treated at over 400°C inconsistent with the Zhuravlev model [2]. Our results also indicated that AA-05 Stöber silica was nanoporous with a lower density (1.9 g/cm^3) than that (2.2 g/cm^3) of the fully condensed N-2329 which was obtained through the water glass route. The considerable carbon content (~ 2wt%) in AA-05 was also consistent with incomplete condensation during Stöber synthesis. Both AA-05 and N-2329 showed better thermal stability than did V-258, which melted at 800°C. The increased density of AA-05 after treatment at 600 and 800°C suggested that the nanopores in Stöber silica begin to collapse at 600°C.

Carbon biogeochemical cycle in the impounded Wujiang River, China

B. WANG[1,*], C. Q. LIU[1] AND F. WANG[2]

[1]Chinese Acad Sci, Inst Geochem, State Key Lab Environm Geochem, Guiyang 550002, Peoples R China (*correspondence: baoliwang@163.com) (liucongqiang@vip.skleg.cn)

[2]Shanghai Univ, Sch Environm & Chem Engn, Inst Appl Radiat, Shanghai 201800, Peoples R China (fswang@shu.edu.cn)

Wujiang River is a major hydropower source for China□s massive West-to-East Power Transmission Project. A series of reservoirs were constructed along it and now it becomes a typical impounded river. We have seasonally determined the $\delta^{13}C$ values of dissolved inorganic carbon (DIC), particulate organic carbon (POC), and phytoplanktonic carbon (PPC), and related hydro-chemical parameters to understand the carbon biogeochemical cycle in the impounded Wujiang River.

Soil organic matter and aquatic phytoplankton are the possible contributors of riverine POC. $\delta^{13}C_{PPC}$ showed a perfect linear relationship with $\delta^{13}C_{POC}$, suggesting that POC was mainly derived from phytoplankton. With the development of reservoir after damming, riverine heterotrophic ecosystem is transformed to autotrophic one, and phytoplankton becomes the dominant contributor of POC. pH values in the reservoir waters were generally larger than 8, indicating a predominance of bicarbonate in DIC. HCO_3^- concentrations decreased while the $\delta^{13}C_{DIC}$ and $\delta^{13}C_{POC}$ increased in the surface water of the reservoirs. And with the increase of phytoplanktonic biomass, algae assimilate more inorganic carbon and thereby exhibit more positive $\delta^{13}C$ value. So, photosynthesis is one of the main processes that affect $\delta^{13}C_{DIC}$ and $\delta^{13}C_{POC}$ in the surface water. Compared to the surface water before dam, DIC in release water showed the deficit in ^{13}C when thermal stratification developed. Release water is from deep water of reservoir and $\delta^{13}C_{DIC}$ values decrease with water depth as photosynthesis declines and respiration increase. Thus, respiration, which makes the DIC pool enriched in ^{12}C, is the other main process affecting $\delta^{13}C_{DIC}$ in the reservoirs. Compared to DIC, POC showed larger fluctuations in $\delta^{13}C$ values because phytoplankton had more influences on $\delta^{13}C_{POC}$ than that on $\delta^{13}C_{DIC}$ during the transformation of inorganic carbon into organic carbon. Our results demonstrated that river damming has important impacts on riverine carbon biogeochemical cycling.

Multiple generations of granitic magma in the West Kunlun, NW China: Implications for crustal melting and mantle-crust interaction at an active continental margin

C. WANG[1,2]*, L. LIU[2], W.Q. YANG[2], Y.T. CAO[2], R.S. LI[1] AND S.P. HE[1]

[2]State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi'an 710069, P R China

Active margins along accretionary orogens are considered to be major sites of the formation of juvenile continental crust [1], but subduction processes also produce crustal recycling and differentiation rather than growth [2]. West Kunlun is a large accretionary orogen formed by long-standing subduction, arc-continent collision and closure of Paleo-Tethys between the south margin of the Tarim Block and western portion of the Himalayan-Tibetan orogen from the early Paleozoic to the early Mesozoic. Two major granitoid belts based on geochronology data were identified, the early Paleozoic suite and the early Mesozoic suite. Mafic magmatic enclaves are abundant in most of these granitoids. There is a strong mantle component to these rocks, and imply production of the rock series has involved mixing between mantle and crustal magma components. The source characterstics of granites and zircon Hf isotope characteristics indicated that the West Kunlun granitic magma was formed on the base of continental crust. Recycling of older continental crust, and of Mesoproterozoic crust in particular, appears to be an important process in the evolution of the orogenic continental crust of West Kunlun between early Paleozoic and Mesozoic. There is not of pronounced new crust formed and formation of the West Kunlun orogen in the outboard of the ancient Tarim margin related with Paleo-Tethys subduction. Such processes may represent an advancing orogen.

13α(*n*-alkyl)-tricyclic terpanes: A series of biomarkers for the unique microbial mat ecosystem in the middle Mesoproterozoic (1.45~1.30Gyr) North China Sea

C. WANG*, M. WANG, J. XU, Y. LI, Y. YU, J. BAI, T. DONG, X. ZHANG, X. XIONG AND H. GAI

State Key Laboratory of Oil Science and Prospecting, China Univ. of Petroleum, Beijing, 102249, China (*correspondence: wchj333@126.com)

Anoxygenic photosynthesis may have modulated Proterozoic oxygen production and sustained an intermediate redox state in the oceans for the Earth's middle age [1, 2]. A special biomarker assembly indicates that a unique prokaryotic microbial mat ecosystem may have contributed to the major primary production in the middle Mesoproterozoic (1.45~1.30Gyr) North China sea [3]. However, we know little about the microbial structures of the Mesoproterozoic microbial mats. Here, we report for the first time that the series of 13α(n-alkyl)-tricyclic terpanes (C_{18}~C_{33}) (13αNATTs) occurs in the organic-rich shales from this middle Mesoproterozoic sequence, including Hongshuizhuang Fm, Tieling Fm and Xiamaling Fm. We infer the long straight-chain substitution (up to C_{15}) in 13αNATTs to be originally of n-alkyl-substituted chain, while not of demethylated isoprenoid chain [4]. This scenario is probably just like that of hopanes. Thus, 13αNATTs may have originated from prokaryotes, given the robust evidence of steranes being undetectable in the shales [3].

The fact that 13αNATTs have not been detected from the post-Mesoproterozoic sedimentary sequences in China, may suggest that 13αNATTs could be a unique series of biomarkers for some special Mesoproterozoic prokaryotes, which probably disappeared from the late geological record. The remaining key question is to reveal what kinds of prokaryotes may have contributed to 13αNATTs?

Phase equilibrium of the Cd-bearing quaternary reciprocal system at 298 K

WANG CHUNLEI[1], HUANG YI[1,2]*, ZOU FANG[1] AND NI SHIJUN[1,2]

[1]Department of Geochemistry, Chengdu University of Technology, Sichuan, PRC (*correspondence: huangyi@cdut.cn)

[2]Applied Nuclear technigues in Groscience Key Laboratory of Sichuan Proviance, PRC

Solid-Liquid Equilibrium of reciprocal quaternary system K^+, Cd^{2+}//Cl^-, SO_4^{2-}-H_2O at 298 K were studied by an isothermal solution saturation method. Experimental results indicate that there are seven univariant curves F_2E_2, F_4E_2, E_2E_1, F_3E_1, E_1E_3, F_5E_3, F_1E_3, three invariant point: : E_1, E_2 and E_3 and five crystallization fields in the reciprocal quaternary system. There is double salt $Cd_3KCl_7{\cdot}4H_2O$ existing in the reciprocal quaternary system. The crystallization zones of equilibrium solid phases are K_2SO_4 ($F_2E_2F_4$), KCl ($F_4E_2E_1F_3$), $CdCl_2{\cdot}H_2O$ ($F_5E_3F_1$), $Cd_3KCl_7{\cdot}4H_2O$ ($F_3E_1E_3F_5$), $3CdSO_4{\cdot}8H_2O$ ($F_1E_3E_1E_2F_2$), respectively. The point E_1 represents the equilibrium of three solid phase KCl, $Cd_3KCl_7{\cdot}4H_2O$, and $3CdSO_4{\cdot}8H_2O$. The eutectic point E_2 represents the equilibrium of three solid phase K_2SO_4, KCl and $3CdSO_4{\cdot}8H_2O$. The other eutectic point E_3 represents the equilibrium of three solid phase $Cd_3KCl_7{\cdot}4H_2O$, $CdCl_2{\cdot}H_2O$ and $3CdSO_4{\cdot}8H_2O$. Potassium Sulfate has the biggest crystallization fieldwhile Cadmium Chlorine has a smaller crystallization region than others.

Integrated development and management of water resources: A typical area in China

DONG WANG[1]*, JICHUN WU[1], LACHUN WANG [2] AND YUN LIANG SHI

[1]Department of Hydrosciences, School of Earth Sciences and Engineering, State Key Laboratory of Pollution Control and Resource Reuse, Nanjing University, Nanjing 210093, China (*correspondence: wangdong@nju.edu.cn)

[2]School of Geographic and Oceanographic Sciences, Nanjing University, Nanjing 210093, China

It is unfortunate that problems with water are considered to grow worse in the coming decades. Water Scarcity is one of the most pervasive problems afflicting people throughout the world. According to the World Water Council, human beings have access to less than eight-tenths of one percent of the total water on our blue planet.Although freshwater is a renewable natural resource, its circulation rate is determined by climate system, human activities, etc., and there is an upper limit to the volume of freshwater natural resource.

More intense droughts in the past decade, affecting an increasing number of people, have been linked to higher temperatures and decreased precipitation, but are also frequently a consequence of the misunderstanding of water resources. The increased exposure to potential hazards has led to more awareness of intergraded groundwater and surfacewater development and management, especially in Karst area, which have complicated hydrologic and hydrogeologic conditions.

Houzhai Catchment is a typical Karst area in Guizhou Province in the southwest of China. A conceptual Karst streamflow model is established, whose parameters are calibrated and determined by Genetic Algorithm. According to three indexes (Relative Error, Cross-correlation Coefficient and Deterministic Coefficient), the results show that the proposed model can simulate and forecast the special runoff yield and flow concentration process of this typical Karst area, which is useful to improve the evaluation method and promote growing awareness of the need for properly integrated development and management of water resources.

Effects of soil environment on activity of rare earth elements: Implications for land utilization

D.Y. WANG[1], Y.F. LI[1], Y. Y. YANG[1], Y. SHANG [2] AND M. WANG [1]

[1]College of Earth Sciences, Jilin University, Changchun 130061, China (wang_dy@jlu.edu.cn, yfli@jlu.edu.cn, yyyang10@mails.jlu.edu.cn, wangmeng880716@163.com)

[2]Land Surveying and Mapping Institute of Shandong Province, Jinan 250013, China (rulyshang@yahoo.com.cn)

Rare earth elements (REEs), as an agent for increasing products, have been widely used in agricultural processes. However, how do the soil environments affect the activity of REEs in the soil? It is one of the hotly-discussed issues in the land utilization. This paper reports the total REE contents of 40 surface soil samples and available REE contents of 20 samples from the Yanbian region in the eastern Jilin Province, NE China analyzed using ICP-MS. The total REE contents range from 95.7 to 266 ppm, yielding a weighted mean value of 150 ppm, which is lower than the average REE content (187 ppm) of soil in China. The available REE contents for 20 samples vary from 18.5 to 118 ppm, yielding a weighted average value of 56.8 ppm. The average REE activity indexes in the soil, i.e., available REE contents/total REE contents, are between 23.2% and 46.5% (average 37.9%). Correlation analyses done by SPSS software indicate that the total and available contents of Yb and Lu exhibit evidently positive correlations while these of other REE have extremely remarkable positive correlations. The activity indexes of Y, Sm, Gd, Er, Tm, Yb, and Lu show evidently positive correlations with pH values in soil. Additionally, the difference of REE activity indexes between different types of soils also occurs. Compared with the similar studies of Hainan province, southern China where the climatope, soil type and soil physical and chemical properties are different from the Yanbian area, REE activity index in the soils from NE China is evidently low, suggesting that the climatope, soil type, and soil physical and chemical properties have important affects on REE activity in soil. Therefore, it is of important implications for scientifically using land, protecting soil environment, and maintaining agro-ecosystems to understand and utilize relationship between soil environment and REE activation in them.

Late Triassic bimodal magmatism in the Lesser Xing'an-Zhangguangcai Range, NE China: Constraints on the timing of transformation of Paleo-Asian ocean into circum-Pacific ocean tectonic systems

F. WANG, W.L. XU *, E. MENG, F.H. GAO AND H.H. CAO

College of Earth Sciences, Jilin University, Changchun 130061, China (jlu-wangfeng@sohu.com; *correspondence: xuwl@jlu.edu.cn)

The Lesser Xing'an-Zhangguangcai Range, NE China, is located in the eastern section of Central Asian Orogenic Belt (CAOB) [1]. Geochronological and geochemical data of Triassic igneous rocks from the region provide constraints on the timing of the transformation of the Paleo-Asian tectonic system into the circum-Pacific system. LA-ICP-MS and SIMS zircon U-Pb dating results for two basalts, one gabbro, two rhyolites, and one dacite indicate that they formed during the Late Triassic (208-228 Ma). The mafic rocks have SiO_2 = 48.97-51.89 wt.%, TFe_2O_3 = 7.86-10.13 wt.%, K_2O = 1.05-1.72 wt.%, Mg# [Mg/(Mg+Fe^{2+})] = 0.54-0.63, Cr=107-405 ppm, Ni=44-102 ppm, whereas felsic rocks have SiO_2 = 73.60-75.69 wt.%, TFe_2O_3 = 0.69-1.19 wt.%, K_2O = 4.10-4.36 wt.%, Mg# = 0.05-0.23, suggesting a typical bimodal igneous association. In addition, these mafic rocks are characterized by enrichment in LREEs and LILEs, depletion in HREEs and HFSEs (such as Nb, Ta, Ti), and weak Eu anomalies (0.87-1.05), whereas felsic rocks exhibit strongly depletion in Sr, P, Ti, enrichment in Th, U, K, and relatively obvious negative Eu anomalies (0.61-0.65). The above findings, combined with the coeval A-type rhyolites in eastern Heilongjiang and Jilin provinces [2], imply that they formed under a post-collisional extensional envirnment related to the final collision between the North China Craon and the Siberia Craton in the Late Permian and/or Early Triassic. Meanwhile, this finding also suggests that the subduction of the Paleo-Pacific plate beneath the Eurasian continent could took place after the Late Triassic.

This research was financially supported by research grants from the Natural Science Foundation of China (Grant 41072038) and the Geological Survey of China (Grants 1212010070301 and 1212010611806).

Genetic and functional properties of uncultivated Miscellaneous Crenarchaeota Group (MCG): Implication from the metagenome analysis

FENGPING WANG[1]*, JUN MENG[2], YANPING ZHENG[1,2], DAN QIN[2,], JUN XU[1] AND XIANG XIAO[1],

[1]State Key Laboratory of Microbial Metabolism and State Key Laboratory of Ocean Engineering, Shanghai JiaoTong University, Shanghai, 200240, People's Republic of China (*correspondence: fengpingw@sjtu.edu.cn)

[2]The School of life science, Xiamen University, 361005, People's Republic of China

The MCG Archaea is one of the most predominant Archaeal groups in various environments. Till present, no member of MCG has been cultivated or characterized, and its ecological roles and evolutionary position remain obscure. Within this study, the genetic potential and physiology of MCG and its evolutionary relationship with other archaeal members were analyzed and inferred based on metagenomic analysis. Comparisons of gene organizations and similarities around the 16S rRNA genes of available MCG Fosmid and Cosmid clones found completely no synteny, demonstrated big genetic variations within groups of MCG. A topoisomerases IB gene (TopIB) was found in a MCG Fosmid genome fragment, TopIB phylogenetic analysis placed MCG within the newly postulated archaeal Phylum-Thaumarchaeota. Functions of some genes on the genome fragment were tested by in-vitro expression. Gene involved in protocatechuate degradation and chemotaxis were found in a genome fragment, suggesting a role of this group of archaea in protocatechuate degradation. The up-expression of 4-carboxymuconolactone decarboxylases was observed when the sediment was amended with protocatechuate, further supporting the idea of MCG group as protocatechuate degrader.

Study on diagenetic environments of calcite veins hosted in marine carbonate rock in middle Yangtze region of Southern China

WANG FURONG[1,2], HE SHENG[1,2] AND YANG XINGYE[2]

[1]Key Laboratory of Tectonics and Petroleum Resources Ministry if Education, China University of Geosciences, Wuhan 430074, China
[2]Faculty of Earth Resources, China University of Geosciences, Wuhan 430074, China

Thin slices suggest that calcite veins hosted in marine carbonate rock of appearing locating in middle Yangtze region of southern China develop two crystal forms including radiaxial calcite and isometric structure calcite in Triassic, and isometric structure calcite can be identified of calcite veins in Permian and Ordovician. And some calcite veins develop double-crystal pattern.

Cathodeluminescence document that different structure calcite veins show different luminous intensity in Triassic which can identified three periods of calcite veins, and luminous intensity has no different between calcite veins and surrouding rocks in Permian and Ordovician with medium orange to dark light.

Carbon-oxygen isotopes of calcite veins show that The range of $\delta^{13}C$ is -6.76 ‰ ~ 4.01‰(PDB), $\delta^{18}O$ is -17.95‰ ~ -5.67‰(PDB) in calcite veins, which indicates that calcite veins deposit in marine phreatic environment and mixing phreatic environment. Calcite veins in Triassic are sedimentary origin, and part of calcite veins in Permian and Ordovician suffer latter diagenesitc fluid dissolution. Fluid generating from organic-matter maturation effect the information of calcite veins in Permian to some degree.

Tectonothermal evolution of the Triassic flysch in the Songpan-Garzê orogen, Eastern Tibetan plateau

H. WANG[1], M. RAHN[2], J. ZHOU[3], X. TAO[4]

[1]School of Earth and Space Sciences, Peking University, China (*correspondence: hjwang@pku.edu.cn)
[2]Swiss Federal Nuclear Safety Inspectorate (ENSI), 5200 Brugg, Switzerland
[3]Chinese Academy of Geological Sciences, China
[4]College of Earth Sciences, Chengdu University of Technology, China

Low temperature metamorphic indicators give an insight into the tectonothermal evolution of the Triassic flysches in the Songpan-Garzê orogen, eastern Tibetan plateau. The Triassic flysches experienced large-scale folding, faulting and a thermal overprint from diagenesis to lower greenschist facies. Maximum metamorphic conditions were 380 ± 25ºC and low to intermediate pressures. Iso-thermal zones mapped with illite crystallinity (IC) describe following relationships between thermal zones and fold axes, faults and strata boundaries: i) anchizonal boundaries run across strata boundaries and fold axes indicating the main folding of the flysches occurred prior to metamorphism; ii) large-scale faults make boundary offsets in thermal zones suggesting the structural movement along the Longmenshan (LMS) and the Xianshuihe faults took place after low grade metamorphism.

From NW to SE, the Triassic flysches in the Songpan-Garzê orogen show a complex pattern. From this pattern a general increase in grade towards the LMS fault belt and across the LMS fault belt, greenschist facies rocks on its NW side are juxtaposed to diagenetic rocks in the Sichuan basin on its SE side. This juxtaposition is marked by IC jumps of 0.23ºΔ2θ in SW of LMS, 0.40ºΔ2θ in the Middle and 0.66ºΔ2θ in NE of LMS. Across the Xianshuihe fault, the truncated IC zones within the flysches suggest a total offset of roughly 60 km due to post-metamorphic sinistral strike-slip.

Compression at the end of the Triassic induced by the interaction of the South China, North China and the North Tibetan blocks caused the closure of the Paleotethys ocean and led to folding of the flysches within the Songpan-Garzê basin. Very low to low grade metamorphism may have been caused by the increase in thermal gradient due to large-scale magmatic activity in the Jurassic. FT ages reveal Early to mid-Cretaceous exhumation. Finally the India–Asia collision caused the formation of the Longmenshan fault and the Xianshuihe strike-slip fault in the early Tertiary and disturbed the distribution of metamorphic zones.

3.84 Ga crustal material in Dunhuang Block, Gansu Provence, China

HONG-LIANG WANG,XUE-YI XU ,TAO ZHU, TING LI AND ZHI-PEI LI

Xi'an Center of Geological Survey (Xi'an Institute of Geology and Mineral Resource), CGS, Xi'an,shaanxi 710054, China

Crustal materials formed in the early period of solid earth (≥3.8Ga) are few reserved in the world. We get magma crystallization age 3841±16 Ma from metamorphic amphobolite of Dunhuang block rock recently (Fig. 1, Table.1), which is the oldest crustal material had been detected in Dunhuang block, and early earth material found in metamorphic basic volcanics is also rare in the world yet. This metamorphic basic volcanics belong to sub-alkaline volcanics and tholeiite series with $SiO_2 = 47.94\times10^{-2} \sim 49.32\times10^{-2}$. We also get metamorphic zircon ages of ~3.5Ga and 3.3Ga, consistent with previous Sm-Nd age 3487Ma. It indicates that Archean basement exist in Dunhuang block. This new result has important significance for exploreing and studyting the age、properties and growth characteristic, and developing comparison study between Dunhuang block and Huabei craton.

Implications of fault spilling gases in searching active ruptures

HUALIN WANG[1], GUODONG ZHENG[2], JIQIANG WANG[1], CHAO HU[1] AND XIA LIU[1]

[1]Shandong Institute of Seismic Engineering, Jinan 250021, China

[2]Key Laboratory of Petroleum Resources Research, Institute of Geology and Geophysics, CAS, Lanzhou 730000, China

The seeped gases as called as fault spilling gases may contain abundant information about the geological processes in the deep Earth, and also be significant in searching and studying on the spatial distribution and activity of faults. In this paper, a systematic study was performed on the Yishu tectonic zone, the Haiyuan tectonic zone for an Ms8.5 earthquake in 1920, the Tancheng tectonic zone for an Ms8.5 earthquake in 1668, the Xanshuihe tectonic zone, and several active faults in the Shandong flatlands and some major results were summarized as the followings.

1, the concentration of Rn and Hg and their variation degree of fault spilled gas could be used as sensitive index to evaluate the activity of faults connection. Higher concentration of Rn and lower Hg may indicated stronger stress accumulation and poorer connection of faults, lower concentration of Rn and higher Hg may indicated lower stress accumulation and better connection of faults, and lower concentrations of both Rn and Hg may indicate poorer stress accumulation and poorer connection of faults.

2, the measurement of fault spilled gas has been implied well in searching active faults in the flatlands area. The Rn measurement of fault spilled gas combined with engineering drilling profiles to the Yidu fault zone, the Shuangshan-Lijiazhuang fault zone, and the Heze fault zone for the Ms7.0 earthquake in 1937 was successful to identify all the locations and displacement of faults, and their activity times.

3, the measurement of fault spilled gas can be also used well in the geometric and kinetic studies of faults. The structural pivot area, the pull-apart area and the compression area of strike-slip faults could be located according to the distribution pattern of geochemical surroundings from the measurement of fault spilled gas, which may supply a fast and simple method to study on the geometric and kinetic properties of faults and used successfully to the Haiyuan seismic fault zone and the Xianshuihe fault zone.

Assessment of heavy metal pollutions from lead-zinc mining activities in the North River Basin, China

J. WANG[1], J. LIU[1], Y.H. CHEN[1]*, T.F. XIAO[2], C.L. WANG[3], X.P. LI[1] AND J.Y. QI[4]

[1]School of Environmental Science and Engineering, Guangzhou University, Guangzhou 510006, China (*correspondence: chenyheng@eyou.com)
[2]Insititute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (xiaotangfu@vip.gyig.ac.cn)
[3]Guangdong Provincial Academy of Environmental Science, Guangzhou 510045 (wangchunlin1982@163.com)
[4]South China Institute of Environmental Sciences, MEP, Guangzhou 516005, China (qjyyjq78@163.com)

Chemical analysis of 120 samples of surface sediments and 82 samples of surface water around the lead-zinc ore mining area in the North River Basin (upper part of the Pearl River Delta), South China was performed in order to (i) determine the contamination levels of heavy metals (Tl, As, Cd, Cr, Cu, Hg Ni, Pb and Zn) by means of Inductively Coupled Plasma Mass Spectrometry (ICP - MS); (ii) identify potential sources of the heavy metals; and (iii) to identify those processes that determine the spatial variability of the heavy metals between the source areas and some distant locations in downstream direction. Among the examined elements, high contents of Tl, As, Cd, Cu, Pb and Zn were found in the sediments from the mainstream and feeders of the North River close to the mining area. We interpret the most likely sources of the heavy metal contamination in the sediments are wastewater discharges, mineral tailing materials and dust depositions resulting from the excessive mining activities, since the heavy metal distribution in the basin generally shows a decreasing trend from the location closest to the mining sites towards the downstream directions, and most importantly because the heavy metal contents are mostly related to the Tl contents. Thallium, as a rare element is seldom found in the normal environmental settings but is highly concentrated in the lead-zinc ore minerals in this area. Thus, the good relationships between the Tl contents and the contents of other heavy metals signify that Tl could be used as a special environmental tracer to track, and eventually to quantify the heavy metal contaminations from mining activities of ore specifically bearing Tl. This work enhances our understanding of heavy metal contaminations around a mining site. The local environmental protection and future mineral resources exploitation activities might also benefit.

The characteristics of generation and distribution of CO_2 gas pools in Songliao Basin, China

J.H WANG[1], X. LUO[2], L.H HOU[3] AND Y.WANG[4]

[1]Research Institute of Petroleum Exploration and Development, Beijing, China (284174762@qq.com)
[2]Research Institute of Petroleum Exploration and Development, Beijing, China
[3]Research Institute of Petroleum Exploration and Development, Beijing, China (lhhou@petrochina.com.cn)
[4]Research Institute of Petroleum Exploration and Development, Jilin Oil Company, songyuan, China (wangy1@petrochina.com.cn)

There are so many gas pools with high CO_2 component are distributed in volcanic reservoir. It also indicates that the CO_2 in CO_2 gas pools are mainly of magma origin by the analysis of the characteristics of gas components, carbon isotope composition of CO_2 and helium isotope composition of He in 10 of CO_2 gas pools in Songliao Basin. The main characters of CO_2 gas pools are $\delta^{13}C_{CO2} > -8‰$ and R/Ra=1.9~7.2. Geological background and analysis of fluid inclusion indicate that the CO_2 in Changling, De hui and Gu long etc fault depression are mainly forming lately. The reasons are following. The first is that the fluid inclusions of CO_2 are late period fluid inclusions which are banded occurrence in cracks of transecting quartz grain or transecting widen quartz. Their homogenization temperatures are 120~140°C. So, the forming stage of CO_2 may be mainly between 72Ma and 48 Ma. The formation and distribution of CO_2 are relatives with many kinds of faults including lithosphere faults, crust fractures, basement rifts and overburden faults especially relatives with NE-NNE deep faults which have strike slip motion in late stage. These kinds of faults mainly controlled depression formation in early stage and had NE-NNE left-lateral strike slip motion in late stage. Also, volcanic erupted with amazing amount of CO_2 in this stage and the faults became the channel of the CO_2 migration and then prompted the formation of CO_2.

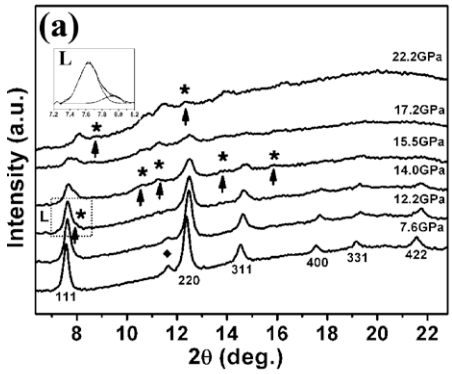
High-pressure behavior of CaF_2 nanocrystals

J.S. WANG, C.L MA, J HAO, D ZHOU AND Q.L CUI*

State Key Laboratory of Superhard Materials, Jilin University, Changchun 130012, PR China
(*correspondence: cql@jlu.edu.cn)

The alkaline-earth fluoride CaF_2 is a well-known face-centered- cubic ionic minerals, and has long been used as mineralogical models for the behavior of ionically bonded minerals in the Earth's mantle [1]. It is widely accepted that the actualization of nanosized materials have opened doors for finding new properties with respect to their macroscopic counterparts. Although there are many high-pressure studies on bulk CaF_2, pressure induced structural phase transitions in nanoscale system has rarely been reported [2, 3].



High-pressure behavior of nanocrystalline CaF_2 samples with an average grain size of 8 nm have been studied by *in situ* synchrotron radiation x-ray diffraction. A pressure-induced fluorite structure to orthorhombic $PbCl_2$-type structure transition starts at 14.0 GPa, and phase transition is sluggish. The orthorhombic phase of nanocrystalline CaF_2 is stable up to 46.5 GPa. The enhancement of transition pressure in CaF_2 nanocrystals as compared with the corresponding bulk material is mainly caused by the surface energy difference between the phases involved.

Elastic properties of hydrous and anhydrous mantle minerals at high pressure

J. WANG AND J.D. BASS*

Geology Department, University of Illinois, 1301 W Green Street, Urbana, IL 61801 USA
(*correspondence: jaybass@uiuc.edu)

Anyhdrous and hydrous forms of wadsleyite and ringwoodite, high-pressure phases of $(Mg,Fe)_2SiO_4$ +- H_2O, are major constituents of the transition zone of Earth's mantle, and are likely abundant in many subducting slabs. Therefore, the seismic properties of these phases are essential to understand the chemical and thermal state of these regions, as well as the seismic signature of water in the mantle to 660 km depth. We have measured the acoustic wave velocities of several key anhydrous and hydrous forms of these minerals up to transition zone pressures by Brillouin spectroscopy on samples compressed in a diamond anvil cell. Hydrous samples contained roughly 2% by weight of H_2O. These experiments allow us to assess the effects of pressure, Fe and H_2O on the elastic properties of these phases. These measurements should provide insight on key questions such as the olivine content and hydration state of the transition zone. It appears that one of the critical issues in addressing the effects of hydration on these phases is the accurate measurement of water content. Our results indicate that determinations of the structurally-bound hydrogen content by SIMS and IR spectroscopy on these samples can vary greatly.

Primordial ages of lithospheric mantle vs ancient relicts in the asthenospheric mantle: *In situ* Os perspective

KUO-LUNG WANG[1]*, S.Y. O'REILLY[2], W.L. GRIFFIN[2], N.J. PEARSON[2], V. KOVACH[3] AND V. YARMOLYUK[4]

[1]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan (*correpsondence: kwang@earth.sinica.edu.tw)
[2]GEMOC, Macquarie University, Sydney, Australia
[3]IPGG, Russian Academy of Sciences, St. Petersburg, Russia
[4]IGEM, Russian Academy of Sciences, Moscow, Russia

Recent studies have shown that volumes of ancient depleted material can survive in the convecting asthenospheric mantle for long periods so that the use of Os model ages of mantle xenoliths to constrain the age of lithospheric mantle events should be approached with caution. In this study, we use *in situ* Os-isotope dating on sulfides in peridotitic xenoliths from cratonic (Tok, Russia) and off-craton (Tariat and Dariganga, Mongolia) settings of the Neoproterozoic-Phanerozoic Central Asia Orogenic Belt (CAOB) to examine lithosphere formation. A few Tok sulfides yield an apparent isochron indicating an age of 3.2 Ga. The high initial $^{187}Os/^{188}Os$ (0.117) of the apparent isochron suggests that it represents a mixing line, possibly involving an Archean component. In Tariat, both T_{MA} ages from the least-disturbed sulfides ($^{187}Re/^{188}Os<0.07$) and T_{RD} ages from higher-Re/Os sulfides yield model ages ranging from 0.5 to 3.0 Ga, with peaks around 1.7-1.5, 1.2 and 0.7-0.5 Ga. These ages suggest that SCLM beneath the Tariat region existed at least by Proterozoic time, and that some domains are Archean. The Os model ages are well-correlated with crustal events recorded in the overlying Precambrian Tarvagatay Terrane. It would be a remarkable coincidence if sulfides derived from randomly selected fragments of refractory materials in the convecting asthenospheric mantle would combine to give such a systematic correlation. We therefore prefer the simplest interpretation: the sulfide Os ages in the Tok and Tariat peridotites record major events that affected the crust+SCLM. The oldest of these events may record major melt extraction, and the later ones metasomatic events. Sulfides in Dariganga peridotites also have Mesoproterozoic Os model ages. Although Proterozoic crustal events have not been reported in this region so far, Proterozoic Nd model ages for basement rocks around the Xilinhot region in the vicinity of the Dariganga Plateau (B. Chen, pers. comm.) suggest that a Precambrian crustal terrain should be expected and might be found by studies of deep-crustal xenoliths in the Dariganga region.

The geochemistry of fluid inclusions in Yimen Sanjiachang copper deposits

LEI WANG[1], RUN-SHENG HAN[1], GUO TANG[1], YI-DUO HU[2] AND JIAN-GUO HANG[1]

[1]Kunming University of Science and Technology; Southwest Institute of Geological Survey, Geological Survey Center for Non-ferrous Mineral Resources, Kunming, China, 650093 (*correspondence: cumtwl1983@yahoo.com.cn)
[2]Kunming Vocational and Technical College of Industry, Kunming, China, 650302

Sanjiachang copper deposits including three copper deposits of Shishan copper deposit, Caiyuanhe copper deposit and Fengshan copper deposit[1]. Shishan Copper deposit is a diagenesis - weak reworked deposit Fengshan copper deposit is a strongly reworked deposit which controlled by diapir structure[2], Caiyuanhe copper deposit is a transitional type of the first two deposits, The fluid inclusions have significant differences of the three copper deposits with the following characteristics: From Shishan copper Caiyuanhe copper deposit Fengshan copper deposit Inclusions size are increase(1.5μm-2.15μm), and number are increase, pure liquid inclusions in order to reduce and liquid inclusions in order to increase, Fengshan copper found gas inclusions (about 15%) and a small amount of NaCl sub-inclusions. From Shishan copper Caiyuanhe copper deposit Fengshan copper deposit gangue mineral homogenization temperatures are gradually increasing there are two homogenization temperature range of 113.4 ~ 194.3 °C (95% of this range) and 220 ~ 320 °C in Fengshan copper deposit-hishan copper depost salinity inclusions have the feature of high K^+ content, low Na^+ content, Caiyuanhe copper deposit and Fengshan copper depost have the feature of high Na^+ content , low K^+ content [2], Fengshan copper has two salinity content range of 4-10% and 12-18%.

The results show that from Shishan copper deposit - Caiyuanhe copper deposit - Fengshan copper deposit is gradually enhanced the role of structural transformation, Fengshan copper mineralization has the characteristics of two and the main ore mineralization in the low temperature of 113.4 ~ 194.3 °C.

Microecology perspective and environmental impact of coal mine sulfur-bearing waste dump

L.L. WANG[1]*, M. YUE[2] AND L.L. WANG[1]

[1]School of Resources and Environmental Engineering, Hefei University of Technology, Hefei 230009, China (wangllhfut@gmail.com)
[2]Hefei University, Hefei 230022, China

Coal mines in Chian are mostly located in the north. Below the coal layer, there is a fracture-karst aquifer with strong anisotropy often used as drinking water source for local inhabitants[1-2]. Mining has caused environmental pollution. Some studies involve flow and solute transportant in fractured media[3-7]. Others pay attentions to the pollution control from sources [8]. In this study, by hydrogeological survey, sampling and testing in the sulfur-containing waste dump of the mining area in Sitai mine, Shanxi Province, the content of the material and its environmental characteristics were analyzed. The advantage of microbial flora in the sulfur-containing waste dump and its colony structure were discussed. The 16S rDNA of the special microorganisms was determined; The role of microorganisms and kinetic parameters in the weathering process of sulphide were studied.

The pH values of leaching water in the yard of sulfur containing waste dump were around 2.5, the color of leaching filtrate were almost reddish-brown.

The 9 strains which isolated from the acid water belonged to two species: *Acidiphilium sp.* and *Acidithiobacillus ferrooxidans*, they were the advantage microbial flora in this environment.

The initial pH of liquid phase, temperature, solid-liquid ratio and particle sizes of mining rocks would affect the behavior of microorganisms in the process of pyrite weathering.

When microorganisms and culture medium were coexist, the pyrite oxidation rate reached 3.14 mmol.d-1.L-1, it was 28.55 times of the control group. the release regularities of As, Cu, Zn, Ni, Pb influenced obviously by microorganisms.

Precious metal (Pt, Pd, and Au) in Fengshan porphyry Cu-Mo deposit, China

MINFANG WANG[1,2]

[1]Faculty of Earth Resources, China University of Geosciences, Wuhan, Hubei, 430074, China (wang_minfang@163.com)
[2]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan, Hubei, 430074, China

Nine hand specimen and four flotation concentrates have been analyzed (Table 1).

Sample	Type	Au ppb	Pt ppb	Pd ppb
FS50	intrusive rock	11	0.137	0.165
FS94	altered rock	4	0.234	0.288
FS57	altered rock	10	0.389	3.907
FS4	ore, skarn	1480	0.037	3.095
FS9	ore, skarn	531	0.204	17.979
FS45	ore, skarn	310	0.099	0.403
FS64	ore, skarn	402	0.07	1.314
FS8	ore, porphyry	28	1.765	13.888
FS36	ore, porphyry	220	0.175	6.877
SC	sulfide concentrate	897	15.9	13
CFC	copper flotation concentrate	6070	21.8	32
MFC	molybdenum flotation concentrate	2360	81.4	32
CMFC	copper-molybdenum flotation concentrate	12	1.3	1

The results show that concentrate samples have the highest content of precious metal and almost are 1-2 orders of the magnitude higher than ore samples, while the rock samples are the poorest. Meanwhile, the porphyry ore samples have the higher content of Pd, Pt and Au than in the skarn ore samples. PGE enrichment in porphyry deposits probably requires a mantle source region, liberation of mantle sulfides during partial melting in the source region, and an oxidized melt that effectively prohibits the formation of magmatic sulfides during fractionation.This study clearly demonstrates the potential for further research.

Contrasting microbial communities and geochemical patterns reflect different styles of methane oxidation and methanogenesis in terrestrial mud volcanoes

PEI-LING WANG[1], LI-HUNG LIN[2], TING-WEN CHENG[2], YUNG-HSIN CHANG[2], WEN-JING LAI[1], JING-YI TSENG[1], WEN-YU TSAI[2] AND CHIH-HSIEN SUN[3]

[1]Institute of Oceanography, National Taiwan University
[2]Department of Geosciences, National Taiwan University
[3]Exploration and Development Research Institute, CPC Corporation Taiwan

Hydrocarbon seeps and mud volcanoes are ubiquitous in marine and terrestrial environments where gaseous fluids with unconsolidated sediments ascend along fractures tapping into potential gas or petroleum reservoirs in deep subsurface. Although extensive geochemical and microbiological studies have been conducted on marine settings, terrestrial counterparts remain poorly constrained.

This study combined molecular screening of 16S rRNA and functional genes, and geochemical analyses of porewater, sediment and gas collected from mud volcanoes distributed in eastern and southwestern Taiwan to determine how microbial communities respond to various methane fluxes and geological contexts. Our findings indicated that mud volcano systems in both regions were characterized by stratified geochemical characteristics and community assemblages resembling or contrasting those in marine settings in several aspects. In particular, anaerobic methanotrophy was linked to different electron accepting processes (sulfate versus iron reduction) in different regions, suggesting various affinities of functional expression on the presence of specific minerals. The proliferation of anaerobic methanotrophy is apparently decoupled from the supply of deeply-sourced methane but strongly dependent on the in-situ methanogenesis controlled by the fermentative production of specific methanogenic precursors. Microbial communities compartmentalized into different depth intervals collectively enable less than 40% of methane inventory emitted to atmosphere. Contrasting patterns of metabolic and geochemical stratification reflect microbial communities thriving on inherited minerals and geochemical disequilibria induced by the interaction between the upward transport of gaseous, reducing, diluted fluids and the downward infiltration of oxidizing, solute-enriched fluids subjected to surface evaporation.

Potential-pH diagram for the V-Cl-H_2O system at high chlorine concentration

R. L. WANG[1], Y. ZENG[1,2]* AND S. H. ZHANG[1]

[1]Department of Geochemistry, Chengdu University of Technology, Chengdu, 610059 China;
[2]Mineral Resources Chemistry Key Laboratory of Sichuan Higher Education Institutions, Chengdu 610059, China (*correspondence: zengyster@gmail.com)

Vanadium, widely distributed in the nature, is essential to human and closely related to human health. While the total amount of vanadium in human body gathers to a certain degree, it shows middle-high toxicity. The toxicity of vanadium depends on its species and valence, which are mainly due to pH value, potentials, the total concentration of vanadium, and the kinds of coexistent ions in the solution. Moreover, the toxicity of vanadium increases with increasing oxidation state.

Under natural environmental conditions in soil and water, vanadium dominantly exists in either +4 or +5 oxidation state as aquatic species of vanadyl(VO_3^{2-}) or vanadate(VO_4^{3-}), respectively. Under weak reducing conditions, vanadyl(V^{IV}) species is stable, while in oxidizing conditions, vanadate (V^{V}) is stable across almost the entire pH range. VO_3^{2-} and VO_4^{3-} can coexist depending on the redox potential and pH value of the solution and concentration.

In this paper, the potential and pH value of the V-Cl-H_2O system at $C_{T(Cl)}$ = 1.0 mol·L^{-1} are determined by using a concentration comparison method. Based on the measured data, the preliminary predominance diagrams were constructed. A Comparison between the predominance diagrams for the V-Cl-H_2O system with $C_{T(Cl)}$ = 1.0 mol·L^{-1} at different vanadium concentrations ($C_{T(V)}$ = 1.0×10^{-3} mol·L^{-1} and $C_{T(V)}$ = 1.0×10^{-5} mol·L^{-1}) [1],[2] has been done. It is shown that the location and size of the advantage regional of vanadium ion VO_2^+, $H_2VO_4^-$, VO_4^{3-} are similar. Under the conditions with pH 0.00-5.68, and Eh 0.5-0.9 V, the area of VO^{2+} advantage region is decreased at $C_{T(V)}$ = 1.0×10^{-5} mol·L^{-1}. At Eh value of 0.0-0.5 V, the $HV_2O_5^-$ advantage region is replaced by VO^+ with pH 3.68-14.00.

The temporal and spatial variations of N_2O saturations in a eutrophic lake

SHILU WANG

Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences (wangshilu@mails.gyig.ac.cn)

Much of the N_2O emitted from aquatic ecosystems is anthropogenically derived [1]. However, there remains considerable uncertainty in the magnitude of anthropogenic N_2O emitted from aquatic environments and how N_2O emissions respond to increasing loads of anthropogenic N and eutrophication in general. In this study, N_2O saturations were examined in the ecologically heterogeneous, eutrophic lake, Lake Taihu, in eastern China. I found that anthropogenically-enhanced inorganic nitrogen N inputs act as a limited primary control on the spatial distribution of N_2O saturations in heavily eutrophied parts of the lake only and that overall, lake N_2O production and emission are not raised as significantly as expected due to high N input [2]. A distinct diurnal pattern of N_2O saturations is displayed in July, which is controlled by biogeochemical processes [3]. While large-scale changes (~25-fold) in N_2O fluxes in Lake Taihu are a function of variable N loading, biogeochemical processes concerning O_2 and N transformation at the sediment-water interface have significant (~twofold) impacts on the regulation of N_2O production over very short time scales.
