Continuous gas charge of low-permeability tight-gas sandstones creates a dynamic system where pore pressure increases locally and temporarily to near lithostatic pressures, and fractures the rocks. Methane concentrations of aqueous fluid inclusions trapped in crack-seal fracture cements can be used as proxy to determine the pore pressure variations in these systems. The natural fracture network creates pathways that allow upward gas migration to form a continuous gas-saturation interval in the absence of a top seal in the deep-central parts of sedimentary basins. The Piceance Basin, Colorado, has been considered a basin-centered gas accumulation. This model contrasts with models of low-permeability reservoirs where gas accumulates in conventional traps. To test these models, we determined the temperature, pressure, and fluid composition history during fracture opening in Mesaverde Group sandstones of the Piceance Basin based on fluid inclusion microthermometry and Raman microspectrometry. Homogenization temperature of aqueous fluid inclusions record systematic temperature trends from ~140 to 185°C and to 158°C over time. In contrast, we observe oscillating pore fluid pressures ranging from ~55 to ~110 MPa over time. We interpret the oscillating pressure record to indicate migration of gas in high pressure cells that move upward by natural hydraulic fracturing. Repeated passage of high pressure cells result in cyclic fracture opening and sealing. Comparison of microthermometry data with burial models suggests that gas generation, migration of high pressure cells, and natural hydraulic fracturing lasted for ~33 m.y. in the Piceance Basin.

Gold ore-forming fluids and metallogeny in the Zhaoyuan-Laizhou concentration region of Jiaodong peninsula, Eastern China

HONG-RUI FAN, FANG-FANG HU, XIAO-HUI JIANG, KUI-FENG YANG AND TING-GUANG LAN

Key Laboratory of Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences, P.O. Box 9825, Beijing 100029, China (fanhr@mail.igcas.ac.cn)

Zhaoyuan-Laizhou gold concentration region in the Jiaodong Peninsula of Eastern China is currently the most important gold producer in China. Several world-class gold deposits (>100 t gold) have been discovered in the region. There are two main types of gold deposits, namely quartz vein-style (Linglong type) and fault-zone hosted disseminated/stockwork-style (Jiaojia type).

Detailed fluid inclsuion studies have been carried out in the Linglong and Jiaojia type deposits in the region. Three types of fluid inclusions have been distinguished from quartz in gold lodes: (A) H_2O-CO_2 inclusions, (B) CO_2-H_2O±CH_4 inclusions, and (C) aqueous H_2O inclusions. The pre-gold H_2O-CO_2 fluid inclusions occur isolated in samples of the early milk-white quartz and are assumed to have been trapped during crystallization of the earliest quartz. Fluid inclusions associated with gold mineralization contain mostly CO_2-H_2O-NaCl±CH_4 fluids, and occur isolated, and sometimes in healed fractures particularly in smoke-grey quartz with variable CO_2 and CH_4 contents. There are similar changes of molar volumes of H_2O-CO_2 and CO_2-H_2O±CH_4 inclusions with 50 - 70 cm^3/mole from the depsoits. Estimated fluid trapping pressures of pre-gold and gold-stage are 1.0 - 3.5 kbar and 0.7 - 2.5 kbar, respectively. The pressure is tending towards depression along with fluid evolution.

Obtained Rb-Sr and Ar-Ar isochron ages from the Zhaoyuan-Laizhou gold concentration region give gold mineralization time around 120 Ma. Gold deposits in the region are formed in the same mineralizing-geodynamic circumstance, and related with Mesozoic tectonic transition in the eastern North China craton.

Genesis of carbonatite from Hannuoba and Yangyuan, North China

QICHENG FAN, JIANLI SUI, XINGXXNG DU AND YONGWEI ZHAO

Institute of Geology, China Earthquake Administration, Beijing100029, China (fqc@ies.ac.cn)

Most of the mantle-derived magmas are silicate melt, with very few others, such as carbonate magmas. However these rare carbonate magmas tell quite different but important stories on mantle evolution. Here we report a new case of mantle-derived carbonate magma found in the Cenozoic basalts in Hannuoba and Yangyuan, North China. The carbonate melts occur in small veins, which cut through the basalts and mantle peridotite xenoliths. The carbonatite veins are mainly dominated by calcite (>90%), with a little amount of mantle minerals, e.g. olivine, clinopyroxene, orthopyroxene and spinel. The xenoliths are altered by the carbonate melt, and their colors changed from originally yellow or green to purplish brown-amarance, with grayish white network stringers of carbonatite cut through. Whole rock chemical compositions reveal that the carbonatite veins have low rare earth elements (ΣREE =8.7-13.7×10^{-6}) and trace elements, with slightly enriched LREE patterns. Stable isotopes of C and O in the carbonatite veins are $\delta^{13}C$=-11.2~-12.3‰ and $\delta^{18}O$=22.6~22.8‰, respectively. Only a few fresh samples from Hannuoba have mantle carbonatite C and O isotopic ratios ($\delta^{13}C$ = -5.7~-7.3‰ , $\delta^{18}O$ = 8.5~10.1‰), while most samples show significant characteristics of weathering. Radioactive isotopes of Sr, Nd, Pb are $^{87}Sr/^{86}Sr$= 0.7078-0.7079, $^{143}Nd/^{144}Nd$=0.5129, $^{206}Pb/^{204}Pb$=18.0, $^{207}Pb/^{204}Pb$=15.5, $^{208}Pb/^{204}Pb$=38.0, respectively. ε_{Nd} of two samples in Hannuoba vary in 5.3-5.5, and reveal their DM mantle origin. The carbonatite indicate that they have the same origin of depleted mantle as the basalt, but weathering after magma eruption modifies the carbonatite.

Biosynthesis of sterols and wax esters by *Euglena* of acid mine drainage biofilms: Implications for eukaryotic evolution and the early Earth

JIASONG FANG[1,2], SHAMIK DASGUPTA[2], SANDRA S. BRAKE[3], STEPHEN T. HASIOTIS[4] AND LI ZHANG[5]

Acid mine drainage (AMD) environments are potential analogs for Earth's primordial environment. We studied biofilms of an AMD system (pH 2.0-3.5) in western Indiana, USA. Biofilms, either floating or attached to the bottom of the AMD flow channel, are formed by the acidophilic, microeukaryote *Euglena mutabilis*. Lipid analysis of benthic and floating biofilms revealed the dominance of photosynthetic organisms, *Euglena mutabilis*, as indicated by the detection of abundant phytadiene, phytol, phytanol, polyunsaturated *n*-alkenes, polyunsaturated fatty acids, short-chain (C_{25-32}) wax esters (WE), ergosterol, and tocopherols. The WE were probably synthesized in mitochondria under anaerobic conditions, whereas the sterols (ergosterol and ergosta-7,22-dien-3β-ol) were likely synthesized in the cytosol in the presence of molecular oxygen by the acidophilic, photosynthetic microeukaryotes *Euglena*. The dual aerobic and anaerobic biosynthetic pathways may be the biochemical relics of the anaerobic past of the Earth. Given that the oxygenation of the oceans is a relatively recent event (i.e., ~580 Ma ago), ca 1 billion years after eukaryotes arose, the conserved compartmentalization of *Euglena* biosynthetic machinery may have allowed early eukaryotes to survive and diversify early on Earth, when the oceans were anoxic and sulfidic, and despite their evolution, they preserved this physiology. Wax esters and their diagenetic products (short-chain *n*-alkanes and alkanoic acids) may be the molecular biosignatures of these organisms in the geologic record.

Unconstrained fluxes to the ocean: Calcium isotopes in dust-producing regions

MATTHEW S. FANTLE[1], HEATHER TOLLERUD[1], ANTON EISENHAUER[2] AND CHRIS HOLMDEN[3]

Though mineral dust can be an important input to the ocean over geologic time scales, little is known about its Ca isotopic composition (delta44/40Ca). This study measures the Ca isotopic composition of sediments from an active dust source in the western U.S. (Black Rock Desert, NV). We present geochemical, mineralogical, and isotopic data from 22 sediments collected from the upper 0.5 cm of the playa. Isotope data for sequential water & 0.5 N HCl leaches and leached residues are presented. Lithium metaborate fusions of bulk sediments reveal Ca concentrations between 0.28 and 40 wt.% (median: 6.8 wt.%), an 80% enrichment relative to upper continental crust. XRD data indicates calcite concentrations of 2–32%, with most samples containing 7–14%. Water leaches generally sample <1% of total Ca, while acid leaches sample >60%. Water leaches are, on average, +0.33±0.16‰ (1SD) heavier than acid leaches; the degree of fractionation varies (Δ_{w-a} = ~0-0.6‰) and appears to depend only on the fraction of Ca in the acid-soluble fraction. Acid leaches are, on average, -0.45±0.07‰ (bulk Earth scale), similar to the delta44/40Ca of modern nannofossil ooze (-0.4‰) and modern rivers (-0.41±0.08‰; Tipper *et al*., 2010).

Dust-derived Ca is an important mass flux to constrain. Assuming a modern mineral dust flux of ~10^3 Tg/yr to the global ocean (e.g., Duce and Tindale, 1991) and a calcite concentration <10%, the inferred Ca mass flux to the ocean is <100 Tg/a. This flux is comparable to the mass flux of Ca delivered by rivers to the modern ocean (~550 Tg/yr). The implication of this work is that the "mobile" fraction of playa-derived dust (water- & acid-soluble pools) is not fractionated relative to riverine input to the ocean. If, however, the acid-soluble fraction is not readily released into the water column, the water-soluble fraction (which can be significantly heavier) is the appropriate flux to consider when discussing atmospheric inputs of Ca to the ocean. During transport, calcite dissolution can be inhibited by high pHs (>8) generated when soluble Na-carbonates dissolve in aerosols. Such pHs are seen in modern systems close to dust sources (e.g., the Mediterranean), where the bulk of dust is deposited.

Isotope constraints on the biogeochemical cycling of calcium (Ca) in a base-poor forest ecosystem

JURAJ FARKAŠ[1], ADRIEN DÉJEANT[2], MARTIN NOVÁK[1] AND STEIN B. JACOBSEN[3]

[1]Department of Geochemistry, Czech Geological Survey, Geologická 6, 152 00 Prague 5, Czech Republic

[3]Department of Earth and Planetary Sciences, Harvard University, 20 Oxford Street, Cambridge, MA, USA

We studied the biogeochemical cycling of Ca in an old-growth forest at Wachusett Mountain, which feeds the Nashua River Watershed located in central Massachusetts, the northeastern USA. The forest grows on naturally base-poor soils (i.e. Ca and Mg depleted) developed on the granodioritic bedrock of Precambrian age. Trees are thought to obtain dissolved Ca mainly from an easily accessible soil-water reservoir termed the 'exchangeable cation pool'. The status of Ca reserves in this soil pool is sensitive to anthropogenic soil acidification and excessive timber harvesting. Our study shows that in the base-poor forest at Wachusett Mountain the 'exchangeable Ca pool' of mineral soils has a unique isotope signature that is significantly enriched in radiogenic ^{40}Ca due to the dissolution of K-rich silicate minerals such as biotite. In contrast, samples of local vegetation (i.e. woody tissues of red oak) show no detectable excess of the radiogenic ^{40}Ca, thus challenging a prevalent belief that the 'exchangeable cation pool' of mineral soils plays an important role as the source of Ca in forest nutrition. This study shows that base-poor forests are able to bypass the 'exchangeable Ca pool' in mineral soils, and still meet their nutritional needs, thus being largely independent of the rock-derived nutrient sources. Consequently, the growth of base-poor forests must rely primarily on alternative Ca sources, which do not show the radiogenic ^{40}Ca excess. Such sources of Ca may include (i) atmospheric deposition [1, 2], (ii) recycling of the forest-floor organic matter, and/or (iii) the fungal-mediated dissolution of apatite [3]. Finally, we will also discuss temporal variations in the Ca isotope composition of a tree-ring record from a 260-year old red oak collected at our study site.

Rapid climate change during marine isotope stage 5-4 glacial inception in the subpolar North Atlantic

ELIZABETH J. FARMER* AND MARK R. CHAPMAN

School of Environmental Sciences, University of East Anglia, Norwich, UK. (*correspondence: e.farmer@uea.ac.uk)

Previous work from North Atlantic core NEAP 18K highlighted the occurrence of a number of previously unrecognised ice rafting events occurring not only during periods of greatest ice volume, but also during periods of ice sheet growth and decay. Ice core records highlight two events (Dansgaard-Oeschger (DO) events 19 and 20) during the transition between MIS 5 and 4 as the largest events in the last 100 ka, with temperature shifts in excess of 10°C over a matter of decades.

In the present work, the new record from NEAP 17K is presented. A neighbouring core to NEAP 18K, this core has a higher accumulation rate through the MIS 5/4 period, and, like NEAP 18K, is in a key region for monitoring the movements of the polar front and changes in the surface to deep ocean connectivity and potential for NADW production over glacial-interglacial time scales

Two rapid shifts in faunal assemblage are clearly evident during the transition. SST estimates indicate temperature shifts in the order of 8°C. These oscillations correlate with DO events 19 and 20, and are preceded by small ice rafting events, C19 and C20, coincident with a freshening of the surface waters. Benthic stable isotope data provide stratigraphic control and allow us to examine the relative strength of North Atlantic Deep Water production. Mg/Ca records separate the response of the surface and subsurface water masses and provide an intriguing alternative temperature record.

These records support the ice core proxies in suggesting that this interval was a period of extreme and rapid climatic change in the North Atlantic. The linkage between the surface and deep ocean, and the parallels in the Greenland ice cores, would indicate that these events were not local to Greenland alone but were felt across the North Atlantic region and are associated with a significant reorganisation of North Atlantic circulation.

Development of a micro-interdigitated electrode array for use in high precision TIMS-based isotope ratio determinations

G. L. FARMER* AND E.P. VERPLANCK

Dept. of Geological Sciences and CIRES, University of Colorado, Boulder, CO 80309, USA; (*correspondence: farmer@colorado.edu)

Thermal ionization mass spectrometry (TIMS) remains the method of choice for high precision Pb isotopic measurements, but "silica gel" techniques used to generated thermalized Pb ions have ionization efficiciencies of only 10% at best. To improve Pb ionization efficiencies from liquid glass ion emitters and ultimately the precision of U-Pb age determinations we are using electrochemical techniques to increase Pb ionization efficiencies *in situ* in liquid glasses. Our initial work demonstrated that Pb-doped high temperature (~1,300ºC) liquid glass can serve as the electrolyte in an electrochemical cell and that Pb metal atoms prevalent in the glass under vacuum conditions can be oxidized to Pb^+ by the application of ~1V across Pt wire electrodes. To take advantage of this ionization mechanism, we are developing a micro-interdigitated electrode array (IDA) for use as an "electrochemical" ion source. This array consists of a "comb" structure of interleaved tungsten electrode "fingers" sputtered onto a pure silicon wafer. The array fabrication process includes spinning photoresist on an oxidized 275µ thick silicon wafer and exposing the wafer to UV light through a photomask. The DC sputter deposition system applies a 1µ layer of tungsten to the wafer. A photoresist liftoff procedure removes most of the metal layer, leaving the IDA structures on the wafer. The electrode lengths and widths range from 100-200µ and 10-200µ, respectively. There are 1-14 pairs of these electrodes on each IDA, with gap widths of 10-15µ. Our initial results reveal that a Pb-doped silica suspension can be dried and melted on the IDA surface by a metal ribbon resistive heater placed in contact with the electrically non-conducting silicon wafer substrate of the IDA. Our next step will be to install the IDA and heater ribbon in a Finnigan-MAT 261 TIMS, and to connect the assembly to a specially-designed potentiostat that will allow the IDA to float at 10KV while a differential voltage from 0.1 to 10V is applied across the IDA electrodes. This work is currently in progress.

Potential for manganese oxidation in shallow groundwater induced by water table fluctuation

C. E. FARNSWORTH[1,2], A. VOEGELIN[1] AND J. G. HERING[1,3,4]*

[4]École Polytechnique Fédérale de Lausanne, School of Architecture, Civil, & Environmental Engineering, Lausanne, Switzerland

On-off cycles of production wells, especially in bank filtration settings, cause oscillations in the local water table, which can entrap significant amounts of dissolved oxygen (DO) in the shallow groundwater. Although attempts to quantify air entrapment and transport in groundwater are ongoing, less attention has been paid to the potential geochemical reactions initiated by DO introduction to low-DO groundwater.

The potential for DO introduced in this manner to oxidize manganese (Mn), mediated by the obligate aerobe *Pseudomonas putida* GB-1, was tested in a column of quartz sand with anoxic influent solution and 1.3-m water table changes every 30-50 h. The frequency and amplitude of the oscillations simulated those of a bank filtration site in Berlin, Germany. After a period of filter ripening in the column, 100 µM Mn was rapidly removed during periods of low water table and high dissolved oxygen concentrations. The accumulation of Mn in the column was confirmed by XRF analysis of the sand at the conclusion of the study, and both measured net oxidation rates and XAS-derived speciation suggest microbial oxidation as the dominant process. The addition of Zn, which inhibited GB-1 Mn oxidation but not its growth, interrupted the Mn removal process, but Mn removal recovered within one water table fluctuation. Thus transient DO conditions could support Mn oxidation, and the conditions under which this process could be relevant in shallow groundwater in alluvial sediments will be presented.

Redox and early Earth's sulfur cycle

JAMES FARQUHAR[1], MARK CLAIRE[2], SHAWN DOMAGAL-GOLDMAN[3], BRIAN HARMS[1], SIMON W. POULTON[4]* AND AUBREY L. ZERKLE[4,1]

[1]Department of Geology and ESSIC, Univ. Maryland, USA

[3]NASA Headquarters, Washington, D.C., USA
[4]School of Civil Engineering and Geosciences, Newcastle University, UK (*correspondence: s.w.poulton@ncl.ac.uk)

It has been a little over 10 years since it was recognized that mass-independent sulfur isotope signatures in the Archean and earliest Paleoproterozoic rock record provided information about the redox state of Earth's surface environments. As the dataset has grown, new features of the record have emerged, including the recognition of a relatively clear change in the magnitude of $\Delta^{33}S$ that defines the range of variation between the Eo-Paleoarchean, the Mesoarchean, and the Neoarchean [1], a change in the symmetry of this signal about the origin for this same interval [(maximum positive $\Delta^{33}S$)/(maximum negative $\Delta^{33}S$)] [2], and changes in the relationship between $\Delta^{36}S$ and $\Delta^{33}S$ that are corelated with the age and stratigraphy of the measured samples (e.g., [3,4]). It also appears that the the mean value of $\Delta^{33}S$ (and $\Delta^{36}S$) for different parts of the Archean varies, which bears on the issue of whether the available samples can be used to close the sulfur cycle.

Our work over the past few years has focused on understanding these and other aspects of the sulfur cycle, and also on connections between the implied causes of MIF-S and the sources/sinks in the sulfur cycle, and their collective implications for the evolution of the redox state of the Archean and Paleoproterozoic atmosphere and oceans. The picture that emerges appears to call for a change in the cycling of sulfur extending from the Eoarchean, through the Paleo- and Mesoarchean, and into the Neoarchean. The record implies significant changes in structure of the sulfur cycle pathways – specifically related to the role of those for reduction and reoxidation of sulfur compounds. These data, sulfur cycle models, and the basis for these assertions will be discussed.

Evidence for subduction history recorded by mineral inclusions in high-grade metamorphics of the Modanubian zone, central Europe

SHAH WALI FARYAD, ONDREJ LEXA, MARTIN RACEK, DAVID DOLEJŠ AND RADIM JEDLIČKA

Institute of Petrology and Structural Geology, Charles University Prague, Albertov 6, Prague 2, Czech Republic

Felsic granulites with lenses of eclogites and garnet peridotites in the Variscan orogen of central Europe contain various mineral inclusions that can be used to reconstruct their early prograde metamorphic history. Ultrahigh-pressure conditions for some of these rocks were deduced by conventional geothermobarometry and from inclusions of microdiamonds. These rocks are usually interpreted to be exhumed from lower crust or upper mantle by crustal thickening followed by extrusion to middle crustal levels.

We investigated mono- and polyphase mineral inclusions and their replacement products in garnets from granulites and mantle peridotites. Inclusions of Cr-rich spinel were commonly encountered in garnet or in pyroxene enclosed by garnet. In clino- and orthopyroxene, garnet form by destabilization and exsolution of Al-Tschermak end-member during pressure increase and/or temperature increase. In addition, garnet grains from pyroxenites and eclogites contains inclusions of omphacite and a variety of single- or multiphase inclusions, which consist of combinations of sodic-calcic amphibole, alkali feldspar, phlogopite, chlorite, and carbonate. The inclusions have negative crystal shapes and their mineral assemblages and composition may point to crystallization in the presence of chlorine-bearing aqueous fluid(s). These features suggest (re)crystallization of mantle peridotites and pyroxenites during pervasive fluid percolation probably driven by slab dehydration and decarbonation during subduction. Eclogite-facies prograde history is independently supported by the presence omphacite and phengite in garnet, respectively.

[6]Laboratory of Ecology, Gembloux Agricultural Univ., 5030 Gembloux, Belgium

Metallophytes are plants that mostly occur on metal-rich soils. Some metallophytes grow particularly on soils contaminated by Co, especially in South of Central Africa. *Crepidorhopalon perennis* and *C. tenuis* show a variable ability to accumulate Co in shoots, which can be explained both by synergistic and antagonistic interactions among several trace metals [1]. In fact, Co accumulation in shoots is favoured by high Co concentrations and hampered by high concentrations of Fe and Mn in soils [2].

In this study, we focus on Co fractionation in soil in order to explain the large variation in Co accumulation in *Crepidorhopalon perennis* and *C. tenuis* species, and also the interactions among various trace metals. Organic matter, pH as well as total (using the mixture HF-HCl-$HClO_4$) and extractable (acetate-EDTA 1 mol/L, pH=4.25) concentrations of Mn, Cu, Co, Fe, Ca, Mg and Zn, were measured. Cobalt fractionation was furthermore modelled using Windermere Humic Aqueous Model (WHAM 6) [3]. Positive correlation between sum of organic and free Co concentrations estimated by WHAM 6 and concentrations of extractable (acetate-EDTA) Co was found. Furthermore, fractionation modelling shows a strong affinity of Mn-oxides for Co, which can explain the lower Co levels in the plants grown on Mn-rich soils. The high Mn and Fe status of Cu-Co soil in South of Central Africa may actually exert a protective effect against the toxic effects of Co.

Bioavailability of tungsten in soils and tailings of mining areas with distinctive paragenesis (Northern Portugal)

PAULO FAVAS[1,3], JOÃO PRATAS[2,3] AND ELISA GOMES[1,3]

[1]Dep. of Geology, UTAD, Ap.1013, 5000-801 Vila Real, Portugal (pjcf@utad.pt)
[2]Dep. of Earth Sciences, University of Coimbra, Largo Marquês de Pombal, 3001-401 Coimbra, Portugal
[3]Geosciences Center, University of Coimbra

This paper compares five mining areas of Northern Portugal with distinctive paragenesis (Ervedosa Mine with cassiterite and diverse sulphides; Rio de Frades Mine and Regoufe Mine with wolframite, scheelite, cassiterite and sulphides; Adoria Mine with volframite, cassiterite and sulphides; and Tarouca Mine with scheelite, cassiterite and sulphides) for bioavailable levels of tungsten in soils and the resulting bioaccumulate levels in six species of plants (*Erica arborea* L., *Halimium umbellatum* (L.) Spach, *Pinus pinaster* Aiton, *Pteridium aquilinum* (L.) Kuhn, *Pterospartum tridentatum* (L.) Willk. e *Quercus faginea* Lam.).

The mechanisms relating to the mobility and bioavailability of this metal have been explored using sequential chemical extraction techniques. The procedure adopted in this study allows the separation of the water-soluble fraction, so the extracted chemical elements must be considered highly bioavailable because they are easily mobilised. The elements extracted from the so-called exchangeable fractions, which in this study were leached through the use of NH_4 OAc, are an important part of the potentially available elements and can be considered as an estimate of bioavailability.

Tungsten appears to be relatively immobile in most studied sites, but soils of Tarouca mine show significant increases in bioavailable fraction.

The soils of the Tarouca mine area stand out by their higher content of W in the bioavailable fraction. Probably as a result of easier fragmentation and dissolution of scheelite, compared to wolframite. This is reflected in the bioaccumulated concentrations in the tissues of the studied species at this site. It's in the samples of Tarouca mine that occur higher bioaccumulated levels of W than all five mines. This exemplifies the importance of soil mineralogy, controlling the biogeochemical distribution of elements.

The characteristics of three different subduction zones in Iranian plateau

ARDALAN FAZELVALIPOUR

Member of Young Researchers club, Islamic Azad University Mashhad Branch- Iran, (dra_fv@yahoo.com)

Iranian plateau is a tectonically young complex region resulting from collision of Arabian Plate with Eurasia. Existence of three different subduction zones within different geographical parts provides different tectonic and geodynamic characteristics with the plateau. In this study, we use surface wave tomography method to image S-velocity structure of upper mantle and Moho depth variations across the Iranian plateau. Our results show that there is a clear evidence for subducting of Arabian plate beneath central Iran across the Zagros collisional zone in south-west Iran. Active subduction still occurs to the southeast of Iran where the oceanic part of Arabian plate is being subducted beneath Makran coast. The oceanic crust of South Caspian Basin is being westward under thrusting under Talesh and Alborz mountains in northern part of Iran.

To image *S*-velocity structure of upper mantle and Moho depth variations of Iranian plateau ,we apply surface wave tomography based on Partitioned Waveform Inversion (PWI) method(Nolet, 1990). PWI method consists of two steps: in the first step, 1-D average S-velocity model and average Moho depth is determined for each event-station propagation path using nonlinear waveform inversion. The results are given based on absolute S-velocity variations with depth for the given path. Then, 1-D S-velocity models obtained in the previous step, are firstly reformulated (normalized) with respect to a common background model and are secondly combined using a damped linear inversion algorithm to image 3-D S-velocity perturbations and Moho depth variations for the studied area. Depending on epicentral distances and quality of the data, the selected time window for waveform-fitting in the first step is started from beginning of S phases (for $\Delta \leq 30^{o}$) or SS (for $\Delta \leq 70^{o}$) to end of fundamental mode of surface waves. This indicates that only those phases with turning point in the upper-mantle are included in the inversion. Synthetic seismograms are constructed by mode-summation using the first 30 modes of Ray leigh waves, with phase velocitiesbetween2 and 10 km/s.

The efficiency of PWI method strongly depends on path coverage of waveforms in the studied region (Fig. 1). Our dataset consist of Z-component of broadband seismograms from events with a magnitude between 5.5 and 7.7 recorded by one temporary array and two permanent networks Of nearly 3000 seismograms originally analysised, we have fitted 974 waveforms from 47 events and 39 stations (Fig. 2) which result in 11688 linear constraints on upper-mantle S-velocity structure and Moho depth for the studied area

The damped linear inversion of the constraints derived from waveform fittings yields a 3-DS-velocity model and Moho map across Iranian plateau. In the following sections, we explain the results.

Diamond record of metasomatism

Y. FEDORTCHOUK[1]* AND Z. ZHANG[1,2]

[1]Dalhousie University, Halifax, Nova Scotia, B3H4J1, Canada (*correspondence: yana@dal.ca, Zhang.Zhihai@dal.ca)

[2]China University of Geosciences, Wuhan, 430074, China

The majority of diamond population from a kimberlite carry surface features developed during accent in kimberlite magma. However, a small proportion of each diamond population shows other resorption styles reflecting diamond-dissolution events prior to the kimberlite emplacement. In order to better understand the nature of diamond-destructive fluids (or melts) in the mantle we focused this study on the latter group. Detailed study of diamond morphologies, nitrogen content and aggregation, and internal structure using cathodoluminesence images was done for micro-diamonds from four kimberlite pipes from the Ekati Mine, Canada.

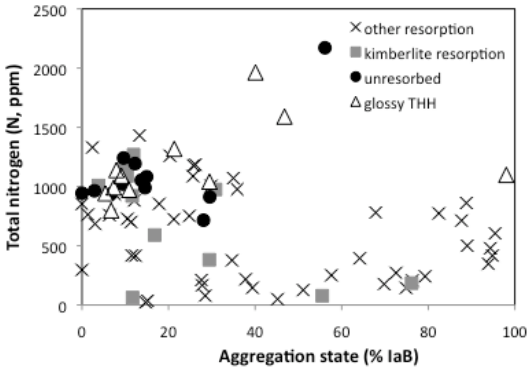

Figure 1: Nitrogen data for morphological groups.

We defined four groups: 1) unresorbed octahedral diamonds and those with “kimberlitic” resorption features; 2) stones with deep hexagonal and trigonal etch pits; 3) several types of step-faced crystals; 4) other surface features different from the “kimberlite-induced” resorption. A correlation between the resorption style and nitrogen content and aggregation state of diamonds determined by Fourier Transform Infrared analyses (Fig. 1) indicates similar thermal /crystallization history of diamonds with similar resorption style. Comparison to the products of high-pressure experiments [2] suggests diamond interaction with water-rich fluids in the mantle source. Further work will refine diamond grouping. The conditions of these resorption events will be constrained through diamond dissolution experiments.

Fluids at continental margins: What we can learn from ^{129}I results

UDO FEHN

Dept. of Earth and Environmental Sciences, U. Rochester, Rochester, NY, 14627, USA (ufehn@ur.rochester.edu)

The close association of iodine with organic material and the presence of the long-lived radio-isotope ^{129}I ($T_{1/2}$ = 15.7 Ma) make this isotope system an interesting tracer for fluid movements at continental margins. The system was applied to studies of volcanic fluids associated with subduction zones [1] as well as to methane-rich fluids at passive [2] and active margins [3]. Volcanic fluids are characterized by iodine concentrations close to 10 μM, i.e. only moderatly higher than in seawater (0.4 μM) and by CO_2 as their dominant carbon species. Results for volcanic fluids show ^{129}I/I ratios which are site-dependent and are consistent with derivation from subducting marine sediments. In contrast, fluids associated with gas hydrates or emanating from mud volcanoes along continental margins are enriched in iodine by factors of 500 or more compared to seawater and are dominated by the presence of CH_4. ^{129}I/I ratios in these methane-rich fluids predominantly fall into a narrow range between 200 and 400x10^{-15}, regardless of site or age of subducting slab present in active margins. Because the ^{129}I results show neither relation to the age of the host sediments nor to the ages of subducting slabs or other tectonic features, a significant proportion of iodine in the fluids in these locations probably is derived from sources in the upper plates of active margins. More specifically, the iodine age distribution suggests that organic sources of Eocene age or older have contributed to the iodine present in these fluids. These sources are found in the deeper sections of passive margins and in the continental parts of subduction zones. The ^{129}I/I results demonstrate that different processes are active in fore arc and main arc areas: volcanic fluids in the main arcs show the recycling of volatiles from subducting marine sediments but fluids in fore arc areas are predominantly derived from sources in upper plates, i.e. the terrestrial parts of continental margins.

The plastic deformation of minerals in the mantle is believed to be controlled by diffusion. Si is the slowest diffusion species in most mantle minerals, and therefore expected to limit the creep rates [1]. Jaoul *et al*. [2] measured the Si self-diffusion coefficient (D_{Si}) in forsterite (*Fo*) at ambient pressure, showing log[D_{Si} *(m^2/s)*]= -22.1 at 1600 K. Such a value is approximately 3 orders of magnitude lower than that expected from the deformation experiments [3]. Moreover, measurement of D_{Si} at high pressures [4] showed very high D_{Si}, i.e., logD_{Si} = -19.8 at 1600 K. In order to solve these discrepancies, we revisited D_{Si} in *Fo* in this study.

Fo crystals were polished in colloidal silica solution, deposited with 300-500 nm of ^{29}Si enriched Mg_2SiO_4 films coverd by 100 nm of ZrO_2 films. They were annealed at 1600 K and 0, 1 and 8 GPa for diffusion. The diffusion profiles were obtained by SIMS.

Surface roughness is a serious error source for SIMS analysis. Although the roughness just after deposition was less than 10 nm, that after annealing become as large as 250-300 nm. Hence, the samples were polished again in colloidal silica solution after diffusion. The final roughness was thus reduced to be less than 50 nm.

logD_{Si} was determined to be -19.3±0.5 at 0 GPa and 1600 K in this study, which is 2.8 orders of magnitude higher than that by Jaoul *et al*. [2]. Their low D_{Si} could be obtained due to the bad contact of the coating layer with the host. The present D_{Si} is consistent with the high dislocation climb rates in deformation experiments. Our data also indicates a small activation volume as 3.0×10^{-6} m^3/mol.

Efficient carbon leaching in silicate through fluid/melt migration and implications for diamond formation

YINGWEI FEI[1]*, CHI ZHANG[1] AND RENBIAO TAO[1,2]

[1]Geophysical Laboratory, Carnegie Institution of Washington, 5251 Broad Branch Road, NW, Washington, DC 20015, USA (*correspondence: fei@gl.ciw.edu)

[2]School of Earth and Space Sciences, Peking University, Beijing 100871, China

Natural diamond forms in silicate metrix at depths great than 150 km. Carbon concentration in the mantle is very low and there must be an efficient process to concentrate carbon to form diamond. Carbon-bearing fluids and carbonates are considered to be the major carbon sources for diamond formation, and their migration in silicate rocks at high pressure and temperature could provide important clues for understanding the mechanism of carbon enrichment during diamond formation.

Fluid and melt migrations in the mantle are droven by tempertaure/pressure and chemical gradients and gravity. High-pressure experiments in silicate-fluid and silicate-carbonate systems were performed to examine migrations of C-saturated fluid and carbonate melt in silicate matrix. We start with homogeneous mixture of amorphous carbon and silicate minerals (olivine or pyroxene). With presence of fluids, we observed efficient separation of graphite/diamond from its matrix and it concentrated at the end of the capsule. We further examined the effect of thermal gradient and gravity on the separation by a multiple-capsule techniqued.

Carbon can exist in its reduced (e.g., elemental C and CH_4) or oxidized (e.g., CO_2 and CO_3^{2+}) forms. Redox reaction plays an crucial role in diamond formation process. It is important to determine if carbon enrichment is more efficient in its reduced form than in its oxidized form. We examine the CO_2-rich melt distribution in solid silicate phase by SEM imaging and 3D tomography. The carbon enrichment through oxidized melt is not as efficient as in the form of elemental carbon, indicating that efficient diamond growth may require reduction of carbon to its reduced form first.

Upper crustal overprinting of lower crustal processes at Maipo Volcano (34˚10'S), Southern Volcanic Zone

MAUREEN D. FEINEMAN[1], DANA DREW[1], TIMOTHY MURRAY[1] AND PATRICIA SRUOGA[2]

[1]Pennsylvania State University, University Park, PA 16802, USA (mdf12@psu.edu, dld5066@psu.edu, ttm5055@psu.edu)

[2]CONICET-SEGEMAR, Av. J. A. Roca 651, Buenos Aires, 1067 ABB, Argentina (patysruoga@gmail.com)

The Diamante Caldera – Maipo Volcanic Complex is situated in the northernmost part of the Andean Southern Volcanic Zone (SVZ), upon ~50 km thick continental crust. Receiver function data suggest magma stalling at the base of this thickened crust in the northern SVZ [1], which is consistent with along-arc trace element variations that show increasing evidence for equilibration with garnet in basalts and basaltic andesites erupted to the northern end of the SVZ [2]. In a suite of basaltic andesite to dacite lavas sampled at Maipo, we observe clear evidence of assimilation and fractional crystallzation (AFC) processes in the upper crust, overprinted upon the lower crustal, presumably garnet-equilibrated trace element signature. The basaltic andesites are characterized by Sr/Y = 35-40, Eu/Eu* >0.85, $^{87}Sr/^{86}Sr$ = 0.7045-0.7050, and $^{144}Nd/^{143}Nd$ = ~0.5126. These chemical characteristics reflect a significant lower crustal input relative to basalts and basaltic andesites from the central and southern portions of the SVZ, which sit upon much thinner crust and are characterized by Sr/Y = 15-30, Eu/Eu* ≈ 1, $^{87}Sr/^{86}Sr$ = ~0.7040, and $^{144}Nd/^{143}Nd$ = ~0.5129 [3]. The Maipo data show continuous geochemical trends from the basaltic andesites to the dacites, which are characterized by Sr/Y = 14-24, Eu/Eu* ≈ 0.50-0.75, $^{87}Sr/^{86}Sr$ = 0.7054-0.7057, and $^{144}Nd/^{143}Nd$ = ~0.5125. These dacites are consistent with differentiation from the basaltic andesites by AFC with a plagioclase-rich crystallizing assemblage in an upper crustal magma chamber. Constant Gd/Yb (2.5-3.1) in the lavas may reflect a buffering effect of amphibole during differentiation, although it is rarely observed in the phenocryst assemblage. The high Sr/Y in the more primitive magmas, which suggests garnet fractionation at depth, has been erased in the more evolved magmas. Thus we note that the absence of high Sr/Y in intermediate arc magmas does not necessarily indicate that the magma did not interact with garnet at depth.

The Zabuye salt lake, located in Tibet, is famous for its high concentration of lithium, potassium and borate. During the process of natural evaporation, metastable phenomena existed in different degree. The metastable phase diagrams are the basis of comprehensive utilization of saline lake brine. In this paper, the solubility of the system was measured at 273.15 K using an isothermal evaporation method.

Figure 1 is the metastable phase diagram of the system at 273.15 K. The diagram consists of three crystallization fields corresponding to single salts $K_2CO_3 \cdot 3/2H_2O$, KCl and K_2SO_4, respectively. There are three univariant curves corresponding to curves AE, BE and CE, indicating the cosaturation of two salts. Invariant point E is saturated with salts $K_2CO_3 \cdot 3/2H_2O$, KCl and K_2SO_4. The crystallization field of K_2SO_4 is the largest, and the crystallization field of K_2CO_3 is the smallest. These results indicate that salt K_2SO_4 is easy to be saturated and crystallized from the aqueouse solution coexisting with sulphate, chloride and carbonate of potassium.

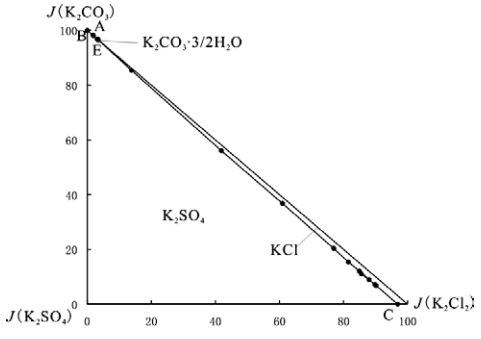

Figure 1. Metastable phase diagram of the quaternary system $K^+//Cl^-$, CO_3^{2-}, SO_4^{2-}-H_2O at 273.15 K

Rivers deliver huge amounts of terrestrial organic carbon (OC) into oceans in both dissolved and particulate form. The fate of dissolved organic matter (DOM) and particulate organic matter (POM) may vary due to different degradation pathways and physical protection mechanisms. Determining the composition and residence time of DOM and POM during riverine transport is crucial for understanding the role of terrestrial OC in global carbon cycling. As a uniquely terrestrial biomarker, lignin serves as an effective tracer of vascular plant OM in river DOM and POM. While it has been established that lignin is a prominent component of POM and is widely dispersed by rivers, much less is known about the fate of lignin in the dissolved form. Here we investigate the abundance and composition of lignin-derived phenols in the DOM and POM from the Ganges-Brahmaputra river system. Lignin phenols were liberated from POM collected on filters and from DOM collected on C_{18} solid-phase cartridges using the CuO oxidation method. We compared the abundance, composition, and degradation stage of lignin phenols to assess lignin fractionation and degradation in the dissolved and particulate phases during the land-river transport. Furthermore, we collected large-volume samples of riverine DOM and POM in order to isolate sufficient quantities of lignin phenols by high pressure liquid chromatography for compound-specific radiocarbon and stable carbon isotopic analysis. The radiocarbon age of dissolved lignin versus lignin in sedimentary particles provides insights on the fate and transport of terrestrial organic matter within fluvial systems.

East Africa and Indian Ocean Trade

This research examines the provenance of non-ferrous metals found at East African Swahili sites dating from the late 1st and early 2nd millennium AD. Previous archaeological work on the Swahili Coast documented evidence of long-distance Indian Ocean maritime trade including imported objects from the Middle East, India and China [1, 2, 3]. Recent research has also examined the movement of specific commodities (e.g., ceramics, glass beads) from various regions of the Indian Ocean to the East African coast [4, 5].

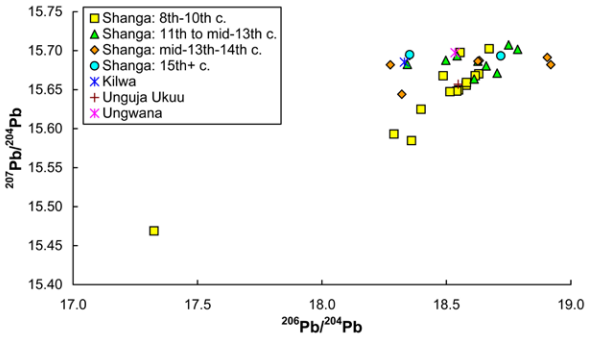

Figure 1: Lead isotopic ratios of non-ferrous metals from the Swahili sites of Shanga, Kilwa, Unguja Ukuu and Ungwana.

Metals Trade to the Swahili Coast

Very little research has been made on the movement of metals to the East Africa coast [6, 7]. The current research conducted elemental composition and lead isotopic analyses of more then 30 non-ferrous objects and has identified several different source regions supplied metal to the Swahili coast. Results indicate that Iran likely was a major source, but that metals also came from the Arabian Peninsula and China, but that none appear to have originated from India.

Cation adsorption at the muscovite-electrolyte solution interface

P. FENTER[1]*, S.S. LEE[1], M. SCHMIDT[1], L. SODERHOLM[1], R.E. WILSON[1], C. PARK[2], K.L. NAGY[3] AND N.C. STURCHIO[3]

[1]CSE Division, Argonne National Laboratory, Argonne IL 60439 (*correspondence: Fenter@anl.gov)
[2] HP-CAT, Geophysical Laboratory, Carnegie Institution of Washington, Argonne, IL 60439,
[3]Dept. of Earth and Environmental Sciences, MC-186, University of Illinois at Chicago, Chicago IL 60607.

The interaction of ions with charged mineral surfaces is central to many geochemical processes, including the transport and bioavailability of dissolved species. The muscovite (001)-electrolyte interface is apparently simple, with a fixed lattice charge of the muscovite located below the surface and without under-coordinated surface oxygen sites that would lead to a strong pH dependent surface charge. Yet, we find that the adsorption structure of cations at this interfaces is unexpectedly complex.

Previously, we found that Rb^+ adsorbs in the ditrigonal site as an inner-sphere (IS) species, while Sr^{2+} adsorbs as both IS and outer-sphere (OS) species [1]. A systematic study of a range of divalent cations has shown that there exists a third adsorbed species, an extended OS species (OS_{ext}), and the partitioning between these three species is controlled by the cation hydration enthalpy [2]. Ongoing work has extended these observations to other multivalent ions (Y^{3+}, Th^{4+}) whose adsorption structure can be understood in the same context as that observed for divalent ions.

We have also explored the role of competitive adsorption to influence the distribution of adsorbed cations. Specifically we have found that the partitioning of cations between IS, OS and OS_{ext} species can change with the introduction of competing cations. Furthermore, the introduction of natural organic matter (in the form of dissolved fulvic acid) can dramatically alter the adsorbed cation distribution which is controlled by a balance between cation hydration, cation organophillicity, and cation-mineral interactions.

This work was supported by DOE/BES Geoscience Research Program (ANL and UIC) as well as the National Science Foundation (UIC). The Th results were supported by DOE OBER, NSF and EPA.

Bioavailability of metals in a creek environment in Mumbai, India

LINA FERNANDES AND G. N. NAYAK

Department of Marine Sciences, Goa University-403206

A sediment core collected from Thane creek (north-east of Mumbai) in India was studied, with an aim to assess the degree of sediment contamination and bioavailability of metals. The concentration and chemical distribution of elements (Al, Fe, Cu, Cr, Mn, Co, Pb, Ni, Zn) along with speciation of selected metals was determined to know the extent to which selected elements were bioavailable and also to differentiate the anthropogenic metals from those of natural origin.

Geoaccumulation index computed for the studied elements, show Cu, Pb and Cr are moderately polluted. In accordance with these results, sequential extraction was carried out, to identify if Pb, Cr and Cu in the different sediment phases are bioavailable. From the results, for Cu, the order of percentage contribution is Residual (F5) >Fe-Mn oxides (F3)>organic/sulphide (F4)>carbonates (F2) >Exchangeable (F1), for Cr it is F5>F4>F3>F2>F1 which clearly indicates that, these metals are primarily immobile and have or bear the least bioavailability. For Pb it appears to be F5>F3>F4>F1>F2. Metals, especially of anthropogenic input, are expected to associate with the first four fractions and metals found in the residual fraction are considered to be of natural occurrence derived from the parent rock. For Pb, the percentage of the first two fractions (F1 & F2) are high when compared to first two fractions of Cu and Cr. F1 and F2 are very important from an ecotoxicological point of view because these are the fractions that are readily bioavailable to organisms that ingest sediments and hence can pose a health threat to the aquatic environment.

Use of CO_2/H_2O IRGA-based evolved gas analysis during thermal analysis of soil organic matter

JOSÉ M. FERNÁNDEZ[1], JOSEPH M. CRAINE [2] AND ALAIN F. PLANTE[1]

[1]Dept. of Earth and Environmental Science, Univ. of Pennsylvania, PA-19104, USA. (*correspondence: joseman@sas.upenn.edu, aplante@sas.upenn.edu)

[2]Div. of Biology, Kansas State Univ. KS-66506, USA (jcraine@ksu.edu)

Despite the increasing use of thermal analysis to characterize soil organic matter (SOM) in recent years, the exothermic region that represents the temperature range in which SOM is oxidized has not yet been equivocally defined.

In this study, surface soils from 28 sites across North America, ranging from Alaska to Puerto Rico, were analyzed in an oxidizing atmosphere (synthetic air, 30 mL min^{-1}) with a simultaneous thermal analyzer (thermogravimetry and scanning differential calorimetry) coupled to an infrared gas analyzer (IRGA) to measure CO_2 and H_2O gases evolved from thermal reactions.

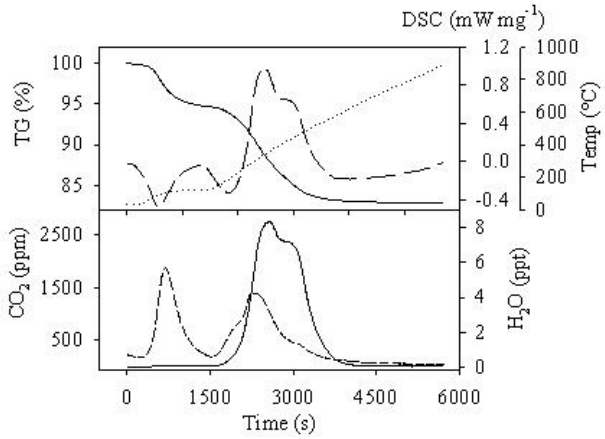

Figure 1: a) DSC (mW mg^{-1}), TG (%) and temperature (°C) of thermal analysis of a bulk soil sample, and **b)** evolved CO_2 (ppm) and H_2O (ppt) measured by IRGA.

Evolved CO_2 gas analysis suggests the onset temperature of the exothermic region was 256 ± 18 °C, though CO_2 evolution typically began near 125 °C. The endset temperature was typically 537 ± 36 °C, but varied widely due to the presence of pyrogenic C or carbonates. Defining the exothermic region is essential to characterizing SOM using thermal analysis.

Determining the influence of the mineral matrix on thermal analysis of soil organic matter in bulk samples

JOSÉ M. FERNÁNDEZ[1]*, CRAIG RASMUSSEN[2] AND ALAIN F. PLANTE[1]

[1]Dept. of Earth and Environmental Science, Univ. of Pennsylvania, PA-19104, USA. (*correspondence: joseman@sas.upenn.edu, aplante@sas.upenn.edu)
[2]Dept. of Soil, Water and Environmental Science, Univ. of Arizona, AZ- 85721, USA. (crasmuss@cals.arizona.edu)

Thermal analysis has the potential to analyze the quality continuum of soil organic matter (SOM) in a quick and inexpensive way, most importantly without pre-treatment of the sample [1]. However, many soil mineral components also exhibit diverse thermal effects. There are different reactions related with the soil mineral matrix (e.g., clay dehydration) that could interfere in the interpretation of thermogravimetry (TG) and differential scanning calorimetry (DSC) results, affecting both weight loss and energy flux measurements, and leading to an over- or underestimation of parameters initially assigned to the thermal oxidation of soil organic matter [2].

To study the effect of the mineral matrix on thermal properties of SOM, five forest soils from conifer ecosystems of the western U.S. with different mineralogy but similar clay to organic C ratios were selected. One aliquot of each soil was treated with HF (10%) to remove minerals, while a second aliquot was treated with NaOCl (6%) to remove organic matter. Bulk soil, HF-treated and NaOCl-treated samples were then analyzed using a simultaneous thermal analyzer under: i) an oxidizing atmosphere (synthetic air, 30 mL min^{-1}) to assess the combustion characteristics of the organic material, and ii) an inert atmosphere (N_2, 30 mL min^{-1}) that suppresses combustion but allows the observation of other thermal reactions. All samples were re-run after each analysis to establish a baseline thermal signature.

Results obtained allowed for quantification of the influence of the mineral matrix on different parameters estimated for the thermal decomposition of SOM in bulk soil samples, and support the hypothesis that on a per-mass basis, the thermal reactions of organic matter are significantly greater than those of the mineral fraction. Thus, only a moderate concentration of SOM is necessary for the mineral phase to have a negligible effects on the DSC signal of bulk soil.

Modelling of a bentonite column experiment with CrunchFlow including new clay-specific transport features

R. FERNÁNDEZ[1]*, U. K. MÄDER[2] AND C. I. STEEFEL[3]

[1]Departamento de Geología y Geoquímica, Facultad de Ciencias, Universidad Autónoma de Madrid, Campus de Cantoblanco, 28049. Madrid, Spain (*correspondence: raul.fernandez@uam.es)
[2]Institut für Geologie, Universität Bern, Batzerstrasse 1-3, CH-3012 Bern, Switzerland (urs.maeder@geo.unibe.ch)
[3]Earth Sciences Division, Lawrence Berkeley National Laboratory, One Cyclotron Road, M.S. 90-1116 Berkeley, CA 94720 USA (CISteefel@lbl.gov)

The porosity concept in bentonite has become an important issue since bentonite is foreseen as a confining and buffer material in high level radioactive waste repositories. The mechanisms associated to transport in the bentonite barrier play a critical role to characterize the chemical and mineralogical evolution of the repository near field.

As a consequence of the interest generated in the last years on this topic, the geochemical code CrunchFlow [1] has been recently implemented to take into account an explicit diffuse layer model associated to charged surfaces in clay systems.

A multi-component advective-diffusive ion transport experiment performed for 304 days at laboratory scale with a cylindrical column of a compacted MX-80 saturated bentonite was proposed as a benchmark experiment to test the new features in CrunchFlow. An artificial saline solution was infiltrated from one column end and the outflow solution was collected in syringes at the other end.

The Cl^- evolution in the experiment and the breakthrough of a non-reactive tracer were used to constrain the microporosity (diffuse layer) and macroporosity (free water) volume fractions and the transport parameters (advective flow rate and specific diffusion coefficients of aqueous species).

The chemical and mineralogical behaviour observed in the experimental system is rather complex. However, the model shows good agreement with the experimental results and demonstrates the relevance of the partition of the pore water in sub-volumes with different characteristics.

Geochemical partitioning and mineral speciation of Zn in naturally metal-enriched soils of SW Spain

J.C. FERNANDEZ-CALIANI[1]*, I. GIRALDEZ[2], M.B. RIVERA[1] AND C. BARBA-BRIOSO[1]

[1]Dept. Geology, University of Huelva, Spain (*correspondence: caliani@uhu.es)

[2]Dept. Chemistry and Materials Science, University of Huelva, Spain

Some soils of the Sierra de Aracena (SW Spain) have been naturally highly enriched in Zn, and other metals, by intensive supergene alteration of sulphide-bearing parent rocks. The soils are mineralogically composed of illite, vermiculite, kaolinite, quartz, feldspars with minor hematite, and have a near neutral reaction (pH: 6.6-6.9).

Results from the BCR sequential extraction procedure modified by using focused ultrasound [1] showed that the vast majority of Zn was present in the residual immobile fraction of soils (F4, Table 1). The exchangeable fraction of Zn, assessed by single extraction with $MgCl_2$ and NH_4AcO, was found to be virtually negligible (< 1%). A SEM-EDS analysis hinted that Zn is hosted mainly in the crystal lattice of vermiculite (up to 0.37 pfu).

These findings conclusively indicated that potential mobility of Zn should remain low under the present soil conditions.

Samples	**FH-4a**	**FH-5a**
Total concentration in soil	7680	5540
Sequential extraction (in triplicate)		
F1 (HOAc 0.11 M, 7 min)	195±4	295±11
F2 ($NH_2OH.HCl$ 0.1 M, pH 2, 7 min)	572±23	610±21
F3 (H_2O_2 8.8 M, 2 min, 85° C + NH_4Ac O 1M, pH 2, 6 min)	254±30	265±19
F4 (HF+HNO_3+HCl digestion)	7032±75	4797±93
Total (Σ F1+F2+F3+F4)	8053	5967
Single extractions (in triplicate)		
$MgCl_2$ 1 M, 1 h	26.4±2.3	59.6±5.3
NH_4AcO 1M, 1 h	11.5±0.5	21.4±1.2

Table 1: Concentrations of Zn in soil samples and extract solutions, as determined by ICP-OES. All values are reported in mg kg^{-1}

An experimental study on the role of the tetrahedral SO_4^{2-}, CrO_4^{2-} and SeO_4^{2-} anions in the $CaCO_3$ polymorphism

ÁGELES FERNÁNDEZ-GONZÁLEZ[1,*], LURDES FERNÁNDEZ-DÍAZ[2], NURIA SÁNCHEZ-PASTOR[2] AND MANUEL PRIETO[1]

[1]Department of Geology, Universidad de Oviedo, Spain. (*correspondence: mafernan@geol.uniovi.es)

[2]Department of Crystallography and Mineralogy, Universidad Compltense, Madrid, Spain.

Crystallization in the $CaCO_3$–H_2O system is major topic, in a wide variety of disciplines, from geology and geochemistry to biomineralization and industrial crystallization. Although calcite is its most stable polymorph under Earth's surface conditions, $CaCO_3$ can precipitate as three different crystalline forms: vaterite, aragonite and calcite. Moreover, a number of hydrated and amorphous phases with different water contents can also precipitate. The nucleation and growth of metastable $CaCO_3$ polymorphs is commonly related to the predominance of kinetic factors over thermodynamic properties. The presence of different foreign ions in the fluid during $CaCO_3$ crystallization can also promote the formation of metastable phases. The possible incorporation of foreign ions into the structure of the different polymorphs would change their energetic properties and because the free energy of $CaCO_3$ polymorphs is relatively close, any modification of their energetic properties could determine stability crossovers that would affect the polymorph selection at nucleation and the development of transformations between polymorphs. Therefore, when foreign ions are present in the crystallization medium, both kinetic and thermodynamic factors have to be considered to understand the formation of $CaCO_3$. Recent studies have shown that tetrahedral anions like sulfate, chromate or selenate are among the most influential in the crystallization of $CaCO_3$, contributing to the stabilization of amorphous calcium carbonate in biogenic systems [1] or vaterite [2] in inorganic systems. We present here experimental results that illustrate the influence of some tetrahedral anions on the crystallization of $CaCO_3$ from aqueous solutions. These results include examples of unexpected polymorph formation and transformation pathways that carry the pass by of polymorphs.

Water structure and hydration properties of imogolite nanotubes

A. FERNANDEZ-MARTINEZ[1], G.J. CUELLO[2], I.C. BOURG[1], M.R. JOHNSON[1], G.A. WAYCHUNAS[1], G. SPOSITO[1] AND L. CHARLET[3]

[1]Geochemistry Dept. Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, USA

[3]Environmental Geochemistry Group, LGIT-UJF, Grenoble, France.

Imogolite is a nanotubular aluminosilicate present in the clay fraction of volcanic soils. It has high specific surface areas (~500 m^2/g) and is one of the few minerals reactive towards both anions and cations under the same soil physico-chemical conditions, properties which make it an important constituent of the soils where it is present. However, precise determinations of imogolite structure and geochemical reactivity have been hindered by its nano-crystalline character. Structural analyses, until now, were restricted to standard X-ray and electron diffraction techniques, the diffraction peaks being used mainly as fingerprints for the identification of the mineral in soils. In this work, we present a detailed structural characterization of the structure of synthetic imogolite using high-energy X-ray diffraction (HEXRD), neutron diffraction with isotopic substitution (NDIS), transmission electron microscopy (TEM), and molecular dynamics (MD) simulation methods.

Theoretical and experimental investigations of the structure of water at the imogolite – water interface revealed the presence of highly structured water shells both at the surface and inside the nanotubes. We used these structural inputs to develop a geochemical multi-site complexation (MUSIC) model of the acidity of surface Al_2-OH groups on the external surface of imogolite and compared this to the acidity of similar sites on the equivalent (but planar) surface of gibbsite. This comparison yielded insights into the influence of surface curvature on mineral reactivity. Our MD simulations also probed the energetics of water adsorption and revealed that the external surface of imogolite is more hydrophobic than that of gibbsite. Ongoing work involving the use of inelastic neutron scattering also will be presented and discussed.

Anisotropy of magnetic susceptibility of Triassic Red Beds, Central Portugal

C. FERREIRA[1], C. GOMES[2]* AND H. SANT'OVAIA[3]

[1]DCT, Universidade de Coimbra, Portugal
[2]*CGUC, DCT, Universidade de Coimbra, Portugal (*correspondence: romualdo@dct.uc.pt
[3]Centro de Geologia da U. Porto, DGAOT, FCUP, Porto, Portugal.

Three sites in the Conraria and Castelo Viegas Formations, belonging to the "Silves Group" of Upper Triassic age, in the Coimbra region, central Portugal, were studied using the Anisotropy of Magnetic Susceptibility (AMS) methodology. The Conraria Formation is the lower unit and has mean thickness of 160 ± 15 m. The Castelo Viegas Formation is thicker (170-190 m) and the sediments are generally coarser and lighter than the sediments of the Conraria formation. The main goal of this study is to compare the AMS of the of the Conraria Formation, site A, with the two levels from the Castelo Viegas Formation, sites B and C. Site B is on a lower stratigrafic position than site C. AMS were carried out on 99 samples, 45 from site A, 10 from site B and 34 from site C. The magnetic susceptibility ranges between 40.6 and 239.7 x 10^{-6} SI in site A, between 64.4 and 100.0 x 10^{-6} SI in site C and between 51.5 and 58.4 x 10^{-6} SI in site B. Magnetic anisotropy (described by the parameter (kmax/kmin-1) x100) ranges between 0.4 and 8.3% in A, from 0.7 to 0.8 % in site C and between 2.3 and 3.0% in site B. The AMS ellipsoid is dominantly oblate in A and in site B, however site C present both oblate and prolate AMS ellipsoids. AMS fabric show different patterns in the studied sites: NW-SE subhorizontal magnetic foliations associated with subhorizontal N-S trending magnetic lineations in site A; N-S subvertical magnetic foliations associated to N-S trending magnetic lineations in site B; and scattered AMS ellipsoid axes in site C due to its lower anisotropy. Our results show that sites A and site C have higher magnetic susceptibility than site B which is related with mineralogical composition. Sites A and B have a magnetic foliation that probably underlines a primary sedimentary fabric however this foliation has tilted in site C. The N-S magnetic lineation probably materializes the paleocurrents. The general parallelism of the magnetic fabric with bedding indicates a composite fabric between a primary sedimentary fabric and an early tectonic event as is attested by the magnetic anisotropy of Conraria formation and site B of Castelo Viegas Formation.

Highly felsic peraluminous granitoids in the Borborema province, northeastern Brazil

V.P. FERREIRA[1], A.N. SIAL[1], M.A. PARADA[2] AND A.J. TOSELLI[3]

[1]NEG-LABISE, Dept. Geol. UFPE, Recife, Brazil (*correspondence valderez@ufpe.br)
[2] University of Chile, Santiago, Chile
[3]University of Tucuman, Tucuman, Argentina

Only few Neoproterozoic peraluminous granitoids occur in the oriental Borborema province, northeastern Brazil. Among these peraluminous granitoids are the two-mica Chã Grande (CHG), the two-mica Mamanguape (MAMA) that locally presents almandine, and the Ouro Branco (OBR) with three facies (two mica, tourmaline muscovite, and garnet muscovite) granitoids. The granitoids present A/CNK > 1.1, are silica-rich (70-76%, with narrower variation within individual pluton), have Rb/Sr >>2 and their chemistry form overlapping trends in most major oxide variation diagrams. Chondrite-normalized REE patterns are fractionated with variable negative Eu anomaly, both increasing from the CHG through OBR and MAMA. In a normative Qz-Or-Ab diagram, CHG compositions cluster about a minimum-melt composition typical of water-saturated granite system. Compositions of the other plutons form a spread suggestive of variable water activity, and distinct source compositions, with a trend from the field of orthoclase to the quartz-orthoclase cotectic for the MAMA, and a trend next to the albite-orthoclase cotectic to the minimum melt point for the OBR. Major- and trace-element compositions suggest that the OBR and MAMA granitoids formed by vapor-absent muscovite melting of felsic pelites and greywackes, respectively. The CHG granitoid was produced by vapor-saturated muscovite melting of greywackes. The granitoids present strongly negative $\varepsilon Nd_{0.6Ga}$ values (-12.8 – 16.6), and very high initial $^{87}Sr/^{86}Sr$ ratios (0.720-0.729), and Nd model ages Archean to Paleoproterozoic (3.1 to 2.3 Ga), the oldest T_{DM} already found in the Borborema province. These granitoids resemble Himalayan-type peraluminous collision-related leucogranites.

Atmospheric lead deposition in ombrotrophic peat bogs of Southern Poland

BARBARA FIAŁKIEWICZ-KOZIEŁ[1]*, NADINE MATTIELLI[2] AND NATHALIE FAGEL[3]

[1]Department of Biogeography and Paleoecology, Institute of Geoinformation and Geoecology, Adam Mickiewicz University, Poznań, Poland. (*basiafk@amu.edu.pl)
[2]Unité de recherche: "Isotopes : Pétrologie et Environnement", Département des Sciences de la Terre et de l'Environnement, CP 160/02, Université Libre de Bruxelles, Avenue FD. Roosevelt 50, 1050 Bruxelles, Belgium
[3]Department of Geology, AGEs Argiles, Géochimie et Environnements sédimentaires, Université de Liège, Allée du 6 août, B18, 4000 Liège, Belgium

The aim of this study was to differentiate anthropogenic *vs*. natural sources of lead in cores from two ombrotrophic peat bogs, located in Southern Poland. Total lead concentrations were measured by (ICP-AES) after HF-HNO_3-HCl digestion. Stable lead isotopes were measured by (MC-ICP-MS). A detailed age model was constructed using both ^{210}Pb and ^{14}C measurements.

The main results show a record of *ca*. 2000 years of variations in lead concentration and isotopic compositions. In the lowest part of the cores (IIthBC to IVth AD) the $^{206}Pb/^{207}Pb$ ratio equals 1.187. Historically it is a period of Celts and Przeworska culture. Lead isotope ratios point to possible impact of both cultures on the peat bogs. From Vth to VIth century AD, the $^{206}Pb/^{207}Pb$ ratio averages 1.192, reflecting that the Pb supplied to the bog is mainly originated from natural sources (*i.e*. erosion). Then, from the IXth to the XVIIth century AD, the $^{206}Pb/^{207}Pb$ ratio ranges from 1.176 to 1.179, which is in good agreement with Polish galena and coal from Eastern countries. A dramatic increase in lead accumulation rates during the 1920-1930's, it may reflect the higher metal demand for the armament industry, the influence of coal combustion and the latter use of leaded gasoline.

Partitioning of S(-Cl) and S-isotopes between fluid and andesitic melt

A. FIEGE[1]*, H. BEHRENS[1], C. MANDEVILLE[2] AND N. SHIMIZU[3]

[1]Institute for Mineralogy, Leibniz University Hannover, GER (*correspondence: a.fiege@mineralogie.uni-hannover.de)
[2]US Geological Survey, Reston, USA
[3]Woods Hole Oceanographic Institution, Woods Hole, USA

Isothermal decompression experiments were conducted at ~1030°C in IHPV. A hydrous S-(Cl-)bearing silicate melt with a composition close to Krakatau andesite was used as starting material. Pressure was released continiously from 400 MPa to 70 MPa using a novel type of automatic high-pressure valve. Decompression rates range from slow (~0.0005 MPa/s) to very fast (~0.1 MPa/s) and oxygen fugacity (fO_2) ranges from QFM+0.5 to QFM+3.5. The samples were directly quenched after decompression or further annealed for 1 to 48.5 h at final conditions. The partitioning coefficient of S between aqueous fluid and andesitic melt ($D_s^{fl/m}$) was determined by measuring S, Cl (EMP) and H_2O (FTIR) in the quenched glasses and subsequent mass balance calculations. SIMS was used to determine the isotopic abundance of sulfur ($\delta^{34}S_{melt}$) in the glasses. A suite of silicate standards with known $\delta^{34}S$ was used for SIMS calibration. XANES at ANKAs SUL-X beamline (Germany) was conducted to evaluate the sufur speciation in the experimental products.

For directly quenched samples, $D_s^{fl/m}$ was observed to increase significantly at QFM+0.5 from 59 ± 17 to 252 ± 103 with decreasing decompression rate (~0.1 MPa/s to ~0.0007 MPa/s). Upon further annaeling (1 to 48.5 h), at QFM+3.5 $D_s^{fl/m}$ decreases from 337 ± 124 to 24 ± 1. In addition, the molar $(S/Cl)_{fluid}$ ratio increases exponentially with increasing $(S/Cl)_{melt}$ at QFM+1.8. XANES measurements may have revealed significant amounts of H_2S in fluid inclusions at $fO_2 \leq$QFM+1.2 while at $fO_2 \geq$QFM+1.8 predominantly SO_2 seems to be present. Preliminary SIMS data indicates a major influence of fO_2 on fluid/melt fractionation of S isotopes upon degassing. $\delta^{34}S_{melt}$ decreases by 3.2-5.4 ‰ at QFM+1.2 and increases by 2.1-3.1 ‰ at QFM+3.5 if ~90% of the S in the melt is released. Thus, the isotopic fractionation is slightly larger than predicted by the model of de Hoog *et al*. [1] but in agreement with the data of Mandeville *et al*. [2] for oxidizing conditions. Hence, combining S and Cl data in volcanic gases with *in situ* sulfur isotope analyses might become a powerful tracer to forecast volcanic eruptions in near future.

Rapid dyke emplacement as an eruption trigger Dabbahu Volcano, Ethiopia

LORRAINE FIELD, KATE SAUNDERS* AND JON BLUNDY

Department of Earth Science, University of Bristol, Wills Memorial Building, Queens Road, bristol, BS8 1RJ. (Lorraine.Field@bristol.ac.uk,* Kate.Saunders@bristol.ac.uk, Jon.Blundy@bristol.ac.uk)

Dabbahu is a quaternary, central volcano situated at the northern end of the Manda Hararo rift segment in the Afar region of Ethiopia. Magmatic rift segments have formed over the past ~3 Ma as faulting and volcanism have focused into localised regions [1]. In 2005 a small rhyolitic ash eruption and extrusion of a small pumice dome from the Da'Ure vent on the northern flanks of Dabbahu coincided with the largest dyke opening event ever measured [2].

Olivine crystals from an early 65 kyr basaltic flow at Dabbahu are composed dominantly of Mg-rich cores (700-1000 μm) with narrow (10-50 μm) Fe-rich rims. The timescale since the intrusion of this new magma batch and eruption was investigated by diffusion modelling of multiple elements (Fe-Mg, Mn, Ni and Ca) in four crystals. Olivine crystals were forward modelled from an initially homogenous composition using a semi-infinate open boundary, finite difference model for Fe-Mg, Mn and Ni, and where possible Ca. Co-existing clinopyroxene crystals indicate a magmatic temparature of ~1176°C. Calculated timescales from Fe-Mg (0.75-8.92 days), Mn (1.27 -4.05 days) and Ni (0.94-8.11 days) are all similar to each other, demonstrating the strength of this method and the short residence times of these crystals in the final magma after the growth of the Fe-rich rims.

Elevated seismicity associated with the 2005 dyke intrusion at Dabbahu volcano persisted for only 4.5 days before moving south [2]. These timescales are comparable to those obtained from olivine profiles in the > 65 kyr Dabbuhu eruption. We infer that the olivine crystals preserve an early record of dyke intrusion, during the initial shield building episode of Dabbahu volcano, similar to the 2005 event.

Cloud-aerosol interactions in operational NWP: Presently simple, but the future is complicated

P.R. FIELD*, J. WILKINSON, B. SHIPWAY AND A. HILL

Met Office, Fitzroy Road, Exeter, EX1 3PB, UK
(*corresponence: paul.field@metoffice.gov.uk)

Met Office high resolution (dx=1.5, 4.0 km) operational forecasts over the UK and the wider North Atlantic (dx=12km) now couple a simple aerosol tracer to the warm cloud microphysics representation. The first part of the talk will review the performance of this implementation and briefly consider the effects on fog. More complex aerosol representations are now available within the MetOffice model and the second part of the talk will introduce our progress in coupling a new multimoment, multispecies microphysics to such representations. Our eventual goal is to determine what level of complexity is required in the representation of cloud-aerosol interactions to deliver improvements in NWP.

Determination of $\delta^{11}B$ ratios in marine biogenic carbonates via LA-MC-ICP-MS

J. FIETZKE[1]*, F. RAGAZZOLA[1], A. HEINEMANN[1], I. TAUBNER[1], F. BÖHM[1], J. EREZ[2], T.H. HANSTEEN[1] AND A. EISENHAUER[1]

[1]Leibniz Institute of Marine Sciences, IFM-GEOMAR, Kiel, 24148, Germany (* jfietzke@ifm-geomar.de)
[2]Institute of Earth Sciences, The Hebrew University of Jerusalem, 91904, Israel

A new in-situ method using LA-MC-ICP-MS for the determination of stable boron isotope ratios ($\delta^{11}B$) in carbonates was developed and recently published.[1] Data were acquired via a standard sample standard bracketing procedure typically providing a reproducibilty of 0.5 ‰ (SD) for samples containing 35 ppm of boron. A single ablation interval consumed about 5 μg of the sample corresponding to about 0.2 ng of boron.

The major analytical finding was the similar instrumental fractionation behaviour of carbonates, silicates and sea salt with respect to boron isotopes. As no matrix induced offset was detectable between these distinct materials we propose the use of NIST glasses as internal standards for boron isotope ratio measurements via LA-MC-ICP-MS. This finding overcomes the problem of a missing matrix matched carbonate standard for in-situ boron isotope studies.

As a first test application a set of coral samples from a culturing experiment was analysed. $\delta^{11}B$ values range from 19.5 – 25 ‰ depending on the pH of the water used in the particular treatment being in good agreement with the results of earlier studies. Further results from cultured marine calcifiers (e.g. bivalves and coralline red algae) will be presented.

The geographic and stratigraphic record of Ordovician $\delta^{13}C_{carb}$ in outcrops and the subsurface of Anticosti Island, Canada

DAVID A. FIKE[1], DAVID S. JONES[1,2] AND WOODWARD W. FISCHER[3]

[1]Department of Earth & Planetary Sciences, Washington University, CB 1169, 1 Brookings Dr., St. Louis, MO 63130, USA. (dfike@levee.wustl.edu)
[2]Geology Department, Amherst College, Amherst, MA 01002, USA. (djones@amherst.edu)
[3]Division of Geological and Planetary Sciences, California Institute of Technology, MC 100-23, Pasadena, CA, 91125, USA. (wfischer@caltech.edu)

The Ordovician Period contains both an interval of intense biodiversification as well as one of the largest mass extinctions of the Phanerozoic. The latter, in particular, is associated with an interval of widespread glaciation across the southern supercontinent of Gondwana, together with the global Hirnantian $\delta^{13}C_{carb}$ positive excursion. Here we analyze the mixed carbonate-siliciclastic facies found in outcrops across Anticosti Island, Canada. These data allow us to generate a record of geographic and stratigraphic variability in Late Ordovician $\delta^{13}C_{carb}$ across Anticosti Island during this important interval of Earth history. High-resolution paired $\delta^{13}C_{carb}$ and $\delta^{13}C_{org}$ data both record the +4‰ Hirnantian positive isotope excursion and provide an independent measure of time for stratigraphic correlation [1]. Discontinuities in the isotope record at key lithologic transitions vary as a function of geographic location across the island, providing the foundation for a diachronous model of the deposition of the Hirnantian strata. Moving into the subsurface, we examine the record of Late Ordovician strata preserved in cores and well cuttings from multiple borehole locations across Anticosti island. These data reveal the presence of multiple $\delta^{13}C_{carb}$ excursions throughout the > 1 km of Late Ordovician strata in the subsurface, providing multiple new points for generating stratigraphic correlations across Anticosti Island and between other Late Ordovician locales.

Antimony in the environment: The facts – or maybe not

M. FILELLA

Institute F.-A. Forel, University of Geneva, Route de Suisse 10, CH-1290 Versoix, Switzerland (montserrat.filella@unige.ch)

Antimony belongs to group 15 of the periodic table of the elements, along with N, P, As and Bi. It is ubiquitous throughout the environment as a result of natural processes and human activities and it has no known function in living organisms. After a long history of neglect as an element of environmental relevance, Sb attracted increasing public attention in the mid 1990s following a series of claims that it was involved in Sudden Infant Death Syndrome. It has remained a focus of considerable scientific research since that time and a substantial number of papers have now been published on the element and its behaviour in the natural environment.

However, a critical analysis of existing information, its sources, and the methods applied to obtain it [1-8], shows that, aside from a few well-established facts, many key aspects of the environmental chemistry of Sb remain poorly understood. Unfortunately, gaps in knowledge are too often hidden by a strong tendency to blindly reproduce some 'well-known' facts and references without looking them up or tracking down additional, more updated information. Well-focussed research, building on thorough knowledge of what is already known, will undoubtedly shorten the path towards a better understanding of Sb behaviour in environmental and biological systems. With this aim, this communication will discuss critical areas identified in [4], with special emphasis on the update of low temperature equilibrium and solubility data [9-11] and the description of antimony interactions with potential natural binders. Implications for the interpretation of existing ecotoxicity data and the prediction of the fate of antimony in water and soils will be critically presented.

Selenide retention by mackinawite: A multi-edge XAS approach

N. FINCK[1]*, K. DARDENNE[1] AND D. BOSBACH[2]

[1]Institute for Nuclear Waste Disposal (INE), Karlsruhe Institute of Technology (KIT), P.O. Box 3640, D-76021 Karlsruhe (*correspondence: nicolas.finck@kit.edu).
[2]Institute for Energy and Climate Research, Safety Research and Reactor Technology (IEF-6), Nuclear Waste Management, Forschungszentrum Jülich GmbH, D-52425 Jülich.

The fission product ^{79}Se ($T_{1/2} > 10^6$ a) is of concern for the safe disposal of High Level nuclear Wastes (HLW). The chemistry of selenium resembles that of sulfur, and the Se solubility is controled by its oxidation state. Ubiquitous in nature, iron sulfides are believed to control the *in situ* redox potential of most rock formations envisaged for the disposal of HLW. Under HLW repository relevant (reducing) conditions, Se may occur in low oxidation states. Robust structural data for selenide (Se(-II)) binding to mackinawite were obtained by collecting multi-edge XAS data.

Disordered mackinawite (FeS_{am}) was precipitated in the presence of Se(-II) (SeMack). XAS data were collected at the S, Fe and Se K-edge for SeMack, at the S and Fe K-edge for pure FeS_{am} and at the Fe and Se K-edge for FeSe. For each sample, the data were fit at all edges simultaneously. The (compelling) formation of a FeSe-like phase in SeMack is ruled out from the absence of detected neighboring Se atom in the Se first shell. In contrast, the detection of Fe neighbors at ~2.38 Å and higher distances S backscatterers strongly points to Se located in a FeS-like environment. Separately, selenide ions were contacted with pre-existing FeS_{am} in suspension (Se/FeS). Analysis of the Fe and Se K-edge XAS data reveals the presence of different crystal-chemical enviroments. The detection of Se neighbors in the Se first coordination sphere points to the presence of Se(0). The (compelling) presence of selenium in a FeSe-like environment is ruled out by the absence of higher distance Se backscatterer. In contrast, part of retained Se may be located in an environment close to that of SeMack. The presence of Se in a reduced form (0, -II) in SeMack and Se/FeS will ensure a low mobility in the near field of HLW disposal sites.

This multi-edge XAS approach places high confidence in the molecular scale process understanding of selenide binding to mackinawite.

Osmium, carbon and trace element investigations into archaeological material

A.J. FINLAY[1], J. MCCOMISH[2], R. BATES[3], D. SELBY[1]

[1]Department of Earth Sciences, Durham University, Durham, DH1 3LE, U.K. (a.j.finlay@durham.ac.uk)
[2]York Archaeological Trust for Excavation and Research Limited, 47 Aldwark, York, YO1 7BX, U.K.
[3]Department of Earth Sciences, University of St Andrews, North Street, St Andrews, Fife, KY16 9AL, U.K.

We present initial results from two studies investigating how the utilisation of Osmium (Os) and Carbon (C) isotope analysis as well as trace element geochemistry can be used to provide information on the source and manufacture of archaeological artifacts.

The first study comprises Os and C isotope analysis of drillings from an iron cannon from the pinnace Swann recovered off the Isle of Mull (Scotland). Os isotope analysis of the cannon provides a radiogenic $^{187}Os/^{188}Os$ ratio (0.825 ± 0.032) which has not been reset during casting. Therefore the $^{187}Os/^{188}Os$ ratio may be applied to identify the source of the ore. Furthermore the $\delta^{13}C$ ratio of the cannon (-30.3 ‰) is similar to charcoal and may reflect the use of charcoal as a reducing agent in the manufacturing of the cannon.

The second study (incorporating trace element and Os isotopic analysis of source clay, fired souce clay and Roman ceramic building material (CBM)) was undertaken to test how trace elements can be utilised to identify the centres of manufacture of tile. Aliquots of raw clay and fired clay as well as CBM samples from York (U.K.) and Carpow (Fife, U.K.) roman fortresses are geochemically indistinguishable, yet are distinct from the published literature. Therefore we believe that trace element geochemistry can be used to identify the centre of construction of CBM and so further understand trade networks within the roman world. Re-Os isotopic analysis of the CBM samples to further aid protolith identification is ongoing. Initial results show that the CBM contains Re and Os abundances similar to average upper continental crust, however, the $^{187}Os/^{188}Os$ ratio is very radiogenic (4.8 ± 0.8) and so may be useful in geochemically isolating CBM manufactured from different sources.

These studies demonstrate how combining isotopic and trace elemnt analysis can further our understanding of the source and manufacture of a wide range of archaeological material.

Paleohydrological communication between Baksa Gneiss and overlying Carboniferous sediments

KRISZTIÁN FINTOR

Univ. of Szeged, H-6701, P.O. Box 651, Hungary (efkrisz@gmail.com)

The investigated area the Baksa Gneiss Complex (BC) and its overlying Téseny Sandstone formation (TS) are located at the SW part of the Pannonian Basin near to the low and medium level nuclear waste disposal site (Mórágy Granite Formation) of Hungary. Quartz-carbonate veins of the BC and TS were analyzed by fluid inclusion micothermometry and stable isotope geochemistry in order to reveal the paleohydrological relationship between them.

Veins show rather similar features. In BC qtz→dol→cal1→cal2 is characteristic while in TS qtz→dolC→dolMn→dolFe sequence is typical. Results of microthermometry are also very similar. Quartz phases contain aqueous inclusions exhibiting H_2O-NaCl-$CaCl_2$ model composition. Calculated salinity varies within 20-25 wt% NaCl and 1-7 wt% $CaCl_2$, while T_h values are within 50-130 °C range. Primary inclusions in dol and dolC phases show H_2O-NaCl-$CaCl_2$ composition and high salinity is presumable from low T_m(Ice) data (-20 – -25 °C). T_h values are in a 90-180 °C range. Fluid captured in dolFe phase exhibiting different character with H_2O-NaCl composition and low 2.5 -5 wt% eq. NaCl salinity, T_h values are in a short 80-110 °C range.

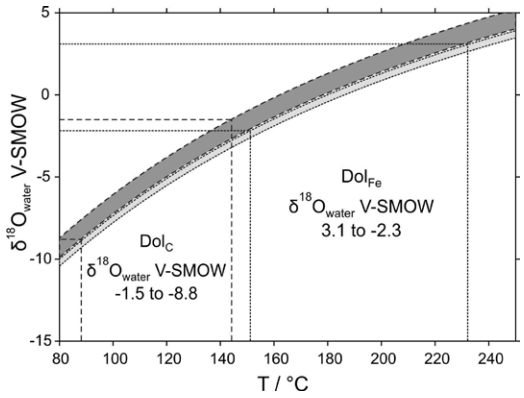

Figure 1. $\delta^{18}O$ signatures of pore fluids

The calculated $\delta^{18}O$ signature of the mineralizing fluid (Fig. 1.) (dolC: 3.1 – -2.3 $\delta^{18}O$ V-SMOW; dolFe: -8.8 – -1.5 $\delta^{18}O$ V-SMOW) together with fluid chemistry indicating paleohydrological communication between crystalline basement and sedimentary cover.

Evidence of water degassing in Archean Komatiites

M.L. FIORENTINI,[1], S.W. BERESFORD[1], W.E. STONE[2] AND E. DELOULE[3]

[1]Centre for Exploration Targeting, School of Earth and Environment, University of Western Australia
[2] Metals Exploration Division, North American Palladium Ltd., Toronto, Canada
[3]CPRG, CNRS, Vandoevre Les Nancy, France

Komatiites are ancient volcanic rocks, mostly over 2.7 billion years old, which formed through >30% partial melting of the mantle [1]. Establishing the volatile content of komatiites is crucial to constraining the thermal evolution of the Early Earth and its primordial atmosphere. The Agnew-Wiluna greenstone belt of Western Australia contains three co-genetic komatiite units that 1) display laterally variable volcanological features, including thick cumulates and spinifex-textured units, and 2) were emplaced as both lava flows and intrusions at various locations. 500m-thick komatiite sills contain widespread occurrence of hydromagmatic amphibole in orthocumulate- and mesocumulate-textured rocks, which contain ca. 40-50 wt% MgO and ≤3 wt% TiO_2. Conversely, komatiite flows do not contain any volatile-bearing mineral phases: ~150 meter-thick flows only contain vesicles, amygdales and segregation structures, whereas <5-10 meter-thick flows lack any textural and petrographic evidence of primary volatile contents.

Existing models on the thermal evolution of the Early Earth are mainly based on data from komatiite flows rather than intrusions [1]. In the Agnew-Wiluna greenstone belt, we hypothesize that the original volatile content of the flows was lost, but that of the sills was partially retained. Accordingly, evidence from komatiite flows in the Agnew-Wiluna greenstone belt does not necessarily reflect the total volatile content of parental komatiite magmas, because the flows, irrespective of their initial water content, have degassed upon emplacement and crystallization. Therefore, we suggest that evidence from komatiite intrusions worldwide should be considered along side with data from lava flows to evaluate the thermal architecture of the Early Earth and the complex chemo-physical zonation that occurred at the interface between water and seafloor in the primordial oceans.

[4] European Synchrotron Radiation Facility, 38043 Grenoble cedex, France

Melting phase relations and major elements partitioning have been determined for a fertile peridotite (KLB-1) between 36 and 140 GPa. The experiments were conducted in diamond-anvil cells at the high-pressure beamline ID27 of the European Synchrotron Radiation Facility (ESRF) so as to use clear in situ melting criterion and to determine phase relationships from X-ray diffraction. Focused ion beam (FIB) sections of the recovered diamond-anvil cell samples were further investigated at the nano-scale by scanning and analytical transmission electron microscopy to check melting/crystallization sequences as well as variations of phase composition with temperature and pressure. Our results show that Mg-perovskite is the liquidus phase above 50 GPa, whereas ferropericlase is the solidus phase. Our results also yield strong constraints on the solidus curve of the lower mantle, which is measured at 4180 ± 150 K at core mantle boundary pressure. Since this value matches estimated mantle geotherms, molten regions may exist at the base of the present-day mantle. Melting phase relations and element partitioning data show that the produced liquids could be dense and host many incompatible elements at the base of the mantle. Such a melt could indeed segregate from the crystalline solids and accumulate at the core mantle boundary over time as fertile material passes through the boundary layer. Incompatible elements might accumulate in such a partial melt, and further add excess heat production to the melt piles at the base of the mantle. The data also allow us to constrain the way the putative magma ocean would have crystallized. The change in melting phase relations observed between 40 and 60 GPa indicates that a perovskite rich layer may be created in the mid-lower mantle during crystallization of this magma ocean whereas dense liquids having both a higher iron content and a higher oxide/perovskite content could sink to the core mantle boundary.

GIS based spatial distribution mapping for surface waters in Solaklı Basin (Trabzon, Turkey)

ARZU FIRAT ERSOY[1], FATMA GULTEKIN[1], ESRA HATIPOGLU[1] AND SECIL CELEP[2]

[1]Karadeniz Technical University, Engineering Faculty, Geological Engineering Department, 61080, Trabzon, Turkey (fatma@ktu.edu.tr, firat@ktu.edu.tr, hatipogluesra@gmail.com)
[2]Provincial Directorate Disaster and Emergency Management 53000, Rize, Turkey

Shortage of clean ground water to satisfy the need for drinking-potable water of increasing human population is one of the most significant problems encountered in today's world. On the other hand, surface water is contaminated due to lack of sufficient conservation. This study aims at revealing the current status of surface and groundwater in Solaklı (Trabzon) Basin by means of physical and chemical investigation. Quality assessment parameters are determined at 33 points in the basin with 2 points selected for groundwater and 31 points selected for surface water quality assessment. A Geographical Information System (GIS) tool was used to construct thematic maps for surface water quality in the Solaklı Basin. Water chemistry data were integrated and overall picture about the spatial variation in the surface water quality of Solaklı Basin was defined. While the amounts of the chemical components found in natural waters basins in don't vary considerably throughout the basin, amounts of pollutant parameters such as NO_2, NO_3 and PO_4 increase depending on the discharge of settlement areas. Surface waters in Solaklı basin are classified as high quality for many parameters according to criteria designated in Inland Surface Water Classification. Surface waters are classified as polluted water in terms of the Cu and NO_2^- values. Amounts of Mn and Ni in the Solaklı basin groundwater using as potable water for Of Town are found to be above Turkish Drinking Water Standards.

Integrating multivariate statistical analysis for geochemical assessment of groundwater quality in Gümüşhacıköy Plain (Amasya, Turkey)

ARZU FIRAT ERSOY, ESRA HATIPOGLU* AND FATMA GULTEKIN

Karadeniz Technical University, Depaertment of Geological Engineering, 61080, Trabzon, Turkey (*correspondence: hatipogluesra@gmail.com)

Groundwater is the main source for drinking water, agricultural and the industrial sector, the demand for water has increased over the years and led to water scarcity in all over the world. In the Gümüşhacıköy Basement, in the mid-northern part of the Turkey, agriculture is the most important mainstay and this area includes the most important agricultural areas of Turkey. The groundwater is extracted by wells drilled in the alluvium of the Gümüşhacıköy Plain to meet municipal, industrial and especially agricultural requirements. Factor analyses technique is useful in the analysis of groundwater data corresponding to large number of variables. Principal Component Analysis (PCA) performed on correlation matrix of the raw data in which a water sample is described by 15 physical and chemical parameters for 38 samples. The PCA produced 4 for significant component that explained 78 % of the cumulative variance. Piper and Chadha graphical methods were used to identify geochemical facies of groundwater samples and geochemical processes occurring in the study area. The water is mainly of Ca-Na-HCO_3 type.

Retention of colloids at rough rock surfaces

CORNELIUS FISCHER[1,2] GOPALA K. DARBHA[1] ALEXANDER MICHLER[1] AND THORSTEN SCHÄFER[3]

[1]GZG, Georg-August-Universität Göttingen, Germany; (cornelius.fischer@geo.uni-goettingen.de)
[2]Department of Earth Science, Rice University, Houston, TX, USA
[3]Inst. f. Nukleare Entsorgung, KIT, Karlsruhe, Germany

The retention of colloidal particles at mineral and rock surfaces is of fundamental importance for numerous processes, including trace metal and contaminant mobility, wastewater treatment, or diagenetic and weathering reactions. In nature, particle attachment conditions are often electrostatically unfavourable due to the pH-dependent mineral surface charge. In such cases, surface roughness of the collector surfaces may play an important role in governing the retention efficiency.

In this study, we compare the retention of colloids (polystyrene latex colloids [d = 1 μm] and hematite colloids [d = 0.95 μm]) at rough single mineral surfaces (quartz, albite, K-feldspar, biotite) and surfaces of mineral aggregates (Granodiorite from Grimsel test site, Switzerland). Surface roughness variations are in a range of 0.05 to 3 μm. Experiments were repeated under defined ionic strength variations. Particle retention experiments were performed at pH = 5.

Vertical Scanning Interferometry (VSI) was applied for characterization of surface topography, quantification of surface roughness, as well as quantification of colloid deposition. This method provides a large field-of-view that is sufficient to detect common inhomogeneities at mineral surfaces and to quantify their lateral extent. Application of so-called *converged* roughness parameters enabled the quantification of roughness differences at irregular surfaces.

A positive correlation between colloidal deposition flux (*Sh*) and surface roughness (*Rq*) of single mineral samples was observed for retention under unfavourable consitions. For granodiorite surface samples, however, the observed particle retention was tenfold higher. The experiments showed the quantitative and predictable impact of intergranular porosity as well as roughness variations caused by mineral aggregates on the retention of colloids.

Long-term CO_2-exposure experiments – Mineralogical results and reactive geochemical modeling

SEBASTIAN FISCHER[1,2] AND AXEL LIEBSCHER[1]

[1]Helmholtz Centre Potsdam, GFZ German Research Centre for Geosciences, Centre for CO_2 Storage
[2]Technical University of Berlin, Faculty VI, Working Group Mineralogy-Petrology

Rock core samples of the Upper Triassic Stuttgart Formation (saline aquifer) from the Ketzin pilot CO_2 storage site were exposed to pure CO_2 and synthetic reservoir brine at simulated reservoir P-T conditions (5 MPa, 40 °C). Autoklave reactors were opened and samples were taken after 15, 21, 24 and 40 months, respectively. The samples were then analysed mineralogically and geochemically and compared to baseline data of untreated samples. Rietveld refined XRD data show no significant trends for the studied intervals. On freshly broken rock fragments of the CO_2-treated samples, corrosion textures were found on plagioclase, K-feldspar and anhydrite surfaces. BSE images of the respective twin samples show (intensified) alterations of feldspar minerals. EMPA data display a change in the mineral chemistry of plagioclase, namely a preferred occurrence of sodium-rich endmember compositions after CO_2 exposure. Inorganic fluid data show, besides others, highly increased calcium, potassium and sulfate concentrations [1]. The experimental observations were reproduced using the reactive geochemical modeling code PHREEQC.

The mineralogical-chemical measurements imply preferred dissolution of calcium out of plagioclase (albitization) next to dissolution of K-feldspar and anhydrite. Due to the heterogenic character of the Stuttgart Formation, which formed in a fluvial environment [2], it is often difficult to distinguish between natural variability and CO_2-related changes. Additional profound evaluation is needed to interconnect the indicated changes during the experiments and to better understand CO_2-brine-rock interaction occurring within the Ketzin reservoir.

A dynamic Archean sulfur cycle

W.W. FISCHER[1], D.A. FIKE[2], Y. GUAN[1], J.M. EILER[1], J.L. KIRSCHVINK[1] AND T.D. RAUB[1]

[1]California Insitute of Technology, Pasadena, CA, USA (wfischer@caltech.edu)
[2]Washington University, St. Louis, MO, USA (dfike@levee.wustl.edu)

Many aspects of the Earth's early sulfur cycle, from the origin of mass anomalous fractionations to the scale and degree of biological involvement, remain poorly understood. We have been studying the nature of multiple sulfur isotope (^{32}S, ^{33}S, and ^{34}S) signals using a novel combination of scanning high-resolution low-temperature superconductivity SQUID microscopy and secondary ion mass spectrometry (SIMS) techniques in a suite of samples from distal slope and basinal environments adjacent to a major Late Archean-age (~2.6-2.52 Ga) carbonate platform. Coupled with petrography, these techniques allow us to interrogate, at the same microscopic scale, the complex history of mineralization in samples containing diverse sulfide-bearing mineral components. Because of a general lack of Archean sulfate minerals, we focused our analyses on early diagenetic pyrite nodules, precipitated in surface sediments. This allows us to assay fractionations by controlling for isotope mass balance.

These rocks record meaningful differences in sulfur isotopic composition at microscopic scales. We observe large gradients in $\Delta^{33}S$ (> 5‰) over short length scales, pointing to substantial environmental heterogeneity and dynamic mixing of sulfur pools. Petrography and magnetic imaging demonstrate that these mass anomalous fractionations were clearly acquired prior to burial and compaction. We also commonly observed large radial $\delta^{34}S$ gradients (> 20‰) in nodules, from low values near their centers, increasing to heavier values near their rims. These observations imply that microbial sulfate reduction was a conspicuous metabolism during organic diagenesis in environments with particularly high rates of organic carbon delivery.

Age and nature of meteoritic components on the Moon

M. FISCHER-GÖDDE[1,2]* AND H. BECKER[2]

[1]Institut für Planetologie, Westfälische Wilhelms-Universität Münster
(*correspondence: m.fischer-goedde@uni-muenster.de)
[2]Institut für Geologische Wissenschaften, Freie Universität Berlin, Germany

Osmium isotopes and highly siderophile elements (HSE: Re, Os, Ir, Ru, Pt, Rh, Pd, Au) in ancient lunar impact rocks provide further constraints on ages and compositions of meteoritic materials accreted to the early Earth-Moon system. We report the first Re-Os isochron age on a lunar impact melt rock from Apollo 16 (67935, 4.21±0.13 Ga). The Re-Os age together with recent age data underscores the significance of pre 4.0 Ga basin forming impacts on the Moon. The new HSE data will be discussed along with previous precise data sets to identify specific impactor compositions and to evaluate mixing processes in ancient lunar impact rocks. Granulites from Apollo 16 and 17 (67915, 67955, 79215) display HSE ratios and $^{187}Os/^{188}Os$ largely similar to volatile element depleted carbonaceous chondrites. Apollo 16 impact melt rocks 60315 and 67935 show strongly fractionated HSE compositions with subchondritic Os/Ir, chondritic Re/Ir, and suprachondritic $^{187}Os/^{188}Os$, Ru/Ir, Pt/Ir, Rh/Ir, Pd/Ir and Au/Ir, similar to some IVA iron meteorites. Slightly suprachondritic ratios of $^{187}Os/^{188}Os$, Ru/Ir, Pt/Ir, Pd/Ir observed for Apollo 14 sample 14310 are similar to ratios observed for other Apollo 14 and and Apollo 17 poikilitic impact melt rocks. The Re-Os age of 4.2 Ga obtained on 67935 in combination with a previously reported Sm-Nd recrystallization age of 4.2 Ga for 67955, support previous notions that significant contributions of meteoritic material were supplied to the lunar surface before the 3.9-3.8 Ga basin forming era. Similar ages, but different HSE compositions of the meteoritic components in 67935 (iron meteorite-like) and 67955 (carbonaceous chondrite-like) indicate two different impact events on the Moon at ≥4.2 Ga. The occurence of granulites with similar composition at Apollo 15, 16 and 17, and the iron meteorite signature at Apollo 14, 15 and 16 suggests a wide dispersal of these compositions over the lunar nearside. Following this reasoning, the slightly subchondritic Os/Ir and slightly suprachondritic $^{187}Os/^{188}Os$, Ru/Ir, Pt/Ir and Pd/Ir of poikilitic Apollo 17 and Apollo 14 impact melt rocks may be explained by mixing 80-95% of a carbonaceous chondrite-like HSE end-member composition as indicated by the granulitic impact rocks (e.g. 67955) with 5-20% of a fractionated iron meteorite-like impactor composition as inferred from 67935 and 60315.

Silicon isotope evidence against an Enstatite Chondrite Earth

CAROLINE FITOUSSI*[1,2] AND BERNARD BOURDON[1,2]

[1]Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon and UCBL, CNRS, France
(*correspondence: caroline.fitoussi@ens-lyon.fr)
[2]Institute of Geochemistry and Petrology, ETH Zurich, Switzerland

Enstatite chondrites are undifferentiated meteorites which formed at particularly reducing conditions as testified by the presence of Si in the metal phase. Enstatite chondrites are striking in having terrestrial compositions for several isotope systems such as O, Cr, Ti, and several others. Javoy *et al*. [1] interpreted these similarities as evidence for the Earth to be made of these chondrites. Silicon is particularly difficult to reconcile with this interpretation since it requires 28 wt% Si to be incorporated into the core which is way above the maximum Si core content (~7wt%). To get around this problem, a layered model with a Si-enriched hidden reservoir was proposed [1].

The silicon isotope compositions of enstatite chondrites and aubrites were measured on the MC-ICPMS Nu1700 at ETH Zurich. Bulk meteorites and separate enstatite minerals of the same meteorite were analyzed. The heaviest Si isotope composition was measured in an enstatite separate of an EH3 chondrite and gave $\delta^{30}Si$=-0.38 ± 0.03‰. Even in an extreme scenario of Earth's core formation in which (i) the accreting material is assumed to have a composition $\delta^{30}Si_{sil}$=-0.38‰ for its silicate phase (which is unlikely given that most bodies experienced thermal metamorphism or even metal-silicate differentiation, which would both give a lighter $\delta^{30}Si_{sil}$ ([2]; this study)) and (ii) there is no equilibration between metal and silicate during core merging of an impactor with the proto-Earth's core (e.g. [3]) (which is also unlikely given that it was shown that more than 36% of equilibration is necessary to account for both siderophile element abundances in the Earth's mantle and Hf-W data [4]), the resulting $\delta^{30}Si_{BSE}$ would never exceed -0.38‰. This is significantly lighter than the now agreed Si isotope composition of the Bulk Silicate Earth (BSE) $\delta^{30}Si_{BSE}$=-0.28‰ ± 0.03‰ [2; 5-6]. Therefore, while being quite intriguing meteorites from their similarities with the Earth, enstatite chondrites or aubrites cannot have been the material accreting the Earth.

Apatite fission track and (U-Th)/He dating in the world's youngest UHP terrane: The Woodlark rift of southeastern Papuan New Guinea

P.G. FITZGERALD[1]*, S.L. BALDWIN[1], S.R. MILLER[1], T.A. LITTLE[2], L.E. WEBB[3], J.R. METCALF[1] AND S.E. PERRY[1]

[1]Syracuse University, Syracuse, NY 13244, USA (*corrspondence: pgfitzge@syr.edu)
[2]Victoria Univ., Wellington 6040, New Zealand
[3]Univ. of Vermont, Burlington, VT 05405, USA

Seafloor spreading in the Woodlark Basin of southeastern Papua New Guinea was underway by ~6 Ma and propagated westwards via stepwise spreading nucleation. Just west of the active seafloor spreading tip, extensional gneiss domes form topographic highs of the D'Entrecasteaux Islands (DEI) within the central portion of the Woodlark rift. Since ~8 Ma, HP and UHP rocks were exhumed rapidly from depths of up to ~100 km. Low-temperature thermochronology (apatite fission track (AFT) and apatite (U-Th)/He dating (AHe)) is used to constrain the late-stage exhumation histories in the DEI and conjugate rift margins of the Woodlark Basin. AFT ages generally decrease from ~8 Ma at Misima Island in the east, to between ~1.5 and 0.5 Ma in the DEI. AHe minimun ages similarly decrease to the west, from ~6 Ma at Misima Island to between 2.0 and 0.3 Ma within the DEI with ages youngest on Goodenough Island, the western-most DEI.

Higher temperature thermochronometers and exposure at the Earth's surface provide boundary constraints within which to interpret AFT and AHe results. Detailed age trends are difficult to establish due to the young age and low uranium concentrations resulting in few fission tracks plus small yields of radiogenic ^{4}He. ^{4}He concentrations in these recently and rapidly exhumed samples are often near background levels, and consequently difficult to accurately measure, making some ages unreliable and significantly increasing single grain age variation. We compare AFT ages and AHe ages to higher precision ^{40}Ar/^{39}Ar ages (e.g., biotite, K-feldspar) from the same samples in order to judge their reliability and reproducibility. Single grain AHe age variation is large with no apparent variation with respect to [eU], therefore the RDAMM model is not applicable in this case. In the absence of variable [eU] control, minimum single grain AHe ages are reliably closer to the "real" AHe ages, and it is these ages that show the westward younging pattern. Lithology also plays a strong role in the relative signal size; for example, higher [eU] from pegmatitic apatites give reliable ages whereas lower [eU] from a muscovite granite yields unreliable ages.

Dissolved iron partioning between soluble and colloidal fractions in the tropical North Atlantic Ocean

J.N. FITZSIMMONS AND E.A. BOYLE

Mass. Institute of Technology, E25-615, Cambridge MA 02139 (jessfitz@mit.edu)

Dissolved iron distribution and size partitioning were investigated in the tropical North Atlantic Ocean. "Dissolved Fe" (dFe, 0.4µm filtered) was collected along a 27-station transect to 1000m; "soluble Fe" (sFe, 0.02µm filtered) was collected at seven of those stations including one full depth station to 4370m at the transect's deepest point. "Colloidal Fe" (cFe) was defined as the difference between dFe and sFe. In the seven stations where Fe size partitioning was monitored, surface dFe ranged from 0.46 to 1.10nM and was dominated by cFe in all samples but one, averaging 81% (±7) of the surface dFe at these six stations. This reinforces the hypothesis that dust-derived dFe is preferentially distributed into the colloidal size fraction. At the two westernmost sites, a transition towards more subtropical gyre-like characteristics was observed (pycnocline extended to ~400m), and cFe maintained low values throughout the pycnocline (28±9%). sFe, in contrast, was relatively constant with depth directly below the pycnocline, averaging 0.51±0.04nM and 0.37±0.05nM between 500-1000m at the two western stations. From mid-basin to the eastern stations an oxygen minimum zone develops, and across the five stations where Fe size partitioning was monitored oxygen concentrations at 500m decreased from west to east from 105 to 48µmol/kg, increasing to 63µmol/kg at the easternmost station near the African continent. At the same time, there was a shift in the sFe distribution from fairly constant sFe with depth in the west/mid-basin to a strikingly regular peak in sFe at 500m in the OMZ of 0.70±0.01nM in the four eastern stations. In the OMZ, cFe was also high, contributing ~45% of the dFe at 500m. This OMZ peak in sFe was in contrast to the constant sFe profiles observed by Bergquist *et al*. [2] in the same OMZ, although their profile was on the western edge of the OMZ with lowest oxygen concentrations of only 100µmol/kg. Finally, North Atlantic Deep Water was seen in the deep profile from 1500-4370m. Average dFe was 0.79±0.06nM, slightly higher than the deep ocean value further north observed by Wu *et al*. [1] and further west and North by Bergquist *et al*. [2]. sFe was constant at 0.30±0.01nM throughout the NADW, occupying ~38% of the dFe present.

To date, the late Holocene climatic history of Oman and the entire Arabian Peninsula is poorly understood due to the lack of well dated and highly resolved paleoclimate records. In order to fill this gap of knowledge an actively growing stalagmite (specimen H12) was collected from Hoti Cave located in northern Oman. Total annual rainfall in this area varies between 50 and 255 mm yr^{-1}, with more than 65% of total annual rainfall occurring between December and March. The chronology of stalagmite H12 is based on 24 Th-U ages, which indicate that H12 grew continuously during the last 2650 years. The H12 oxygen isotope record ($\delta^{18}O$) is based on 1345 measurements corresponding to a temporal resolution of around 2 years. The comparison of the H12 $\delta^{18}O$ record with meteorological data reveals that $\delta^{18}O$ values reflect the amount of precipitation.

The H12 $\delta^{18}O$ time series shows distinct centennial- to decadal-scale changes in the amount of precipitation. The most striking feature of the H12 isotope profile is a series of severe droughts between A.D. 500 and A.D. 1000, the most severe perennial drought is centred at around A.D. 530. During this time South Arabia experienced a series of profound societal changes, such as the collapse of the Himyarite Kingdom which was the dominant state in Arabia. Our stalagmite $\delta^{18}O$ time series from Northern Oman seems to support the hypothesis that the collapse of the 1500-year-old South Arabian civilizations and transition from the pre-Islamic to the Islamic era in the 6th and early 7th century A.D. may have been triggered by reoccurring severe droughts.

The role of siderophores and biofilm formation in phosphate acquisition and Pb release from pyromorphite by *Pseudomonas mendocina* bacterium

JUSTYNA FLIS[1,2]*, CAROLYN A. DEHNER[3], JENNIFER L. DUBOIS[3], MACIEJ MANECKI[1] AND PATRICIA A. MAURICE[2]

[1]Dept. of Mineralogy, Petrography and Geochemistry, AGH-University of Science and Technology, 30-059 Krakow, Poland, (*correspondence: flisjustyna@tlen.pl)

[3]Dept. of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN 46556 USA

The phosphate-ammendment immobilization is recommended to be one Best Management Practice (BMP) to treat Pb contaminated soils. (USEPA, 2005). In this method the highly insoluble mineral pyromorphite (PY), $Pb_5(PO_4)_3Cl$ is formed. Despite the extreme insolubility of pyromorphite ($logK_{sp}$=-79.6), Pb has remained unexpectedly mobile at a number of remediated soils (SERDP 2008). The activity of the soil oragnisms is a potential cause of the secondary excesive pyromorphite dissolution and several mechanism that can play a role were identified.

In order to investigate the role of siderophores and biofilm formation by soil bacteria in Pb and P release from PY, two sets of the batch microbial growth experiments were carried out: 1 – bacteria were grown in a direct contact with the mineral surface; 2 – the access to mineral surface was limited to the bacteria by a use of dialyse membrane. In both experiments, the siderophore-producing *P. mendocina* bacterium and an engineered mutant of the species incapable of producing and releasing siderophores were used. P was the limiting nutrient and the synthesized crystals of pyromorphite were the sole source of phosphates in the experimental media. Both, the siderophore-producing wild type and the mutant were able to obtain P from PY. However, the association or attachment of the bacteria to the mineral surface appeared to be important for P acquisition. The OD of the bacterial suspension was two times lower when the microbial – mineral contact was limited. Pb release from PY was substantially greater in the presence of the siderophore-producing wild type than the siderophore(-) mutant and when the bacteria were capable to attach to the PY surface. This substantiates the role of siderophores and biofilm formation by bacteria in Pb remobilization from PY.

Diffusion induced by pressure gradients in natural garnets

D. FLOESS*, L. BAUMGARTNER AND Y. PODLADCHIKOV

Faculty of Geosciences – University of Lausanne, CH
(*correspondence: david.floess@unil.ch)

Recently, we proposed that diffusion relaxation of major elements in garnet induces pressure gradients within the crystal [1]. This is based on the fact that the molar volumes of the garnet end-members vary roughly by 10%. Consequently, the re-equilibration of a zoned garnet by diffusion will produce pressure gradients due to the elastic (nearly isochoric) response of the crystal. Diffusion experiments [2], which show apparent uphill diffusion, were used to argue that such pressure gradients do exist and that ductile accommodation of volume changes only occured in the experiments at the highest temperature (1250 °C). We examined HP garnets with coesite inclusions in order to investigate the significance of this process for natural environments.

Whiteschists from the Dora Maira Massive in the Western Alps underwent eclogite facies metamorphism (3.3-4.3 GPa, 720-780 °C) during the Alpine event at 35Ma [3]. Coesite included in garnet ($py_{0.96}gr_{0.02}alm_{0.02}$) during the HP stage was partially transformed to quartz during the subsequent, rapid exhumation (from 3.5 to 1 GPa within 2 Ma [4]). Coesite is preserved by maintaining a high pressure on the inclusion wall due to the large volume change of the phase transition. The surface of the host garnet experiences a lower pressure controlled by the exhumation *P-T* path. This pressure difference should induce a diffusion of major elements in the garnet surrounding the inclusion. Element distribution maps show well-defined Fe-rich, Ca-poor halos surrounding the coesite-inclusions. The observed diffusion profiles are in agreement with predictions, assuming a positive ΔP around the inclusions. The measured diffusion lengths (40-150 μm) agree with simple diffusion models using published diffusion coefficients.

Thus, understanding the effect of pressure gradients on diffusion and, alternatively, the generation of pressure due to relaxation of chemical gradients by diffusion, is crucial for interpreting *P-T-t* paths of zoned minerals correctly.

Interaction of particulate pollution and precipitation

A.I. FLOSSMANN AND W. WOBROCK[12]

[1]Clermont Université, Université Blaise Pascal, Laboratoire de Météorologie Physique, F-63000 Clermont-Ferrand, France
[2]CNRS, INSU, UMR 6016, LaMP, F-63177 Aubière, France

In the litterature, numerous studies regarding a possible reduction of precipitation as a result of anthropogenic pollution have been published. A scientific review of the aerosol pollution impact on precipitation can be found in [1].

Often, these results were obtained by modelling exercises in an individual cloud using a simple dynamical framework. We have studied extensively the validity of the simple “air parcel” type assumption, in focussing on the particular role of supersaturation in a bin resolved microphysics model and a 3-D dynamics of an entire cloud. We could confirm a strong dependancy of the results on the dynamic framework used.

The results of parcel model studies seemed to indicate that increasing particulate pollution and decreasing solubility suppresses rain formation. In individual and short time cloud simulations this behaviour was confirmed in our 3D model studies. However, we could identify an important amount of particle processing by repeated super- and subsaturation cycles.

Thus, taking into account entire cloud fields over longer periods of time yields the strong spatial and temporal variability of the results with isolated regions of inverse correlation of the effects. Even though in general the expected behaviour was found, after several hours of simulation, the integrated precipitation of the more polluted cases caught up. This suggests that a changing pollution will affect the spatial and temporal pattern of precipitation, but will probably not reduce the overall long term precipitation amount which might be entirely governed by the moisture state of the atmosphere [2].

Pre-biotic organic matter from comets and asteroids

GEORGE J. FLYNN[1] AND SUE WIRICK[2]

[1]Dept. Of physics, SUNY-Plattsburgh, 101 Broad St., Plattsburgh, NY 12901 USA (george.flynn@plattsburgh.edu)
[2]CARS, University of Chicago, Chicago IL 60637 USA (swirick@bnl.gov)

Anders (1989) suggested interplanetary dust particles (IDPs), ~5 to 50 μm in size, delivered a layer of organic-rich material from asteroids and comets to the surface of the early Earth and proposed this organic matter may have been important for the origin of life. Recent modeling by Nesvorny and Jenniskens (2010) suggests >85% of the interplanetary dust results from fragmentation of Jupiter-family comets like 81P/Wild 2, sampled by NASA's Stardust spacecraft, and 26P/Grigg-Skjellerup, the target of a short stratospheric dust collection coinciding with the Earth's crossing of the dust steam from a recent outburst on that comet. Analyses of organic matter in Wild 2 samples was further complicated by organic contamination in the aerogel. Nonetheless, volatile aliphatic hydrocarbon, co-located with the particle tracks, but distributed out to several track diameters, was seen in some Wild 2 tracks by infrared spectral mapping. In addition, using carbon x-ray absorption near-edge structure spectroscopy, we detected several spectrally distinct C=C and C=O bearing organic phases spatially associated with surviving Wild 2 particles. We also analyzed particles from the Grigg-Skjellerup timed collection. These were collected from the stratosphere after relatively gentle deceleration, better preserving indigenous organic matter than for the Wild 2 particles. We found a diversity of mineralogies and elemental compositions and abundant organic matter, identified by detection of the aliphatic C-H_2 and C-H_3 functional groups, in particles from the Grigg-Skjellerup timed collection. The organic/silicate ratio in both the Wild 2 impactors and the particles from the Grigg-Skjellerup timed collection is significantly larger than in carbonaceous chondrite meteorites, which have reflection spectra very similar to C-type asteroids, the most common type of asteroid in the outer-half of the main-belt. This indicates both direct delivery by cometary impacts (Chyba *et al*., 1990) and accretion of cometary IDPs (Anders, 1989) contributed significant quantities of organic matter, including aliphatic hydrocarbons (C-H_2 and C-H_3), C=C (most likely C-rings), and C=O, to the surface of the early Earth. Further analysis should determine the abundance and speciation of N in this organic matter.

Fe isotopes and the contrasting petrogenesis of A-, I and S-type granite

J. FODEN[1], P. SOSSI[1,2] AND G. HALVERSON[3]

[1]School of Earth and Environmental Sciences, University of Adelaide, Adelaide, SA 5000, Australia
[2]Department of Earth and Planetary Sciences, McGill University, 3450 University Street, Montreal, Quebec, H3A 2A7, Canada
[3]Now at RSES , ANU Canberra

Our study of closed to oxygen differentiation of a tholeiitic dolerite sill [1], from mafic dolerite parent through to highly differentiated felsic granophyre, shows strong fractionation of the isotopic composition of iron with a strong positive correlation of δFe^{57} with $Fe^{3+}/\Sigma Fe$. Both initially rise during fractionation controlled by ferrous iron bearing phases (pyroxenes) and then fall abruptly after magnetite saturation is reached. This is consistent with the model of Dauphas *et al* [2] that assumes $\Delta^{57}_{Fe3+\,-\,Fe2+}$ =0.45‰.

Our new data from a range S-, I- and A-type (ferroan) granites from the Cambrian Delamerian orogen in South Australia [3] yields similar results to Dauphas and Freydier [4] and shows that the A-types have very heavy δFe^{57} values (0.3-0.45) whereas the I- and S-types tend to be less fractionated and lighter. These results suggest the ferroan A-types result from protracted closed magma chamber fractionation with delayed magnetite saturation. This is also consistent with their depletion in compatible elements (Mg, Ni and Cr) and enrichment in incompatibles (REE, U, Th). S- and I-types are generated at least in part by crustal partial melting, where the persistent buffering by restitic residual minerals and early magnetite or Fe^{3+}-rich biotite saturation prevents iron isotope fractionation.

Exploring the mobility of actinyl ions in the biogeosphere: A spectroscopic and theoretical study of U(VI) complexes with organic phosphate groups

HARALD FOERSTENDORF[1]*, SATORU TSUSHIMA[1], SEBASTIAN BRÜNING[2] AND BO LI[1]

[1]Helmholtz-Zentrum Dresden-Rossendorf, Institute of Radiochemistry, Dresden, Germany (*correspondence: foersten@hzdr.de)
[2]University of Applied Science, Dresden, Germany

The high affinity of uranyl(VI) ions to distinct functional groups of biomolecules is considered to contribute decisively to the migration behaviour of these metal ions in the biogeosphere [1]. In particular, organic phosphate groups are predestined to form actinide complexes at a physiologically relevant pH level [2]. Because the phosphorylated sites of biomolecules often represent a key role in their proper physiological function, the study on the complexation is of great significance.

In this work, U(VI) complexes of phosphorylated amino acids, namely p-serine and p-tyrosine, were investigated by vibrational spectroscopy serving as model compounds for more complex systems. The spectra obtained demonstrate the high affinity of the actinyl ion to phosphate groups. Contributions from the carboxyl and amino groups to the U(VI) complexes can be neglected.

These results are compared with spectra obtained from our recent investigation with a naturally occurring highly phosphorylated protein, phosvitin [3]. The spectral homologies confirm the suggestion that U(VI) is preferentially bound by organic phosphate groups under physiologically relevant conditions.

The derivation of molecular structures from vibrational spectra can be supported by theoretical approaches, such as density functional theory (DFT) calculations. A series of calculations was performed to reproduce the vibrational spectral data focusing on the frequency range of the vibrational modes of the phosphate groups. A comparison with the experimental data provides additional structural information on a molecular level.

Linking early atmospheric composition to volcanic degassing from a reduced mantle

STEPHEN F. FOLEY[1] AND MIKHAIL I. EREMETS[2]

[1] Geocycles Research Centre and Institute for Geosciences, University of Mainz, 55099 Mainz, Germany.
[2]Geocycles Research Centre and Max Planck Institute for Chemistry, Postfach 3060, 55020 Mainz, Germany.

The composition and chemical evolution of the atmosphere is inextricably linked to volcanic degassing, and so to the oxidation state of the upper mantle and long-term recycling of surface material into the mantle. Early warming of the Earth may be explained by a thick, N_2-rich atmosphere [1], but how the atmosphere came to be so N_2-rich has not been explained. Most information on the oxidation state of the mantle comes from oxygen barometry on mantle rocks, but with a bias in favour of continental mantle lithosphere, especially garnet peridotites. Cratonic mantle peridotites mostly formed in the late Archean, and information on their oxidation state is overprinted by the oxidizing effects of later melt infiltration. Correcting for this and the effect of pressure leads to the conclusion that the early mantle was more reduced than modern asthenosphere [2]. In reducing conditions, the speciation of carbon and nitrogen differs from modern conditions. Carbon occurs as CH_4 rather than CO_2 at mantle pressures, and nitrogen dissolves in melts as NH_2^- or NH_3 rather than N_2. The consequences for volatile solubilities in melts of the mantle are immense: the solubility of reduced carbon is <0.2 wt% in contrast to >20 wt% for CO_2 [3], whereas nitrogen solubility is 3-4 times higher in reducing conditions [4]. This means that early degassing was dominated by N_2 and H_2O, whereas CO_2 degassing first became important later in Earth history. Later loss of nitrogen from the atmosphere may have occurred by loss to space in the absence of a strong dynamo before 3.4 Ga [5] or by return to the mantle in subduction zones. Here, the mantle inventory of nitrogen in solid form may be higher than previously thought, as shown by the stability of solid polymeric nitrogen at lower mantle pressures [6,7].

Chemical analysis of Saharan dust in marine aerosols

K.W. FOMBA*, K. MÜLLER, T. GNAUK AND H. HERRMANN.

Leibniz-Institut für Troposphärenforschung, Permoserstr. 15, 04318 Leipzig, Germany
(*correspondence: Fomba@tropos.de)

The interaction between the ocean and the atmosphere is very important in understanding various factors that control the global climate. Amongst others, mineral dust deposition onto the oceans plays a vital role. Understanding the influence of mineral dust onto the ocean requires adequate information about its chemical composition.

The chemical composition of marine aerosols at the Cape Verde Atmospheric Observatory has been analyzed. The data were collected during six intensive field campaigns and continuous measurements from January 2007 until date. For the collection of samples, a high volume DIGITEL DHA-80 sampler (PM_{10}-inlet) was routinely operated throughout the year in a 72 h- sampling period collecting particles on 150 mm quartz fiber filters. In addition, a five-stage BERNER impactor with a PM_{10} cutoff (0.05-10 μm size range) was used to collect size-resolved samples. The samples were analyzed for ions, OC/EC and trace metals.

Our observations show both Saharan dust and marine influenced air masses. Air masses with Saharan dust storms contained significant amounts trace metals and organic carbon compared to marine air masses. Dust events were observed mostly during the winter months of the year. During the events, the contribution of sea salt to the total PM_{10} mass was found to be low. The sea salt and Saharan dust in the particle were found in the coarse mode fractions while the organics and non sea salt components were observed mostly in the submicron fraction.

Significant differences were observed in the trace metal composition (especially iron) between days of Saharan dust outbreak (about 4.2 Fe, 3.4 Ca, 0.3 Ti, and 0.1 Mn $\mu g/m^3$) and days without (less than 1.0 ng/m^3), confirming that the Sahara desert is an important source of trace minerals in this region of the tropical Northern Atlantic. Typically, ions contributed about 55 % to the PM_{10} mass but decreased to a minimum of about 7% during dust episodes. OC and EC were found in very low concentrations except during dust events where the concentration increase by about a factor of five due to the influence of air masses from the African continent.

Timescale of quartzarenite xenoliths assimilation by trachybasaltic melt: Case of 2001 Etna eruption

I.S. FOMIN* AND P.YU. PLECHOV

Lomonosov Moscow State University, Russia
(*correspondence: fomin@web.ru, pavel@web.ru)

Lavas of Etna 2001 eruption contain abudant quartzarenite xenoliths.

According to [1] and [2] we can suppose, that xenolith's source is located between 0 and 3 km b.s.l. Seismic data and direct observation [3] give us 12-19 days for magma to go through this layer and to stream out of vent. Reaction rims between xenolithes and host rock have width up to 300-500 μm, which give us time of interaction as 12-19 days ([4],[5]).

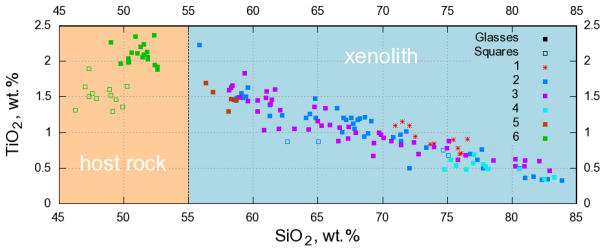

Figure 1: TiO_2 content in xenolithes (1 – inner parts; 2 – cracks in xenolith's surface with host rock groundmass penetration; 3 –near edge; 4 – near neogenic quartz dendrites) and host rock (5 - mingled zone near xenolith; 6 – outside xenolith). Filled squares for glass, open squares for square analyses.

A sample plot for compositions of glasses and whole-rock squares inside and outside xenoliths is presented on Fig.1. Analyses for host rock give us single clouds of compositions for all elements. We suppose, that 0-200 μm mingled zone is insignificant. In xenoliths we estimated good linear mixing trend. Sharp border between two mediums give us significant gap in SiO_2 content.

We conclude, that influence of assimilation on melt composition is insignificant in comparison with crystal differentiation.

Experimental constraints on the development of Os isotopic heterogeneity in the Earth's mantle

RÁUL O. C. FONSECA*, AMBRE LUGUET, CHRIS BALLHAUS AND FLORIAN POHL

Steinmann Institut, Universität Bonn, Germany (*correspondence: raul.fonseca@uni-bonn.de)

Owing to differences in compatibility between Re and Os, the decay of ^{187}Re to ^{187}Os is an exceptional tracer of melting in the Earth's upper mantle. There is a wide consensus that the mantle displays Os isotopic heterogeneity at the grain scale, which is exemplified by large variations of ^{187}Os/^{188}Os in oceanic basalts. The decoupling of the Re-Os isotopic system during partial melting of the mantle, is thought to be associated with alloy/sulfide equilibrium at high temperature. Alloys remain at the source and develop non-radiogenic Os isotopic ratios, as they have very low Re/Os. On the other hand, sulfides have high Re/Os and develop more radiogenic ^{187}Os/^{188}Os over time. However, not much is understood on the timing and conditions at which the de-coupling of the Re-Os isotope system takes place. Alloy model ages calculated using Os isotopes can be as old as 4.1Ga. The relative long-lived nature of these alloys implies that these phases are extraordinarily resilient to isotopic re-equilibration despite being hosted by mantle lithologies. Sulfides on the other hand, are broadly younger than alloys and are vulnerable to low-T metasomatic re-equilibration.

In order to provide constraints on the high-T stability of Os-rich alloys, we have carried out piston-cylinder experiments where variable proportions of Re, Os and Ir were equilibrated with FeS at temperatures ranging between ~1800 and ~2000K and constant pressure (15 kbar). Experiments were carried out in closed graphite capsules, with oxygen fugacity buffered near the C-CO redox buffer. Results show that Re, Os and Ir form an almost complete solid solution in the alloy at temperatures exceeding 1900K. At T lower than 1900K, a miscibility gap develops in the Re-Os-Ir-Fe-S and run products consist of a Re-rich sulfide melt, an OsIrFe alloy and a discrete Re alloy phase. We also show, that depending on the initial proportions of Re, Os and Ir in the charge, alloy-sulfide pairs will develop different ^{187}Os/^{188}Os over time.

Our results preclude equilibration of Os-rich alloys in the mantle at temperatures exceeding 1900K, as alloys would be richer in Re, which is not the case for natural alloy compositions. Furthermore, we show that alloys have to be isolated from mantle sulfides for up to several billion years, with implications to our understanding of mantle convection.

The fate of sorbed contaminants during the biogeochemical cycling of iron in natural environments

D. FORTIN

Dept, Earth Sciences, University of Ottawa, 140 Louis Pasteur, Ottawa, ON, Canada, K1N 1J6, (dfortin@uottawa.ca)

Bacteriogenic iron oxides (BIOS) naturally occur in a wide range of environments, including wetlands, hydrothermal sea vents and hot springs. BIOS are essentially composed of neutrophilic iron-oxidizing bacteria and poorly ordered iron oxides, such as ferrihydrite. Given their high surface reactivity and surface area, they have been shown to be efficient sorbents of aqueous contaminants. The present study investigates the redox stability of naturally occurring BIOS and the fate of their sorb contaminants (As and Sr). Results indicate that BIOS samples (composed of ferrihydrite and smaller amounts of lepidocrocite and goethite) from a wetland area and gold mine tailings undergo rapid microbial reduction in the presence of a well known iron-reducing bacterium (i.e., *Schewanella putrefaciens*CN32). In fact, the reduction rates observed for the various BIOS samples far exceed those of synthetic iron oxides (ferrihydrite). The results also show that the presence of sorbed Sr and As (present as outer-sphere and inner-sphere complexes, respectively) stabilizes BIOS during microbial reduction by blocking reactive sites onto the iron oxides. Finally, the fate of Sr and As during reduction mirrors that of Fe(II), suggesting that all sorbed contaminants are likely sorbed onto the iron oxides.

Optimization and application of engineered nanocrystalline iron oxides (nMAG) for uranium analysis in environmental samples

JOHN D. FORTNER

Department of Energy, Environmental and Chemical Engineering, Washington University in St. Louis, Brauer Hall, Campus Box 1180, One Brookings Drive, St. Louis, Missouri 63130, (jfortner@seas.edu)

Here, we demonstrate optimization and application of engineered, monodispersed, nanoscale iron oxide particles (termed nMAG) as concentration/seperating agents for uranium analysis in aqueous samples. Taking advantage of favorable sorption chemistries, sorbed uranium (as uranyl species) can reach >25% by weight associated with nanoscale magnetite particles (12 nm) which are surface stabilized with an oleic acid bilayer. Because these materials exhibit strong, permanent magnetic properties, they can be selectively removed from complex samples using magnetic fields resulting in high (uranium) concentration factors. Furthermore, as these materials are surface stabilized and monodispersed, dense and extremely thin films can be formed minimizing the self-absorption of α-particle emission from uranium isotopes. Taken together, engineered material features enhance uranyl detection (via α-counting) by over 1000 times when compared to a commercial available, aggregated, "nanoscale" iron oxide.

The relationship between ice volume, CO_2 and climate in the Middle Miocene

GAVIN L. FOSTER[1]*, CAROLINE H. LEAR[2] AND JAMES W.B. RAE[3]

[1]School of Ocean and Earth Science, National Oceanography Centre, Southampton, Southampton, (*correspondence: gavin.foster@noc.ston.ac.uk)

[2]School of Ocean and Earth Sciences, Cardiff University, Cardiff, LearC@cardiff.ac.uk

[3]Bristol Isotope Group, Department of Earth Sciences, University of Bristol, Bristol, James.Rae@bristol.ac.uk

The global cooling from the early Cenozoic ice-free world (~50 Ma) to today's bipolar icehouse world has long been ascribed to declining levels of CO_2 [1]. This overall cooling trend is recorded by a ~4 ‰ increase in deepwater benthic foraminiferal $\delta^{18}O$ values, which reflects both a ~12 °C cooling of bottom waters, and the formation of Earth's continental ice caps. Roughly half of this signal (a ~2 ‰ increase in benthic foraminiferal $\delta^{18}O$) occurs between the Miocene Climatic Optimum (~16 Ma; MCO) and today, including a ~1 ‰ step marking the Middle Miocene Climate Transition (MMCT) at ~14.5 Ma. The MMCT is thought to coincide with the expansion of the Antarctic ice sheet, changes in ocean circulation patterns, and a ~50 m lowering of global sea level. Although most pCO_2 reconstructions display an overall decline through the early Cenozoic, there is little agreement between them for this crucial period and estimates of pCO_2 during the middle Miocene are either higher (stomatal index [2]), lower (boron isotopes in foraminifera [3]), or around the same [4] as the pre-industrial. This has led to suggestions that either existing proxy records are flawed, or climate and pCO_2 have been decoupled for some portions of Earth's history [4] with uncertain implications for the prediction of future climate change. Here we use boron isotopes in planktonic foraminifera to show that the MCO was associated with elevated pCO_2 and that drawdown from this maximum was related to orbitally-paced organic carbon burial during the MMCT. Contrary to previous studies (e.g. [4]) our new boron based pCO_2 record therefore reaffirms the link between CO_2, climate and the cyrosphere for this important part of the Cenozoic.

Quantifying ocean acidification during the Palaeogene hyperthermals

L.C. FOSTER [1]*, D.N. SCHMIDT[1], A. RIDGWELL[2] , E. THOMAS[3], C.D. COATH[1], R. HINTON[4] AND T.B. SCOTT[5]

[1]University of Bristol, Department Earth Sciences, BS8 1RJ, Bristol, UK, (*correspondence: l.c.foster@bristol.ac.uk, D.Schmidt@bristol.ac.uk)

[5]Interface Analysis Centre, University of Bristol, BS2 8BS UK (T.B.Scott@bristol.ac.uk)

Palaeogene hyperthermals are associated with rapid negative Carbon Isotope Excursions (CIE) and global warming and hence may provide an analogue for future ocean acidification. We present $\delta^{11}B$ (pH), Mg/Ca (temperature), B/Ca (carbonate ion concentration) and wall thickness data from the benthic foraminifer *Oridorsalis umbonatus* to study the extent of the change in the carbonate system and the calcification response. In addition, we present Electron Backscatter data to assess preservation and diagenetic alteration.

Our study examines both the temporal and geographical response of ocean acidification during Palaeogene hyperthermals. For the former we present data from Walvis Ridge (1262, paleodepth 3500 m) for three proposed paleo-ocean acidification events: Early Late Palaeocene Event (ELPE), Paleocene-Eocene Thermal Maximum (PETM) and ELMO (59- 53 Ma). These events differ in the extent of carbonate dissolution and thus allow us to study the relative changes in ocean carbonate chemistry. We also present a detailed study of the PETM across a range of sites on Exmouth Plateau (762), Kerguelen Plateau (1135) and a shallower site on Walvis Ridge (1263, paleodepth 1500 m) to determine the global response.

Spatial and temporal tritium variability at Vostok station

E. FOURRE[1]*, P. JEAN-BAPTISTE[1], J.R. PETIT[2], V. LIPENKOV[3], R. WINKLER[1] AND A. LANDAIS[1]

[1]LSCE, CEA-Saclay, 91191 Gif-sur-Yvette, France (*correspondence : Elise.Fourre@lsce.ipsl.fr)
[2]LGGE, CNRS-UJF, 38402 St Martin d'Hères, France
[3]Arctic and Antarctic Research Institute, 199397 St Petersburg, Russia

Tritium (^3H) concentration was measured in snow deposited at the Vostok station (East Antarctica) from two snow pits covering the period mid-50s to 2006 and 2008 respectively. At Vostok, ^3H concentrations are relatively high: low vapour pressure and almost no snowfall make this site specially sensitive to stratospheric inputs highly enriched in tritium. In the upper part of both pits, the post-bomb tritium record shows interannual variability.

As shown in the figure below, the records versus depth are affected by spatial distorsion, although the two pits are only distant of a few hundreds of meters. This can be attributed to redistribution of snow by wind, formation of dunes at different scales, locally different densification processes, etc..., as reported for instance by Ekaykin *et al*. (2002) for δD and $\delta^{18}O$.

However, despite this stratigraphic noise, a similar cyclic interannual pattern can be identified on both pits. This suggests that tritium can be used as a tracer of the relative contribution of stratospheric and tropospheric moisture to the snow deposition.

Ca fluxes linked to particles exchange with seawater during Himalayan erosion

CHRISTIAN FRANCE-LANORD[1], MAARTEN LUPKER[1], BRUNO LARTIGES[2] AND JÉRÔME GAILLARDET[3]

[1]CRPG-CNRS, Université de Lorraine, Vandoeuvre Nancy, France
[2]GET-OMP, Université Paul Sabatier, Toulouse, France
[3]Institut de physique du Globe de Paris (IPGP), France

Silicate weathering as a long term sink for atmospheric CO_2 must be coupled to carbonate precitation and burial. At the global scale, this process is hampered if the alkalinity exported by rivers is derived from alkaline silicates as no Ca (or Mg) is then supplied to the ocean to precipitated carbonates. One process to compensate for alkaline cation flux is the adsorbed cation exchange at the Contient-Ocean transition. In the river system, the dominant dissolved species, Ca^{++} is also the main adsorbed cation on the sediment load. Upon transfer in seawater, Ca^{++} is potentially exchanged for seawater Na^{+}, leading to a yet unacounted Ca flux [ref].

We atempt to evaluate this process on the Ganga-Brahmaputra rivers (G-B) which generate ca. 10% of the global river particles flux to the oceans. In addition, the Himalayan crust mostly delivers alkaline silicates to weathering. We measured Cation Exchange Capacity (CEC) on modern river sediments sampled in the Bangladesh delta. Measured CEC are strongly dependant on the grain size and mineralogical composition of the sediments. It varies between 15 meq/100g for clay rich sediment and 1 for coarse quartz rich sediment. This CEC is primarly bounded to Ca^{++} (85%) and Mg^{++} (12%) with minor proportions of K^{+} and Na^{+}.

Assuming conservatively a G-B sediment flux of 1×10^{9} t/yr and an average composition for the sediment with Al/Si = 0.23; this leads to a maximum of $\approx 2.5\times10^{10}$ moles of exchangeable Ca. Assuming a complete efficiency of Ca-Na exchange in seawater, this corresponds to ca. 20% of the present dissolved flux of silicate derived Na. CEC of Himalayan sediments is therefore largely insufficient to strenghthen the long term CO_2 uptake through alkaline silicate weathering in the Himalayan basin. The fate of Himalayan silicate alkalinity is therefore more likely to be involved in reverse weathering reactions with no net effect as sink for atmospheric CO_2.

This conclusion is likely generalisable to other large Asian rivers. On the contrary, rivers draining volcanic terranes may generate higher CEC given their sedimentological characteristics.

The Eger Graben deposits provide a geochemical archive covering Early to Middle Miocene fluvial to lacustrine environments. Proxy data based on bulk rock pyrolysis and molecular fossils provide evidence of a series of sedimentary events and climatic perturbations.

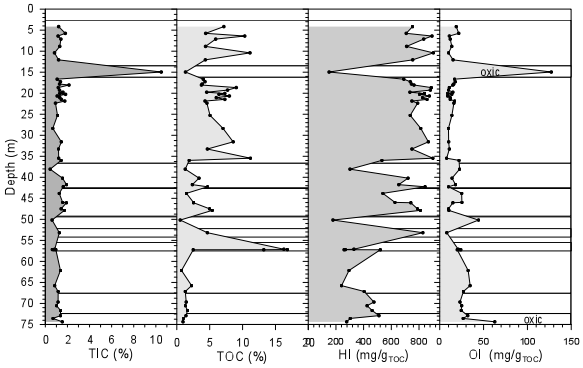

Figure 1. Total inorganic and organic carbon (TIC, TOC), hydrogen index (HI), and oxygen index (OI) in the DP-333 profile – clay interval starting above the coal seams.

Sudden flooding terminated the coal deposition. Aquatic plants and later algae became the major biological producer of organic matter. 6 epizodic drops of lake level were associated with drying, partial oxidation and formation of semifusinite. Analogical phases of palaeo-environmental evolution manifested by proxy data were identified in Sokolov and other Miocene basins.

This study was supported by the Czech Ggrant Agency (GAČR 205/08/1087).

The influence of local cation-distribution on the magnetic properties in ilmenite-rich α-Fe_2O_3-$FeTiO_3$ systems

CATHRINE FRANDSEN* AND STEEN MØRUP

Technical University of Denmark, Department of Physics, Building 307, DK-2800 Kongens Lyngby, Denmark (*correspondance: fraca@fysik.dtu.dk)

The ilmenite-hematite (xFeTiO$_3$ – (1-x)Fe$_2$O$_3$) system has attracted significant attention because of its complex magnetic properties. Both ilmenite (FeTiO$_3$) and hematite (α-Fe$_2$O$_3$) are antiferromagnetic, but intermediate compositions can be strongly ferrimagnetic [1] and finely exsolved structures of hematite and ilmenite are found to have a magnetization larger than expected [2].The system is of significant interest as a source of natural remnant magnetism on the Earth, the Moon and Mars [2].

Here, we compile some recent Mössbauer studies of ilmenite-rich samples with different degree of local Fe^{3+}-ordering, ranging from a disordered cation distribution in a ball milled ilmenite [3], to Fe^{3+} in nanometer-sized hematite clusters in rapidly cooled ilmenite-rich samples [4], to nano- to micrometer-sized hematite lamellae exsolved in a slowly cooled natural sample of hemoilmenite [5]. We discuss the influence of the local cation ordering on the magnetic properties of the (xFeTiO$_3$ – (1-x)Fe$_2$O$_3$) system.

In the ball milled ilmenite-rich sample, the cations are disordered, and this has a large influence on the magnetic hyperfine interaction, but the Néel temperature is essentially not affected [3]. Nanometer-sized hematite clusters within an ilmenite-like matrix of rapidly-cooled samples show ferrimagnetic behaviour due to superexchange coupling with Fe^{2+} in ilmenite [4]. In the natural sample, high-field Mössbauer measurements indicate the presence of a minor ferrimagnetic hematite component [5].

Secular depletions in highly siderophile elements recorded in >3.6 Ga komatiites

E.A. FRANK[1]*, W.D. MAIER[2] AND S.J. MOJZSIS[1]

[1]University of Colorado, Department of Geological Sciences & Center for Lunar Origin and Evolution (CLOE), NASA Lunar Science Institute, Boulder, CO 80309-0399, USA (*correspondence: elizabeth.frank@colorado.edu)

[2]University of Oulu, Linnanmaa, 90014 Oulu, Finland

Plume-derived extrusive ultramafic rocks of peridotitic composition (komatiites) - and their metamorphic equivalents - can be used to probe changes in highly siderophile element (HSE) abundances for the komatiite source (mid- to lower mantle). These rocks appear to show a time-dependent depletion trend (see figure) in HSE abundances from Neoarchean to Paleoarchean samples [1]. In the figure, the solid line denotes the modern peridotite Pt concentration, while the dashed line shows the mean abundance for the oldest three analyzed komatiites.

HSEs should have strongly partitioned into the core during differentiation, but they show a higher than expected mantle abundances. This conundrum has led to the proposal that a "Late Veneer" (LV) delivered ~1% of Earth's mass after core closure [2], although this explanation is contested [3, cf. 4]. Recent modeling [5] shows that it is dynamically feasible for a ~2700-km diameter impactor to have delivered 1% of Earth's current mass as an LV after the Moon-forming impact. Assuming CI compositions, such an event is enough to explain the observed HSE enhancement. Some evidence also exists for LVs on the Moon and Mars in lunar basalts and SNC meteorites [6, 7]. While Mars' abundances are roughly equivalent to Earth's, the Moon is apparently ~1000× less enhanced for uncertain reasons.

We report new data from >3.6 Ga komatiitic rocks that exhibit a low HSE abundance. If Earth experienced an LV, it likely occurred between Moon formation and solidification of the first continental crust (pre-4.4. Ga). We postulate that the LV polluted the upper mantle with suspended platinoid elements that became progressively mixed. Additional samples in the data gap between 2.9 and 3.2 Ga will be measured for their HSE abundance to determine whether they too follow the postulated mixing trend.

Distribution of neodymium isotopes in Eastern Equatorial Pacific seawater

MARTIN FRANK[1]*, PATRICIA GRASSE[1], TORBEN STICHEL[1,2] AND LOTHAR STRAMMA[1]

[1]IFM-GEOMAR, Wischhofstr. 1-3, 24148 Kiel, Germany (*correspondence: mfrank@ifm-geomar.de)

[2]SOEST, University of Hawaii 1680 East-West Rd, Honolulu, HI 96822, USA

The Rare Earth Element (REE) neodymium (Nd) is introduced into seawater through continental weathering and exchange with the continental shelves. Due to its intermediate oceanic residence time and the fact that it is independent of biological fractionation it is a powerful chemical water mass proxy and can also be applied for the reconstruction of past ocean circulation. For its reliable use a precise knowledge of the present-day distribution and input mechanisms is required. Over the last years, a large number of Nd isotope data have been produced for Atlantic seawater but only very few data are available for the Pacific Ocean.

In this study we present the first dissolved Nd isotope data for the Eastern Equatorial Pacific (EEP), where one of the globally largest Oxygen Minimum Zones (OMZ) is located. Samples were recovered along several zonal and meridional sections during "FS Meteor" cruises M77/3 and M77/4 in 2009. Surface waters in the study area show a wide isotopic range (ε_{Nd}= -8 to ε_{Nd}= +3), due to contributions from land accompanied by leaching of particles and shelf sediments. Near surface circulation in the EEP is controlled by the complex Peru-Chile Current System and intense coastal upwelling. These water masses originate from the western and central Pacific, such as the Equatorial Undercurrent, which is the main feeder of the Peruvian Upwelling. This current, which enters the system near the equator is characterized by highly radiogenic isotope values (ε_{Nd}= -1.8), significantly different from less radiogenic subsurface currents stemming from the south, as well as from central and northern Pacific areas (ε_{Nd}= -4). Deep and bottom waters at the southernmost stations (14°S) of the study area (ε_{Nd}= -7) are clearly influenced by less radiogenic water masses originating from the Southern Ocean. Towards the equator, the bottom waters show a trend towards more radiogenic values (ε_{Nd}= -2). In addition, the REE patterns of the same seawater samples were analyzed to better understand the input mechanisms (potential release from reducing sediments within the OMZ) and vertical exchange processes (biological productivity) in this highly dynamic system.

Formation of nanoparticles with stereochemical effects using the polyphenol-pseudoboehmite complexation

MARTINA FRANKE

Department of Soil Science, University of Trier, D-54296 Trier, Germany (s6mafran@uni-trier.de)

Stereochemical effects were observed by the formation of organominerally nanoparticles using the system of polyphenol-pseudoboehmite. In this study, four types of phenolic compound, being pyrocatechol, resorcin, pyrogallol and guaiacol, were used for the preparation of four types of organomineral complexes. The complexes were synthesized by adsorption in a gas-solid phase at 50 °C in the presence of atmospheric pressure for a period of 60 days in total darkness. Subsequently, a comparative structure analysis was conducted from pseudoboehmite and polyphenol-pseudoboehmite complexes by using methods of VNIR spectroradiometry and Fourier transform infrared (FTIR) spectrometry. The complexation took place at surface level between OH atoms of pseudoboehmite and the functional groups of polyphenol due to the elimination of H_2O. However, the growth of nanoparticles was dependent on stereochemical effects, based on the constitution, configuration and conformation of molecules.

Geochemical mapping of phosphorus in drainage sediments of Pernambuco State, Brazil

M. FRANZEN*, E.A.M. LIMA AND R. CAVALCANTE

Geological Survey of Brazil (CPRM) –
(*correspondence: melissa.franzen@cprm.gov.br;
enjolras.lima@cprm.gov.br;
rogerio.cavalcante@cprm.gov.br)

Phosphorus (P) is an essential element for life as primary nutrient. Their presence and availability in soils is essential, however, when available in excess in the water, may be responsible for the eutrophication of water bodies.

Analytical results of P in sediments from drainage obtained at the Multipurpose Geochemistry Project in Pernambuco State, executed by the Geological Survey of Brazil (CPRM), were used to produce the geochemical mapping of low density.

Were analyzed by ICP-OES sediments in fractions <80 mesh. Statistical analysis of dispersion of data obtained provided thresholds above which the levels of P may be considered anomalous. The geochemical maps combine statistical distribution of the percentiles (25%, 50% and 75%) to levels of toxicological and crustal reference, resulting in products that serve both for environmental purposes regarding the delineation of prospective areas.

The regional geochemical mapping confirmed areas of known occurrences, as the phosphorite mineralization of the Pernambuco-Paraíba Basin and the mining district of Sumé, and also highlights some areas within the State of likely prospective potential. These are located mainly over the Meso-Neoproterozoic complexes and predominantly in falt zones, where the paragenesis and tectonic setting suggest the possibility of lenticular bodies of carbonatite [1], although these are not yet mapped.

The hypothesis suggests potential to prospective studies of detail, since the anthropogenic contamination is unlikely because of the semi-arid climate does not favor the accumulation of organic matter and the agricultural activity is limited.

Chiral interactions of amino acids in a hydrated vermiculite clay

DONALD G. FRASER, NEAL T. SKIPPER, MARTIN V. SMALLEY AND H. CHRISTOPHER GREENWELL[1234]

[1]Department of Earth Sciences, University of Oxford, Parks Road, Oxford OX1 3PR, UK
[2]Department of Physics & Astronomy, University College London, Gower Street, London WC1E 6BT, UK
[3]Department of Physics, University of York, Heslington, York YO10 5DD, UK
[4]Department of Chemistry, Durham University, South Road, Durham DH1 3LE, UK

Recent work suggests a link between chiral asymmetry in the amino acid iso-valine extracted from the Murchison meteorite and the extent of hydrous alteration.

We present the results of neutron scattering experiments on an exchanged, 1-dimensionally ordered n-propyl ammonium vermiculite clay. The vermiculite gel has a (001) d-spacing of order 5nm at the temperature and concentration of the experiments and the d-spacing responds sensitively to changes in concentration, temperature and electronic environment. The data show that isothermal addition of D-histidine or L-histidine solutions produces shifts in the d-spacing that are different for each enantiomer. This chiral specificity is of interest for the question of whether clays could have played an important role in the origin of biohomochirality.

Biogeochemical redox transformations of pertechnetate ($^{99}TcO_4^-$)

J.K. FREDRICKSON[1], J.-H. LEE[1], A.E. PLYMALE[1], A.C. DOHNALKOVA[1], S.M. HEALD[2], T. PERETYAZHKO[1], J.P. MCKINLEY[1], AND J.M. ZACHARA[1]

[1]Pacific Northwest National Laboratory, Richland, WA, USA
[2]Argonne National Laboratory, Advanced Photon Source, Argonne, IL, USA

Technetium-99 is an important risk-driving radioactive subsurface contaminant at the U.S. Department of Energy (DOE)'s Hanford Site in southeastern Washington State. The monovalent anion $Tc(VII)O_4^-$ (pertechnetate) is subject to subsurface migration but Tc is considerably less soluble in its most reduced form, $Tc(IV)O_2$. Reduction can be catalyzed directly by a range of anaerobic microorganisms but also indirectly by products of microbial metabolism including ferrous iron and sulfide. We have investigated Tc(VII) reduction reactions in Hanford subsurface sediments and in well-defined model systems that include metal-reducing microorganisms and Fe-bearing minerals to explore speciation effects on reaction rates and Tc endproducts. In Hanford sediments collected from anoxic regions of the subsurface or oxic sediments subjected to microbial reduction, 2×10^{-5} M (20 μM) aqueous Tc(VII) was reduced to below the detection limit (3.98×10^{-9} M) over times ranging from days to months. The rate and extent of reduction was dependent on sediment source, Fe(II) speciation, and sulfide concentration. X-ray microprobe analyses, including fluorescence mapping, elemental multichannel analysis, and micro-diffraction, were used to deduce Tc speciation and mineralogic association in the various sediments. In bioreduced Hanford formation sediments Tc(IV) was associated with phyllosilicates (mica), as indicated by associated Fe and Rb (analogous to K) signals. X-ray absorption spectroscopy (XAS) revealed the presence of $Tc(IV)O_2$ and Fe(III)- associated Tc(IV). Tc(VII) was also reduced by sediment-associated biogenic sulfide; Tc-S bonding at the nearest coordination environment around absorber Tc atom was revealed by XAS. These results indicate that Fe(II) associated with Hanford subsurface sediments can be a facile reductant of $Tc(VII)O_4^-$ and that the rate of reduction and nature of Tc end product is a function of Fe(II) speciation. These results have implications for far-field ^{99}Tc migration at Hanford where groundwater flow paths traverse Fe(II)-bearing sediments that can reduce Tc(VII) to relatively insoluble Tc(IV) phases.

High CO_2 concentrations negatively affect methanogenesis and sulphate reduction in gas fields of the North German Plain

J. FRERICHS[1]*, C. GNIESE[2], A. SCHULTZ[3], H.-H. RICHNOW[3], D. KOCK[1] AND M. KRÜGER[1]

[1]BGR, Hannover, Germany
(*correspondence: Janin.Frerichs@bgr.de)
[2]TUBAF, Freiberg, Germany
[3]UFZ, Leipzig, Germany

In consequence of their global warming potential, large-scale solutions are needed to reduce the emissions of greenhouse gases like CO_2 or CH_4. The carbon capture and storage offers one option to reduce CO_2 emissions. Favorable CO_2 storage sites are depleted gas and oil fields. Our study is focusing on the direct influence of high CO_2 concentrations on the autochthonous microbial population and environmental parameters at such sites. The studied reservoir formation is operated by Gaz de France Suez E&P DEUTSCHLAND GmbH. The conditions in the reservoir around two production wells differ in various geochemical and microbiological parameters (Ehinger *et al*. 2009). Based on these results our study included cultivation and molecular-biological approaches. The two wells differed in the indigenous and inducible (with substrate addition) microbial activity. The addition of methanol to fluids of both wells induced biogenic methane production only in well A. Fluids of well B showed induced sulphide production after addition of hydrogen and CO_2. Results from molecular biological analysis of original fluids supported the activity profile for both sites. The abundance of archaeal 16S rDNA and *mrcA* was several magnitudes higher in fluids of site A whereas site B was dominated by *Bacteria*. Incubations with high carbon dioxide concentrations showed a significant decrease of methane and sulphide production with increasing CO_2 levels. In a second step actively growing methanogenic and sulphate-reducing enrichments from the reservoir fluids were incubated under in situ pressure and temperature with high CO_2 levels. First experiments indicated that the microorganisms survived short termed incubation although the respiratory activity was not detectable. From this experiment viability rates of micro-organisms together with molecular analysis of community changes were investigated. At the end, these experiments will provide information about biogeochemical and micro-biological changes during and after the storage of CO_2 and their potential impacts on reservoir geology, storage capacity, and long-term stability.

Oxide surfaces: Geometric and electronic structure

H.-J. FREUND

Faradayweg 4-6, 14195 Berlin, Germany,
(freund@fhi-berlin.mpg.de)

Single crystalline oxide surfaces have been prepared by physical vapour deposition on suited metal single crystals. The geometric structures of surfaces have been characterized by a number of techniques, including STM and NC-AFM as well as LEED, and LEEM. The electronic structure has been studied using photoelectron spectroscopy NEXAFS as well as EPR, and augmented by FTIR. In this talk a number of specific examples including iron oxides, ceria, vanadia, and MgO are discussed. The study of water on those surfaces has been investigated.

Felsic magma generation in the oceanic crust: A geochemical study of Pacific Antarctic Rise lavas

SARAH FREUND, KARSTEN M. HAASE, CHRISTOPH BEIER AND MARCEL REGELOUS[1]

GeoZentrum Nordbayern, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany
(Sarah.Freund@gzn.uni-erlangen.de)

Glassy lavas from the Pacific Antarctic Rise show variable SiO_2 contents between 49 and 68 wt.% and range from basalts to dacites. The trace element compositions range from depleted to slightly enriched mid-ocean ridge basalts whereas the evolved lavas are more enriched in most incompatible elements but show negative anomalies of Ba, Nb Sr, Ti and positive anomalies of Rb, U, Zr and Hf compared with the basalts. In terms of major elements the lavas lie on typical tholeiitic fractionation trends. The evolved lavas show the same trends as the basalts in Nd and Pb isotope space while there is a deviation towards higher Sr isotope ratios at a given Nd isotope ratio. The evolved glasses tend toward anomalously low $\delta^{18}O$ values and show increasing Cl content with increasing SiO_2. These isotopic and chemical variations likely reflect assimilation of hydrothermally altered crustal rocks. Because light $\delta^{18}O$ values occur only in the lower part of the oceanic crust (> 1 km bsf) the assimilation and fractional crystallization processes probably occurred at the lower boundary of the sheeted dikes. Crustal partial melting yielding dacite magma and mixing of these melts with basalts can be ruled out based on trace element ratios and major element distributions. The petrogenesis of the evolved magmas has been modeled quantitatively using MELTS [1] and EC-RAFC [2]. We conclude that AFC processes lead to the formation of evolved magmas beneath the PAR with trace element similarities to the continental crust.

Measuring annual variation of soil air composition focusing on the effect of oxygen depletion on noble gas partial pressures

F. FREUNDT, T. SCHNEIDER AND W. AESCHBACH-HERTIG*

Institute of Environmental Physics, Heidelberg University, 69120 Heidelberg, Germany (*correspondence: aeschbach@iup.uni-heidelberg.de)

While it is known that the partial pressures of soil air components like oxygen, carbon dioxide and nitrous oxides show fluctuations on both temporal and spatial scales [1] primarily caused by microbiologic activities in the soil, the use of dissolved noble gases as a climate proxy utilizes the basic assumption that the ground air equilibrating with water during recharge is of atmospheric composition with regard to noble gases [2].

This assumption has been questioned to account for lower than expected noble gas temperatures, suggesting an enrichment of noble gas partial pressures in ground air caused by removal of CO_2 (produced by oxygen depletion) due to its high solubility [3].

To test this proposition, two permanent sampling sites were built in clay dominated soil, allowing for sampling of ground air in regular intervals and depths up to 6 meters. The locations were chosen based on preliminary data by T. Schneider [4] indicating the possibility of high oxygen depletion. O_2 and CO_2 concentrations were measured on site while the noble gases helium, argon, neon, krypton and xenon were measured using mass spectrometry.

Preliminary noble gas data from the first four months of sampling indicate no deviation of noble gas partial pressures from atmospheric values, suggesting that the proposed oxygen depletion model cannot be supported by actual data from the sampled clay soils. Further data extending the record to ten months (August to May) will be presented.

Molybdenum isotopes as a novel tracer for subduction components in the Mariana arc

HEYE FREYMUTH*, TIM ELLIOTT AND MATTHIAS WILLBOLD

Bristol Isotope Group, University of Bristol, Wills Memorial Building, Queen's Road, Bristol BS8 1RJ (*correspondence: glxhf@bristol.ac.uk)

At least two different slab-derived components have been proposed to be present in arc volcanoes: a sediment component and a component derived from altered mafic oceanic crust. Despite a widely held belief of the involvement of these components in the genesis of arc volcanoes [1,2] the unambiguous identification of these components and discrimination of their chemical signatures from residual phase mineralogy remains difficult. We propose stable molybdenum isotopes as a novel tracer for subduction components in arc magmas.

Molybdenum has seven stable isotopes, which have been shown to fractionate during the incorporation of dissolved Mo into oceanic sediments. Under oxic conditions, Mo slowly adsorbs to particles in the sediment, a process that is particularly efficient when Fe-Mn oxides are present. The adsorption of Mo is associated with isotopic fractionations from $\delta^{97/95}Mo_{seawater} \approx 1.8$ ‰ to $\delta^{97/95}Mo_{oxic\text{-}sediments} < 0$ ‰. Under anoxic conditions, Mo is quantitatively removed from the water column and sediments with a heavy isotopic composition are produced [3,4].

We measured Mo isotopes on basalts from the Mariana arc as well as representative samples of subducting sediments from ODP sites 800, 801 and 802 using a double-spike technique [5]. The sediments are light in their isotopic composition with $\delta^{97/95}Mo_{sediments} < 0$ ‰, consistent with the incorporation of Mo into the sediment under oxic conditions. The arc basalts are enriched in Mo relative to Pr, an element with similar degree of incompatibility during mantle melting. The Mo isotopes in the arc basalts correlate well with Mo/Pr, Ba/La and Ce/Pb ratios, with samples containing a larger sediment component [6] also having the lowest $\delta^{97/95}$Mo. Less incompatible element enriched samples are isotopically heavy and their $\delta^{97/95}$Mo exceeds the range of ocean island basalts and continental material. They presumably trace a fluid derived from deeper parts of the subducted lithosphere.

Selenium uptake in otoliths from cold-water fish species captured downstream from coal mining

LISA A. FRIEDRICH[1]*, NORMAN M. HALDEN[2] AND VINCE P. PALACE[1]

[1]Department of Fisheries and Oceans Canada, Winnipeg, Manitoba, Canada R3T 2N6 (*correspondance: lisa.friedrich@dfo-mpo.gc.ca, vince.palace@dfo-mpo.gc.ca)

[2]Department of Geological Sciences, University of Manitoba, Winnipeg, Manitoba, Canada R3T 2N2 (nm_halden@umanitoba.ca)

Establishing the exposure histories of wild fish to trace element contaminants within an aqueous environment is often difficult for fish species with large home ranges. Chemical analyses of muscle or visceral tissues can provide information on recent exposure, but depuration, metabolic transformation, and tissue redistributions preclude temporal resolution. Otoliths, the calcified structures in the inner ear of teleost fish, are considered to be metabolically stable and therefore may serve as continuous recorders of exposure to trace elements in the environment. Otoliths are composed of layers of aragonite in a protein matrix deposited annually throughout the lifetime of the fish, thus providing a time scale. Both the inorganic portion and protein matrix have the capacity to incorporate a wide range of trace elements, and, as such, otoliths may be used to determine a fish's history of contaminant exposure in the wild.

Otoliths from three cold water fish species from Elk River, British Columbia, Canada were examined to delineate any selenium (Se) contamination signatures contained therein relating to adjacent coal mining activity. The Elk River watershed contains elevated levels of Se owing to naturally occurring seleniferous host rock surrounding coal deposits, as well as five coal mining operations that mobilize Se from exposed host rock into the watershed. Selenium concentrations in otolith primordia tended to be low, indicating that these fish emerged in low Se areas, and moved into areas of increased Se later in life. Individuals captured from the same area had varying Se exposure profiles, indicating the fish do not move *en masse* into and out of high-Se areas. Year-to-year variability of Se exposure patterns within an otolith suggests inconsistent utilization of high- and low-Se areas by the individual. The contrasting exposure profiles for these fish, which have home ranges of tens of kilometres, indicate that soft tissue concentrations would not necessarily reflect the relative abundance of Se in their environments.

Fe(II)-induced trace element release from crystalline iron oxides

A.J. FRIERDICH* AND J.G. CATALANO

Earth & Planetary Sci., Washington Univ., St. Louis, MO 63130, USA (*correspondence: frierdich@wustl.edu)

Interfacial electron transfer and atom exchange (ET-AE) between aqueous Fe(II) and Fe(III) oxides induces surface transformations resulting from spatially separated growth and dissolution processes [1-4]. Redox-active elements are known to experience speciation changes during Fe(II)-Fe(III) ET-AE but the fate of redox-inactive elements remains poorly understood. We have recently shown [5] that aqueous Fe(II) can catalyze Ni(II) cycling through goethite and hematite by inducing adsorbed Ni to become incorporated into the mineral and pre-incorporated Ni to be released to solution. Here we examine the kinetics of Ni(II) and Zn(II) release from Ni(II)- and Zn(II)-substituted goethite and hematite when these minerals are exposed to aqueous Fe(II) solutions.

Ni and Zn release follows a 2nd order kinetic rate law and occur on a different timescale than Fe(II) adsorption but on a similar timescale as Fe isotope exhchange for goethite [2]. This suggests that the mechanism for release is not related to displacement of surface associated Ni but rather occurs during the Fe(II)-Fe(III) ET-AE process. The concentration of Fe(II) and pH strongly influence the quantity and rate of metal release. The type of metal substituent also affects reactivity; Zn release is more pronounced from hematite vs. goethite whereas the opposite trend occurs for the Ni systems. Sequential batch experiments (i.e., periodic fluid replacement to remove products while the solid remains for further reaction) display greater total Ni and Zn release than observed in single batch experiments (cf. 28% vs 9% of Ni released from goethite), demonstrating that the aqueous metal concentration is a negative feedback on release. Incorporated redox-active trivalent metals [Mn(III) and Co(III)] exhibit similar release to solution, suggesting that their release is coupled to reduction and that they may cause net Fe(II) oxidation. Our results illustrate a previously unrecognized role of Fe(II) on the release of trace elements from iron oxide minerals. Such reactions may liberate essential trace elements or cause enhanced mobility of contaminants in natural environments and engineered systems.

Potential products of fluid-rock interactions in the Soultz-sous-Forêts Enhanced Geothermal System

B. FRITZ[1]*, A. BALDEYROU-BAILLY[1], AND O. VIDAL[2]

[1]LHYGES, Université de Strasbourg/EOST, CNRS, France (corresponding author : bfritz@unistra.fr)
[2]ISTerre, Université J. Fourier, CNRS, Grenoble, France

A geochemical modelling approach of fluid-rock interactions has been applied to the potential water-rock interaction processes in the Enhanced Geothermal System (EGS) of Soultz-sous-Forêts (France) [1,2,3] which started in 2008. The aim of the study was to detect the possible risks of minerals precipitation in the circulation loop in the temperature range between 200°C at depth (5km) and 60°C in the surface power system before re-injection, in conditions reproducing those of the industrial exploitation of the site.

The major result of the simulations highlights the role of carbonates as possible products of the thermal fluids particularly in the low temperature part of the thermal loop and on short term. In the reservoir rock-forming silicates may be partially dissolved by the reinjection of fluids leading to the long term formation of clay minerals in the porosity of the rock. The modelling approach has been combined with an experimental approach of water-rock interaction under a strong thermal gradient which confirms the dynamics of silicates in these temperature conditions and with this type of saline fluid (TDS about 100g/l).

The formation of clay minerals (illites and / or chlorites) may modify the porosity and the permeability of the granitic reservoir during future exploitation.

Composition, structure and shape of *in situ* precipitated Fe-oxide nanoparticles from a soil effluent

A. FRITZSCHE*, A.K. WIECZOREK, T. RENNERT, M. HÄNDEL AND K.U. TOTSCHE

Institute of Earth Sciences, Friedrich Schiller University of Jena, Burgweg 11, 07749 Jena, Germany (*correspondence: a.fritzsche@uni-jena.de)

Iron oxides are generally highly reactive. In nanoparticulate form, the reactivity of Fe oxides and their mobility in the aqueous phase is even increased. Thus, dispersed Fe-oxide nanoparticles are considered as key reactive components for biogeochemical processes that involve Fe. However, the majority of related investigations is based on synthetic Fe-oxide nanoparticles, the composition and properties of which may not reflect those of Fe-oxide nanoparticles actually occurring in nature.

In this study, soil columns were filled with material from a topsoil horizon. The soil columns were operated in duplicate under water-saturated conditions with a low ionic influent. The activity of soil microorganisms led to anoxic conditions and thus the reductive dissolution of pedogenic Fe oxides and the accumulation of Fe^{2+} in the column effluent. The effluent was re-aerated after its discharge resulting in the oxidation of Fe^{2+} and the precipitation of Fe oxides. The effluent was dialysed to separate the Fe oxides from non-particulate compounds.

X-ray diffraction and Mössbauer spectroscopy revealed the formation of short-range ordered ferrihydrite (Fh). Its crystallisation was probably disturbed by dissolved organic matter and inorganic species (e.g. As, Si) that associated with Fh. Fourier transform infrared spectroscopy pointed to mainly polysaccharides, aliphatics and carboxyls as available organic compounds to associate with the Fh particles. The aggregation intensity decreased in response to decreasing effluent ionic strengths. Dynamic light scattering revealed aggregate sizes from 50 nm to 500 nm, which was confirmed by atomic force microscopy and scanning electron microscopy. The latter approaches consistently revealed the coexistence of bulky and to a lesser extent linear-aligned nanoaggregates. Both aggregate types exhibited similar mechanical and physical properties and were composed of smaller particles (~ 10 nm).

This study demonstrated the reproducible stabilisation of nanoaprticulate Fh also in complex solutions like effluents from soil. Such near-natural nanoparticles represent eligible specimen to investigate the fate and effect of nanoparticulate Fe oxides in the (soil) environment.

Strontium isotope fractionation in scleractinian corals

N. FRUCHTER*[1], F. BÖHM[1], A. EISENHAUER[1], M. DIETZEL[2], A. KRABBENHÖFT[1], A. NIEDERMAYR[2], S. REYNAUD[3], B. LAZAR[4] AND M. STEIN[5]

[1]Leibniz Institute of Marine Sciences, IFM-GEOMAR, Kiel, Germany. (*nfruchter@ifm-geomar.de)

[4]Institute of Earth Sciences The Hebrew University of Jerusalem, Israel.
[5]Geological Survery of Israel, Jerusalem, Israel.

Preferentially lighter strontium isotopes ($\delta^{88/86}Sr_{carbonates}$(NBS987) ~0.15 to 0.25 ‰) are taken up from seawater ($\delta^{88/86}Sr_{seawater}$: ~0.39 ‰) by marine calcifiers during calcium carbonate precipitation. A temperature sensitivity of Sr isotope fractionation has been reported [1,2,3]. However the published results are discrepant and enigmatic.

In order to shed light into the temperature dependency of strontium isotope fractionation, we conducted inorganic precipitation experiments of aragonite, and investigated cultured and natural modern corals. The aim of the study is to enhance our understanding of strontium isotope fractionation mechanisms for biocalcification of corals and for the applicability of $\delta^{88/86}Sr$ as a temperature proxy. Strontium isotope distribution was measured by TIMS using the double spike method [4]. In addition to strontium isotope analyses we determined elemental ratios like Sr/Ca.

Preliminary results indicate seasonal $\delta^{88/86}Sr$ variations in modern corals which are positively correlated with the Sr/Ca ratios and hence, inversly correlated with temperature. The seasonal amplitude in the Sr/Ca ratios is 0.43 mmol/mol and corresponds to a temperature variation of ~7°C. The seasonal variation in $\delta^{88/86}Sr$ in the same coral is 0.04‰. The positive correlation between $\delta^{88/86}Sr$ and Sr/Ca is not in accordance with the Rayleigh distillation model for Sr/Ca ratios in corals that was proposed by Gaetani *et al*. [4].

Modeling glass alteration layers

P. FRUGIER*, S. GIN, N. RAJMOHAN AND M DEBURE

CEA Marcoule, DTCD/SECM/LCLT, BP 17171, 30207 Bagnols-sur-Cèze Cedex, France, (*correspondence: pierre.frugier@cea.fr, stephane.gin@cea.fr, nrmohan_2000@yahoo.com , mathieu.debure@cea.fr)

Glasses major constituents interact chemically within the amorphous layers resulting from glass alteration in water. These interactions determine the composition, the dissolution kinetic and the apparent solubility of the amorphous layers as well as their potential passivating properties with respect to the underlying glass. The knowledge of these interactions is required to predict concentrations in solution, pH and eventually glass alteration rates. However, these amorphous layers are complex solids resulting both from initial glass structure and recondensation processes, constantly reorganizing as solution composition changes. Identifiying the main phenomenologies is required for modeling the amorphous layers with a number of parameters consistent with experimentaly accessible data and geochemical modeling tools. These phenomenologies were translated in modeling hypothesis which are part of a model called GRAAL [1,2].

GRAAL model is implemented within a geochemistry and transport code called HYTEC [3]. Therefore, it can account for the thickness and composition of the amorphous layer whatever the time and position in space of a glass under alteration. Chemical description whithin GRAAL has been recently improved thanks to 24 experiments relative to six simple glasses containing Si, B, Na, Ca, Al and Zr, altered for months at four different neutral to alkaline pH [4]. Ten new modeling hypothesis were done for describing these six elements chemical interactions in the amorphous layer. One example: orthosilicic acid activity in solution is significantly lower than amorphous silica solubility only if enough aluminum is also available. Therefore a silica-aluminum rich end-member is taken into account to model the amorphous layer whereas Ca, Na, B and even Zr interactions with Si can be neglected to account for Si activity in solutions (in our experimental conditions at least).

We aim here at sharing both the success and limits of GRAAL model fundamental hypothesis and we will try to demonstrate the usfullness of the approach.

Phase equilibria constraints on the magma evolution of basanite-phonolite series of the Cumbre Vieja volcano (La Palma, Canary Islands)

P. FUCHS[1]*, R. ALMEEV[1] AND A. KLÜGEL[2]

[1]Institute of Mineralogy, Leibniz University Hannover, Germany (*p.fuchs@mineralogie.uni-hannover.de)
[2]Geosciences Department, University of Bremen, Germany

Eruptive products of the recent Cumbre Vieja volcano (La Palma oceanic island) cover a large spectrum of alkali-rich rocks ranging from basanites to phonolites. Current model of Cumbre Vieja plumbing system is based on cpx-barometry and xenoliths and includes three major intervals of magma stagnation and fractionation at mantle and crustal depths (430–780MPa, 180-420MPa and <150MPa) [1]. However, the relative influence of different thermodynamic parameters on stability fields of minerals is still unknown. We present first results of our experimental project aimed at evaluating p-T-aH_2O-fO_2 conditions in the course of basanite-tephrite-phonolite magma differentiation.

As a prerequisite study for these experiments phase equilibria simulations were conducted for a highly magnesian sample of Cumbre Vieja volcano (12.7 wt% MgO) utilizing the MELTs model [2]. Calculations were performed using solid phase fractionation mode, at QFM+1 oxygen buffer, in the pressure interval from 100 to 800 MPa (including both isobaric and polybaric simulations), and with various H_2O contents in parental melt (2-6 wt%). Good agreement between residual melt compositions and natural liquid lines of descent (LLD) were obtained only for the stage of "basanite to tephrite" magma evolution by crystallization of 25-30% ol+sp and subsequent ol+cpx+sp at pressures between 400 and 800 MPa and hydrous conditions. This stage is characterized by strong MgO depletion at nearly constant SiO_2 contents and proceeds until an inflection point at 5 wt% MgO (tephritic melt). Subsequently CaO, FeO and TiO_2 start to decrease and SiO_2 increases up to 58 wt% until the magma reaches phonolitic compositions. This strong change in melt composition is explained by appearance of kaersutite on the liquidus of tephritic melts, which has been so far impossible to reproduce in MELTs mainly due to the lack of kaersutite crystallization model. Thus, the conditions of kaersutite crystallization are crucial to understand the evolution of La Palma magmas from tephrite to phonolites. This problem is prioritized in our ongoing experimental investigations.

The transport of gold in petroleum: An experimental study

S. FUCHS*, A. MIGDISOV AND A.E. WILLIAMS-JONES

Department of Earth and Planetary Sciences, McGill University, Montreal, QC, H3A 2A7, Canada (*Correspondence: sebastian.fuchs@mail.mcgill.ca)

Although there is a close spatial association between gold and organic matter in intracratonic basins such as the Witwatersrand (South Africa), the role of the organic matter in the ore-forming process is not understood. One hypothesis is that the organic matter aids in the deposition of remobilized gold by reducing gold-bearing hydrothermal fluids. Another is that the organic matter represents hydrocarbon liquids, which acted as agents of gold transport. In the case of the Witwatersrand, the latter hypothesis would be consistent with the observation that organic-rich shales, which could have acted as source rocks, are present in the basin, that during burial these rocks passed through the thermal window for oil generation (90°C-160°C) and that structures (thrusts) and porous rocks (sandstones and conglomerates) were present, thereby facilitating hydrocarbon migration.

We report here the results of a study designed to determine the solubility of gold in crude oil and its refined fractions. The experiments were conducted in titanium alloy autoclaves at temperatures in the range 100°C to 300°C for 7-10 days. At the end of an experiment, the quenched oil was sampled. Gold that may have condensed on the walls of the autoclave was dissolved in aqua regia after heating the autoclave to 400°C. This washing solution and the crude oil were analysed using neutron activation to determine the solubility of gold in the crude oil. The results of these experiments show that gold solubility in crude oil reaches a maximum of 39ppb to 48ppb at 250°C. Below and above this temperature, the solubility of gold is significantly lower. Concentrations of gold in the refined fractions (distillates and residua) were significantly lower than in the crude oil. In the residual fractions, gold reached a maximum concentration at 150° (8 ppb), whereas in the distillates the maximum concentration occurred at 300°C (27 ppb). As large aromatic molecules were likely degraded during the refining process and the solubility of gold was low in all the refined fractions, we consider it likely that these molecules exercise an important control on gold solubility. The concentrations of gold in crude oil measured in this study are similar to or higher than those of epithermal ore-forming fluids, suggesting that petroleum can act as an agent for the transport of gold in environments such as the Witwatersrand basin

On the hygroscopic behaviour of marine particles enriched with biogenic nanogels

E. FUENTES[1], H. COE[1], D. GREEN[2] AND G. MCFIGGANS[1]*

[1]Center for Atmospheric Science, SEAES, University of Manchester, M13 9PL, UK (*correspondence: g.mcfiggans@manchester.ac.uk)

[2]Scottish Association for Marine Science, Oban, UK

The present study investigates the effect of nanogel organic matter <0.2 μm exuded by marine biota on the organic enrichment and hygroscopic behaviour of the submicron primary marine aerosol. This investigation is based on the laboratory generation of primary aerosol from seawater enriched with biogenic organic matter released by laboratory-grown algal cultures [1].

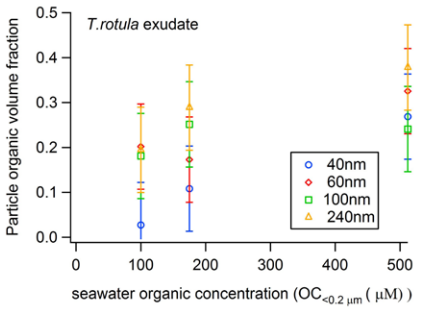

Figure 1. Particle organic volume fraction as a function of seawater organic concentration (OC<0.2 μm).

The primary particles organic fraction was found to correlate with the seawater organic concentration, with values on the order of 5–37% for seawater organic content between 175-512 μM. The particle organic fractions were found to be lower than those reported in atmospheric measurements [2] and no saturation in the particles organic composition was observed even for unrealistically high seawater organic content [3]. Because of the effect of the organic matter, the hygroscopic growth and cloud condensation nuclei activity of the organics-enriched particles were reduced in a 5–24% with respect to the organics-free primary marine aerosol.

Prediction of coral reef calcification in Sesoko Island by ocean acidification

H. FUJIMURA[1]*, A. AOYAMA[1], T. OOMORI[1], T. HIGUCHI[2], B.E. CASARETO[2] AND Y. SUZUKI[2]

[1]Univ. of the Ryukyus, 1 Senbaru, Nishihara, Okinawa 903-0213, Japan (*correspondance: fujimura@sci.u-ryukyu.ac.jp)

[2]Shizuoka Univ., 836 Ohya, Suruga-ku, Shizuoka-shi, Shizuoka 422-8529, Japan

Carbon dioxide has been increasing rapidly by fossil fuel combustion since industrial revolution, causing various global climate changes. Anthropogenic CO_2 induces lower pH in the ocean which is known as an "oceanic acidification". Lower pH level causes the decrease in the calcification rates of many calcifying marine organisms such as shellfish and coral. While many studies have been investigated on the influence of pH to individual marine species, the effects of oceanic acidification on the natural coral reef have not been elucidated. We present relationship between calcification rates and seawater CO_2 concentration (PCO_2) in Sesoko coral reef, Okinawa, Japan and predict the time when the calcifying environment in coral reef will turn to the dissolution with respect to $CaCO_3$.

We had continuously monitored the reef water PCO_2 (LI840A, Li-cor), total alkalinity (Alk-01, Kimoto), water current (Compact-EM, Alcec) and depth (U20, Onset) at Sesoko coral reef since October 2010. Outer reef water samples were taken about every few months to obtain the oceanic values. Alkalinity depletion method was applied to calculate the community metabolism under the natural water flow condition.

Calcification rate increased during daytime and decreased at night. However we observed no dissolution at Sesoko coral reef. Threshold of PCO_2 value at which $CaCO_3$ production turns to dissolution was calculated to be 945 ppm. This value was similar to the results derived from Molokai reef flat of Hawaii [1].

Search for nucleosynthetic tellurium isotopic anomalies in meteorites by N-TIMS

Y. FUKAMI AND T. YOKOYAMA

Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2-12-1 Ookayama, Meguro, Tokyo 152-8551, Japan (fukami.y.aa@m.titech.ac.jp)

Tellurium is one of the promising elements for the study of nucleosynthetic isotope anomalies recorded in meteorites. Tellurium has eight stable nuclides, of which ^{120}Te is produced by the p-process, $^{122, 123, 124}$Te by the s-process, and $^{128, 130}$Te by the r-process. ^{125}Te and ^{126}Te are produced by both the r- and s-processes. The isotopic composition of Te is also affected by short-lived ^{126}Sn – ^{126}Te decay system ($T_{1/2}$ ~ 234 kyr) [1]. The ^{126}Sn is generated only by the r-process, and ^{126}Te excesses in meteorites would provide a smoking gun evidence for the injection of freshly synthesized nuclides by supernovae into the molecular cloud, which presumably triggered the formation of the solar system [2]. It has been reported that presolar diamonds from Allende (CV3) have large nucleosynthetic isotope anomalies of r-process Te isotopes [3,4], whereas bulk chondrites, iron meteorites and terrestrial samples have a uniform Te isotopic composition [5]. Small potential nucleosynthetic Te isotope anomalies in Allende CAIs have been reported, however, the possibility of analytical artifacts is not excluded [6].

It is considered that samples which potentially have nucleosysthetic anomalies (e.g. presolar grains) contain subnanograms of Te. In this study, we developed a precise Te isotope measurement technique using subnanograms of Te by applying a Negative Thermal Ionization Mass Spectrometry (N-TIMS) with secondary electron multiplier. We achieved ~14‰ for δ^{120}Te/^{124}Te, ~3‰ for $\delta^{123, 125}$ Te/^{124}Te, ~5‰ for δ^{126}Te/^{124}Te, ~7‰ for δ^{128}Te/^{124}Te, and ~10‰ for δ^{130}Te/^{124}Te as the external reproducivility (2S.D.) when 200 pg of Te was used. This analytical method will be applied to acid resistant fractions of primitive chondrites that are enriched in various types of presolar grain in order to identify whether nanodiamonds and other presolar phases have Tellurium isotopic anomalies.

The Ag, Fe, and Zn isotopic compositions of Ag-Au ore deposits in Japan

M. FUKUYAMA[1]*, D-C. LEE[1] AND S-C. YANG[2]

[1]Institute of Earth Sciences, Academia Sinica, Taipei 11529, Taiwan(*correspondence: mayuko@earth.sinica.edu.tw)
[2]National Taiwan University, Taipei 11677, Taiwan

Recent MC-ICPMS studies have been able to improve the analytical precision to resolve sub-per mil differences in Ag isotopic compositions. This has led to the discovery of Ag isotopic variation in native Ag ore deposits, which have been attributed to mass dependent stable isotopic fractionations during natural chemical processing [1]. This suggests that Ag isotope may be a useful tracer for the studies of the origin and chemical evolution of ore deposits.

We have investigated the Ag isotopic variations for a series of Ag-Au ore deposits in Japan in order to better constrain the formation and evolution of these ore deposits. These include the Au-Ag epithermal vein type deposits, Pb-Zn vein type deposits, polymatallic vein type deposits, and Kuroko type deposits, while Ag occurs as either native or sulfide minerals in these deposits. The $\varepsilon^{107/109}$Ag data vary from -7.1 to 1.5 relative to the NIST SRM 978a, while both the lowest and highest Ag isotopic data were obtained from the Kuroko type deposits. These deposits have similar geological signature, yet they exhibit the largest Ag isotopic variations among the samples included in this study. Most of samples include a suite of Ag hosted minerals, however, no significant variation of εAg was found among these minerals. Further study is required to understand the causes for Ag isotopic variation in these ore deposits. Consequently, we have started to measure Zn and Fe isotopes to evaluate the effect of other potential factors, e.g., redox condition, pH and temperature, to the Ag isotopes in these ore deposits.

Redox transformations of Cu in periodically flooded soils

B. FULDA[1]*, A. VOEGELIN[2] AND R. KRETZSCHMAR[1]

[1]Insitute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland
(*correspondence: beate.fulda@env.ethz.ch)
[2]Eawag, Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland

Copper is an essential nutrient, but due to its high toxicity for microorganisms also of concern as soil contaminant. Cu(II) dominates in oxic soils and strongly binds to natural organic matter (NOM). In redox-dynamic environments such as wetland soils, however, periodic flooding and soil reduction may lead to the transformation of Cu(II) to Cu(I) or even Cu(0) [1] and may thereby strongly affect the solubility and mobility of soil Cu. Sulfate reducing conditions during soil flooding may lead to the precipitation of Cu sulfide minerals [1]. However, the soft metal cation Cu^{+} probably also exhibits a high affinity to reduced organosulfur compounds, as it is known for other soft metal cations [2].

In a laboratory batch incubation experiment with paddy soil, we therefore investigated changes in the oxidation state and speciation of Cu over a soil reduction-reoxidation cycle as a function of the molar ratio between reducible sulfate and soil Cu (sulfate/Cu 0.1; 0.4; 1.2). Cu K-edge EXAFS data suggested that, after oxic equilibration, spiked Cu(II) mainly adsorbed as Cu(II) to soil organic matter and minerals. During the first few days of soil reduction, a large fraction of soil Cu became reduced to Cu(I) that was complexed by organic thiol groups (based on EXAFS and wet chemical data), and a small fraction was reduced to metallic Cu. During further reduction over 40 days of flooding, Cu was completely transformed to Cu sulfide at high initial sulfate/soil Cu ratio, whereas the Cu(0) fraction increased at low initial sulfate/soil Cu ratio. This difference in Cu speciation during soil flooding also affected Cu speciation after subsequent reoxidation. Whereas metallic Cu was rapidly oxidized to adsorbed Cu(II), a significant part of the S-coordinated Cu(I) remained stable over 14 days of aeration. Our data suggest that metallic Cu may control Cu solubility during soil reduction, especially in sulfate-limited soil. Our data also support the hypothesis that reduction of Cu^{2+} to the much softer chalcophile cation Cu^{+} prior to sulfate reduction may induce a shift in Cu-complexation from O/N- to reduced S-functional groups of organic matter.

Coenzyme F430, understanding methanotrophy in methane rich environments

JAMES M. FULTON [1,2], LAURENCE R. BIRD[1] AND KATHERINE H. FREEMAN [1]*

[1]Dept. of Geosciences, Pennsylvania State University, University Park, PA 16802, USA
(*correspondence: khf4@psu.edu)
[2] Marine Chemistry and Geochemistry Department, Woods Hole Oceanographic Inst., Woods Hole, MA 02543, USA

Large amounts of methane are oxidized by communities of methanotrophic archaea and sulphate reducing bacteria, preventing this potent greenhouse gas from reaching the atmosphere [1,2,3]. Methyl-coenzyme M reductase, an enzyme traditionally associated with methanogenesis, has recently been linked also to the anaerobic oxidation of methane [3]. Cofactor F430 is a tetrapyrrole nickel complex contained within the active site of methyl-coenzyme M and appears to be used in both methanogenesis and methanotrophy [3, 4]. Here we present a new approach for purifying F430 from natural samples and determining its stable isotopic composition (^{15}N and ^{13}C). F430 is isolated using multi-dimensional preparatory and high-performance chromatographic separations. Compound identity and purity are confirmed using molar C:N ratios, light absorbance and MS^{n} detection and fragmentation of F430 isolated from pure cultures of *Methanosarcina acetivorans*. C isotope analyses using nano-EA/IRMS [5] of natural samples are challenged by the presence of co-eluting non-tetrapyrrole structures. Our efforts to date document evidence for F430 in environmental samples, enrichment cultures as well as pure cultures of *Methanosarcina acetivorans*. The identification of F430 in environmental samples potentially provides evidence for anaerobic methane oxidation in a low oxygen environment via the reversal of the enzymes involved in methanogenesis.

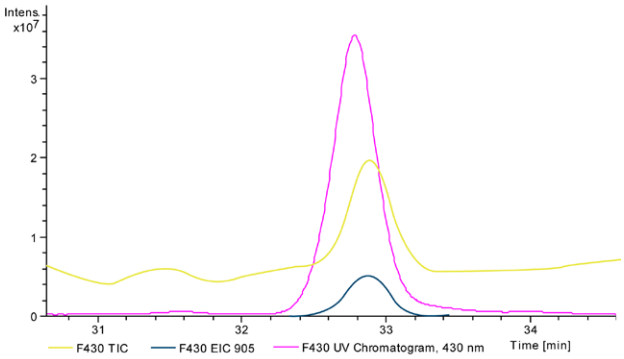

Figure 1: F430 is identified in samples based on adsorption in the 430 nm wavelength and the 905 ion

An experimental study of minettes and associated mica-clinopyroxenite xenoliths from the Milk River area, Southern Alberta, Canada

S.P. FUNK* AND R.W. LUTH

C. M. Scarfe Laboratory of Experimental Petrology, Department of Earth & Atmospheric Sciences, University of Alberta, Edmonton, AB, Canada (*correspondence: sfunk@ualberta.ca)

Because of their hydrous nature, lamprophyres provide unique insights into the cycling of water into and out of the Earth's interior. Lamprophyres from southern Alberta, Canada, were studied by Buhlmann *et al*. [1], who suggested they were derived from a mantle source containing mica, clinopyroxene, and olivine. The present experiments were conducted using a piston-cylinder apparatus at conditions appropriate for the Earth's upper mantle (~1.5 - 2.5 GPa, ~1200°C - 1400°C). A multiple saturation point of olivine and orthopyroxene was found at ~2.0 GPa and ~1350°C. This result was unexpected because partial melting of refractory harzburgite should not yield lamprophyric magmas [2]. We suggest that during ascent the minette magma chemically re-equilibrated with harzburgitic wall-rock [3]. These experiments show that these minettes are not primary.

We also conducted a set of melting experiments on three chemically distinct cognate xenoliths to determine their solidus temperatures at 1.5 - 2.5 GPa, and to characterize the glass composition. The near-solidus melts have striking similarities to madupitic lamproites studied by Barton & Hamilton [4] from the Leucite Hills, Wyoming. They hypothesized that madupitic magmas could be the product of partial melting of mica-pyroxenite. The present experiments confirm this hypothesis.

Origin and flux of lunar (micro-) impactors: Constraints from N-Ar analyses of single Luna 24 grains

E. FÜRI[1]*, B. MARTY[1] AND S.S. ASSONOV[2]

[1]CRPG/CNRS, BP20, 54501 Vandoeuvre-les-Nancy, France (*correspondence: efueri@crpg.cnrs-nancy.fr)
[2]Universität zu Köln, 50674 Köln, Germany

The $^{15}N/^{14}N$ ratio of N trapped in the lunar regolith varies by ~300 ‰, which has been attributed to either a) a secular increase of the N isotope composition of solar wind (SW) [1], or b) varying mixing proportions between solar N and non-solar N sources that are enriched in ^{15}N [2, 3]. In light of the recent Genesis findings, which revealed that modern SW N is isotopically light [4, 5], we use in this study the approach of single grain analyses to re-evaluate the provenance of N in Luna 24 soils. Our new N-Ar data, together with previous results from the Apollo sites, allow us to place limits on the proportion of solar and non-solar N trapped in lunar regolith, as well as on the recent flux of planetary material to the Moon's surface.

Single Luna 24 grains with $^{40}Ar/^{36}Ar$ ratios < 1 have $\delta^{15}N$ values between -54.5 and +123.3 ‰ relative to air. Thus, low-antiquity lunar soils record both positive and negative $\delta^{15}N$ signatures, and the secular increase of the $\delta^{15}N$ value [1] is no longer apparent when the Luna and Apollo data are combined. Instead, the N isotope signatures, corrected for cosmogenic ^{15}N, are consistent with binary mixing between SW N ($\delta^{15}N_{SW} \approx$ -407 ‰ [5]) and a non-solar N component with a $\delta^{15}N$ value of +100 to +150 ‰.

Micrometeorites and interplanetary dust particles, which dominate the current flux of extraterrestrial matter on Earth, match well the required characteristics of the non-solar component present in the lunar regolith. In contrast, a possible cometary contribution to the non-solar N flux is constrained to be ≤ 8 to 15 %, assuming a $\delta^{15}N$ value of +900 ‰ for cometary material [6]. Based on the observed mixing ratio of solar to planetary N, we estimate the flux of micro-impactors to be (2.2 to 6.2) × 10^3 tons yr^{-1} at the lunar surface. Thus, assuming a water content of ~10 wt%, characterizing carbonaceous chondrites [7], micro-impactors may deliver up to ~600 tons of water per year to the Moon.

Chemical compound classes supporting microbial methanogenesis in coal

A. FURMANN[1], A. SCHIMMELMANN[1], S. C. BRASSELL[1], M. MASTALERZ[2] AND F. PICARDAL[3]*

[1]Department of Geological Sciences, Indiana Univ., Bloomington, IN 47405, USA
[2]Indiana Geological Survey, Bloomington, IN 47405, USA
[3]School of Public and Environmental Affairs, Indiana Univ., Bloomington IN 47405, USA
(*correspondence: picardal@indiana.edu)

Microbial generation of coalbed methane (CBM) occurs in numerous basins worldwide. This study aims to identify specific classes of chemical compounds in coals from the Illinois Basin in southwestern Indiana that are degraded during methanogenesis. Springfield (SPR) coal is rich in vitrinite and Lower Block Coal (LBC) coal has greater liptinite and inertinite contributions. Anaerobic bioreactors contained a mineral-salts medium, operationally-defined coal extracts and a microbial inoculum obtained anoxically via filtration of formation water from a CBM-producing well. Our experiments investigated methanogenesis and concurrent degradation of organic matter (OM) using H_2O-, CH_3OH-, and CH_2Cl_2-soluble fractions of extractable OM from coal as the sole carbon source. This approach allowed us to trace specific molecular changes in the OM during methanogenesis. GC/MS and FTIR techniques were employed to compare the molecular composition of the initial organic extracts with their biodegraded residues.

Periodic GC-FID methane measurements over several months revealed greater CH_4 generation in reactors containing extracts from SPR coal, and slightly more CH_4 produced from CH_3OH-extracts than from CH_2Cl_2 (DCM) extracts. Inoculated controls containing H_2:CO_2 or acetate instead of coal extracts showed significant methanogenesis indicating that a viable inoculum was used in all reactors. GC/MS characterization of organic extracts enabled assessment of the occurrence and distribution of constituent *n*-alkanes, acyclic isoprenoid alkanes, hopanes in higher abundance than steranes, methylphenanthrenes, phenanthrene, anthracene, fluoranthene, and pyrene in the non-polar fraction, as well as carboxylic acids in the polar fraction. FTIR results showed higher aromaticity and presence of longer aliphatic chains in DCM extracts than in methanol extracts. The expected greater biodegradability of lower-MW compounds with lesser aromaticity might explain greater CH_4 production in the reactors containing methanol extracts. Continued analysis through June 2011 is expected to result in diagnostic changes in molecular composition, most likely affecting *n*-alkanes and possibly some aromatics.

Different types of Precambrian ophiolites

H. FURNES[1], Y. DILEK[2] AND M. DE WIT[3]

[1]Dept. of Earth Science & Centre for Geobiology, Univ. of Bergen, Norway
(*correspondence: harald.furnes@geo.uib.no)
[2]Dept. of Geology, Miami Univ., Oxford, Ohio, USA
[3]AEON & Dept. of Geological Sciences, Univ. of Cape Town, South Africa

Phanerozoic ophiolites are classified into subduction-related and unrelated types based on their tectonic and geochemical association with palaeo-subduction zones [1]. These two main types are further subdivided into several subtypes that exhibit different crustal architecture and igneous stratigraphy, with or without a sheeted dike complex. The geochemistry of the lavas and/or dikes of the two main types show pronounced differences in the concentration of elements that are sensitive to subduction processes (Cs, Pb, Rb, K, Ba, Th, U and LREE), and thus define contrasting patterns with respect to element-element -, element ratio -, and multi-element diagrams. We apply this new ophiolite classification to some of the well-preserved Precambrian greenstone belts, ranging in age from ca. 2.0 – 3.8 Ga. The metabasalts of the Isua (Greenland) and Barberton (South Africa) greenstone belts, 3.8 and 3.5 Ga, respectively, show geochemical signatures comparable with those of the best-documented Phanerozoic suprasubduction-zone ophiolites. The 2.7 Ga Wawa greenstone belt (Superior Province, Canada) and the 1.95 Ga Jormua Complex (Finland), on the other hand, display subduction-unrelated geochemical patterns, and are classified as plume- and continental margin type ophiolites, respectively. This approach to identifying Precambrian ophiolites with their distinct geochemical and tectonic fingerprints can be used effectively to decipher the geodynamic setting of the formation of ancient oceanic crust during the geological evolution of the greenstone belts.

Arsenic distribution in an unconformity related hydrothermal vein system

TOBIAS FUßWINKEL[1], THOMAS WENZEL[1], THOMAS WAGNER[2], MARKUS WÄLLE[2] AND JOACHIM LORENZ[3]

[1]Department of Geosciences, University of Tübingen, Wilhelmstr. 56, D-72072 Tübingen, Germany (tobias.fusswinkel@uni-tuebingen.de)
[2]Institute of Geochemistry and Petrology, ETH Zurich, Clausiusstr. 25, CH-8092 Zürich, Switzerland
[3]Graslitzer Straße 5, D-63791 Karlstein am Main, Germany

Many active geothermal systems discharge large amounts of arsenic, contributing significantly to geogenic arsenic contamination. This study aims at a better understanding of the physicochemical controls that favor transport or fixation of arsenic in geothermal environments. The unconformity related hydrothermal vein system at Sailauf (Germany) provides a well suited natural field laboratory, with As enriched mineral assemblages exposed immediately below the Permian unconformity. Hydrothermal minerals of the rhyolite hosted veins comprise mainly Ca-Mn carbonates, which are intergrown with braunite, hematite, hausmannite and manganite. Arsenate minerals are present as late vug fillings, intergrown with late stage carbonates, and fracture fillings of native arsenic. The textural features suggest a significant mobility of As in the hydrothermal fluids, in particular during late-stage low-temperature fluid-mineral reactions.

As a first step towards a quantitative As budget of the system, we determined the distribution of arsenic and other trace elements in cogenetic gangue and ore minerals by combination of EPMA and LA-ICPMS. The work is complemented by fluid inclusion studies that involve As analysis by LA-ICPMS of single fluid inclusions. While early primary calcites are virtually devoid of As, cogenetic main stage braunites were found to contain arsenic in oscillatory zoning patterns. Concentrations range from 100 ppm in the As-poor to 6000 ppm within the As rich growth zones. Primary tabular hematite exhibits variable As contents of 100 to 1000 ppm, whereas late stage carbonates can have as much as 1000 ppm As. The trace element distribution, in conjunction with fluid inclusion and stable isotope data, will be used as input for geochemical modeling of the As mineralization processes. The modeling will look at the competing effects of precipitation of As phases as a consequence of fluid boiling or mixing processes, and As incorporation into oxide minerals controlled by surface complexation.

Irreducible uncertainty in estimates of silicate mineral weathering rates

M.N. FUTTER[1]*, J. KLAMINDER[2], R.W. LUCAS[3] AND S.J. KÖHLER[1]*

[1]Swedish University of Agricultural Sciences, SE750 07 Uppsala, SE (*correspondence: martyn.futter@slu.se)
[2]Umeå University, SE90187 Umeå. SE
[3]Swedish University of Agricultural Sciences, SE90183 Umeå SE

The notion that precise estimates of silicate mineral weathering rates are possible is a key assumption behind many environmental policies. Earlier, we showed that an ensemble of published silicate mineral weathering rate estimates was insufficiently precise to evaluate sustainability of forest harvest at a single site [1]. Here, we extend this analysis with a comprehensive dataset from 82 different sites on 3 continents where 3 or more published weathering rate estimates were available. The range (max/min) of published weathering rate estimates at a single site (below) had a median value of 6 and a maximum of 52.

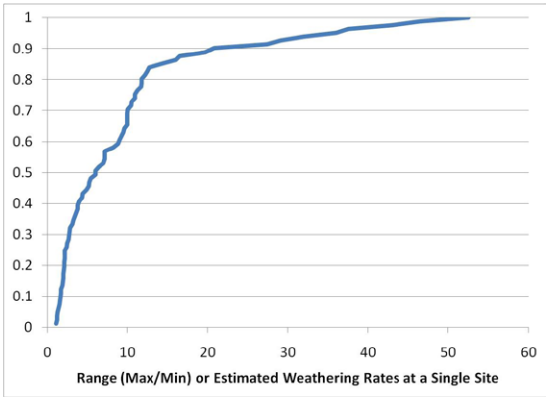

Figure 1: Cumulative distribution plot of range (max/min) or published weathering rate estimates for single sites.

While the weathering rate uncertainty can be partitioned into model structural, weathering zone depth, parameter and data terms, there is an irreducible factor of 2 uncertainty in rate estimates. Failure to consider this uncertainty can have profound consequences for critical load estimates, sustainable forest harvesting or assessing the feasibility of geo-engineering projects for climate change mitigation.

Siderite in Archaean banded iron formations - A sensor for CO_2 partial pressures of ancient atmospheres?

F.M. GÄB[1]*, C. BALLHAUS[1] AND J. SIEMENS[2]

[1]Steinmann Institut, Universität Bonn, Germany (*correspondence: fgaeb@uni-bonn.de)

[2]Institute for Crop Science and Resource Conservation-Soil Science, Universität Bonn, Germany

It has been around for some time that siderite in Archaean BIFs can serve as a CO_2 sensor for Archaean atmospheric compositions [1], according to

Fe^{2+} (aq) + $3H_2O$ + CO_2 (atm) = $FeCO_3$ (siderite) + $2H_3O^+$ (aq).

This equilibrium is seemingly shifted to the right as the CO_2 partial pressure (pCO_2) of the atmosphere rises, triggering the precipitation of marine carbonates including siderite if there is sufficient Fe^{2+} (aq) dissolved in seawater. In reality, rising pCO_2 causes the H_3O^+ activity to increase (ocean acidification), lowering the CO_3^{2-}/HCO_3^- activity ratio in water until carbonate minerals become unstable. Hence, the above equilibrium is metastable and unviable to describe natural atmosphere-seawater interactions, contrary to assertions by Ohmoto *et al*. [1]. We are equilibrating natural and artificial seawater at 25°C with oxidized N_2-O_2-CO_2 and reduced N_2-CH_4-H_2-CO_2 atmospheres with variable pCO_2 ranging from $< 10^{-5}$ to 1 atm. Up to a pCO_2 of ~ 0.05 atm, the carbonate alkalinity of seawater is independent of pCO_2 as predicted by thermodynamics, however, when pCO_2 increases above 0.07 atm (pH < 6.5) carbonate alkalinities gradually decline and carbonate minerals become unstable. Carbonate minerals find ideal conditions when the pCO_2 of the atmosphere is at its minimum and the CO_3^{2-}/HCO_3^- activity ratio in seawater at its maximum (i.e. high weathering rates, low atmospheric pCO_2). When the $pCO_2 < 2*10^{-4}$ atm (< 200 ppm CO_2 in the gas phase), natural seawater at 25°C spontaneously precipitates aragonite in the form of micro-ooides. The precipitation of siderite in Fe^{2+}-doped seawater equilibrated with a reduced atmosphere is impossible, so long as the water contains the current marine Ca^{2+} concentrations. In an artificial, NaCl-$NaHCO_3$-$FeCl_2$-bearing, Ca^{2+}-free seawater proxy (100 ppm Fe^{2+}, carbonate alkalinity 4000 μmol kg^{-1}), falling pCO_2 causes the precipitation of an amorphous blue-green phase that we tentatively identify as ferrous-ferric carbonate hydrate. Precipitation of that phases lowers the carbonate alkalinity by around 40 percent. That phase may qualify as precursur to siderite and could be an important primary inorganic precipitate from an Fe^{2+}-bearing, sulfate-poor, reduced Archaean ocean in exchange equilibrium with a reduced CH_4-bearing, CO_2-poor atmosphere. We conclude that siderite is not likely to be a primary precipitate from Archaean seawater. We further conclude that potential precursor phases to siderite (i.e. amorphous Fe-carbonate-hydrates) are most stable at maximum CO_3^{2-}/HCO_3^- activity ratios in the water, hence are favoured at atmospheric compositions poor in CO_2.

Growth rate effect on oxygen isotope fractionation between calcite and fluid: *In situ* data

R.I. GABITOV *, A.K. SCHMITT[1], E.B. WATSON[2], K.D. MCKEEGAN[1] AND T.M. HARRISON [1]

[1]University of California, Los Angeles, CA, 90095, USA (*correspondence: gabitr@ucla.edu)

[2]Rensselaer Polytechnic Institute, Troy, NY, 12180, USA

The oxygen-18 content of carbonates (expressed as $\delta^{18}O$) is widely used in paleoclimatology, yet it is clear from comparison between experimental and natural carbonates that isotopic equilibrium is not always achieved. This observation underscores the importance of exploring possible effects of growth rate on isotopic fractionation, which is the focus of this study.

In situ Secondary Ion Mass Spectrometry (SIMS) analyses of $\delta^{18}O$ were performed on single crystals of experimentally grown calcite at an external reproducibility of 0.25 ‰ (1σ). Growth rate (V) variations within crystals grown isothermally (at 15, 20, 22, and 25°C) were monitored by sequentially spiking calcite-precipitating fluids with rare earth element (REE) dopants. The REE were analyzed with SIMS at spots matching those where $\delta^{18}O$ was determined. REE patterns reveal concentric domains of calcite growth. The growth rate of calcite generally decreases with time - i.e., crystal rims advanced at slower rates than cores. The compositions of $\delta^{18}O$ in bulk calcites and experimental fluids were measured by Fisons Optima and Finnigan MAT 251 mass spectrometers, respectively. The average of SIMS $\delta^{18}O$ values agrees with bulk $\delta^{18}O$ determined by conventional mass spectrometry within analytical uncertainty. The fractionation factor ($\alpha^{18}O$) decreases by 0.8±0.08 ‰ with increasing V (0.12–16 μm/day) at 25°C. If the core is included at an estimated V>30 μm/day, a total range of 1.7 ‰ is observed at 25°C. A maximum difference of 3 ‰ was observed between the rim and core of the calcite crystal grown at 15°C.

Our results provide the first *in situ* evidence that ^{18}O may be depleted in the near-surface region of calcite relative to the bulk crystal lattice, consistent with the surface entrapment model [1]. As predicted, this effect increases with decreasing temperature. Therefore, knowledge of crystal growth rates needs to be accounted for when using $\delta^{18}O$ in natural carbonates as a proxy for sea-water temperature.

Post-entrapment changes to H_2O and CO_2 in olivine-hosted melt inclusions

GLENN GAETANI[1]*, JULIE O'LEARY[1,2] AND NOBUMICHI SHIMIZU[1]

[1]Geology & Geophysics, Woods Hole Oceanographic Institution, Woods Hole MA 02543 USA (*correspondence: ggaetani@whoi.edu)
[2]ExxonMobil Production Company, Houston TX 77067

Olivine-hosted melt inclusions are an important source of data on magmatic volatiles. The strength of the olivine protects inclusions from decompression and degassing during ascent and eruption, preserving pre-eruptive volatiles. However, inferring mantle volatiles requires that melt inclusions remain closed systems from the time of entrapment. We used a combination of experiments and modelling to investigate the potential for post-entrapment modification of H_2O and CO_2. Our results demonstrate that proton diffusion re-equilibrates H_2O in a matter of hours, but that a significant flux of C through the host olivine is unlikely. However, H_2O changes can affect CO_2 through the formation of vapor bubbles within the inclusion. The combination of diffusive re-equilibration and vapor bubble formation significantly affect degassing paths and entrapment pressures inferred from the volatile content of melt inclusions.

Effects of diffusive re-equilibration were assessed using hydration and dehydration experiments performed on natural inclusion-bearing olivines. All run products were analyzed for major elements by electron microprobe and for H_2O and D/H ratio by SIMS. The oxidation state of Fe was determined by μ-XANES. Our results demonstrate that proton diffusion is extremely efficient at modifying the concentration of H_2O in melt inclusions. These changes do not affect the fugacity of oxygen within the inclusion, which is controlled by the creation or destruction of metal vacancies that diffuse through the olivine at rates comparable to protons.

Initially vapor-saturated inclusions are driven toward undersaturation by the loss of H_2O, so that the concentration of CO_2 is not significantly effected. This produces melt inclusions with variable CO_2 at constant H_2O, resulting in an apparent open-system degassing path. Conversely, the addition of H_2O to melt inclusions, as during magma mixing, drives inclusions toward vapor oversaturation, leading to the production of CO_2-rich vapor bubbles. Therefore, the addition of H_2O will cause melt inclusions to evolve along an isobaric CO_2 degassing path, leading to significant changes in both H_2O and CO_2.

Causes and consequences of Zn, Fe and S isotope fractionation in a large hydrothermal system: The Navan orebody, Ireland

D. GAGNEVIN[1], A.J. BOYCE[2], C.D. BARRIE[2], J.F. MENUGE[1]* AND R.J. BLAKEMAN[3]

[1]School of Geological Sciences, University College Dublin, Belfield, Dublin 4, Ireland (*correspondence: j.f.menuge@ucd.ie)
[2]SUERC, East Kilbride, Glasgow G75 0QF, Scotland
[3]Boliden Tara Mines Limited, Navan, County Meath, Ireland

This study investigates the extent, causes and consequences of Zn and Fe isotope fractionation within the world-class Irish-type Navan Zn-Pb orebody, Ireland. Layered sphalerite (ZnS) has been targeted for isotopic analyses. Using samples of growth-layered sphalerite, as well as bulk Zn ore concentrates and potential source rocks, we are able to examine processes of fractionation ranging from millimeter to kilometer scales.

Large variations in $\delta^{66}Zn$ (of 0.55‰), $\delta^{56}Fe$ (of 2‰) and $\delta^{34}S$ (of 28‰) have been measured in microdrilled sphalerite. Significantly, the range of $\delta^{66}Zn$ (0.33‰) and $\delta^{56}Fe$ (0.95‰) across 3 mm of sphalerite colloform growth banding represents a substantial fraction of the range exhibited by common terrestrial rocks. Moreover, $\delta^{66}Zn$ and $\delta^{56}Fe$ display a well-defined positive correlation and both also correlate with $\delta^{34}S$; S isotope compositions have previously been proven to monitor the extent of mixing between shallow, metal-poor, surface brines and deep, metal-rich, hydrothermal fluids in Irish-type deposits. The observed relationships represent the interplay between kinetic Zn and Fe isotope fractionation during sphalerite precipitation, and mixing of S between hydrothermal fluids and bacteriogenic brines.

Concentrate data clearly show that relatively high $\delta^{56}Fe$ and $\delta^{66}Zn$ dominate the overall system, and that lower $\delta^{56}Fe$ and $\delta^{66}Zn$ found associated with hydrothermal sulphide are a minor component of the overall deposit signature. Basement rock $\delta^{66}Zn$ data confirm that the basement is isotopically not homogenous, nor homogenised in the hydrothermal system.

Our data suggest that incoming pulses of metal-rich hydrothermal fluid triggered sulphide mineralisation, and that rapid precipitation of sphalerite from hydrothermal fluids will strongly fractionate Zn and Fe isotopes at very short time and length scales, thereby limiting the use of Fe and Zn isotopes as exploration tools. However, Zn and Fe isotopes in sulphides appear to be powerful tools to assess and decipher the physical and chemical processes responsible for the genesis of ore bodies.

[3]S.U.E.R.C, East Kilbride, Glasgow, Scotland

This study aims to test whether the chemistry of sphalerite in the world-class, Irish-type, Navan ore deposit may help to decipher the nature and origin of the ore-forming fluids. Detailed electron microprobe traverses were carried out across colloform and other growth-layered sphalerite, on samples that were previously analysed for Zn, Fe and S isotopes (Gagnevin *et al*., Goldschmidt 2011). In particular, the S isotope data enabled us to distinguish between samples that precipitated from hydrothermal, metal-bearing fluids or from cooler, bacteriogenic, sulphide-bearing fluids.

On the hand sample scale, Cd and Fe discriminate between the two fluid sources (Fig. 1); Cd, Sb, and to a lesser extent Cu, are enriched in sphalerite precipitated from hydrothermal fluids ($\delta^{34}S > 0$), while Fe and As are enriched in sphalerite precipitated from bacteriogenic fluids ($\delta^{34}S < 0$), suggesting that sphalerite chemistry is a good guide to fluid origin.

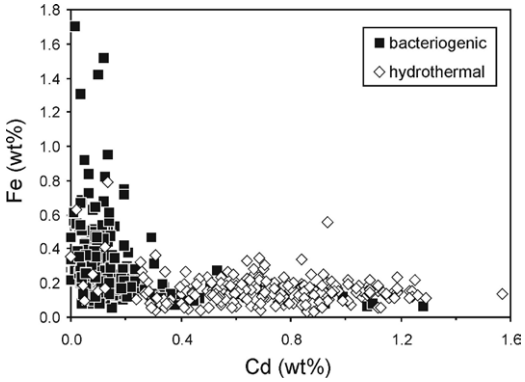

Figure 1: Cd vs Fe concentrations of layered sphalerite investigated in this study.

Frequent large (up to order of magnitude) elemental variations between successive sphalerite layers, whether colloform or not, indicate repeated influxes of hydrothermal fluids, with probable control also from kinetic effects and substitution mechanisms. Moreover, we show that sphalerite texture is sometimes, but usually not, correlated with sphalerite chemical composition.

Calcium isotopes during coral biomineralization

A.C. GAGNON[1,2]*, D.J. DEPAOLO[1], J.F. ADKINS[3] AND J.J. DE YOREO[2]

[1]Earth Sciences Division, Lawrence Berkeley National Lab, USA (*correspondence: acgagnon@lbl.gov)
[2]Molecular Foundry, Lawrence Berkeley National Lab, USA
[3] Geological and Planetary Sciences, Caltech, USA

A mechanistic understanding of biomineralization promises to separate biological and environmental signals in skeletal carbonates, improving the interpretation of paleoproxies. Towards this goal, we measure calcium isotope ratios of micromilled samples from modern scleractinian deep-sea coral, testing two questions in coral biomineralization. Is amorphous calcium carbonate (ACC) an important precursor during skeletal nucleation? Can reservoir effects (Rayleigh models) explain the biologically controlled variability of non-traditional stable isotopes.

Centers of calcification (COCs) are morphologically and compositionally distinct regions of the coral skeleton associated with nucleation. To test if an ACC precursor phase can explain the geochemistry of COCs, we compare the calcium isotope ratios of COCs to synthetic ACC. The $\delta^{44}Ca$ of COCs are similar to the surrounding skeleton and to inorganically precipitated aragonite, but are fractionated significantly more than inorganic ACC ($\Delta^{44}Ca_{COC\text{-}seawater} = -1.0 \pm 0.1$ ‰ while $\Delta^{44}Ca_{ACC\text{-}solution} < -0.2$ ‰). If ACC is involved in skeletal nucleation, then the distinct calcium isotope signature of this phase is lost during subsequent phase transformation. As calcium is the major cation in aragonite, this presumably means the minor and trace element composition of an ACC phase would be altered as well, and suggests that ACC is unlikely to explain the compositional anomalies associated with COCs in coral.

Even when grown under constant environmental conditions, metal/calcium ratios in deep-sea coral vary by more than 5 %. This variability can be explained by skeletal precipitation from closed batches of seawater or a more general steady-state reservoir effect where seawater transport to the site of calcification balances precipitation. Both models make similar predictions regarding calcium isotopes, higher skeletal Sr/Ca ratios should correlate with lighter $\delta^{44}Ca$. We observe this predicted trend in preliminary results from micromilled samples, suggesting that in addition to metal/calcium ratios, reservoir effect models of coral biomineralization may also explain the variability of some isotope systems. Analysis of coral from a range of conditions will test if we can recover biomineralization corrected records of seawater isotope ratios and environmental conditions.

Volcanic gases and redox biogeochemistry at the Archean-Proterozoic transition

FABRICE GAILLARD[1], BRUNO SCAILLET[1] AND NICHOLAS T. ARNDT[2]

[1]Institut des Sciences de la Terre d'Orléans, CNRS-INSU/Université d'Orléans, 45071, Orléans, France
[2]ISTerre, Université Joseph Fourier de Grenoble, CNRS, 38400, Saint Martin d'Hères, France.

A major crust-forming event at 2.7 Ga preceded a major change in the chemistry of surface waters on ancient Earth. Formation of a permanently oxygenated atmosphere at 2.45 Ga dramatically affected redox processes in the exosphere, as recorded in the ancient sulphur biogeochemical cycle. The emergence of oxygenic cyanobacteria and changes in composition of volcanic gases are possible triggers of the rise of atmospheric oxygen, but the sequence of these events and the evidence for such changes are debated. In particular, robust geochemical data indicates that the oxidation state of volcanic rocks and their source regions has remained constant since 3.5 Ga.

Using thermodynamic calculations simulating gas-melt equilibria during magma ascent, we show that change in the average pressure of volcanic degassing due to a global decrease in sea level accompanying the growth of the continental crust provides a simple yet robust explanation: Archean volcanic degassing was mostly submarine, occurring under water pressures of 10-100 bar and producing gases with H_2S/SO_2 >1, with low sulphur content. In contrast emergence of the continents in the late Archean led to widespread subaerial volcanism that yielded gases much richer in S and dominated by SO_2. The transition from H_2S dominated gases at elevated pressure of degassing to SO_2 dominated ones at atmospheric pressure is redox-compensated by a strong H_2 enrichment in the gas.

Archean and early Proterozoic sulphur biogeochemical cycles can be explained by a change in composition of volcanic gases that is unrelated to a change in magmatic source processes but most likely caused by geodynamic and eustatic modifications. The resulting changes in volcanic gas compositions must have impacted on the oxygenation of the atmosphere.

The subduction weathering factory

J. GAILLARDET*, P. LOUVAT*, C. DESSERT AND E. LAJEUNESSE

Institut de Physique du Globe de Paris, UMR 7451, Sorbonne Paris Cité. 75238 PARIS Cedex 05

About 30% of the global consumption of atmospheric CO_2 is due to the weathering reactions involving volcanic rocks. Therefore, volcanic settings are essential to consider both in terms of fluxes and mechanisms of chemical weathering. However few studies have focused on the weathering of volcanic arc islands although it is a key geodynamical setting, for example for the production of continental crust. Most of the degassing of deep CO_2 occurs in subduction zones and subducion volcanism is particularly rich in volatiles, such as sulfuric or chlorhydric acids that are major suppliers of acidity to the earth's surface.

The synthesis of available data on river chemistry in volvanic arc setting and new data from our group on the rivers of lesser Antilles show that the chemical denudation rates are amongst the highest on earth. They range from 10 t/km^2/yr to 700 t/km^2/yr in the most active regions.

Two dominant mechanisms appear to play the major roles in the subduction zone factory. The first is hydrothermal activity, the second is water runoff; the former being linked to the latter though the water cycle. Hydrothermal activity produces high temperatures and additional acidity in the form of sulfuric, chlohydric and carbonic acids. Runoff values are generaly associated to high precipitation regimes, due to the orographic effect. The orographic effect is temperature-dependent based on the Clausius-Clapeyron relationship.

Due to these two main mechanisms, subduction weathering factory transforms the rocks into sediments at a very high rate and is responsible for high CO_2 consumption rates. Our study suggests that chemical denudation is a significant fraction of the total erosion rate of volcanic arcs and that total erosion rates are in the order of the long-term magnatic eruptive rates.

On the peculiarities of Australian and Venezuelan pink diamonds: Influence of the geologic settings

E. GAILLOU[1,2], J.E. POST[1] AND J.E. BUTLER[3]

[1]Department of Mineral Sciences, Smithsonian Institution, Washington, DC 20560, USA.
[2]Department of Terrestial Magnetism, Carnegie Institute, Washington DC 20015, USA.
[3]Chemistry Division, Naval Research Laboratory, Washington DC 20375, USA.

Pink diamonds have a heterogeneous color that typically is restricted to lamellae formed by plastic deformation oriented along {111}. Pink diamonds from Argyle in Australia and from Santa Elena in Venezuela show distinct visual and spectroscopic features compared to diamonds from other localities. Their pink color is prominent and has a banded pattern, sometimes wavy, interlaced with smaller bands of colorless areas. The birefringence indicates that the plastic deformation is located mostly inside the colorless areas for Argyle and Santa Elena diamonds, and inside the pink areas for other diamonds. Cathodoluminescence (CL) images show that plastic deformation features cut across the growth patterns of the diamonds. They quench partially the CL in colorless areas, while the pink areas retain growth sectors, as delineated in CL images by H3 and N3 centers. For other pink diamonds, the colored lamellae contain H3 and 405.5 nm centers. It is possible that for Argyle and Santa Elena diamonds, a pre-existing pink color was partially quenched during a later episode of plastic deformation. Conversely, diamonds from other localities apparently acquired their pink color from a later stage of plastic deformation. The geological settings of diamonds from Argyle in Australia and Santa Elena in Venezuela are similar, forming underneath Proterozoic cratons (and not the typical Archean cratons), that experienced high thermal events in their early histories.

Potential for widespread microbial liberation of structurally-coordinated iron from common clay minerals in marine sediments

ROBERT R. GAINES[1], JOHNSON TRANG[1], SAMUEL SCOTT[1], E.J. CRANE[1], MARIA PROKOPENKO[2] AND WILLIAM M. BERELSON[2]

[1]Pomona College, Claremont, CA, 91711, (robert.gaines@pomona.edu; jt012007@mymail.pomona.edu; sws1@hi.is; ej.crane@pomona.edu)
[2]University of Southern California, Los Angeles, CA, 90089, (prokopen@usc.edu; berelson@usc.edu)

Clay minerals are the most abundant materials found at the surface of earth and they are the primary constituents of marine sediments. Iron, a limiting nutrient in many marine settings, is a common constituent of clay minerals. Recent *in vitro* experimental evidence has shown that lab cultures of Fe-reducing bacteria are able to utilize structurally-bound Fe from the crystal lattice of nontronite, an uncommon and particularly Fe-rich smectitie (>12wt.%). Reduction of structurally-coordinated Fe results in liberation of Fe(II) to solution, where it is available for other biotic processes, and the transformation of smectite to illite. However, it has remained unclear: 1. whether or Fe-reducers are able to access structurally coordinated Fe found in low wt.% in common clay minerals; 2. if naturally occuring populations of Fe-reducers are able to reduce structurally coordinated Fe as some lab strains are; and 3. if this process is significant in the marine Fe-cycle. In order to address these questions, we combined *in vitro* experiments using a suite of clay minerals with iron contents ranging from low (0.8 wt.%) to high (13.9 wt.%) with high-resolution analyses of sediment cores from the Santa Monica Basin, a location noted for a high benthic flux of Fe(II) from the sediments. Experimental evidence clearly indicates that, under *in vitro* conditions, Fe(III) bound in common clay minerals is available for reduction by the lab strain *Shewanella oneidensis* MR-1 as well as by naturally-occuring consortia of Fe-reducers cultured from the San Pedro and Santa Monica Basins. Analyses of sediment cores suggest that structural Fe bound in illite-smectite mixed layer clays (~3.0wt.%) of the Santa Monica Basin is bioavailable. Depth of smectite-illite conversion (<20cm) suggests that Fe may be liberated on the timescale of decades to ~200 years, contributing to the flux of Fe(II) from the sediments. Our findings suggest that common clay minerals may represent a large and previously unrecognized pool of bioavailable Fe in the world ocean that contributes significantly to biogeochemical cycling of Fe and C.

Experimental studies on CO_2 sequestration in basaltic rocks with a plug flow reactor

I. GALECZKA*, D. WOLFF-BOENISCH, AND S. R. GISLASON

Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavik, Iceland (*img3@hi.is)

Mineral trapping in silicate rocks is considered the most stable strategy of CO_2 storage. Conceptual model of CO_2 mineral fixation in Iceland assumes that acidic carbonated waters injected into basaltic rocks will initially cause rock dissolution and release of divalent cations such as Ca^{2+}, Mg^{2+} and Fe^{2+}. As reactions progress, these elements will combine with CO_3^{2-} and precipitate as carbonates due to increasing pH [1]. A large scale experiment with a plug flow reactor imitating chemical and physical conditions within the basaltic rocks after CO_2 injection, gives an opportunity to study the rate of basaltic rock dissolution and solid replacement reactions under controlled CO_2 conditions. The experimental set-up makes it possible to follow changes in pH, Eh and chemical composition of the fluid on different levels along the flow path within the column. Characterization and quantification of secondary minerals (carbonates and clays) enables determination of molar volume and porosity changes with time. Data obtained from experiment will be used in reactive transport models to elucidate the advance of reaction fronts, forecast porosity changes followed by estimation of upper limit CO_2 injected into a given geological formation.

Experimental set-up consists of 7 titanium compartments assembled into a 2.5 m long pipe (5.4 cm OD x 5 cm ID), corresponding to a volume of ~ 5 dm^3. The column is filled with basaltic glass grains, of known chemical composition and surface characteristic (45-100 μm size fraction). CO_2 saturated water will be pumped under 75 bar pressure through the column. This contribution will present first preliminary results from this column experiment.

Stable Sr isotopes in seawater

S.J.G. GALER*, A. KRABBENHÖFT, W. ABOUCHAMI, G. BORNGÄSSER AND H. FELDMANN

Max-Planck-Institut für Chemie, Postfach 3060, 55020 Mainz, Germany (*steve.galer@mpic.de)

Early work on dissolved Sr in GEOSECS ocean profiles from the Atlantic and Pacific showed Sr/salt variations with depth, providing evidence for depletion of dissolved Sr in surface waters [1]. This depletion was attributed to uptake of Sr from surface waters by acantharians, whose skeleton is made of celestite ($SrSO_4$), which subsequently dissolves at depth, thus exerting a control on strontium cycling in the water column [2].

We explore the potential of stable Sr isotopes as a tracer of such nutrient-like behaviour in seawater. We have analysed surface seawater samples and a depth profile collected in the Southern Ocean during GEOTRACES cruise ANT-XXIV-3 along the Greenwich Meridian, as well as the NASS-4 standard and a deep-water North Atlantic sample. The Sr isotope data were obtained using a ^{84}Sr-^{87}Sr double spike by TIMS at MPI. Measured $\delta^{44/42}Ca$ obtained on the same samples are effectively homogeneous with an average value of 0.83 ± 0.04‰ (total range) relative to SRM 915a.

The $^{87}Sr/^{86}Sr$ of both surface water and depth profile samples gave a consistent value of 0.709176±8 (range) relative to 0.710250±7 (2SD) for SRM 987. The $^{88}Sr/^{86}Sr$ ratios, expressed as $\delta^{88/86}Sr$, show little variation in the deep waters, averaging 0.35±0.02‰. In contrast, surface waters show subtle variations along the transect (0.33±0.02‰) just within error of that in deep waters. The Southern Ocean compositions tend to be isotopically slightly lighter, overall, than those of the Atlantic further north (0.36±0.02‰), and as measured for IAPSO seawater [3, 4].

These preliminary data suggest that constancy of $\delta^{88/86}Sr$ in seawater cannot be assumed a priori. Any variations thus far appear to lie on the edge of the analytical precision. Nevertheless, mapping the ocean $\delta^{88/86}Sr$ distribution appears to be an important task, and may help elucidate the internal biological cycling of strontium in the water column.

Continuum model for diffusive transport in the electrical double layer and clay interlamellæ

J.M. GALINDEZ[1]*, C.I .STEEFEL[1] AND U. MAEDER[2]

[1]Lawrence Berkeley National Laboratory, One Cyclotron Road, Berkeley, CA 94720, USA (*correspondence: JMGalindez@lbl.gov)
[2]Universität Bern, Switzerland (urs.maeder@geo.unibe.ch)

A continuum model for diffusive transport in the electrical double layer and the interlamellar space in clays is presented. The model makes use of a Donnan equilibrium assumption to calculate explicitly the composition of the diffuse double layer given an arbitrary bulk solution composition. In this approach, rather than solving the Poisson-Boltzmann equation explicitly, an average electrostatic potential corresponding to the double layer is computed. In the model, the double layer balances the charge of the mineral surface, which may be fixed charge (as in the case of ion exchange) or dynamically computed charge using a surface complexation model. In the case of clay interlamellæ, the charge of the clay is fixed and the ions occupying the space are treated as part of a double layer that may or may not be overlapping. Diffusive transport is handled with the Nernst-Planck equation, with accounting for the local immobile charge of the mineral surface. The approach allows for modeling of anion exclusion in clay-rich materials, as well as ion exchange within clay interlamellæ and edges.

Based on the same theoretical foundations as the single-type porosity model developed by Birgersson and Karnland [1], this continuum model provides identical predictions as long as the entire pore space is assumed to be occupied by the electrical double diffuse layer as, e.g., in highly compacted clays. These predictions were in turn validated by comparison with diffusion experiments conducted by Van Loon *et al*. [2]. The present work also explores the limitations of a discrete two-type porosity model in reproducing the actual continuous distribution of ion concentrations over the pore space as obtained with analytical expressions for very simple cases involving a pore space confined between two parallel electrically charged walls and saturated with a binary salt.

Geochemistry of nickel isotopes in ferromanganese crusts

L.GALL[1]*, H.M. WILLIAMS[2], C. SIEBERT[1] AND A.N. HALLIDAY[1]

[1]Department of Earth Sciences, University of Oxford, Oxford, OX1 3AN, UK (*correspondence: louiseg@earth.ox.ac.uk)
[2]Department of Earth Sciences, University of Durham, Durham, DH1 3LE, UK

The stable isotope behavior of nickel (Ni) has not been studied as intensively as those of other transition metals (e.g. Fe and Mo), even though Ni is ubiquitous in many geological environments and a bioessential trace metal, for example in the production of methane by methanogens [1]. In this study we have measured the mass-dependent isotope composition of Ni ($\delta^{60/58}$Ni, relative to Ni SRM 986) in a variety of terrestrial samples by MC-ICPMS [2]).

Our results demonstrate that there are significant variations in $\delta^{60/58}$Ni in nature (-0.5 – 2.5‰). The Ni isotopic composition of 8 samples of igneous and mantle rocks is effectively homogeneous, with only small variations (<0.2‰) between different rock types. In contrast we find that ferromanganese crusts are much heavier. We analysed surface scrapings from 20 hydrogenetic crusts, including samples from all major ocean basins. The average $\delta^{60/58}$Ni value for these crusts is +1.65‰ with a variation of ±0.4‰.

There is no systematic variation with geographical position, water depth, or Ni concentration. However, given the residence time of Ni in the oceans (10,000 yr [3]), Ni isotope variations in ferromanganese crusts might reflect extreme local effects, such as differences in isotopic composition of source materials, input from hydrothermal vents, and fractionation during removal of Ni from seawater and adsorption. Further studies are needed to identify the specific processes. However, our data clearly demonstrate mass dependent fractionation of Ni isotopes in the marine environment.

The Prestige oil spill after a decade: Evaluation of remediation strategies and the role of bioremediation.

J.R. GALLEGO[1]*, A.I. PELÁEZ[1], J. SÁNCHEZ[1], M.J. GCÍA- MTNEZ[2], J.E. ORTIZ[2], T. TORRES[2] AND J.F. LLAMAS[2]

[1]Environmental Biotechnology and Geochemistry Group. University of Oviedo. C/Gonzalo Gut. S/N, 33600-Mieres (Asturias), Spain. (*correspondence: jgallego@uniovi.es)
[2]ETSMinas, Universidad Politécnica de Madrid. C/Ríos Rosas, 21-28003 Madrid, Spain.

In 2002, the Atlantic and Cantabrian shorelines of Spain were affected by the Prestige heavy fuel oil spill. Initially the fuel was physically removed in rocky areas by means of hot pressurized water washing and similar procedures, whereas in sandy beaches other machinery was used. However, bioremediation was also considered given that the destructive effects of the hot pressurized water on the biota, the difficulties to collect oily waste, and other questions related with the grain-size of the sediments affected and the strong fuel adhesion in the shore rocks [1, 2, 3].

Our research carried out several studies all along the coasts in which natural attenuation, biostimulation and bioaugmentation techniques were tested in pilot and full-scale experiments for remediating oil-coated sands, gravels, pebbles, cobbles and boulders. Microbiological control and normalization by means of non-degradable chemical biomarkers were made to monitor these procedures. To improve bioremediation yields, novel *in situ* fresh-water irrigation and on-site techniques were developed, following similar strategies than those habitually used in soil remediation. The results obtained underscored the utility of these innovative designs to be used as an alternative to the limited effectiveness of the application of oleophilic fertilizers, clearly limited by the recalcitrance and by the reduced bioavailability of resin and asphaltene fractions. As a conclusion, long-term strategies for the bioremediation of other spillages with similar characteristics are suggested.

Evidence of Fe-oxide clusters in obsidians

L. GALOISY, G. CALAS AND N. MENGUY

Institut de Minéralogie et de Physique des Milieux Condensés (IMPMC), UPMC; Université Paris 7; CNRS; 4, Place Jussieu, 75252 Paris Cedex 05, France. (Laurence.galoisy@impmc.upmc.fr)

Iron has long been known to play an important role in determining the properties of natural magmatic liquids. The determination of the sites occupied by ferrous and ferric cations in natural glasses may provide information on the physico-chemical conditions prevailing at the magmatic stage as well as on the cooling conditions of the magma. We discuss the spectroscopic data obtained on the Fe environment in calc-alkaline rhyolitic glasses (obsidians) from various localities, at the light of transmission electron microscopic observations. Fe^{2+} and Fe^{3+} ions partly occur within the glass structure, as indicated by XANES [1], EPR and optical absorption spectroscopy (OAS). OAS reveals that some Fe^{2+} occurs in a regular octahedral site, an unusual environment in glasses.

The presence of Fe-oxide nano-clusters, suspected from previous EPR spectroscopy data, is confirmed by variable-temperature OAS in all the obsidians investigated. Specific absorption bands, assigned to Fe-Fe and Fe-Ti intervalence charge transfers (IVCT), are characterized by a spectacular intensity enhancement at low temperature (10K). This thermally-activated behavior shows an activation energy similar to that observed for IVCT in various minerals. The evidence of specific Fe^{2+} sites and of IVCT processes, indicate the presence of Fe-oxide clusters. These clusters, showing a local re-arrangement around Fe, are related to the cooling history of the glass, as they are not found in synthetic glasses [2]. They may be also precursors of the amorphous and crystalline Fe-oxides (Ti-magnetite and magnetite), 5-10 nm large, evidenced using TEM. The existence of these clusters and their nature seem to be related to the conditions of formation of the investigated obsidians and they may obscure the information brought by these glasses about its magmatic history.

Looking for PON in fluviatile and marine sediments: Insights from nitrogen isotopic compositions

A. GALY[1,*], R. G. HILTON[2], N. HOVIUS[1], J. SMITH[1] AND R. B. SPARKES[1]

[1]Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge CB2 3EQ, UK (*correspondance: albert00@esc.cam.ac.uk)

[2]Department of Geography, Durham University, Science Laboratories, South Road, Durham, DH1 3LE, UK

Processes involved in the cycling of organic matter can be preserved in sediments and recent studies have unravelled the importance of the erosion of the continents to the global organic carbon transfer [1-3]. The significance of such transfer to the biogeochemical cycles of other chemical elements associated to the organic matter (H, N, O, P, S, …) is, however, hampered by the small (<1%) abundance of particulate organic carbon in sediments transported by river in active margins and the occurrence of inorganic phases. This is particularly the case when N is considered since nitrate particulate deposition and ammonium in phyllosilicate can both be present in sediments. Here, we present case studies from modern systems investigating soil and river sediments from Taiwan and the Swiss Alps with modern marine clastic sediments from Taiwan and their Cenozoic analogue from the foreland basins of the Alps and the Pyrenees. Sediments have been decarbonated using hydrochloric acid and the decarbonatation process can have a significant impact on the N-isotopic composition, depending on how well lithified the sediments are. However, variations in the isotopic composition of bulk soils and common plant species are correlated in the tropical mountain forest of Taiwan. This suggests that the physical erosion of fixed-N in organic debris can be significant for the N cycle in vegetated active mountains belts. It also suggests an accurate quantification of the particulate organic nitrogen (PON) in these types of material [4]. The offset of ~4 permil between soil PON and standing biomass PON can be a powerful tool to distinguish erosional regimes where the erosion of the vegetation is insignificant (Swiss Alps) or not (Taiwan).

Speciation of trace elements in Strengbach soil solutions by ultrafiltration

S. GANGLOFF*, P. STILLE AND F. CHABAUX

LHYGES – UMR7517 1rue Blessig – 67084 Strasbourg, France (* sgangloff@unistra.fr, pstille@unistra.fr, francois.chabaux@eost.u-strasbg.fr)

This study deals with colloidal phases of soil solutions collected in the Strengbach watershed (OHGE). These solutions carry the chemical elements in the first meter of soil. The sampling has been performed below spruce at different depths (-5cm, -10cm, -30cm and -60cm) of a brown acidic to ochreous podzolic soil with help of lysimetric plates. The colloidal phase has been studied by frontal filtrations (1μm, 0,45μm and 0,22μm) and tangential ultra-filtrations (300kDa, 30kDa, 10kDa and 5kDa). Then, the initial solution, the different permeates and retentates have been analyzed for major, trace element and Dissolved Organic Carbon (DOC) concentrations.

The study elucidates the behavior of the different chemical elements in the various colloidal fractions separated from the soil solutions. The retention rate, derived during the ultra-filtration experiment, allows determining the proportion of each element in different forms, i.e. proportions in dissolved form and in the different colloidal fractions. The comparison of each element with DOC indicates that only some of the elements are correlated with DOC. Among the latter, it is possible to distinguish two elemental groups showing different behaviors: those correlated only with DOC and those correlated with DOC and another secondary phase such as iron oxy-hydroxides. The mass balance of the ultra-filtrations showed that in the >1μm filtrates some elements (REE, PO_4^{3-}, Pb, Fe, Al) occur as precipitates, as colloids or as dissolved phase. The precipitates contain among others secondary minerals fluorencite and pyromorphite. The formation of these minerals occurs below 5 cm depth.

The ultra-filtrations of samples taken at different depths of the soil profile indicate that the chemical compositions of the colloidal fractions change in function of depth. Such depth variations may point to indicate the occurrence of different levels of colloid formation in these soil solutions.

Climate-carbon cycle feedback during glacial cycles

A. GANOPOLSKI[1]*, V. BROVKIN[2], R. CALOV[1], D. ARCHER[3] AND G. MUNHOVEN[4]

[1]PIK, Potsdam, 14412, Germany (*correspondence: andrey@pik-potsdam.de)
[2]MPI-M, Hamburg, Germany (victor.brovkin@zmaw.de)
[3]University of Chicago, Chicago, 60637, IL, USA (d-archer@uchicago.edu)
[4]University of Liège, B-4000 Liège, Belgium (guy.munhoven@ulg.ac.be)

Paleoclimate records reveal a close link between global ice volume and atmospheric CO_2 concentration, at least, through the last 800,000 years. Despite many efforts over the last two decades, mechanisms of glacial-interglacial CO_2 variability and its role for the glacial cycles remain elusive. Here using the Earth system model of intermediate complexity CLIMBER-2 which includes all major components of the Earth system – atmosphere, ocean, land surface, ice sheets, terrestrial biota, eolian dust and marine biogeochemistry – we performed simulations of the last glacial cycles employing variations in the Earth's orbital parameters as the only prescribed climatic forcing.

In the experiments with constant CO_2 concentration, temporal dynamics of the simulated glacial cycles strongly depend on the CO_2 level. For CO_2 concentrations about and above preindustrial one, the model simulates only short glacial cycles with precessional and obliquity frequencies. However, for lower CO_2 concentrations the model simulates long glacial cycles with dominant 100 kyr periodicity. Simulated glacial cycles agreed favorably with paleoclimate reconstructions, but their amplitude is underestimated compared to those of the simulations with time-dependent CO_2 concentration. These results confirm that the positive climate-carbon cycle feedback plays an important role in amplification of long glacial cycles. Experiments with fully interactive CO_2 shed some light on the mechanism of climate-carbon cycle feedback during glacial cycles. Forced by orbital variations only, the model is able to reproduce the main features of CO_2 changes: the 40 ppmv CO_2 drop during glacial inception, the minimum concentration at the last glacial maximum being 80 ppmv lower than the Holocene value, and the relatively abrupt CO_2 rise during the deglaciation. The main drivers of atmospheric CO_2 evolve with time: changes in sea surface temperature and volume of bottom water of southern origin exert CO_2 control during glacial inception and deglaciation, while changes in carbonate chemistry and marine biology are dominant during the first and second parts of the glacial cycles, respectively.

Evaluation of marine primary organic aerosol emission schemes

BRETT GANTT*, MATTHEW JOHNSON AND NICHOLAS MESKHIDZE

North Carolina State Unverisity, Raleigh, NC, USA (*correspondence: bdgantt@ncsu.edu)

In the last decade, there has been an increase in research concerning primary organic aerosol (POA) emissions from the ocean. Global source of ocean-emitted POA has been shown to be comparable to primary organic carbon particles emitted from combustion [1] and are sometimes found in concentrations more typical of organic aerosols in urban areas [2]. Due to their importance, several attempts have been made to better quantify the emission rate of marine POA for use in air quality and global climate models. In this work, we present results from the chemical transport model GEOS-Chem in which five distinct emissions schemes [1, 3, 4, 5, 6] of marine POA are implemented using a consistent sea spray function and chlorophyll-a concentrations ([Chl-*a*]). Model simulations are evaluated against long- and short-term observations collected in multiple coastal sites.

Calculations show that these schemes emit marine POA at different magnitudes and have distinct temporal/spatial distributions. Three of the emission schemes [3, 4, 5] are strongly tied to the wind speed dependence of the sea spray function and to a much lesser extent the [Chl-*a*]. On the other hand, the Spracklen *et al*. [1] emission scheme is primarily driven by [Chl-*a*] and is insensitive to surface wind speed. Between these two extremes is the Gantt *et al*. [6] scheme, which is affected by both wind speed and [Chl-*a*].

Preliminary results show that the emission schemes with strong wind speed dependence overpredicted concentrations in the winter relative to the summer at sites in the Northern Atlantic and Southern Ocean [7, 8]. The high organic concentration episode at Mace Head [2] was not reproduced well by any scheme, although the emissions with wind speed dependence outperformed the emissions based solely on [Chl-*a*]. This study shows that large uncertainty in marine POA emissions exists and requires further evaluation.

Mechanism of water–rock interaction of alkaline leaching uranium in Shihongtan deposit

B. GAO[1,2] * AND Z. X. SUN[1,2]

[1]School of Civil and Environmental Engineering, East China Institute of Technology, Fuzhou 344000, China (*correspondence: gaobai2007@sohu.com)

[2]Key Laboratory of Radioactive Geology and Exploration Technology Fundamental Science for National Defense Fuzhou, Jiangxi, 344000, China

The saturation index of sulphate and carbonate in groundwater of Shihongtan uranium deposit in Xinjiang has been calculated by geochemical model PHREEQC (table 1).

Calcite	Dolomite	Anhydrite	Gypsum	Uraninite
0.75	1.44	0.04	0.30	-6.34
-1.30	-2.76	-0.81	-0.60	-2.76
0.00	-0.17	-0.77	-0.56	-3.71
-0.23	-0.49	-1.56	-1.35	-5.69
-0.51	-0.37	-0.97	-0.66	-3.15

Table 1: The calculated results of saturation index of mineral.

The results indicate that mining of the deposit is a difficult task by traditional acid or alkaline *in situ* leaching. Experimental researches of laboratory and field show that mining the uranium deposit is possible because of avoidance of precipitation of calcium sulphate and calcium carbonate in the aquifer, if the total dissolved solides of groundwater were diluted less than 3.45 g/L[1]. The uranium leaching is controlled by species of uranium mineral with study of electron probe. The uranium associated with kaolin or in between the grains of minerals is easier to be leached out than those associated pyrite or encompassed by the minerals[2]. Experimental researches show that more time of leaching, higher content of Ca^{2+} in recovery solution because of calcic mineral dissolution in uranium ora and wall rock. The precipitation jam of calcium carbonate during *in situ* leaching will come into being because of reducing the liminal value of HCO_3^- content.

The study was supported by the project of the National Natural Science Foundation of China(40872165) and Science Bureau of Jiangxi Province (2009AF00100).

Geochemical characteristics of trace elements of sandstone-type uranium deposits in the Ordos Basin

E.G. GAO, S.G. HE* AND S.C. SUN

Institute of Disaster Prevention Science & Technology, Yanjiao 101601, Beijing, China (grg@ustc.edu.cn)

The Ordos basin is the second largest sedimentary basins in China, as called Shan-Gan-Ning basin, and its main body area is 2.5×10^5 square kilometers. The Yimeng Uplift in the north, the Weibei Uplift in the south, the West Fold and Fault Belt in the west, and the Western Shanxi Flexure Belt in the east form a particular structure pattern. The Ordos basin is enriched with many energy resources and deposits [1-3], therefore, it has profound scientific sense and industrial value. Recent exploitation indicates that the sandstone-type uranium minmeralization has economic value in this basin [4], it becomes the hotspot in the uranium exploration in China.

High precision ICP-MS was hired to study trace elements and REE from sandstone-type uranium deposit in the Ordos Basin, Northwestern China. We focus on the mechanism of uranium enrichments so that to present basis for further exploration. Results of total REE ranges from 30.3 to 713.4μg/g, REE distribution patterns of the sandstone-type uranium samples is light REE enriched and high REE depleted. Our study shows that high Y abundance and abnormity of Eu between 0.70~1.92. results show that U abundances are 0.73~150μg/g showing strong correlation between U enrichments and the related elements such as Ti, V, Zr, Mo and Au. In addition, thorium enrichments in most samples are correlated with ΣREE with some accordance of former study [5,6].

Extensive N-loss from permeable Wadden Sea sediments due to aerobic denitrification

H. GAO, A. KHALILI, D. DE BEER, G. LAVIK AND M.M.M. KUYPERS*

Max Planck Institute for Marine Microbiology, 28359 Bremen, Germany
(*correspondence: mkuypers@mpi-bremen.de)

The role of permeable sediments in the oceanic N-budget is poorly understood. In this study, nitrogen (N) loss rates were determined in permeable sediments of the Wadden Sea using a combination of stable N isotopes, microsensor measurements and model simulation approaches. Results indicate that permeable Janssand sediments are characterized by some of the highest denitrification rates in the marine environment. Moreover, several lines of evidence showed that denitrification occured under oxic conditions. N loss rates generally showed little temporal and spatial variation (207 ± 30 μmol m^{-2} h^{-1}) over the three field campaigns conducted in autumn 2006 and spring and summer 2007. Utilizing an extensive time series of nutrient concentrations and current velocities obtained from a continuous monitoring station, NO_x^- flux into the sediment was modeled over a full annual cycle. Modeled NO_x^- fluxes were sufficiently high to support the experimentally derived N-loss rates. Combining the measured rates with the modeled results, an annual N-removal rate of 745 ± 109 mmol N m^{-2} y^{-1} was estimated for permeable sediments of the Wadden Sea. This rate agrees well with previous N loss estimates for the Wadden Sea based on N budget calculations. Our results indicate that permeable sediments, accounting for 58- 70 % of the continental shelf area, are an important N-sink and their contribution to the global N-loss budget should be reevaluated.

Applications of laser microprobe analysis for silicon and oxygen isotopes (Fujian, China)

J.F. GAO AND T.P. DING

The Key Laboratory of Metallogeny and Mineral Assessment, Institute of Mineral Resources; Chinese Academy of Geological Sciences, Beijing 100037, China.
(correspondence: tony_and_mary@126.com)

The O and Si isotope compositions of minerals from the miarolitic cavity granite and pegmatite in Yunxiao county, Fujian province are measured by using conventional method and laser probe analytic method for determining their material sources and forming conditions. The results are listed in the Table 1.

Sample	$\delta^{18}O_{V\text{-}SMOW}$ (‰)			$\delta^{30}Si_{NBS\text{-}28}$ (‰)		
	Q	Fs	Gar*	Q	Fs	Gar*
Gr-01	7.6	6.4		-0.1	-0.1	
Gr-02	8.0	5.6		-0.3	0.0	
Peg-01	7.7	6.3	3.3, 3.3	-0.2	-0.2	-1.8, -1.9
Peg-02	7.4	5.6	3.1, 3.6	-0.5	-0.3	-1.8, -2.2
Peg-03	7.7	6.0	3.4	-0.4	0.2	-2.0

Table 1 : The results of oxygen and silicon isotope compositions
*minerals were analyzed by using laser probe isotope analytic method. Q-quartz; Fs-feldspar; Gar-garnet.

The O and Si isotope compositions of quartz and feldspar from the pegmatite are very similar to those of the granite, indicating that they have the same magma source.

From the oxygen isotope fractionation between quartz and feldspar, a temperature of 461°C is obtained for the granite, indicating that the granite may be subjected some extend of water-rock interaction after crystallization. This is consistent with the extensive development of pegmatite miarolitic cavity in granite. From the oxygen isotope fractionation between quartz and feldspar, a temperature range between 505°C and 532°C is obtained for pegmatite, indicating that fluid temperature was more than 500°C when the pegmatite was formed.

The silicon and oxygen isotopic ratios of garnet were both significantly lower than those of coexisting quartz and feldspar in miarolitic cavity, indicating that parallel silicon and oxygen isotopic fractionations are present between garnet and quartz (and feldspar), although the extent of silicon isotopic fractionation is smaller that those of oxygen isotope fractionation.

Quasi-simultaneous observation of currents, salinity and nutrients in the Changjiang plume on the tidal timescale

L. GAO* AND D.J. LI

State Key Laboratory of Estuarine and Coastal Research, East China Normal University, 3663 North Zhongshan Road, Shanghai 200062, China
(*correspondence: lgao@sklec.ecnu.edu.cn)

During both the spring- and the neap-tide periods of November 2005, quasi-simultaneous observations were carried out by six boats over 26 h at 12 stations in the Changjiang plume. The simultaneous observations provided the actual distribution isopleths of salinity and nutrients that displayed considerable intra-tidal variations at surface, especially in the southeastern section of the study area (Figure 1). The lack of synopticity in sampling might lead to large discrepancies of the interpolated contours of salinity from the actual distribution isopleths. No clear flood-ebb asymmetry of salinity stratification was observed; whereas at inner stations, surface-to-bottom bulk velocity difference always tended to be greater during the ebb fraction of a semidiurnal cycle. At a given station, the weaker neap tides commonly induced stronger salinity stratification, less intra-tidal variability of salinity and nutrients, and less intrusion of bottom saltwater. Nutrients showed more nonconservative behaviors during the neap tides, presumably as a result of the prolonged residence time of seawater and decreased suspended particulate matter levels than during the spring tides.

This study was jointly funded by Ministry of Science and Technology of China (2010Cb951203), Shanghai Municipality (10JC1404400) and State Key Laboratory of Estuarine and Coastal Research of China (2009KYYW03).

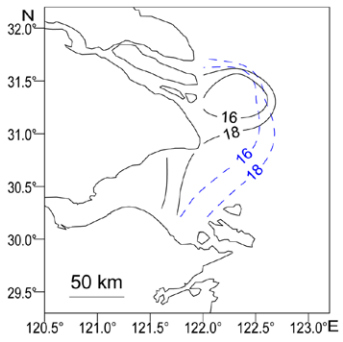

Figure 1: Comparison between the snapshot distribution isopleths of salinity at surface on the two occasions of 12:00 (solid black lines) and 18:00 on November 2 (dashed blue lines) during the spring-tide survey. The two occasions are roughly regarded as the peak high- and peak low-tide phases for the entire survey region.

Study on endocrine disrupting chemicals removal features in pingshantou waterplant of Huainan City, China

LIANGMIN GAO* AND GUIRONG SU

School of Earth and Environment, An Hui University of Science and Technology, Huainan 232001, China
(*correspondence: gaolmin@163.com)

Using a method for solid-phase extraction concentrated and high performance liquid chromatography analysis, detected the EDC_S content of different water treatment process in pingshantou waterplan of Huainan city, researched the distribution characteristics and removal efficiency of EDC_S in different water treatment process. The research results are as follows: DMP and DEP could be removed by rate of 100%, but BBPDBP, EE_2, E_1, BPA and NP were detected in different water treatment process, the detection rate was 100%. While the content of DMP, BBP, DBP, BPA increased in water treatment process. The content of BBP, DBP, EE_2, BPA increased after pipe delivering. Conclusions: Conventional drinking water treatment process of EDC_S removal is very limited; There are no rule to follow with EDC_S in coagulation-sedimentation and chlorination process, the reasons may be: degradation products and secondary pollution were produced in processing process, which caused the content of BBP, DBP elevated in coagulation-sedimentation and chlorination process; And several byproducts of BPA and NP were found in chlorination. In addition, the impact of pollution substances exudated from conveying water pipe on EDC_S should not be ignored.

Fluorescence spectrum characteristic of the extractable humus in soil from Shannan developed area

LIANGMIN GAO*AND QINQIN ZHANG

School of Earth and Environment, An Hui University of Science and technology, Huainan 232001, China (*correspondence: gaolmin@163.com)

Humus is a kind of amorphous, brown or brownish black, hydrophilic, acidic, polydispersed organic matter and more dispersed widely in soil, sediment, and water (such as lakes, rivers, oceans and groundwater, etc.). It is not only a major source of soil nutrients but also has a significant impact to physical, chemical and biological properties of soil, it is one of the indicators of soil fertility.

Contents of extracted humus in soil planted with different crops were determined, and the fluorescence spectra features of extracted humus in the same sampling point in different soil layers were analyzed. The results showed that contents of extracted humus in soil planted with different crops are different, there is no obvious rule. For different soil layers of the same sampling point, the distribution of extracted humus is not the same, mostly show that: the surface (0~20cm)> the middle (40~60cm)> the lower (80~100cm). The excited state fluorescence spectra of extracted humus in soil of different land types have similar fluorescence characteristics, peak obvious presents in about 390nm and 455nm. The fluorescence emission spectra are all broadband peak without obvious features. emission wavelength is about 500nm.The stimulate spectra of extractable humus in cotton soils has two distinct peaks around 445nm and 460nm, with the deepening of soil the two peaks separate more obviously. And extractable humus in surface layer, middle layer and lower layer has inspired fluorescence peak in 503nm, 498nm and 492nm in turn, peak type is moderate, and along with the increase of soil depth, fluorescence intensity greatly increase.

Geochemical and U-Pb age constraints on the occurrence of polygenetic titanites in UHP metagranite in the Dabie orogen

X.-Y. GAO[1]*, Y.-F. ZHENG[1], Y.-X. CHEN[1] AND J.L. GUO[2]

[1]CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (*correspondence: gaoying@ustc.edu.cn)

[2]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

Accessory minerals such as zircon and titanite are common in continental subduction-zone metamorphic rocks, and time and process of their formation can be dated by the U-Pb method and geochemical tracers. This is a great advantage to identify their genesis with respect to the origin of host rocks. Magmatic titanite was identified in the core of a few titanite grains with the overgrown rim of metamorphic titanite in UHP metagranite in the Dabie orogen. LA-ICPMS U-Pb dating gave Neoproterozoic ages for the magmatic titanite but Triassic ages for the metamorphic titanite. The magmatic and metamorphic titanites are clearly distincted by differences in petrological and geochemical compositions. The magmatic titanite occurs as residual cores that show bright BSE, the presence of allanite and quartz inclusions, low contents of CaO, Al_2O_3 and TiO_2 but high contents of Fe_2O_3 and MgO. In trace elements, the magmatic titanite exhibits high REE and HFSE contents, distinctly negative Eu anomalies with flat MREE-HREE patterns, and high Th/U ratios. In contrast, the metamorphic titanite occurs as rims and grains of homogeneously dark BSE that contain inclusions of epidote, quartz, K-feldspar, rutile, biotite and phengite, and have relatively high contents of CaO, Al_2O_3 and TiO_2, but low contents of Fe_2O_3 and MgO, and relatively low REE and HFSE contents, slightly negative Eu anomalies with HREE depletion relative to MREE, and low Th/U ratios. The Zr-in-titanite thermometry yields 727 to 877°C at 0.5 to 1.0 GPa for the magmatic titanite, and 729 to 870°C at 1.5 to 2.0 GPa for the metamorphic titanite. The Neoproterozoic U-Pb chronometric system of magmatic titanite survived the Triassic continental subduction-zone HP-UHP metamorphism. This suggests a relatively high closure temperature of >800°C for the titanite U-Pb system. The metamorphic titanite is principally a product of retrograde metamorphism during decompression exhumation at the transition from HP eclogite-facies to amphibolite-facies. Therefore, titanite holds a great potential to petrology and geochemistry of continental subduction-zone processes.

Effect of phosphate fertilizer on the mobility of arsenic in fairdpur soil, central Bangladesh

X.B. GAO[1], Y.X. WANG[1]*, Q.H. HU[2] AND T. MA[1]

[1]School of Environmental Studies and MOE Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Wuhan, 430074 P. R. China (Xubo.gao.cug@gmail.com; *correspondence: YX.Wang@cug.edu.cn; Tengma@cug.edu.cn)

[2]Department of Earth and Environmental Science, The University of Texas at Arlington, Arlington, TX 76010 (maxhu@uta.edu)

Effects of long term using of phosphate fertilizer on the mobilization of arsenic from soils have been seldom studied. In this study, the effects were investigated by column experiments using surface soil samples collected from fairdpur, central Bangladesh, an area with high arsenic presence in groundwater. A solution of 160 mg/L $Ca(NO_3)_2$ was first applied to the fully-saturate columns packed with soils to establish the stable As concentration in the effluent, and followed by leaching with phosphate fertilizer solution (represented with 10 mg/L Na_2HPO_4). An increase in the arsenic concentration in the effluent was observed after the $Ca(NO_3)_2$ input solution was replaced with either Na_2HPO_4 solutions. Dissolution of soluble arsenic-bearing minerals in the sediment with a rapid release of As, major cations, Fe, Mn, and Si was observed in the first hour. During the leaching period, there is no significant increase of As(III)/As(V) ratios in the effluent due to the oxic conditions in the experiment. Desorption of As from oxyhydroxide sorbents by phosphate is one of the major factors responsible for the elevated As concentration observed in the effluent [1, 2]. During the leaching periods of Na_2HPO_4, sodium mole percentage, as well as Na^+/Ca^{2+} and Na^+/Mg^{2+} ratios, of the effluent increased, probably due to aggregate breakdown, colloidal dispersion and mobilization in the columns, while an increase in Fe and Mn contents of the effluent may result from the release of particulate Fe and Mn oxyhydroxides. In addition, complexation of particulate arsenic with Fe/Mn oxyhydroxides may account for a significant portion of the enhanced arsenic concentration in the effluent.

LA-ICP-MS zircon U-Pb geochronology of granites and its geological implication in the Baiganhu W-Sn deposit, NW China

YONG-BAO GAO[1,2]*, WEN-YUAN LI[1] AND ZHAO-WEI ZHANG[1,2]

[1]Xi'an Center of Geological Survery, CGS, Xi'an, Shaanxi 710054, China

[2]Chang'an University, Xi'an, Shaanxi 710054, China (*correspondence: gaoyongbao2006@126.com)

Baiganhu W-Sn deposit is a new found large W-Sn deposit in Qimantge, NW China, and W-Sn mineralization is closely related to the tonalite and monzonite granite, both of which belong to S-type granites. However, because of lacking of precise isotopic dating, the metallogenic epoch of Baiganhu W-Sn deposit is disputed. This paper provides the LA-ICP-MS zircon U-Pb isotopic dating result of the tonalite (BKN-01) and monzonite granite (BKN-03) from the Baiganhu deposit and discusses its geological significance. The CL images of zircons in the granites show most of the zircons present the typical characteristics of magmatic zircons with zoning structures.The LA-ICP-MS Zircon U-Pb isotopic dating show that the weighted mean $^{206}Pb/^{238}U$ ages of tonalite and monzonite granite are 429.5±3.2 Ma (MSWD = 0.0026), and 430.5±1.2 Ma (MSWD = 0.0111) respectively. Both of the ages are concordant (Fig.1), and they can represent the petrogenic ages of the granites. Therefore, this paper proposed that the S-type granites in Caledonian period, which were formed by the melting of sedimentary strata, are closely related with forming of W-Sn in Baiganhu depsoit. These findings are of great significance in further research on the formation environment of Baiganhu W-Sn deposit, and guiding the ore prospecting directions.

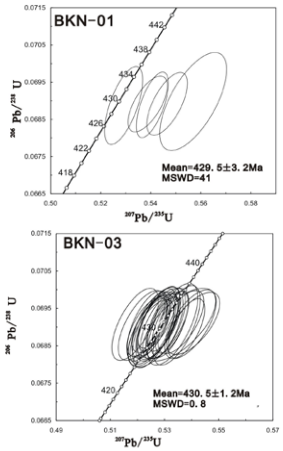

Figure 1: U-Pb concordia diagram of zircons of granites in the Baiganhu W-Sn deposit, Qimantage, NW China.

Geochemistry, paleoenvironment and timing of Lower Aptian organic rich beds of Paja Formation (Eastern Cordillera, Colombia)

TATIANA GAONA-NARVAEZ[1]*, FLORENTIN J.-M.R. MAURRASSE[1], FERNANDO ETAYO-SERNA[2] AND CARRIE REBENACK[1]

[1]Dept. of Earth and Env., Florida Int. Univ. 11200 S.W. 8th Street, Miami, FL 33199, USA (*correspondence: tgaon001@fiu.edu; maurrass@fiu.edu, crebe001@fiu.edu)
[2] Inst. Colombiano de Geología y Minería, INGEOMINAS, Diagonal 53 # 34-53, Bogotá, Colombia (fetayos@gmail.com)

Lower Aptian organic-rich marine sediments are interpreted with respect to anoxic episode, "Oceanic Anoxic Event 1a" (OAE-1a), coeval with $\delta^{13}C$ segments C3 to C6, of duration between 1.0 and 1.3 MA [1,2].

A 115m section of the Lower Aptian Arcillolitas Abigarradas Member of the Paja Fm at Villa de Leiva (Tunja-Villa de Leiva road) includes a prominent 4m-thick interval of black shale 10 meters below the base of the lowest Upper Aptian (Gargasian) *Dufrenoyia sanctorum-Stoyanowiceras treffryanus* ammonite assemblage zone [3]. Similarly, at the Curití Quarry (San Gil-Curití road), a 12m section includes 8m-thick organic-rich shale at the base of the Paja Fm, which overlies Barremian-age carbonate ramp deposits of the Rosablanca Fm. The base of the Paja Fm yielded reworked and phosphatized middle Barremian to lowest Aptian ammonites: *Pulchellia*, *Gerhardtia*, *Toxancycloceras*, *Karsteniceras* and *Prodeshayesites*. High-resolution analyses of these sections, including TIC (wt% $CaCO_3$), TOC (wt% C), and stable carbon isotope values ($\delta^{13}C_{org}$), characterize the stratigraphic relationship of these organic-rich levels of the Paja Fm and OAE-1a.

At Villa de Leiva, the organic-rich interval includes laminae associated with gypsum, pyritic concretions, absence of bioturbation and benthic fossils, and yielded increased TOC values (1.17% to 5.33%). These sediments accumulated under anoxic conditions in a subtidal, hypersaline environment [4]. C- isotope data show $\delta^{13}C_{org}$ values from -19.79‰ to -24.65‰. At Curití, the organic-rich sediments are devoid of benthic fossils and bioturbation, and TOC values are up to 8.4%, also indicative of oxygen-depleted conditions. C- isotope data yielded $\delta^{13}C_{org}$ values between -22.05‰ and -20.47‰. In both sections the range of $\delta^{13}C_{org}$ values, and the trend of the $\delta^{13}C_{org}$ curve are compatible with the Lower Aptian interval C7 [1, 2]. Therefore, both organic-rich intervals of the Paja Fm are subsequent to OAE-1a, which is known to occur between isotopic levels C3 and C6.

Beach placer, a proxy for the average Nd-Hf isotopic composition of a continental area

M. GARCON*, C. CHAUVEL AND S. BUREAU

ISTerre, BP 53, 38041 Grenoble Cedex 9, France (*correspondence: marion.garcon@ujf-grenoble.fr)

Beach placer deposits concentrate detrital heavy minerals which are the erosion products of large areas of continental crust. Here, we report the first analyses of Nd-Hf isotopic ratios and trace element concentrations that we measured in a beach placer from Camargue, France and in its pure mineral separates. Both the bulk composition of the placer and those of its pure mineral separates were determined. We also report mineral proportions obtained using observations under a binocular microscope and X-ray microfluorescence cartography.

Our results indicate that monazite totally controls the placer Nd isotopic composition (ε_{Nd} = -9.3) while zircon dominates its Hf isotopes (ε_{Hf} = -13.0) even though both mineral phases represent only a small proportion of the heavy mineral assemblage (3.5 and 10% respectively). We demonstrate that the Camargue placer provides a good estimate of the average Nd and Hf isotopic composition of the continental area drained by the Rhone River in western Europe ($\varepsilon_{Nd} \approx$ -9 and ε_{Hf} = -13). Using these values, we calculate two-stages model ages and show that almost all the placer minerals are derived from Proterozoic crustal protoliths. This provides valuable information on the history of the continental crust drained by the Rhone River. In particular, it suggests that little juvenile crust was created during the recent geological events that formed the Alps and the Massif Central, the two main massifs from which the placer minerals originate.

More generally, we propose that similar measurements made on other worldwide beach placer deposits could provide estimates of the present-day Nd and Hf isotopic composition of large continental areas, values that are difficult to obtain due to the well-known heterogeneity of continental material but are essential to model the growth of continental crust through Earth history or to model the impact of crustal material when recycled into the mantle.

Analysis of geochemical "twins" Al/Ga and Si/Ge in rock-forming silicate minerals in granitoides using LA-ICP-MS

N. GARDENOVÁ[1]*, V. KANICKÝ[1], K. BREITER[2], AND T. VACULOVIČ[1]

[1]Department of Analytical Chemistry, Faculty of Science, Masaryk University, Brno, Czech Republic (*correspondence: 369148@mail.muni.cz)
[2]Institute of Geology, Academy of Science ČR, Praha

The aim of this study is to determine ratios of Al/Ga and Si/Ge in natural silicate minerals from different types of granitoids from Bohemian massif and compare these ratios with elemental ratios commonly used in geochemistry like K/Rb, Nb/Ta and Zr/Hf. All these ratios represent (i) different source lithology (metasedimentary or metaigneous rocks, subduced slab, metasomatised lover crust) of granitic melts, (ii) evolution via fractional crystallisation, mixing, reaction with fluid atc., (iii) ability of particular crystal lattice of rock-forming minerals to preferentially accommodate Ga or Ge.

The presented results was obtained using three different methods – pneumatic nebulization with inductively coupled plasma mass spectrometry (PN-ICP-MS), laser ablation with ICP-MS (LA-ICP-MS) and electron probe microanalysis (EPMA). PN-ICP-MS was used for determination of whole content of the rock samples after fusion with $LiBO_2$. LA-ICP-MS and EPMA was used for local microanalysis of individual grains of silicate minerals.

The first results show that of Al/Ga-ratio in analyzed rock is relatively stable (Al/100Ga ~5-15), whereas Si/100Ge-ratio during fractionation increased: in the Třebíč pluton from about 80 in amphibole-biotite durbachites to 250-300 in late biotite durbachites, in orthogneisses from about 230 in biotite otrhogneisses to about 380 in some of two-mica facies, in the Melechov pluton from about 150 in the Lipnice facies do about 400 in the Melechov facies. In the Podlesí granite system, the Ge- and Ga-contents are influenced by greisenisation: namely the Ga is during hydrothermal processes mobile and its content remarkably decreases (Al/Ga-ratio increase).

Laser-ablation analyses of individual silicate minerals from the Cínovec borehole showed, that Ga is preferentially concentrated namely in mica (zinnwaldite and protolithionite), and more in albite than in associated K-feldspar. Ge is namely concentrated in mica. Contents of both Ga and Ge in quartz are lower than their detection limits.

Production of superoxide and hydrogen peroxide on photolysis of natural organic matter

S. GARG[1], A.L. ROSE[1,2] AND T.D. WAITE[1]*

[1]School of Civil and Environmental Engineering, The University of New South Wales, Sydney, NSW 2052, Australia (d.waite@unsw.edu.au)
[2]Southern Cross Geoscience, Southern Cross University, Lismore, NSW 2480, Australia

Irradiation of Suwannee River fulvic acid (SRFA) at pH 8.1 with simulated sunlight resulted in production of nanomolar concentrations of superoxide and hydrogen peroxide. Analysis of the results obtained confirmed that SRFA contains a redox-active chromophore which reduced oxygen to yield superoxide upon photoexcitation. Hydrogen peroxide was generated exclusively via uncatalysed disproportionation of superoxide produced in this way.

Superoxide decayed through both uncatalysed disproportionation and an oxidative pathway that did not result in hydrogen peroxide production, whereas hydrogen peroxide did not undergo further reaction to any discernible extent over the one-hour duration of irradiation. Singlet oxygen did not contribute substantially to production of superoxide or hydrogen peroxide, but was found to play a critical role in controlling the mechanism and associated rate of superoxide decay in the irradiated solution.

A kinetic model based on these observations is presented which provides an excellent description of the experimental results and is also consistent with observations from a wide range of other studies investigating various aspects of SRFA redox chemistry and photochemistry.

Dissolution of gold in hydrochloric acid

D. GARIJO* AND N. SHIKAZONO

Graduate School of Science and Technology, Keio University, Yokohama, 223-8522, Japan (*correspondence: garijodiego@gmail.com, sikazono@applc.keio.ac.jp)

The purpose of this work is to study hydrochloric acid as an alternative to cyanide for the dissolution of gold in the mining industry. The use of cyanide is controversial due to its toxicity. With hydrochloric acid the process would be safer for the environment and workers. J. D. Clemens showed that hydrogen gas can pass through Teflon at high temperature [1]. When dissolving gold in hydrochloric acid, several reactions should be taken into account:

$$Au + H^+ + 2Cl^- \rightarrow AuCl_2^- + 1/2H_2$$
$$Au + 3H^+ + 4Cl^- \rightarrow AuCl_4^- + 3/2H_2$$
$$Au + 4H^+ + 4Cl^- \rightarrow HAuCl_4 + 3/2H_2$$

The removal of H_2 in the system should quicken the process by forcing these reactions to proceed from left to right. Research by Nakata using Teflon vessels showed high gold concentrations compared to previous studies [2]. This is supposed to be due to degassing of H_2 from the system.

A proper combination of parameters will determine if the process is possible and economically viable. By now, it has been found that area of the gold particles, concentration of hydrocloric acid, temperature and time are the most relevant variables. The presence of amorphous phase can determine the speed of dissolution in short time intervals. The manufacturing process, apart from creating amorphous phase as a result of mechanochemical reactions, may inject energy into the surface. If this energy is heterogeneously distributed, activated zones could be preferentially dissolved. Regarding the recycling of gold alloys, composition can be important. The nature of the vessel (Teflon, or other non-permeable) is not important when the experiment is very short (less than ten days).

Colloidal arsenic distribution and speciation in mine soils

F. GARRIDO[1], F. LABORDA[3], E. BOLEA[3] M. HELMHART[1] P. O'DAY[2] AND S. SERRANO[1]

[1]Institute for Agricultural Sciences (CSIC), Madrid (Spain)
[2]University of California, Merced, CA 95343 USA
[3]Institute of Environmental Sciences, University of Zaragoza, Zaragoza (Spain)

Arsenic associated with colloidal particles is an important vector for As migration in contaminated soils. Using Asymmetric-Flow Field-Flow Fractionation (AsFlFFF) coupled to an inductively coupled plasma-mass spectrometer (ICP-MS), we determined the As distribution as a funtion of the particle size of the colloidal fraction of soils samples. The samples were collected from stained preferential flow paths and bulk soil samples, impacted by a mine waste. Physical and chemical properties of the colloids were also determined using X-ray-difraction, SEM and TEM. Arsenic and Fe speciation in the colloidal fraction was characterized using X-ray absorption (XAS) spectroscopy techniques.

Preliminary results indicated that more than 47% of the As mobilized in the preferential flow paths (70.5 mg/L) was associated with the colloidal fraction of the soil. Instead, 5% (2 mg/L) of the mobile As in the bulk samples of the soil was colloidal As. Common to both samples, a similar fractogram (1-1000 nm) was obtained for As, Fe and Al, suggesting an association of As with Fe and/or Al colloidal particles. As XAS analysis of the colloidal fractions (>10 nm) of the soil samples, indicated As adsorption on ferryhidrite as the main As-colloid retention mechanism. The presence of Fe-oxyhydroxides in addition to phyllosilicates was also showed by Fe X-ray absorption analisys. These results show the important role of Fe-oxyhydroxides as nanovectors of colloidal As in preferential flow paths and bulk samples of a contaminanted soil.

Platinum group minerals (PGM) from chromitites of Kytlym Uralian-Alaskan type complex (Russia)

G. GARUTI[1]*, F. ZACCARINI[1] AND E.V. PUSHKAREV[2]

[1]University of Leoben, Dept. Appl. Geol. Sci. Geophysics, Leoben, Austria (*correspondence: giorgio.garuti@unileoben.ac.at)

[2]Ural Division of Russian Academy of Sciences, Inst. Geol. Geoch., Ekaterinburgniversity of Leoben, Russia

Several PGM have been found in two different types of chromitites associated with the Kytlym Uralian–Alaskan type complex (Northern Urals, Russia). Type-1 chromitite forms small schlieren or pods irregularly distributed in dunite, whereas the type-2 occurs as thin layers within amphibole-rich clinopyroxenite veins (Butyrin-veins) cutting across the dunite. Type 2 chromitite is enriched in Fe^{3+} and Ti compared to type 1. The concentration of IPGE (Os+Ir+Ru) decreases from 408-580 ppb in type-1 to 293 ppm in type-2. The latter also distinguishes for a much higher PPGE (Rh+Pt+Pd) content (22679 ppb) compared with type-1 (4776-10836 ppb), showing a Pd-Ir ratio of 151 in front of 0.6 in type-1. Alloys in the Pt-Fe-Ni system (isoferroplatinum tetraferroplatinum and ferronickelplatinum), erlichmanite, cuprorhodiste and osmium occur as primary polygonal inclusions in type-1chromitite. Tulameenite is exclusively located along cracks in contact with secondary ferrian chromite, magnetite and chlorite, or constitutes the metasomatic replacement of primary Pt alloys. In contrast, the PGM assemblage of type-2 chromitite consists of Pd, Hg, Pt and Cu alloys (mainly potarite and Cu-rich potarite) and Pt-Fe-Cu with minor unnamed compounds of Rh-Te-Hg, Pt-Fe-Pd and Pd-Fe-Cu-S. With the exception of few Pt-Fe alloys that occur enclosed in fresh chromite, most of these PGM occur as irregular grains in the contact between chromite and silicates (clinopyroxene and amphibole), usually associated with pentlandite and pyrrhotite. Type-1 PGM precipitated in the high-temperature magmatic stage prior to or concomitant with chromite crystallization, under variable condition of S and O fugacities as well as Fe activity. Only tulameenite formed during low temperature, hydrothermal process. The composition and paragenetic assemblage indicates that PGM in type-2 chromitite derived from a more evolved melt (high Pd-Ir ratio) characterized by the activity of high-temperature fluids enriched in Hg, Te and Cu. The origin of this melt, i) last-stage fractionation of the same melt that generated the type-1 chromitite, or ii) fluid-rich melt derived from an external source, is still open to question.

Comparison of biomass used in Polish power-plants with other types of biomass

R. GASEK[1]*, W. WILCZYŃSKA-MICHALIK[1] AND M. MICHALIK[2]

[1]Institute of Geography, Pedagogical University, ul. Podchorążych 2, 30-058 Kraków, Poland (*correspondence: rgasek@ap.krakow.pl; wmichali@up.krakow.pl)

[2]Institute of Geological Sciences, Jagiellonian University, ul. Oleandry 2a, 30-063 Kraków, Poland (marek.michalik@uj.edu.pl)

The aim of this study is to compare general characteristics of biomass used in energy production in Poland with other biomass types. We analyzed wood and woody biomass, agricultural straw, and agricultural biomass.

Moisture content (as-received and air dried) is, respectively, within ranges of 5.4-26.2wt% and 1.2-1.6wt%. Ash yield (dry basis, 550ºC) varies from 0.8 to 10.6wt%. Volatile matter (dry basis) content is between 72.3-84.8wt%.

The C content in biomass is within the range 49.04-54.51wt% (daf – dry, ash-free basis); O content calculated by difference varies in the interval 37.32-43.26wt% (daf); H within the range of 5.58-6.35wt% (daf); N content is from 0.29-2.93wt% (daf); S content varies from 0.01 to 0.23wt% (daf). The Cl content measured in dry material varies from 0.017-0.253wt%.

Negative correlation between VM(db) and ash content (db) is evident; less pronounced negative correlation exists between O and C. Positive correlation between N and Cl content can be noted. Correlations between major elements (e.g. Ca, Mg, K, Fe) are week or absent.

Comparison of studied samples of biomass with published data (e.g. [1]) indicates that values of moisture, volatile matter content and ash yield are within relatively narrow range. Ash yield is relatively low in studied samples and volatile matter values are relatively high. The C content is relatively low in comparison with other types ob biomass. Oxygen content is rather high. The S, N and Cl contents are relatively low.

Changes in Neogene Himalayan erosion regime: Input of Pb and Nd isotopes into the Indian Ocean

J.C. GATTACCECA[1]*, A. GALY[1], A. M. PIOTROWSKI[1] AND M. FRANK[2]

[1]Dept. of Earth Sciences, University of Cambridge, CB2 EEQ Cambridge, UK (*correspondence: jcg54@cam.ac.uk)
[2]Leibniz Institute of Marine Sciences (IFM-GEOMAR), Wischhofstraße 1-3, 24148 Kiel, Germany

Pb- and Nd- isotopic time-series from the authigenic fraction of Central Indian Ocean sediments have been interpreted as responding to changes in the relative amount of Himalayan erosion during the Cenozoic [1,2]. Detrital records of Nd- and Sr- isotopes from the Bengal deep-sea fan suggest a source of sediment dominated by the High Himalaya Series (HHS) for the last 20 Ma [3,4]. Associated variations of Pb-isotopes are not known, and a more precise reconstruction is hampered by the lack of information about temporal changes in the isotopic composition of detrital Pb and Nd carried by rivers draining the Himalayas.

We present new Pb- and Nd-isotope time series, together with rare earth elements, from the bulk detrital and silt-sized fractions as well as the authigenic fraction of deep-sea sediment over the last 20 Ma from Ocean Drilling Program Sites 717 and 718 on the Bengal fan, along with Pb- and Nd-isotopic compositions of the bedloads of Himalayan rivers.

The oldest bulk detrital and silt-sized fraction samples (7-17 Ma) show similar and relatively uniform Pb- and Nd-isotopic compositions characteristic of a stable input from the HHS. The youngest samples (<1Ma) show the same uniformity with a shift towards more radiogenic values, implying a greater contribution of the Lesser Himalaya Series. However, over the Pliocene (1-7 Ma), strongly marked shifts in both isotopes are observed, along with a decoupling between the bulk detrital and silt-sized fractions.

These results imply a strong variability in the erosion and weathering regime of the Himalaya over the Neogene, and we will discuss them in the context of tectonic and climatic changes. We will discuss as well the implications of these changes for the interpretation of the deep water evolution of these isotope systems in the Central Indian Ocean.

Black Reef and Witwatersrand Gold fingerprint, South Africa

C GAUERT[1]*, D BATCHELOR[2], S FUCHS[1,3] AND G KLOESS[3]

[1]Univ. of the Free State, RSA (*correspondence: Gauertcdk@ufs.ac.za)
[2]Karlsruhe Inst. f. Technologie, Inst. f. Synchrotronstrahlung
[3]Inst f. Mat Sc. & Crystal, University of Leipzig, Germany

The origin of the gold, the Uranium and the PGEs in the basal conglomerate of the palaeoproterozoic Black Reef Formation (BR) of the Transvaal Supergroup in South Africa is debated because of the economic significance of this gold ore body. The geochemical trace element fingerprint of the Gold is used to unravel the origin of the Black Reef Gold. Based on EMP, LA-ICP-MS and SR-µ-XRF measurements Black Reef and Witwatersrand (WR) gold can be distinguished by means of their different degree of true fineness, and the Hg, Cu, Fe, S, Ti and Ni trace element content. Among the elements which are correlatible with gold, Sn, Sb, Pd, and Pt, possibly in combination with Mn, Se, Pb, and Ir appear to be the most effective element distinction of gold sources due to their moderate iterative variation.

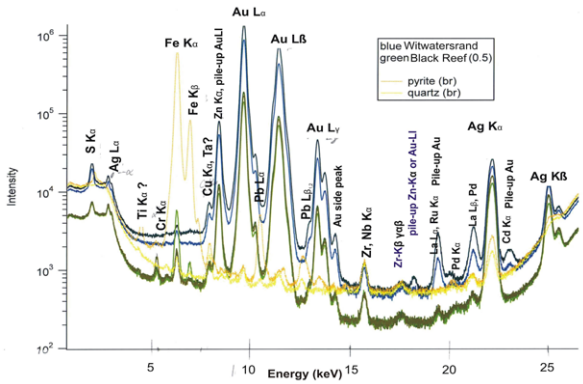

Figure 1: Synchrotron micro-XRF spectrum of BR and WR Gold, and pyrite and quartz at 30 keV energy.

The very similar heavy mineral content argues in favour of a reworked WR gold origin of the BR gold. Against a WR origin argues concretionary pyrite as major component and the less frequently occurring Ni-Co-Fe-sulpharsenides in the Witwatersrand reefs, however its frequent appearance in BR.

The Gold in the BR at Consolidated Modderfontein Au Mine on the East Rand has a lower fineness, lower Hg and Cu content compared to WR gold, whereas Fe, S, Ti and Ni concentrations are higher. Compositions of WR gold from different localities, as well as greenstone-hosted gold will be used in the debate of an alternative source area for the BR gold from the East and West Rand areas.

Characterization of nanoparticulate arsenic in waters draining abandoned gold mine tailings

A.G. GAULT[1]*, M.B. PARSONS[2] AND H.E. JAMIESON[1]

[1]Department of Geological Sciences and Geological Engineering, Queen's University, Kingston, Ontario, K7L 3N6, Canada (*correspondance: gault@geol.queensu.ca)
[2]Natural Resources Canada, Geological Survey of Canada (Atlantic), 1 Challenger Drive, Dartmouth, Nova Scotia B2Y 4A2, Canada

Waters draining abandoned gold mine sites often contain elevated concentrations of As, however, relatively few studies have attempted to distinguish between colloidal As and truly dissolved As. This distinction is important since it impacts the mobility, bioavailability, and toxicity of As. We collected surface waters draining abandoned gold mine tailings in Nova Scotia, Canada and sequentially filtered them through standard 450 nm pore size filters followed by stirred cell ultrafiltration through 10 nm polycarbonate membranes. Arsenic concentrations in the <450 nm fraction, traditionally termed "dissolved", ranged from 0.2 – 1.6 mg/L. Colloids, operationally defined here as suspended solids of 10 to 450 nm diameter, accounted for 5 – 56% of this As. SEM inspection of the 10 nm filters indicated that Fe and Ca were commonly associated with As-bearing nanoparticles. This was corroborated by synchrotron-based μXRF mapping which revealed that As was closely correlated with Fe, and to a lesser extent Ca. Multiple μXANES analyses indicated that arsenate was the dominant form of nanoparticulate As, with minor amounts of arsenite. These analyses showed no evidence for As-bearing sulfides, implying that arsenopyrite, the original mineralogical host of As prior to mining, was not a significant contributor to colloidal As. Synchrotron-based μXRD examination was hampered by the limited sample mass collected on the filter; however, akaganeite was found to be associated with As hotspots identified by μXRF mapping. Taken together, these preliminary data suggest the primary nanoparticulate vectors of As are secondary mineral assemblages such as hydrous (Ca-)Fe arsenates and Fe oxyhydroxides, previously shown to be major As-rich phases within the near-surface, weathered tailings at these historical gold mine sites [1].

Cadmium isotopic composition in cultured marine phytoplankton

M. GAULT-RINGOLD[1,2]*, R. STRZEPEK[1,3], C. H. STIRLING[1,2], R. D. FREW[1] AND K. A. HUNTER[1]

[1]Dept. of Chemistry, Univ. of Otago, Dunedin, New Zealand (*correspondence: melaniegr@chemistry.otago.ac.nz)
[2]Center for Trace Element Analysis, Dunedin, New Zealand
[3]NIWA, Dunedin, New Zealand

Cadmium (Cd) has been used as a marine paleo-nutrient proxy [1] despite its complex and poorly understood biogeochemical cycling in the oceans. The past five years have seen an increasing interest in the stable isotopic composition of Cd in the marine enviroment as this information has the potential to be used as a tracer for the physical and biological controls of Cd cycling in the oceans and its use as a micronutrient. It has also been suggested that Cd isotopes themselves may be a reliable paleoproxy for primary productivity [2].

Both iron (Fe) and zinc (Zn) have been shown to influence the uptake of Cd in both cultured and natural phytoplankton populations [3]. Phytoplankton utilize Cd in the place of Zn for the enzyme carbonic anhydrase (CA) with some species expressing a Cd-specific CA enzyme when grown under Zn-limiting conditions [4].

Using multiple-collector inductively coupled plasma mass spectrometry (MC-ICPMS) combined with double spiking techniques, significant 0.1%-level isotopic fractionation of Cd in seawater has been demonstrated and attributed to biological uptake [5]. Using these techniques, we examined the Cd isotopic fractionation associated with biological uptake in cultured marine phytoplankton under varying Fe and Zn-limiting conditions.

These experiments confirm that there is an isotopic fractionation associated with biological uptake of Cd, leaving the residual medium isotopically heavy. Fractionation factors calculated, assuming a Rayleigh distillation model, for these cultures demonstrate that Zn-limitation is influential in the resulting Cd isotopic compositions.

The importance of Zn bioavailibility on Cd isotopic composition implies that the biogeochemical cycling of Cd in the oceans is complex, which calls into question the potential application of Cd stable isotopes as a paleonutrient proxy.

Water-rock interaction at the Theistareykir geothermal field in NE-Iceland

BJARNI GAUTASON[1]* AND KARLIS MUEHLENBACHS[2]

[1]Iceland GeoSurvey & Univ. of Akureyri, P.O. Box 30, 602 Akureyri, Iceland (*correspondence: bg@isor.is)
[2]University of Alberta, Edmonton AB, T6G-2E3, Canada (karlis.muehlenbachs@ualberta.ca)

The Theistareykir volcanic system constitutes the western most part of the Northern Volcanic Zone (NVZ) in Iceland. Unlike its nearest neighbor to the east, the Krafla system, it does not have a well developed caldera structure. However, near the center of the system there are sporadic outcrops of siliceous rocks.

Bæjarfjall is a sub-glacial tuya located centrally in the system. On its northern slopes extensive acid sulfate alteration provides evidence for a vigorous geothermal system. To date six deep (≈ 2 to 3 km) exploration wells have been drilled in the area. Cuttings from the wells record extensive alteration of the bedrock with epidote-chlorite (T ≥ 240°C) and amphibole-epidote (T ≥ 290°C) facies metamorphism recorded at relatively shallow depths. Temperature logging and modelling shows that the geothermal gradient in the area follows the boiling point curve in the uppermost 2.5 km.

We have separated cuttings from selected depths in well ThG-1, taking care to obtain only cuttings of the dominant lithology from each of the selected depth intervals. These cuttings have been analyzed for their $^{18}O/^{16}O$ ratios. The $\delta^{18}O$ values of the rocks range from -4.0 to -10,2 (‰ SMOW) recording extensive exchange with meteoric derived hydrothermal fluid and very high time-integrated water-rock ratios. A general trend of decreasing $\delta^{18}O$ with depth is observed. From the data gathered to date it appears that most depleted rock occur close to presently active aquifers. More surprising however, is the depleted character ($\delta^{18}O$ < -8.0 ‰SMOW) of apparently unaltered (basaltic) intrusives.

The overall characteristics of the profile ($\delta^{18}O$ vs. depth) is similar to that obtained previously from the Krafla hydrothermal system [2].

Magnesite growth inhibition by organic ligands: Complexation and adsorption

Q. GAUTIER[1,*], P. BÉNÉZETH[1], G. JORDAN[2], U-N. BERNINGER[2] AND J. SCHOTT[1]

[1] Géosciences et Environnement Toulouse (GET), CNRS, UMR 5563, 14 Avenue Edouard Belin, 31400 Toulouse, France (*correspondence: quentin.gautier@get.obs-mip.fr)
[2] Dept. f. Geo- u. Umweltwissenschaften, Ludwig-Maximilians-Universität, 80333 München, Germany

Magnesite is object of scientific attention due to its potential for long-term CO_2 sequestration. Organic ligands are widespread in natural environments, and because of their promoting effect on Mg-containing silicates dissolution, it has recently been suggested that some carboxylate ligands could be used to enhance *ex situ* mineral carbonation [1]. However, the influence of such organic ligands on magnesite precipitation still needs to be elucidated.

We performed macroscopic and microscopic crystal growth experiments using mixed-flow reactors (MFR) and Hydrothermal Atomic Force Microscopy (HAFM) at temperatures between 80 and 150°C and slightly alkaline conditions. Three model ligands were investigated for their different chemical and structural properties: oxalate, citrate and EDTA.

MFR experiments showed that at concentrations above 0.01 mM, the investigated ligands inhibited magnesite growth. Inhibition is positively correlated with the complexation of Mg^{2+} by the ligands. Furthermore, by precisely calculating saturation states, we show that citrate causes a reduction of the kinetic rate constant of magnesite growth: for instance, citrate concentrations as low as 0.2 mM induce a 4-fold decrease of the rate constant, an effect that is not observed for oxalate. These results point towards different surface effects of the ligands.

HAFM observations showed that all three ligands interacted with steps on the magnesite surface, and modified the shape of growth islands. Measurements of step advancement rates suggest that citrate strongly inhibits growth at acute steps, which has been suggested to control magnesite growth at similar conditions [2].

Therefore at the investigated conditions, inhibition of magnesite growth by organic ligands appears to be a consequence of both Mg^{2+} complexation decreasing solution saturation, and specific interactions of the ligands at the magnesite surface. The results help to assess a potential use of organic ligands for mineral carbonation purposes and may improve our understanding of the long-term fate of CO_2 in ligands-containing storage sites.

Magnetic susceptibility of Zafarghand granitoidic pluton

NEGAR GAVANJI*, M. SADEGHIAN AND S. SHEKARI

Shahrood University of Technology, Shahrood, Iran
(*correspondence: g.negar20@yahoo.com)

Zafarghand granitoidic pluton (ZGP) is located in the 160 km of NE Isfahan. This pluton is one of the granitoidic pluton of Orumieh Dokhtar structural zone and its lithological composition range includes: gabbro, diorite, granodiorite and granite.. Eocene volcanic and volcano sedimentary are host rocks. This pluton investigated in the light of Anisotropy of Magnetic Susceptibility (AMS) method. 1008 samples were gotten from 123 stations in ZGP. Based on some criterias, magnetic parameters of these samples have been measured in the magnetic lab of Shahrood University of technology by MFK1-FA kappabridge machine. The measured mean magnetic susceptibility (Km in μSI) of the different rock groups are as follows: Gabbros (38120), diorites (26558), granodiorites (16922) and granites (9885). Based on these values gabbros and diorites have higher magnetic susceptibility [F.1].

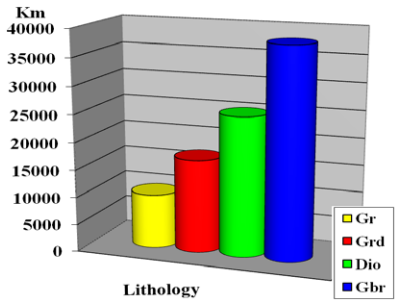

Figure 1: Km- Lithology diagram

This characteristic confirmed by the presence of magnetite in polished sections, thermal magnetic diagrams and Geochemistry analyze. Km values which they are more than (500 μSI) indicate that studied granitoidic rocks are ferromagnetic and correlate with I-type granitoids [1, 2].

Highly siderophile element and Os isotope systematics of pyroxenite layers from the Lanzo peridotite body (Northern Italy)

T. GAWRONSKI* AND H. BECKER

Institut für Geologische Wissenschaften, Freie Universität Berlin, Malteserstrasse 74- 100, D-12249 Berlin, Germany
(*correspondence: gawronsk@zedat.fu-berlin.de)

Mantle pyroxenites are believed to represent a minor constituent of the Earth's mantle, but may yield insight into the origin, modification and transport of mafic magma. Mantle sources enriched in pyroxenite have been suggested as explanation for coupled suprachondritic ^{187}Os-^{186}Os signatures in some mantle plume sources [1, 2].

The spinel and plagioclase facies Lanzo peridotite body includes layers of spinel-and plagioclase-bearing websterite, clinopyroxenites and orthopyroxenites up to several dm in thickness. Abundances of highly siderophile elements (HSE) in the pyroxenites display no correlation with Al_2O_3, CaO and Na_2O. Concentrations of Os, Ir, and Ru range from 1 to 0.01 x values in peridotites. Aluminum rich clinopyroxenites show enrichment of Pt, Pd, Au and Re over Os, Ir, and Rh, and initial γ_{Os} (200 Ma) of +25 to +150. Concentrations of Pt, Pd, Au and Re in such samples are only occasionally higher than estimates for primitive mantle values. Aluminum poor websterites are less depleted in Os, Ir, Ru, Rh and display less enrichment of incompatible HSE, with γ_{Os} (200 Ma) of -2 to +43, reflecting a smaller contribution from melt enriched in incompatible HSE. HSE ratios in the pyroxenites range from sub- to suprachondritic (Os/Ir:0.40-1.66, Ru/Ir:0.26-3.70, Rh/Ir:0.23-0.55, Pt/Ir:1.03-26.48, Pd/Ir:0.79-42.92, Au/Ir:0.02-3.75, Re/Ir:0.15-2.67, Pt/ Re:1.96-151.30). Two samples (out of 12) with unusual composition display Pt/Re high enough to develop coupled suprachondritic ^{186}Os-^{187}Os with time as reported for some picrites and komatiites [2].

With the exception of 3 samples, most pyroxenites are correlated in a Re-Os isochron diagram and yield an errorchron date of 1136±120 Ma (^{187}Os/^{188}Os$_i$ = 0.13±0.01). This date is considerable older than the emplacement during the early Mesocoic (200 Ma) but coincides with a Sm-Nd model age of 1200 Ma for the southern Lanzo peridotite body [3].

Spatial distribution of erosion rates in small Tahitian catchment (10km^2), from cosmogenic ^{3}He in olivine

ERIC GAYER[1], FENGYIN YE[2] AND SUJOY MUKHOPADHYAY[3]

[1]Institut de Physique du Globe de Paris, Sorbonne Paris Cité, UMR 7154 CNRS, 75005 Paris, France (egayer@ipgp.fr)
[2]Université de Polynésie Française, GEPASUD, Tahiti.
[3]Harvard University, Cambridge, 02138 MA, USA.

Understanding mechanisms that modify landscapes is essential for risk assessment in tropical islands. Such an understanding requires quantification of the rates at which landscapes respond to tectonic and climatic signals. Because measurements of long-term erosion rates are critical for understanding landform evolution, the use of cosmogenic isotopes in river sediments to estimate average erosion rates of drainage areas has grown rapidly in recent years.

In this study we present measurements of cosmogenic ^{3}He concentrations ([^{3}He$_c$]) in olivine grains from Tahitian river sediments (French Society Island) to predict the spatial pattern of erosion rates in the drainage area [1].

The olivine-rich sands come from 3 locations along the Matatia River, on the west part of Tahiti (catchment mouth, intermediate and upstream positions). He concentrations and isotopic ratios have been measured in 3 samples of olivine grains (1-2 mm) each weighing ~500 mg. The [^{3}He$_c$] has been calculated using: (i) the ^{3}He/^{4}He ratio measured by crushing and (ii) the ^{3}He and ^{4}He concentrations measured by melting the resulting powder.

Initial results indicate (i) an average erosion rate of 0.39±0.19 mm/yr upstream of the catchment mouth, and (ii) an average erosion rate of 0.0078±0.0007 mm/yr for the upstream sub-basin. The erosion rate at the intermediate position is too high to accumulate measurable amounts of ^{3}He$_c$.

The observed variation of erosion rates along the drainage area could be related to different erosional processes (landslides vs. soil creep), or can represent the erosion rates of different sub-basins (main stream vs. tributary). The measured erosion rates at the different locations allow us to invert for the spatial distribution of the erosion rates through nonlinear slope- and curvature-dependent erosion rates. This approach also enables us to constraint the form of parameterized erosion laws.

Melting conditions with PRIMELT: Examples and future work

ESTEBAN GAZEL[1], CLAUDE HERZBERG[2] AND PAUL ASIMOW[3]

[1]Lamont-Doherty Earth Observatory, (egazel@ldeo.columbia.edu)
[2]Rutgers University, (herzberg@rci.rutgers.edu)
[3]California Institute of Technology, (asimow@gps.caltech.edu)

Determination of the magmatic melting conditions in the mantle is important for understanding the origin of intraplate magmas. The major element composition of primary magmas can provide such information, but there are important limitations. Of these, the best known is fractional crystallization. Other factors are source lithology variations and volatile content. PRIMELT2 [1] was introduced to calculate primary magma composition, but is restricted to primitive lavas that only crystallized olivine. It was calibrated from experiments on fertile mantle peridotite, and provides a mass balance primary magma. It calculates primary magma composition, melt fraction for accumulated fractional and batch melting, mantle potential temperature, olivine phenocryst composition, and warns the user of potentially compromising effects of source lithology variations and CO_2 content.

PRIMELT2 was used to evaluated variations in mantle potential temperature of OIB (ocean islands) [1] and to compare OIB to Large Igneous Provinces (LIPS) [2]. Results show that mantle plumes for LIPS were hotter and melted more extensively than plumes of modern OIB. Petrological solutions obtained from back-arc alkaline lavas from the Central American Volcanic Front yield T_p estimates within expected ambient mantle (1350-1400°C) [3]. These results indicate that PRIMELT2 is applicable for melting in a variety of tectonic environments. Work in progress will test the effects of alteration and simulate a decompression melting path.

How geochemical proxies provide quantifiable evidence of climate shifts over the last 25,000 years

GEOFFREY GEBBIE

Department of Physical Oceanography, Woods Hole Oceanographic Institution, MS #29, Woods Hole, MA 02543 USA (ggebbie@whoi.edu)

Some of the best, but still limited, evidence for large climate shifts, including the end of the Last Ice Age, comes in the form of geochemical proxies preserved in seafloor sediments. The proxy data is actually recording oceanic tracer distributions, which in turn, depend upon the sea surface and the atmosphere in a complicated way. In the terminology of inverse methods, the "observation step" must be modelled as well; that is, the process that translates the physical variables of the ocean into a proxy signal must be explicitly (i.e., mathematically) stated. In many cases, this process is calcification in foraminifera, and empirical relationships are used here as the model of this step. In cases where the observation or proxy step is oversimplified in the model, a whole range of plausible solutions can be excluded without good reason.

While it is clearly of interest to estimate past rates of ocean circulation from geochemical proxies, an inverse method is used to show that the seafloor proxies from the Last Glacial Maximum inform us primarily about shifts in the water-mass configuration. In this particular example, I show that the geochemical proxies, $\delta^{18}O$, $\delta^{13}C$, and Cd/Ca ratio, give quantifiable evidence for a shift in the pathways of the interior ocean, not just changes in surface boundary conditions. Given this information, estimates of the rate of overturning circulation in the Atlantic are revisited, but significant uncertainties remain in the inverse estimate of this particular quantity.

Selenium reduction by pyrite: pH effect and Mossbauer study

ANTOINE GEHIN[1], MINGLIANG KANG[1,2], JEAN-MARC GRENECHE[3] AND LAURENT CHARLET[1]

[3]Condensed Matter Physics Laboratory, IRIM2F, University of Maine, 72085 Le Mans, France

The radioactive isotope ^{79}Se is presently considered as the key mobile fission product for the disposal of spent fuel (SF) and high-level radioactive waste (HLW). Its solubility is largely controlled by oxidation state. Due to the weak adsorption of Se(IV) and Se(VI) on natural minerals, specially on granite and clay minerals, chemical reduction is considered to be the most effective way to immobilize ^{79}Se [1,2].

On the other hand, pyrite is the most frequent sulfide mineral and is also present in geological barriers of nuclear waste repositories [3].

Therefore, we investigate the interaction between pyrite and Se(IV) from pH 5.05 to 8.5. After 1 month, solution analyses show that Se(IV) concentration decreases under the detection limit and suggest that Se(IV) is involved in redox reactions with FeS_2

We focus specially on the behavior of iron species in the immobilization of Selenium. Mossbauer spectroscopy performed on the solid at different pH shows clearly significant iron environment modifications, and thus it suggests particularly the precipitation of new solid phases included Fe and Se, like FeSe or $FeSe_2$.

These resulsts are confirmed by XAFS spectroscopy used to unravel the selenium speciation., and microscopy analysis (SEM and TEM).

U-Pb ages and Hf isotopes of detrital zircons from miogeoclinal strata of western North America

GEORGE GEHRELS AND MARK PECHA

Department of Geosciences, University of Arizona, Tucson AZ 85721 USA (ggehrels@gmail.com)

U-Pb ages and Hf isotope signatures have been determined from 32 samples of Neoproterozoic, Paleozoic, and lower Mesozoic miogeoclinal strata from western North America. Samples have been collected along five transects in eastern Alaska, northern British Columbia, southern British Columbia, Utah-Nevada, and northern Mexico. Detrital zircon grains from these samples were analyzed for U-Pb by ID-TIMS in the mid-90's to generate a spatial-temporal reference for the ages of grains that accumulated along the western edge of North America. We have recently re-analyzed these samples by CL-based LA-MC-ICPMS to determine more robust U-Pb age distributions (~200 grains/sample) as well as complementary Hf isotope signatures (~50 grains/sample).

U-Pb ages from these samples match well with the ages determined by ID-TIMS, and in most cases resemble the ages of nearby basement rocks. Hf isotope signatures for these detrital grains reveal a fascinating history of crustal genesis and recycling. In southern regions, primary age groups are 1.0-1.2, ~1.4, and 1.6-1.8 Ga, which matches the ages of bedrock terranes in the region. Hf signatures of these grains record generation of juvernile crust at 1.6-1.8 Ga, followed by recycling of this crust during younger magmatism. Central transects contain these same age groups, plus a significant Late Archean contribution. Hf data suggest formation of juvenile crust during Late Archean time, with significant recycling of this crust during 1.6-2.2 Ga magmatism. Little juvenile crust is recorded between 1.6 and 1.8 Ga, whereas, surprisingly, 1.0-1.2 and ~1.4 Ga zircons are considerably more juvenile than coeval grains to the south. Northern transects record protracted magmatism from 3.6 Ga to 300 Ma. Some juvenile crust of early Paleozoic, Early Proterozoic, and Late Archean age is represented, but most grains have Hf compositions that lie between observed 1.8-2.0 and 2.5-2.8 Ga evolution bands. This presumably reflects homogeneous mixing of 1.8-2.0 and 2.5-2.8 Ga crust, rather than recycling of 2.0-2.3 Ga juvenile crust, as the 2.0-2.3 Ga grains present are not juvenile.

Actinium-227 in the Atlantic sector of the Southern Ocean: New results from Bonus-Goodhope and UK Geotraces

WALTER GEIBERT[1]*, ALAN HSIEH[2], CLAUDIA HANFLAND[3], ELISABET VERDENY[4], PERE MASQUE[4], GIDEON HENDERSON[2]

[1]School of GeoSciences, University of Edinburgh, West Mains Road, Edinburgh EH9 3JW, UK (*correspondence: walter.geibert@ed.ac.uk)

[2]Department of Earth Sciences, University of Oxford, UK

[3]Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

[4]Institut de Ciència i Tecnologia Ambientals - Departament de Física, Universitat Autònoma de Barcelona, Spain

Actinium-227 is a naturally occurring radionuclide, which is released from marine sediments, in particular deep-sea sediments. With a half-life of 21.77 years, it is an excellent indicator of vertical mixing in the deep-sea, and a tracer for upwelling of deep water masses. Therefore, it has potential to be used to quantify fluxes of micronutrients from the deep-sea.

Here, we present new data from the Southern Ocean that were obtained during the UK Geotraces cruise and the Bonus-Goodhope cruise in the South Atlantic. We characterise the main water masses in the Atlantic sector of the Southern Ocean, and discuss to which extent the Ac data can be expected to remain constant over time within water masses.

We also compare results that were obtained by direct alphaspectrometric analyses (Bonus-Goodhope) to indirect measurements by radium delayed coincidence counting (RaDeCC) and discuss the differences of the methods.

If a general input function for Ac from marine sediments could developed, ^{227}Ac could be used to validate deep ocean circulation and mixing in models, analogue to the application of ^{3}H or chlorofluorocarbon as tracers for surface water masses. New depth profiles from the UK Geotraces cruise promise to give new estimates of ^{227}Ac flux from the deep sea, and bring the implementation of ^{227}Ac in models closer.

Si-isotope fractionation during silica precipitation: An experimental approach

S. GEILERT[1]*, M.J. VAN BERGEN[1] AND P.Z. VROON[2]

[1]Department of Earth Science, Utrecht University, the Netherlands (*correspondence: geilert@geo.uu.nl)
[2]Faculty of Earth and Life Sciences, Vrije Universiteit Amsterdam, the Netherlands

Interpretations of silicon isotope compositions of natural silica deposits suffer from poor constraints on the isotopic fractionation behaviour during precipitation of the silica from a saturated solution. We tested an experimental setup to explore the conditions under which equilibrium precipitation of amorphous silica would occur in the 10-60°C temperature range using flow-through reactors. The objective is to constrain magnitudes and sign of silicon isotope fractionation, the degree of temperature dependence and the sensitivity to non-equilibrium conditions.

Stock solutions, prepared from amorphous silica powder and brought to saturation at 90°C, were forced to pass flow-through reactors, seeded with ca. 200 mg of silica powder with known surface area at well-controlled flow-rates. Precipitation was induced by placing the reactors in a water-bath at the desired temperature. According to a comprehensive set of test runs, our experimental set-up enables us to achieve equilibrium during controlled silica precipitation in the reactors, provided that conditions are carefully tuned. Factors with a strong influence included the applied flow-rate, pH, specific surface area and degree of supersaturation.

Silicon isotope measurements ($^{30}Si/^{28}Si$ and $^{29}Si/^{28}Si$), carried out on input and output solutions using a Finnigan Neptune MC-ICPMS, presented insight into the sign and magnitude of isotopic fractionation. Preliminary results for runs where equilibrium was secured demonstrated that, under these experimental conditions, $\delta^{30}Si$ values for SiO_2 remaining in solution were up to 0.5‰ lower relative to the input solution, implying discrimination against the uptake of the lighter isotopes in the solid. The fractionation increased with decreasing temperature.

The observed direction is opposite to what is often seen in natural solid-fluid systems, indicating that equilibrium versus non-equilibrium conditions during precipitation might be a critical factor in the use of Si isotopes as a proxy.

The rusty sink: Impact of Iron on the sedimentary organic biomarker record

YVES GÉLINAS[1]*, KARINE LALONDE[1], LUC TREMBLAY[2], ANJA MORITZ[1] AND ANDREW BARBER[1]

[1]Chemistry and Biochemistry, Concordia Univ., Montreal (QC), Canada, H4B 1R6 (*correspondence: ygelinas@alcor.concordia.ca)
[2]Chimie et Biochimie, Univ. Moncton, Moncton (NB), Canada, E1A 3E9 (luc.tremblay@umoncton.ca)

The biogeochemical cycles of iron (Fe) and organic carbon (OC) are strongly linked, each element exerting some degree of control over the other. In the oceans, organic ligands control the concentration of dissolved Fe in the water column. In soils, Fe and OC concentrations are typically correlated, suggesting that they are closely associated. Nevertheless, until now, the role of Fe in the preservation of sedimentary OC has not been clearly established. We recently determined that 20 to 40% of the total OC in marine and freshwater sediments is closely associated to solid reactive Fe phases (operationally defined as the solid iron phases that are reductively dissolved with sodium dithionite). In young and mature sediments, solid reactive Fe phases do not provide sufficient surface area for chemisorption of OC onto Fe oxides. Alternatively, high OC:Fe ratios reflect the existence of largely organic Fe-OC macromolecular structures (through chelation and co-precipitation), attached only minimally to the surface of clay mineral grains. The organic matter in these Fe-OM chelates is 'glued' together by iron ions or nanophases of iron oxide crystals. We also found isotopic and elemental fractionation between Fe–associated OC and the rest of the sedimentary OC pool, with ^{13}C and nitrogen-enriched OC preferentially bound to Fe, and suggesting biochemical fractionation. The presence of iron and the interactions between iron and organic matter also affect the recovery of a broad range of organic biomarkers from sediments. In this communication, we will present and discuss the impact of iron on the recovery of amino, lipid and lignin biomarkers as well as on the environmental message obtained through biomarker analysis. Alternative methods that circumvent the effects will also be presented.

T and fO_2 guided, gas phase mediated Na and K exchange between silicate melt drops

M. GELLISSEN[1,2], A. HOLZHEID[1], PH. KEGLER[1] AND H. PALME[2]

[1]Univ. Kiel, Inst. f. Geowissenschaften; (mgellissen@web.de)
[2]Forschungsinstitut und Naturmuseum Senckenberg, Frankfurt a.M.

The overall depletion of volatile lithophile elements in the mantles of the terrestrial planets along with nearly unfractionated Mn/Na ratios [1] as well as the varying abundances of Na and K relative to Si in meteorites and even individual chondrules [2] leads to the question of the nature of the depletion process (evaporation or incomplete condensation). As our early experiments showed little or no loss from Na and K bearing minerals we focussed on evaporation from siliceous melts with different fractions of Al, Na, K and partly Fe, Ti and Mn.

We used 11 synthetic silicates with a molar Si/(Al+Na+K) ratio of 3/1, varying Al/alkali and Na/K ratios and NBO/T from 0 to 0.67. Each run contained samples of different composition. Also a Si, Fe, Ti and Mn bearing mixture enriched with Na and K was used. Samples' weights were about 4 mg. Time series were done in 1 atm CO/CO_2 gas mixing furnaces from 1000 to 1550 °C and log fO_2 from air to IW-2. Sample mounting was by Pt wire loop technique [3].

Under all experimental conditions Na and K are lost from high Na, K samples and gained by low Na, K samples, with all samples reaching an approximately constant level after several hours. The process is faster with increasing temperature and decreasing oxygen fugacity. The Na concentration at the converging point decreases with increasing gas flux, but is independent of Al concentration in the starting composition, despite variations from 0 to 26 wt % Al_2O_3. The effect for K is less pronounced.

Na and K contents are controlled by the Na and K vapor pressures in the furnace, which again is determined mainly by the gas flow in the furnace and by the total amount of alkalis released by heating. The lesser dependence of the K concentration from the gas flux is a hint to a faster kinetic behavior compared to the Na. More experiments with varying gas flow rates are in progress.

Petrology of the Middle Eocene sub-volcanic association of Western Pontides

S. CAN GENÇ[1], FATMA GÜLMEZ[1], MEHMET KESKIN[2], OKAN TÜYSÜZ[3] AND TURGAY IŞSEVEN[4]

[1]ITU Dept of Geology 34469 Istanbul, Turkey (*correspondance: scangenc@itu.edu.tr)
[2]IU Dept. of Geology Istanbul, Turkey;
[3]ITU Inst. of Eurasian Earth Sci., 34469 Istanbul, Turkey;
[4]ITU Dept. of Geophysics 34469 Istanbul, Turkey;

The Middle Eocene (49.3±2 – 38.1±1.9 Ma) magmatic rocks (MEMR) form an east-west trending belt along the northern Turkey. They rest unconformably on the pre-Middle Eocene units. Here, we present geological and petrological data from the western part of this belt, between Armutlu Peninsula and the Almacık Mountains. These rocks forming a "sub-volcanic association" are represented by the basic to intermediate volcanic rocks, dikes and coeval granitic rocks. The volcanic rocks of the MEMR form a continuous trend from basalt to dacite. Granitic rocks comprise granite, granodiorite and tonalities. Both the volcanic and the granitic rocks display medium-K subalkaline affinity, and CA trend with rare tholeiitic lava samples. They display significant enrichment in LIL elements, and slightly enrichment in LREE. There are apparent impoverishments in Ta and N, in N-MORB normalized spider diagrams. Initial Sr and Nd isotopic values for the volcanic rocks of the MEMR are ($^{87}Sr/^{86}Sr_i$: 0.703976-0.706441) and ($^{143}Nd/^{144}Nd_i$: 0.512856-0.512601), respectively. From these data and combined ƐNd(T) (-1.55 - +5.38), Pb and ^{18}O (8.5-13) isotopic values, we conclude that the magma produced the MEMR was hybrid in composition, including depleted mantle and crustal components. AFC processes played an important role for the genesis of magma. According to these geochemical features, MEMR displays close similarity to the subduction-related magmas. In the light of geological and petrological findings, we conclude that the MEMR was produced in a post-collisional setting, and we favour the slab breakoff model that provides a better explanation for the generation of the MEMR.

Redox reactions of Fe^{II-III} oxyhydroxycarbonate minerals in gleysols, fougèrite, trébeurdenite and mössbauerite, and water denitrification

J.-M. R. GÉNIN[1]*, O. GUÉRIN[2], E. KUZMANN[3] AND C. RUBY[1]

[1]Institut Jean Barriol, Université Henri Poincaré, ESSTIN, 2 rue J. Lamour, F54500, Vandoeuvre-lès-Nancy, France (*correspondence: jean-marie.genin@esstin.uhp-nancy.fr)
[2]Laboratoire de Géomorphologie, Ecole Pratique des Hautes Etudes, 15 bd de la mer, F35800, Dinard, France
[3]Department of Chemistry, Eötvös Lorand University, Pazmany Peter setany, H1117, Budapest, Hungary

Colour change from bluish-green to ochre in gleysols is due to redox reactions within Fe^{II-III} oxyhydroxycarbonate, related to a green rust Fe^{II-III} double layered hydroxide of general formula $Fe^{II}_{6(1-x)}\ Fe^{III}_{6x}\ (OH)_{2(7-3x)}\ O_{2(3x-1)}\ CO_3\ 3H_2O$. Minerals are named (i) fougérite for $Fe^{II}_4\ Fe^{III}_2\ (OH)_{12}\ CO_3 \bullet 3H_2O$ green rust Fe^{II-III} hydroxycarbonate (ii) trébeurdenite for $Fe^{II}_2\ Fe^{III}_4\ (OH)_{10}\ O_2\ CO_3 \bullet 3H_2O$ Fe^{II-III} oxyhydroxy- carbonate (iii) mössbauerite for $Fe^{III}_6\ (OH)_8\ O_4\ CO_3 \bullet 3H_2O$ ferric oxyhydroxycarbonate at definite x values of 0.33, 0.67 and 1, respectively; the exceptional redox flexibility comes from toptotactic reactions as shown by XRD and TEM; the relative trivalent cation average ratio x extends from 0.33 to 1 by mixing minerals as shown by Mössbauer spectra (Fig. 1).

Figure not supplied.

Figure 1: Mössbauer spectra measured at 78 K of samples vs x (***a***) fougèrite; (***b***) trébeurdenite (***c***) mössbauerite

In samples extracted out of waterlogged gleys in a water table (Fougères), x varies between 0.33 and 0.67 by mixing fougèrite with trébeurdenite, whereas in those extracted from the schorre of a maritime marsh (Trébeurden), x varies between 0.67 and 1 by mixing trébeurdenite and mössbauerite, due to partial oxidation of the gley at low tide. This redox flexibility is responsible for water denitrification in water tables combined with anaerobic bacterial reduction.

Plume-ridge interaction: Constraints on melting dynamics from the Azores and Iceland

F.S. GENSKE[1,2]*, C. BEIER[1,2], S.P. TURNER[1], K.M. HAASE[2] AND B.F. SCHAEFER[1]

[1]GEMOC, Department of Earth and Planetary Sciences, Macquarie University, Sydney NSW 2109, Australia (*correspondence: felix.genske@mq.edu.au)
[2]GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Schloßgarten 5, D-91054 Erlangen, Germany

Ocean Island Basalts (OIB) erupted in the vincinity of Mid-Ocean Ridges (MOR) provide important information on melting processes, melt movement and composition of the Earth´s mantle. In particular the major element, trace element and Sr-Nd-Pb isotope ratios allow for constraints on the distinct melting behaviour of enriched and depleted mantle sources, their along and across axis distribution and potential changes in melting depth and melting temperatures.

While the flow of melts into the Mid-Atlantic Ridge (MAR) in the Azores and Iceland has been the subject of several studies, both plumes exhibit active volcanism on the western side of the Mid-Atlantic Ridge away from the proposed plume locality. Such off-axis volcanism beneath the North-American plate is comparable for the two OIB settings in terms of trace element and isotopic source composition relative to the main plume centre. Incompatible trace element ratios of Nb/Zr, Ta/Hf and La/Sm are elevated by similar factors in the off-axis (western) lavas when compared to the lavas from the plume centre. We compare the melting dynamics (i.e. P-T conditions of basalt generation) underneath the Snaefelsness peninsula (Iceland) with those underneath Flores and Corvo islands (Azores); both examples of unusual off-axis and "off-plume" magmatism.

We demonstrate that Iceland and the Azores exhibit comparable excess temperatures, but that melting underneath the western Azores islands is initiated deeper. The sources in the Azores are more enriched and degrees of partial melting are slightly lower than compared to Snaefellsness. This implies that for both cases melting dynamics are largely controlled by the geochemical composition of the source and possibly lithosphere thickness rather than upwelling rate. The differences between eastern and western (i.e. plume related vs. "off-plume") sources may reflect different proportions of enriched melts during binary mixing with depleted MORB mantle (DMM) sources.

Late Permian organic-rich shales from the Ravnefjeld Fm in East Greenland yield a precise isochron from drill core samples, but scattered data from outcrop samples. Using Re-Os isochroneity as a gauge to distinguish fresh undisturbed shale from macroscopically fresh but chemically altered shale, we explore additional geochemical parameters that evidence subtle weathering and oxidation of shale.

Systematic differences between weathered and fresh samples are used to characterize and quantify the effect of weathering on shale chemistry. Weathering oxidizes organic matter (OM) and sulfides (mainly pyrite framboids <6 μm on average), sometimes imperceptibly. The kerogen oxygen content (approximated by the S3 parameter of Rock-Eval pyrolysis) is a more consistent proxy for weathering than major or trace element compositions. Comparison with time equivalent fresh shale from the mid-Norwegian shelf reveals that shale weathering is best detected and characterized by the combined use of Rock-Eval indices for oxidation of OM and sulfur content data that document oxidation of pyrite. Based on this example, we present a sampling strategy to optimize the potential for accurate and precise Re-Os geochronology.

Correlations among trace metals, total organic carbon and total sulfur show that both Re and Os are concentrated in OM rather than sulfides. While both Re and Os are mobile during weathering, isotopic disturbance may occur through several contrasting mechanisms depending on local factors from the outcrop to the mm-scale. Depending on the type of isotopic disturbance, weathered shales may yield erroneously younger or erroneously older model ages.

Late Permian shales in this study have exceptionally high Re/Os ratios that lead to rapidly increasing $^{187}Os/^{188}Os$ with time. Mass balance shows that recent (or Cenozoic) weathering of such shales may influence the Os isotopic composition of seawater much more strongly than weathering of typical Phanerozic shales; the effect will be comparable to weathering of Precambrian shales.

Modeling the effects of fertilization and pH on dissolved inorganic phosphorus in soils

F. GERARD[1], N. DEVAU[1], E. LE CADRE[2] AND P. HINSINGER[1]

[1]INRA, UMR 1222 Eco&Sols, Montpellier, France
[2]Supagro, UMR 1222 Eco&Sols, Montpellier, France

We used a set of mechanistic (macro-scale) adsorption models within the framework of the component additive approach in an attempt to determine the effect of repeated massive application of inorganic P fertilizer on the processes controlling the concentration of dissolved inorganic phosphorus (DIP) in soils. We studied a Luvisol with markedly different total concentrations of inorganic P as the result of different P fertilizer history (i.e. massive or no application for 40 years). Soil pH was made to vary from acid to alkaline.

Satisfactory results were obtained using generic values for model parameters and soil-specific ones, which were either determined directly by measurements or estimated from the literature. We showed that adsorption largely controlled the variations of DIP concentration and that, because of kinetic constraints, minor precipitation of Ca-phosphates may have occurred under alkaline conditions, particularly in the P-fertilized treatment. The adsorption of Ca^{2+} onto soil minerals promoted adsorption of phosphates through electrostatic interactions. The intensity of this mechanism was high under neutral to alkaline conditions. The variation in DIP concentration with pH can be related to changes in the contribution of the various soil minerals to P adsorption.

Advances in analyses of radiogenic isotope by LA-MC-ICPMS: The importance of mass bias and interference correction

A. GERDES

Institut für Geowissenschaften, Goethe University Frankfurt, Altenhoeferallee 1, D-60438 Frankfurt am Main (gerdes@em.uni-frankfurt.de)

Isotope analysis by laser ablation sector-field ICP mass spectrometry (LA-SF-ICPMS) becomes increasingly important to study magmatic, metamorphic, and sedimentary processes. The information gained can be, for instance, crucial for a better understanding of the timing and genesis of magmatic and sedimentary rocks, the formation of ore deposits, and the evolution of the continental crust. Due to disturbance of the isotope system by alteration and partial recrystallization the initial isotope composition is often preserved only in single growth domains of minerals.

Developments in LA-SF-ICPMS over the last years make it now possible to analysis precisely the isotopic composition of Sr, Nd, Hf, and U-Th-Pb with a spatial resolution of down to 30 to 5μm, depending on elemental concentration. Hence, a very sensitive detection system coupled to powerful Laser with short wave length and high resolution imaging system is crucial for this type of analyses.

Beside high background (e.g., gas blank), matrix effects, and mass bias correction, the precision and accuracy of these isotope analyses often strongly suffers from isobaric and molecular interferences on the relevant masses. Although these interferences in question can be usually monitored simultaneously on a different mass, the interference correction is hampered by prediction of the mass discrimination behaviour of this isotope pair.

Data will be shown that the discrimination of the lighter isotopes in the plasma interface of the ICP-MS is dependent on element and on the matrix. With examples from the different isotope system, analytical protocols will be discussed to overcome this problem. The results of recent studies performed in our lab demonstrate that LA-MC-ICPMS analyses of $^{87}Sr/^{86}Sr$ (e.g., plagioclase, titanite, apatite, monazite, xenotime, pyrochlor, perovskite), $^{143}Nd/^{144}Nd$ (e.g., titanite, monazite, apatite, pyrochlor, perovskite, garnet) and $^{176}Hf/^{177}Hf$ (e.g., zircon, zirconolite, baddeleyite) isotopes can be precise and accurate to about 0.01% or better, despite of 10 to >50% interference on the relevant isotope ratio. Providing that between different phases the range in the mother-daughter isotope ratio is sufficient large enough, it is even possible to obtain geologically meaningful isochrones in the Rb-Sr and Sm-Nd system by LA-MC-ICPMS analyses.

Geochemical signatures of thermochemical sulfate reduction – Ketones and sulphur species

S. GERMEROTT[1], C. OSTERTAG-HENNING[2] AND H. BEHRENS[1]

[1]Institute for Mineraloy, Leibniz University of Hannover, Callinstr. 3, 30167 Hannover, Germany (*correspondence: s.germerott@mineralogie.uni-hannover.de)

[2]Federal Institute for Geosciences and Natural Resources, Stilleweg 2, 30655 Hannover, Germany

Thermochemical sulfate reduction (TSR) is defined as the abiological, thermally-driven reduction of sulfate with H_2S and CO_2 as major reaction products. The reaction can proceed at temperatures above 120°C when sulfate as well as reducing agents, such as e.g. hydrocarbons or ferrous iron, are present. In spite of its great importance for hydrocarbon reservoir alteration and sulfide ore formation, the TSR process is not adequately understood. In this study we present findings from laboratory experiments that lead to an improved description of the geochemical signature of TSR and thus to a better understanding of TSR reaction mechanisms. A major goal was to identify key chemical compounds that play an important role during TSR.

Experiments were performed in sealed gold capsules, at 300°C and 350°C, 350 bar, for a duration of 24 - 336 h. A redox-mineral buffer, consisting of pyrite (FeS_2), pyrrhotite (FeS) and magnetite (Fe_3O_4) was used to constrain the redox conditions during the experiments. Na_2SO_4, dissolved in water, was used as sulphate source and C_8H_{18} as model hydrocarbon (= reducing agent). Furthermore, the influence of elemental sulphur on the TSR reaction was investigated. After the experiments the products were analyzed by different gas chromatographic techniques. In addition to CO_2 and hydrocarbons, we focused on the analysis of ketones and organosulphur compounds.

In general, a higher reaction rate was found at 350°C compared to 300°C. Concurrent processes in the degradation of octane under the experimental P-T conditions comprise cracking and TSR reactions. A pronounced influence of TSR was indicated by the formation of CO_2, ketones, aromatics and organosulphur compounds. The experiments with elemental sulphur showed the highest yields of TSR products. The analytical data suggest that the oxidation of carbon proceeds via one or more intermediate reaction steps with metastable oxygenated or sulfurized compounds, e.g. the formation of ketones.

Subcrustal CO_2 flux measurement in the Hranice hydrothermal Karst

MILAN GERŠL[1]*, EVA GERŠLOVÁ[1], DUŠAN HYPR[2] AND VLADIMÍR KOLEJKA[1]

[1]Czech Geological Surwey, Brno branch, Leitnerova 22, 679 36 Brno (* correspondence: milan.gersl@geology.cz)
[2]Czech Speleological Society, 6-18 tartaros, Brno

In the Hranice Karst (Czech Republic) the term thermomineral karst was introduced to the international literature [1]. This active thermal karst is developed in the sequence of Paleozoic limestones as a result of deep influx of thermal water charged with subcrustal carbon dioxide (CO_2). Gas origin is also supported by helium isotopic ratio in water-gas mixture [2]. The carbon dioxide concentration in Zbrašov aragonite cave atmosphere reflects seasonal temperature variation and is well documented and described for the last 30 years [3].

Measurement techniques

CO_2 flux measurement was performed in 2009–2010 using accumulation chamber equipped with infrared analyzer in the Hranice field area. CO_2 flux was measured in the Zbrašov aragonite cave system during the summer 2010. The cave atmosphere was suck out to get permanent flow of CO_2. This status was hold for 6:27 hours. Chemical and isotopic composition of selected gas samples were determined in the laboratory by gas chromatography / mass spectrometry.

The average CO_2 concentration was 2.529% and flux ranged from 74 to 125 $g.m^{-2}.d^{-1}$ reflecting venting of subcrustal CO_2 in the Hranice area. In the Zbrašov aragonite cave the CO_2 concentration in the atmosphere varies from 0 to 85% with measured constant flux of 32894,45 $g.m^{-2}.d^{-}1$.

Ophiolites of the Kuznetzky Alatau Ridge (SW Siberia) as a possible ancient crust fragments of the Paleoasian Ocean

I.F. GERTNER* AND T.S. KRASNOVA

Tomsk State University, Lenin avenu 36, 634050 Tomsk, Russia, (*correspondence: labspm@ggf.tsu.ru)

An assessment of initial stages of the Paleoasian Ocean opening is still a matter of researcher's argument. Besides it assumes a quite long time interval which, according to the geodynamic reconstructions within Altay-Sayan folded area, ranging from 700 to 1000 Ma. One of the reasons for doubts about geochronology evaluation of the ophiolitic suite fragments is isotopic data absence for the rocks with ultrabasic and basic composition which are oceanic crust and lithospheric mantle standard.

Ophiolites of the Kuznetsky Alatau Ridge trace an ancient suture zone formed as a result of the collision of few arc island terrains on the active margin of Siberian continent during the Late Cambrian and Early Ordovichian time (530-480 Ma). Their absolute ages was recently estimated by the Sm-Nd mineral isochron for the amphibolite (694±43 Ma) and results of U-Pb dating of zircons from the plagioriolite spaitly associated with ocean basalts (544±8Ma). According to regional geological conclusions the real temporal range of ophiolite forming is about 500 Ma (from Early Cambrian to Late Riphean time). Our data of Sm and Nd isotopes for the whole rocks of mantle hyperbasites and ultramafic-mafic rocks are close to ancient boundary of these rocks.

The Sm-Nd isochron based on the three whole rock samples of harzburgite, chromitite and dunite has a slope corresponding to the age 947±51 Ma at MSWD = 1.18. But the 6-point regression line based on the whole rocks magmatic peridotites and gabbroides of toleitic series is a more reliable. Its slope corresponds to the age 943±39 Ma at MSWD = 0.966. In particular the restitic ultrabasites correspond to the characteristics of the strongly depleted backarc basin -type mantle substrate. Their model age calculation with using modern depleted mantle model certainly suggests a younger initial substrate. For the "restitic" ultrabasites T (DM) values range from 760 to 866 Ma, whereas for "magmatic" rocks these values corresponds to the real isochron age of 945-1000 Ma. These data confirm a possible geochemical heterogeneity of ultramafic-mafic complexes in the suture zone of the thrust-folded systems.

The study was funded by Russian Ministry of Education and Science.

Mantle heterogeneities beneath Laguna Timone volcano, Pali Aike volcanic field, Southern Chile

F. GERVASONI[1]*, R.V. CONCEIÇÃO[1], T.L.R. JALOWITZKI[1] AND Y. ORIHASHI[2]

[1]Geoscience Institute, UFRGS, Porto Alegre - RS, Brazil (*correspondence: fernanda.gervasoni@ufrgs.br)
[2]Earthquake Research Institute, The University of Tokyo, Tokyo, Japan (oripachi@eri.u-tokyo.ac.jp)

Laguna Timone(52°01'39"S, 70°12'53W), inactive Quaternary volcano in Pali Aike volcanic field [1], southernChile, host large mantle xenoliths from the lithosphere. They are characterized by spinel-lherzolite, garnet-spinel-lherzolite, garnet-lherzolite, garnet-harzburgite, glimmerite (PM18-3) and some xenoliths are phlogopite- and/or pargasite-bearing, which suggest their origin in mantle deeper source and a metasomatism. Geochemical data show #Mg between 88 to 91 and major elements depletion compared to primitive mantle (PM) [2]. Rare earth elements (REE), normalized to PM, suggests four: Group 1 has light REE depletion and heavy REE enrichment (Ce_N/Yb_N= 0.12-0.43); Group 2 has LREE enrichment and HREE depletion (Ce_N/Yb_N=2.07-15.3); Group 3 have middle REE enrichment and depletion (Ce_N/Yb_N= 0.96-0.98), and Group 4 have similar values between LREE and HREE (Ce_N/Yb_N= 0.78- 1.68). All samples are more enriched in Ta than Nb, and are strongly depleted in Y; Zr and Hf are enriched in most samples. The Sr and Rb are depleted while Ba is enriched. Spider diagrams show anomalies in some samples such as Nb, Ta, Zr and Hf high enrichment in sample PM18-3. Calculations with no-modal batch melting model shows that Laguna Timone xenoliths have suffered ~20% of melt. The Rb-Sr, Sm-Nd and Pb-Pb isotopes analysis are under progress. Laguna Timone xenoliths came from a deep source in the Patagonian mantle and suffered several thermal multi- stage, indicated by mineralogic evidence (garnet-lherzolite to spinel-lherzolite transitions phases) and a modal metasomatism (phlogopite and pargasite).

Geodynamic regimes of continental crust growth and lithosphere reworking in subduction zones

TARAS GERYA

Institute of Geophysics, Swiss Federal Institute of Technology, Sonneggstrasse 5, 8092 Zurich, Switzerland, (taras.gerya@erdw.ethz.ch)

It is widely accepted that new continental crust can grow in subduction zones. Indeed, physical-chemical controls and dynamics of crustal addition remain partly enigmatic. Based on numerical models we identify the following geodynamic regimes of subduction, crustal growth and lithospheric reworking which may potentially form on Earth: (1) stable subduction, (2) retreating subduction with a focused backarc spreading center, (3) retreating subduction with distributed intra-arc extension, (4) advancing subduction with thickening overriding plate. Transitions between these different regimes are mainly caused by the concurrence of rheological weakening effects of (1) aqueous fluids percolating from the subducting slab into the mantle wedge and (2) melts propagating from the partially molten areas formed in the mantle wedge toward the surface. The aqueous fluids mainly affect the forearc region. Strong fluid-related weakening promotes plate decoupling and reduces subduction drag and thus results in stacking of sediments in the accretion prism. In contrast, reduced weakening by fluids results in strong coupling of the plates and leads to advancing collision-like subduction with enhanced subduction erosion. Thickening of the overriding plate and sedimentary plumes in the mantle wedge are the consequences. On the other hand, melts, extracted from the hot regions above the slab, rheologically weaken the lithosphere below the arc which thus controls overriding plate extension and shortening. Strong rheological weakening by melts in combination with weak plate coupling triggers retreating subduction with a pronounced backarc spreading center. Also, weakening of the arc by melts extracted from sedimentary plumes, generate weak channels through which these structures may be emplaced into subarc crust. If there is insufficient melt-related weakening, plumes cannot ascend but extend horizontally and thus underplate the lithosphere. Models with notable melt- and fluid-related weakening often predict existence of hot, rheologically weak asthenospheric window in the bottom of the arc that allows for potential relamination of positively buoyant subducted rocks to the crust and recycling of dense magmatic residue back into the mantle.

[5]Université Moulay-Ismaël, BP 141, Errachidia, Maroc.

In southwestern Morocco (northern Sahara border) hydrothermal travertine deposits ($CaCO_3$) occurred covering several km^2 with a thickness up to 15m. The main interest in dating such deposits is that travertine formations are generally regarded as remnants of Quaternary humid phases. A continuous core of 12 m mainly consisting of pure $CaCO_3$ alternating with detrital layers of clay was sub-sampled for U-series dating (pure $CaCO_3$) and for magnetic properties in layers rich in detritus. The magnetic record results indicated two main features: 1) normal polarity inclinations with a mean value around 40° is found for all measured samples from surface until 9.03 meter deep and 2) at 9.05 meters deep, reverse polarity inclinations abruptly appear with a mean inclination value around –40°. This polarity inversion was attributed to the Brunhes-Matuyama transition.

U-series dating indicates that samples from the top of the core up to 5.6 m yield ages ($^{230}Th/^{234}U$), ($^{234}U/^{238}U$) compatible with statigraphy ranging between 500 ka and present-day. On the other hand, all samples below the depth of 5.6 m indicate infinite ages implying that secular radioactive equilibrium is reached from this depth down. However, samples above 5.6 m that yielded finite ages allowed us to calculate an initial $(^{234}U/^{238}U)_0$ value for the hydrothermal fluid from which the $CaCO_3$ was precipitated. This calculation was also carried on samples collected in outcrop or section near the coring site that gave calculable ages. Compiling these initial values, the frequency histogram of $(^{234}U/^{238}U)_0$ shows an almost unimodal distribution with a mean value of 5 ± 0.5 for all samples (< 500 ka). Assuming this value constant before 500 ka, we calculated the time needed for the $(^{234}U/^{238}U)_0$ of samples to reach the measured one for the samples older than 500 ka. The decay of ^{234}U excess depends on its half-life (245.2 ± 0.49 ka) and may allow to date up to 10^6 y. We find an age of 800 ± 50 ka for samples located at depth between 8 and 10 m. This age is in agreement, though less precise, than the age of Brunhes-Matuyama transition of 780 ka.

Two easy methods in evaluation of an exploration data set

R. GHAVAMI- RIABI[1]*, R. KHALO-KAKAI[1] AND H. ASADI-HARONI[2]

[1]Mining, Petrolum and Geophysics Faculty, Shahrood Univ. of Tech, 7 Tir square, Danshgh Bolv.

Mineralized factors and data

There are two type of statistical analyses for an easy and rapidly evaluation of an exploration data set. It is possible to evaluate and separate the mineralized and pathfinder elements in an exploration data set by using the discrimination and correspondence analyses [1,2,3]. The results of the two method confirm each other for a data set in the study area (Fig. 1 A and B) [4]. The data will be separated into a few sub-populations, if there are a few source of variation in the concentrations (Fig. 1-A). The anomalous sample numbers could distinguish by using correspondence analysis (Fig.1-B).

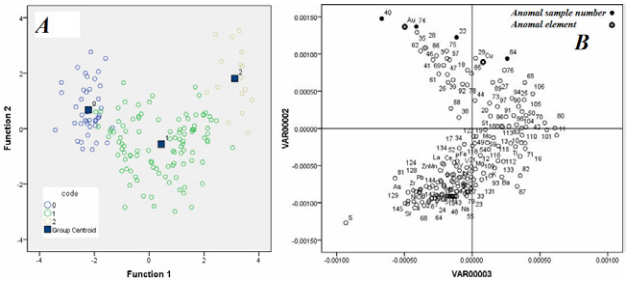

Figure 1: Discrimination (A) and correspondence (B) analysis of an exploration data set

Conclusion

It is important to identify the source of anomaly in a data set, paragentic parameters, and separation of the highly and relatively anomalous data in an exploration or envirnomental evaluation. These aims could be accessable by using discriminationa nd correspondence analyses togetther.

Arsenite oxidation by indigenous bacteria in the Bengal Delta Plain Aquifers (West Bengal, India)

DEVANITA GHOSH[1], JOYANTO ROUTH[2]* AND PUNYASLOKE BHADURY[1]

[1]Dept of Biological Sciences, IISER Kolkata, Mohanpur - 741252, Nadia, West Bengal, India

[2]Dept. of Earth Sciences, IISER Kolkata, Mohanpur - 741252, Nadia, West Bengal, India

(*correspondence: joyanto.routh@iiserkol.ac.in)

Microbial oxidation of arsenite occur in numerous phylogenetically distinct microorganisms, which play a role in As cycling by converting arsenite to the more strongly sorbing, less mobile, and toxic arsenate species[1].

We are studying biogeochemical processes associated with As cycling in Barbakpur village, Rahamatpur block, West Bengal – a region severely affected by high (up to 1 mg/l) As concentrations in groundwater. Water and sediment samples were collected to isolate microorganisms oxidizing arsenite. A new set of primers was designed based on amino acid alignments of several published arsenite oxidase subunit B (*AroB*) genes [2]. Besides, eubacterial 16S rRNA primers were also used to study the microbial communities. *AroB*-like sequences were detected in three wells. Molecular phylogeny based on *AroB* and 16S rRNA sequences reveal the presence of diverse bacterial groups. In addition, ongoing geochemical studies focus on characterizing the organic matter in sediments, which sustain these heterotrophs, arsenite speciation, and trace metal analyses [3].

Stability of phase D at high pressure and temperature: Implications for the role of fluids in the deep mantle

SUJOY GHOSH AND MAX W. SCHMIDT

Institute of Geochemistry and Petrology, ETH Zurich, Switzerland (sujoy.ghosh@erdw.ethz.ch)

Water is transported into the Earth's interior via hydrous phases in descending slabs. Numerous high-pressure studies have clarified that several dense hydrous magnesium silicates (DHMS) are stable at mantle conditions in model compositions [1, 2]. These phases act as water carriers in the subducting slab and may play a critical role in water cycling in the Earth's history and partial melting in the deep mantle. Among these DHMS, phase D is the DHMS phase hosting water in the lower part of the transition zone (where slab may travel along the upper/lower mantle boundary) carrying H_2O from the upper to the lower mantle.

In the present study, we report data on the melting phase relations of phase D and of phase D + olivine + enstatite in (i) MgO-SiO_2-H_2O system (ii) with Al_2O_3 and (iii) with Al_2O_3 + FeO added in proportions appropriate for the mantle. Stochiometric oxide mixtures of brucite and quartz of phase D composition were used as starting material. Multianvil experiments were carried out at pressures between 22 and 24 GPa at temperatures between 1000 and 1800 ºC using 10/3.5 pressure assembly.

Our data show that phase D decomposes to MgSi-ilmenite + stishovite + melt or MgSi-perovskite + stishovite + melt and indicate that phase D can be stable along a slab geotherm up to the base of the upper mantle for a range of H_2O contents. Melt compositions are strongly magnesian with Mg:Si ratio of 1.5-5.2. Furthermore, mass balance calculation of the phase D composition experiments (with Al, Fe) compostion suggests that melts can contain ~ 34 wt% H_2O which fits well with EPMA analysis. The data are used to determine the stabilty of phase D, the proportions of melt formed during melting, the composition of the partial melts and the variation in the melt composition at different pressure temperature conditions. Upon thermal relaxation (to adiabatic temperatures)of a slab travelling along the 660 km discontinuity, phase D would melt releasing a H_2O-rich magnesian melt from the slab. At present experiments at 32 GPa are under way to constrain the P-T slope of the melting.

Impact of groundwater composition and diffusive transport limitations on uraninite stability

D.E. GIAMMAR[1]*, J.M. CERRATO[1], C.J. BARROWS[1], Z. WANG[1], V. MEHTA[1], J.S.-LEZAMA-PACHECO[2] AND J.R. BARGAR[2]

[1]Department of Energy, Environmental and Chemical Engineering, Washington University, St. Louis, MO 63130, USA (*correspondence: giammar@wustl.edu)
[2]Stanford Synchrotron Radiaion Lightsource, SLAC National Accelerator Laboratory, CA, USA

The long-term stability of biogenic uraninite in sediments and groundwater are important to the performance of *in situ* bioremediation strategies for uranium-contaminated sites. Stability is influenced by subsurface biogeochemistry, structure and composition of uraninite (UO_2), and coupling with pore scale transport processes. Laboratory measurements of UO_2 dissolution rates under well-mixed and diffusion-limited regimes were integrated with direct characterization of the solid phase to investigate the effects of groundwater cations on UO_2 stability.

Groundwater contains abundant ions that can moderate U release from biogenic uraninite. Experiments were performed with Ca^{2+} and Zn^{2+} as model non-redox active groundwater cations with differing affinities for adsorption to metal oxides. Calcium only slightly inhibited UO_2 dissolution, but zinc had a much greater inhibitory effect. Complementary sorption experiments verified that Zn^{2+} adsorbed more strongly than Ca^{2+} to the uraninite surface. The inhibition of dissolution by the cations is orders of magnitude stronger for oxic conditions than for anoxic conditions, which suggests that the adsorbing or surface-precipitating cation is acting to block the access of oxygen to the UO_2 surface or inhibit the electron transfer from the UO_2 to a soluble oxidant. The molecular-scale structure around calcium and zinc species present at UO_2 –water interfaces were determined using X-ray absorption spectroscopy.

To examine UO_2 dissolution under diffusion-limited conditions, experiments separated the reacting UO_2 from the bulk solution by placing it in a tube covered with a membrane that allowed diffusive exchange of solutes. Slower net release rates of uranium from the tubes were caused by modest diffusive limitations to oxygen transfer to the UO_2. Experiments were performed in both simple aqueous solutions and synthetic groundwaters to further explore the role of groundwater cations on the dissolution process.

Cu speciation in coastal waters using a vibrating gold microwire electrode

K. B. GIBBON-WALSH, P. SALAÜN AND C.M.G. VAN DEN BERG*

Marine Electrochemistry, School of Environmental Sciences, University of Liverpool, Liverpool, L69 3GP, UK (*correspondence: vandenberg@liv.ac.uk)

Cu speciation by pseudopolarography

Pseudopolarography (PP) was developed and optimised for use on a vibrating gold microwire electrode with the intention of developing a more sensitive technique for the speciation of Cu in seawater, with potential for in-situ application. The method was optimised and a desorption potential and conditioning sequence improved the electrodes reproducibility. Model ligands, including glutathione and other well characterised ligands[1] were studied in order to estimate the strength and class of Cu complexing ligands in Liverpool Bay.

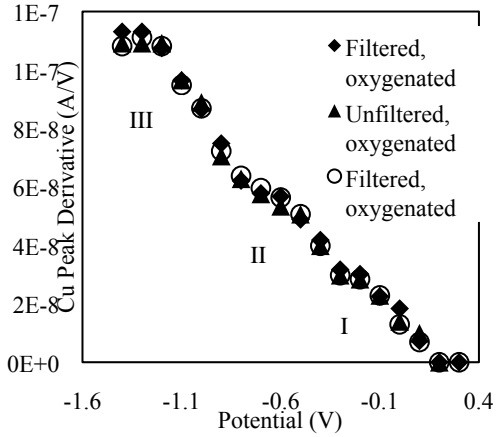

Figure 1: On-board PP analysis in oxygenated coastal sea water (Liverpool Bay)

Cu pseudopolarograms performed on-site, in coastal sea water from Liverpool Bay always show a succession of waves (Fig 1.). The most positive wave corresponds to free+labile Cu complexes while wave II and III represents more strongly bound complexes. Only minor variations were observed between filtered/unfiltered sample and oxygen is not an interference highlighting the potential of the technique to be used in-situ.

Paleogene hyperthermals represent transient global warming events associated with massive carbon injection into the ocean-atmosphere system. Because the rate and magnitude of carbon release varied between the events, they are natural experiments ideal for exploring the relationship between carbon cycle perturbations, climate change and biotic response. Here we investigate how we can quantifiably compare biotic responses to events of differing magnitudes and environmental character, to utilise the wealth of high-resolution microfossil data emerging across a range of climate change scenarios. We quantify marine biotic variability through several hyperthermals from 56 to 40 million years ago, using records of evolutionary turnover and assemblage variance. Microfossil records from the biologically and functionally distinct plankton groups show a linear relationship between assemblage variability and the magnitude of carbon cycle perturbation during the various hyperthermals. These Paleogene plankton data show threshold behavior and scaled response to environmental changes associated with carbon cycle perturbations reflecting behaviour likely inherent in planktonic ecosystems and may suggest future biotic response may scale at least in a similar way to the hyperthermals.

Experimental investigation of the differentiation of iron-rich peralkaline magma

CHRISTOPHER GIEHL*, RAINER BABIEL, STEPHAN REICHE, MICHAEL MARKS AND MARCUS NOWAK

Institute for Geosciences, Eberhard-Karls-University, 72074 Tuebingen, Germany (*correspondence: christopher.giehl@uni-tuebingen.de)

In this study we investigate the magmatic differentiation of peralkaline Fe-rich phonolitic melts. These are highly evolved compositions ((Na+K)/Al ratios >1) and are believed to be differentiated from mantle-derived alkali basaltic and nephelinitic sources. The studied composition (FeO_{tot} = 11.6 wt%, #Fe = 0.98, (Na+K)/Al = 1.46) resembles a dyke rock, which is a potential source magma for parts of the Ilímaussaq peralkaline nepheline syenite complex, South Greenland [1].

However, the liquid line of descent of such Fe-rich phonolitic compositions is not well understood because of a lack of experimental data. Therefore, we performed crystallization experiments with synthetic glass as starting material at 1 kbar and 950 to 750°C. We used hydrothermal rapid quench vessels and covered a wide range of water activities and oxygen fugacities using gold capsules and graphite-lined gold capsules. To achieve near-equilibrium conditions, run times of 4 hours were sufficient for H_2O-saturated experiments, in nominally anhydrous experiments run times of 3 weeks were necessary. H_2O-saturated experiments reproduce only parts of the observed early magmatic phases of the dyke rock (sp + cpx). In contrast, under nominally anhydrous and more reducing conditions, the complete early magmatic phase assemblage of the dyke rock (sp, cpx, ol, afs, ne) and an alkali-rich residual melt ((Na+K)/Al = 1.65) was successfully reproduced at and below 850°C. Experiments already conducted were carried out using an equilibrium crystallization approach. Upcoming experiments will simulate fractional crystallization using multi-step differentiation to elucidate the complex differentiation process due to the unusually large temperature interval of crystallization suggested for such magma compositions.

Dust particles in brochoalveolar lavage fluids from coal miners in Quang Ninh province, Viet Nam

R. GIERÉ*, T.B. HOÀNG-HÒA AND K.P. SEDLAZECK

Albert-Ludwigs-Universität, 79104 Freiburg, Germany
(*correspondence: giere@uni-freiburg.de)

Inhalation is the most important pathway for airborne particles into the human body. The pulmonary system provides an efficient filtering mechanism, which retains most of the coarse particles in the nasal and oral cavities. The fine-particle fraction (≤2.5 μm aerodynamic diameter) penetrates deeper into the respiratory tract and reaches the alveolar region. Here, the particles remain for long periods of time and interact with lung fluid and tissue. The deepest part of the lungs, thus, acts a special type of active sampler for atmospheric dust. The deposited particles can be studied in tissue samples or in brochoalveolar lavage (BAL) fluids.

This investigation aims at characterizing mineralogically and chemically the particles in BAL fluids, which were retrieved from coal miners in the Quang Ninh province, northern Viet Nam. The BAL fluids were filtered to recover the solid fraction, which was dried and studied by X-ray diffraction (XRD). The main mineral component is halite, an artefact from the sterile saline solution (0.9 wt% NaCl, heated to 37 ºC) used during the lung lavages. One of the samples also contains thenardite (Na_2SO_4) and gibbsite ($Al(OH)_3$).

To remove halite, all samples were rinsed repeatedly with deionized water, filtered and dried, and then subject to further investigations. These residues contain the following main components (in wt%): C = 3.3-4.8; Al = 1.7-7.4; Si = 24-94; and Fe = 0.7-1.2. Minor amounts of Na, Mg, S, K, Ca, Cr, Zn, Cd, Ba and Pb are also present, whereas Ni, Cu, As, and Sb were not detected.

XRD analysis of the washed residues revealed that they contain primarily quartz and gibbsite. We are currently using scanning electron microscopy, combined with energy-dispersive X-ray spectroscopy (SEM-EDX), to collect quantitative data on the mineralogical composition of these residues. So far, we have detected the following additional phases: clay minerals, Cr-Fe(Ni)-alloys, K-feldspar, Fe-sulfides, Fe-oxides/hydroxides, gypsum, calcite, dolomite, fly ash spheres, and coal particles. One of the residues also contains Mg-silicates, indicating that the coal miner may have worked in a silicate mine in the past.

Through BAL analysis it is thus possible to deduce the occupational exposure of subjects. This technique could also be applied to humans living in areas with high levels of particulate pollution to identify the main particle sources.

Origin of the differences in redox reactivity of iron (oxyhydr)oxides revealed by time-resolved spectroscopy

[5]Pacific Northwest National Laboratory, USA.

The redox chemistry of nanoscale transition metal oxides, hydroxides and oxyhydroxides is of central importance to broad areas of the Earth sciences, including soil and marine biogeochemistry, contaminant remediation, and paleoclimate records. Iron-bearing phases are the most important redox-active minerals in nature and the complex chemistry of these materials exemplifies the challenges in understanding solid phase redox reactions. For example, following the exposure of ferric iron (Fe^{3+}) (oxyhydr)oxides to reducing agents, interfacial electron transfer (ET) can lead to several transformation pathways including release of soluble ferrous iron (Fe^{2+}) (dissolution), formation of alternative ferric or mixed valence phases (transformation), or particle growth. Understanding and predicting such redox processes will require the application of time-resolved methods capable of observing the intermediate species that control reaction path.

We have applied an optical-pump–X-ray-probe method with subnanosecond time resolution to study the fate of ferrous iron sites formed by electron injection at the surface of three phases of ferric iron (oxyhydr)oxides. We used this approach, combined with conventional kinetics studies, to distinguish the timescales for the elementary redox processes occuring during the reductive dissolution of 6-line ferrihydrite, maghemite and hematite nanoparticles. For each phase we quantified the rates of Fe-to-Fe electron hopping, the rates of interfacial electron transfer, the lifetime of kinetic electron trapping within the nanoparticles, and the rates of the full reaction including ferrous iron release into solution. Comparison of these rates which span from the nanosecond to the second scale reveal new insights into the electronic and structural factors controling the redox reactivity of these phases.

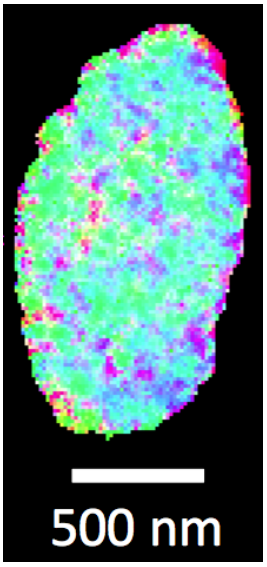
Mapping the amorphous-to-crystalline transitions in $CaCO_3$ biominerals with 20-nm resolution

P.U.P.A. GILBERT

Departments of Physics and Chemistry, University of Wisconsin, Madison, WI 53706, USA (pupa@physics.wisc.edu)



One of the most fascinating aspects of calcite biominerals are their intricate and curved morphologies, quite different from the normal rhombohedral crystal habit of geologic calcite. These morphologies are achieved via amorphous precursor mineral phases [1]. In this talk we will show that in sea urchin larval spicules two distinct phase transitions occur, 1→2 and 2→3 [2]. The 1→2 transition is regulated by inhibiting proteins, while the 2→3 is thermodynamically driven, and occurs spontaneously [3].

Figure 1: Cross-section of a 48-h sea urchin larval spicule, caught in the act of transforming from ACC (type 1 = red, type 2 = green) to crystalline calcite (type 3 = blue), and with imaged XANES-PEEM spectromicro-scopy.

Natural and artifical noble gases as tracers of injected CO_2 migration within a deep reservoir

STUART GILFILLAN[1]*, R. STUART HASZELDINE[1], ROBERT POREDA[2] AND SUSAN HOVORKA[3]

[1]Scottish Carbon Capture and Storage, University of Edinburgh, UK. (*correspondence: stuart.gilfillan@ed.ac.uk)

[3]Gulf Coast Carbon Center, Bureau of Economic Geology, University of Texas at Austin, Texas, USA.

CO_2 capture and subsequent geological storage of CO_2 is gaining momentum as a means of economically abating anthropogenic CO_2 emissions from point sources. For the technology to be universally deployed it is essential that a robust, reliable and inexpensive means to trace the migration of CO_2 within the subsurface exists. Monitoring during injection will increase confidence that the site characteristics were correctly determined and met. Furthermore, should migration and subsequent surface leakage occur, the ability to track origin and ownership of CO_2 at near and ground surface will be critical for remediation purposes.

As an analogue for tracing CO_2 migration within an engineered storage site, this presentation will examine both natural and artificially injected noble gases at the SECARB early project at Cranfield in MS, USA. Natural CO_2 rich in mantle derived noble gases was injected into a portion of the reservoir via a deep injection well and samples were collected via U-tube sampling equipment from two nearby observation wells. Additionally, two separate injections of artificial Kr and Xe tracers injected with the CO_2 were undertaken.

Noble gases are conservative tracers within the subsurface, proving to be invaluable in determining both the origin of CO_2 and how it is stored in natural CO_2 reservoirs [1,2]. This presentation will compare measurements of the natural $^3He/^4He$, $CO_2/^3He$, ^3He, ^4He, Ne and Ar concentrations within the reservoir prior to CO_2 breakthrough with those after CO_2 arrival at the observation wells. We show that a component of the He fingerprint observed in the injected CO_2 can be clearly traced in both observation wells. Additionally, we see a clear spike in Kr and Xe concentrations following CO_2 break through. Our results show that CO_2 can be traced within a storage site using noble gases, illustrating significant potential for monitoring CO_2 migration in future engineered storage sites.

Tracing mantle enrichments into oceanic crust and hydrothermal systems, Juan de Fuca Ridge

JAMES GILL

Earth and Planetary Science Dept., UCSC, Santa Cruz CA 95064 USA (jgill@pmc.ucsc.edu)

High-precision Pb isotopes have become useful in discovering segment-scale (<100 km) heterogeneity in MORB sources. Here I describe how this heterogeneity co-varies with other isotopes and with major and trace elements within a 10-km long "4th order" segmentation of the axial magma chamber at the Endeavour segment of the Juan de Fuca Ridge, and how this heterogeneity is passed on to hydrothermal systems. Basalts in the one km-wide axial valley at Endeavour are characterized by large (3 to 4-fold) variations in their K/Ti, Zr/Nb, and La/Yb ratios at 7-8% MgO. Variations in Sr, Nd, and Hf isotopes are small (<0.0001) but correlate with the element ratios. Variations in Pb isotopes are larger ($^{206}Pb/^{204}Pb$ = 18.4-18.9) and therefore more useful. Pb correlations lie below the NHRL. $^{206}Pb/^{204}Pb$ correlates best with HFSE-enrichment, especially Nb. That correlation differs from what is seen along the southern JdFR and EPR, and defines a type of mantle enrichment specific to the northernmost JdFR. This enriched mantle only began to be tapped within the last ~30 Ka. Qualitatively, I attribute the enrichment to a young pyroxenitic source with a lower solidus than the surrounding perodotite, and with "C"-type isotopic characteristics. The Pb in the vigorous hydrothermal systems at Endeavour is entirely basalt-sourced, without evidence of sediment, which leaves the anomalously high CH_4 and NH_3 in the hydrothermal fluids unexplained. Preliminary results indicate differences in Pb isotopes between hydrothermal fields a few km apart. This may help to map their recharge zones and the integrated architecture of the basaltic crust.

Kinetics of free radical formation at mineral-water interfaces

C. GIL-LOZANO *[1], A.F. DAVILA [2], A.G. FAIREN[2] AND L.G. DUPORT[1]

[1]Universidad de Vigo. 36200 Vigo. Spain. (*correspondence: karolina_gil@uvigo.es)
[2]SETI Institute, Mountain View, CA 94043, USA.

The formation of free radicals on sulphide and silicate mineral surfaces [1,2] is a relevant topic due to its great importance in the treatment of mine wastes, geomedicine and, more recently, as an hypothetic oxidation pathway on Mars and Early Earth [3]. Although the atomic mechanisms involved in mineral surface reactions are relatively well understood, the kinetics pathways as well as the time extent of these reactions in natural environments have not yet been well characterized.

In this work, the kinetics of H_2O_2 generation at mineral–water interface was monitored with real time microlectrode measurements. Experiments were performed under continuous stirring by using aqueous slurries of pyrite, antigorite, olivine, and glauconite, as sample probes, in both oxic and anoxic conditions

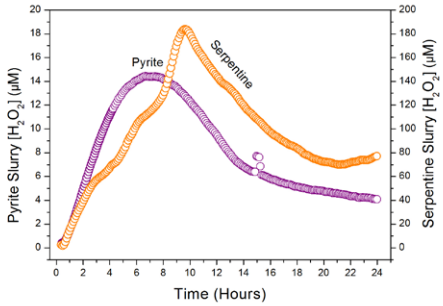

Figure 1. Kinetic of H_2O_2 formation from pyrite and serpentine slurries in water, under anoxic conditions.

Our experimental results show that, under oxic conditions, peroxide formation takes place very fast at the initial stages of the process with a significant consumption of $O_2(g)$, whereas, under anoxic condition, the rate of H_2O_2 generation proceeds more slowly, giving rise to the formation of $O_2(g)$ as a by-product and, thus indicating the presence of different reaction mechanisms. Preliminary kinetics models based on the experimentally determined constants, coupled with surface complexation calculations, will also be presented.

Evaluation of thermodynamic data and activity coefficient models for the geochemical modeling of CO_2 storage systems

M.J. GIMENO*, P. ACERO, V. GUTIÉRREZ, L.F. AUQUÉ, M.P. ASTA AND J. GÓMEZ

Earth Sciences Dpt., University of Zaragoza, Spain (*correspondence: mjgimeno@unizar.es, patriace@unizar.es, vane_rodrigo@hotmail.com, lauque@unizar.es, mpasta@unizar.es, jgomez@unizar.es)

The selection of adequate CO_2 geological storage systems and the evaluation of their storage capacity and behavior rely largely on geochemical modeling, whose results are strongly dependent on the selection of appropriate thermodynamic data and approaches.

In this study, two groups of geochemical calculations were carried out to gain insight into the influence of those issues. In the first group of calculations, the saturation state of several dilute groundwaters with respect to different mineral phases potentially relevant in geologícal storages for CO_2 was assessed by using different geochemical codes and thermodynamic databases. For the second group of calculations, the geochemical evolution in the direct vicinity of a hypotethical well during the dessication caused by the injection of supercritical CO_2 into two types of saline aquifers was simulated with the assistance of the PHREEQC code (Parkhurst and Appelo, [1]) by using two different databases and approaches for the calculation of activity coefficients included with the code: (1) the Wateq4f.dat database with an ionic association approach, and (2) an improved version of the pitzer.dat database with the specific ion interaction approach developed by Pitzer [2].

In the calculations for the dilute groundwaters, signifficant differences in the saturation indexes are only obtained for minerals for which varieties with different cristalinity are included in the databases (remarkably for dolomite). For the modelling exercises focused on the evolution of saline waters, the main differences between the results obtained by the two model approaches described above, are mainly related to the order and dessication degree at which different mineral phases precipitate and to the amounts of precipitated minerals throughout the simulations.

Age and origin of alkaline lavas from Tore-Madeira Rise: Interactions between complex lithosphere motion and multi-components source

J. GIRARDEAU[1], R. MERLE[2]*, A. MARZOLI[2] AND M. CHIARADIA[3]

[1]Université de Nantes, 2 rue de la Housssinère, 44322 Nantes, France (Jacques.Girardeau@univ-nantes.fr)

[2]Università di Padova, via Gradenigo 6, 35100 Padova, Italia (*correspondence: renaud.merle@unipd.it; andrea.marzoli@unipd.it)

[3]Université de Genève, 13 rue des Maraîchers, 1205 Genève, Switzerland (Massimo.Chiaradia@unige.ch)

The Tore-Madeira Rise (TMR) is an alignment of seamounts of 1000×50 km oriented SSW-NNE, extending from the Tore seamount, located 300 km west of Lisbon, to the archipelago of Madeira. Here, we document the petrology, geochemistry and isotopic characteristics of TMR lavas from 22 dredging sites, located on 13 seamounts and 5 localities on Tore seamounts. The exclusive occurrence of alkaline lavas (mafic and differentiated) substantiates the importance of alkaline magmatism in the TMR edification. The dredged basalts display typical OIB-like incompatible elements and REE characteristics similar to those observed in Madeira basalts. Reliable $^{40}Ar/^{39}Ar$ and U/Pb ages suggest five magmatic phases on the TMR and surrounding areas that can be related to the motion of the Iberian plate. No specific isotopic characteristics can relate to a given magmatic phase. Regardless of their age, the Pb isotopic compositions of the basaltic rocks plot below the NHRL, in the field of the Madeira archipelago lavas while the differentiated lavas display a trend from this field toward high $^{207}Pb/^{204}Pb$ which is interpreted as a contamination by the sub-continental lithospheric mantle (SCLM) of the Iberian margin. This precludes the involvement of two distinct mantle plumes (Canary and Madeira) in the genesis of the TMR lavas, as previously suggested. The isotopic composition of the basaltic lavas requires at least three distinct components. The main isotopic characteristics are related to a mixture between a depleted asthenosphere-like mantle and a HIMU-like component. The contribution of an EMI-like component is also required in particular to explain the isotopic characteristics of the Seine-Isabelle-Godzilla seamounts. Considering the position of these seamounts close to the southern branch of the Azores-Gibraltar Fracture zone, we interpret this EMI-like component as due to a sliver of SCLM trapped in the asthenosphere. However, this SCLM is distinct to those involved in the genesis of the differentiated samples.

Insights into marine microbial communities that couple anaerobic biogeochemical cycles to remote oxidants

PETER R. GIRGUIS[1]*, PENGFEI SONG[2] AND MARK NIELSEN[2]

[1]Harvard University, 16 Divinity Avenue Room 3085, Cambridge, MA 02138 (* correspondence: pgirguis@oeb.harvard.edu)
[2]Harvard University, 16 Divinity Avenue Room 3092, Cambridge, MA 02138

Extracellular electron transfer (EET) is a process whereby microbes shuttle electrons outside the cell, and access solid-phase oxidants as well as spatially remote oxidants. EET has been well-studied in cultivated microbes, e.g., heterotrophic iron-reducing δ-proteobacteria. The relevance of EET in nature, however, and its impact on biogeochemical cycles remains poorly constrained. Anaerobic marine sediments host microbial communities that are involved in numerous biogeochemical cycles, and those capable of EET would have access to solid-phase as well as remote oxidants. Here we present the first comprehensive data on the population structure and functional potential of marine bacteria associated with EET. These communities were recovered from two systems: the anode of a bioelectrochemical system (BES) deployed in marine sediments *in situ*, and a BES deployed in high temperature hydrothermal vents. These communities were dominated by distinct groups of Proteobacteria and Fusobacteria. Metagenomic analyses and geochemical considerations suggest that they are participating in a complex sulfur cycle that includes the recycling of sulfur among oxidizers, reducers and disproportionators. Unexpectedly, these analyses revealed numerous other physiological capacities. These data suggest that microbial EET is likely more widespread than previously considered, and the functional potential of these communities requires us to reconsider the canonical view of anaerobic sediment biogeochemistry. If these microbial metabolisms are coupled to remote oxidants such as oxygen and nitrate via EET, the biogeochemical cycling of these elements will likely be more vigorous than previously recognized (as these reactions become more thermodynamically favorable). The findings presented herein provide a plausible explanation for some previously observed elevated rates of recalcitrant carbon degradation, and underscores the need for further investigation into the relevance of EET to global biogeochemical cycles.

Aerobic hydrogen oxidation by a chemolithotrophic *Beggiatoa* strain

A.-C. GIRNTH* AND H.N. SCHULZ-VOGT

Max Planck Institut for Marine Microbiology, Celsiusstraße 1, 28357 Bremen, Germany
(*correspondence: acgirnth@mpi-bremen.de)

Hydrogen oxidation in oxic/anoxic gradients

Transition zones between oxic and anoxic environments are primary habitats for aerobic hydrogen oxidizers. In sulfidic sediments, filamentous bacteria of the genus *Beggiatoa* thrive within this narrow horizon and feature fine-tuned chemotactic responses to keep track of the interface. So far, only anaerobic hydrogen oxidation coupled to reduction of stored sulfur has been shown for a heterotrophic *Beggiatoa* strain [1]. Here we demonstrate aerobic hydrogen oxidation by the chemolithoautotrophic strain *Beggiatoa* 35Flor grown in a mineral medium featuring artificial oxygen, sulfide and hydrogen gradients.

Beggiatoa 35Flor uses hydrogen as an accessory electron donor

In the presence of hydrogen, *Beggiatoa* 35Flor mats exhibit higher oxygen consumption once the sulfide flux decreases, as indicated by a shorter distance of the mats to the air/agar interface. Microsensor profiles show that low hydrogen fluxes are continually and fully oxidized within the oxic region of the *Beggiatoa* mat. Higher hydrogen fluxes have initially a more pronounced influence on the mat position, but oxidation ceases after a few days for a yet not determinable reason. A gene encoding for the large subunit of a hydrogen uptake hydrogenase was retrieved from strain 35Flor. Supply with fixed nitrogen compounds does not impair the hydrogen-oxidizing capacity of this nitrogen-fixing strain, suggesting that the hydrogenase is regulated independently of the nitrogenase. This result indicates that hydrogen is used as an electron donor and not merely oxidized for energy recycling. All attempts to grow the strain 35Flor with hydrogen as the only electron donor failed so far.

Our findings show that the strain *Beggiatoa* 35Flor is capable of aerobic hydrogen oxidation when grown in gradient medium imitating its natural habitat. However, hydrogen appears to serve only as an accessory electron donor since growth on hydrogen alone could not be achieved.

The ash that closed Europe's airspace: Part I, grains size distribution of the Eyjafjallajökull ash and soluble salt coatings

S.R. GISLASON[1]*, E.S. EIRIKSDOTTIR[1], H.A. ALFREDSSON[1], N. OSKARSSON[1], B. SIGFUSSON[3], G. LARSEN[1], T. HASSENKAM[2], S. NEDEL[2], N. BOVET[2], C.P. HEM [2], Z.I. BALOGH [2], K. DIDERIKSEN[2] AND S.L.S. STIPP[2]

[1]Institute of Earth Sciences, University of Iceland, Reykjavik, Iceland; (sigrg@raunvis.hi.is)
[2]Nano-Science Centre, Department of Chemistry, University of Copenhagen, Denmark; (stipp@nano.ku.dk)
[3]Reykjavik Energy, Iceland.

On 14 April 2010, when magma from the Eyjafjallajökull volcano intruded glacier-meltwater, an explosive phreato-magmatic eruption sent unusually fine-grained ash into the jet stream. It quickly dispersed over Europe. Reported airplane encounters with ash have caused sand blasted windows and melting of particles inside jet engines, causing them to fail. Therefore, air traffic was grounded for several days. Concerns also arose about health risks from fallout, because ash can transport acids as well as toxic compounds. Most studies on ash are made on post-eruptive material that have mixed with other atmospheric particles and suffered exposure to water as rain or fog, which would alter surface composition. In this study, a unique set of dry ash samples was collected during the explosive eruption and compared with fresh ash with the same bulk composition from a later more typical magmatic event, when meltwater did not have access to the magma.[1]

Up to 70 mass % of the phreato-magmatic ash particles, collected 50 km from the source, was <60 μm in diameter, 22% was <10 μm and 11% was ≤ 4.4 μm. The finest grain size was found in the centre of the plume. The magmatic ash was coarser and its surface area was an order of magnitude smaller than for the explosive ash. The relative concentration of surface salts was significantly lower on the explosive ash than the magmatic ash, because less volatile compounds were available to condense on the surfaces when water and steam were present. Instead, they dissolved in the meltwater and were transported as solutes in the ensuing floodwaters. The surface salts dissolved rapidly when exposed to experimental and natural waters, releasing pollutants and nutrients. Some of the salts further enhanced bulk dissolution of the ash.

This paper is the first of a two part presentation, where the second part, by Susan Stipp, focuses on the characteristics of the nanoparticles.

The effect of time and climate on volcanic soil formation

S.R. GISLASON[1], E.S. EIRIKSDOTTIR[1], H.A. ALFREDSSON[1], B. SIGFUSSON[2], M.T. JONES[1] AND E.H. OELKERS[3],

[1]Institute of Earth Sciences, University of Iceland, Reykjavik, Iceland; (sigrg@raunvis.hi.is)
[2]Reykjavik Energy, Iceland.
[3]GET-Université de Toulouse-CNRS-IRD-OMP, 14 Avenue Edouard Belin, 31400 Toulouse, France

Andosols, soils derived from volcanic material, cover about 1.9% of the terrestrial surface and store about 4.9% of the Earth's carbon [1]. Andosols cover most of the volcanic islands on Earth. These soils are fertile, most of the islands are heavily populated and much of the river suspended matter delivered to the ocean stems from these islands. To a great extent, the sol is formed from air borne volcanic ash, preventing nutrient depletions with time, but making it prone to mechanical erosion.

In the days, weeks and months after deposition of air borne volcanic ash, nutrients and pollution will migrate into the soil at elevated rates. This is caused by soluble metal and proton salts coating the volcanic ash that dissolve orders of magnitude faster than the bulk volcanic ash that is mostly glass. Between these periodic fluxes of dissolved elements, weathering and erosion rates are primarily governed by climate, lithology, average rock age, topography and vegetation cover. A detailed study of catchements in NE Ieeland shows that for each degree of temperature increase the runoff, mechanical weathering flux, and chemical weathering fluxes in these catchments have been found to increase from 6 to 16%, 8 to 30%, and 4 to 14% respectively, depending on the catchment [2]. These results demonstrate a significant feedback between climate and Earth surface weathering on the timescale of years to millions of years [3], and suggest that weathering rates are currently increasing with time due to global warming.

Effect of alkali content and Fe oxidation state on the S oxidation state and solubility in rhyolitic glasses

G. GIULI[1]*, E. PARIS[1], R. ALONSO MORI[2], P. GLATZEL[2], M.R. CICCONI[1], B. SCAILLET[3] AND S.G. EECKHOUT[2]

[1]School of Science and Technology, Geology division, University of Camerino, ITALY

[2]European Synchrotron Radiation Facility (ESRF), Grenoble, France

[3]Inst. de Sciences de la Terre D'Orleans, UMR, CNRS-UO, Orleans, France

The Fe oxidation state, coordination geometry and <Fe-O> distances have been determined by Fe K-edge XANES and EXAFS for a set of sulphur bearing silicate glasses of rhyolite composition in the aim of determining: 1) the effect of bulk composition on the iron oxidation state and local structural environment;2) the effect of Fe oxidation state on sulphur behaviour in the corresponding magmas/melts. Glass compositions have been chosen so as to represent S- Cl-F bearing rhyolitic magmas with low to high alkali content. These glasses have been equilibrated at a range of different oxygen fugacity conditions typical of magmatic conditions and ranging from –15.4 to –10.75 log units (at 800 °C, 1.5 kbar). Comparison of the pre-edge peak data with those of Fe model compounds allowed to determine the Fe oxidation state and coordination number for all the glasses analysed. The $Fe^{3+}/(Fe^{3+} + Fe^{2+})$ ratio varies from 0.25 to 0.80 (±0.05) in the glasses studied. Moreover, pre-edge peak data clearly indicate that Fe^{3+} can be present in [4] and/or [5] coordination according to the alkali content of the glass, whereas Fe^{2+} is present in [5] coordination units for these compositions. The presence of minor amounts of [6] coordinated Fe cannot be ruled out by XANES data alone. EXAFS derived Fe-O distance in the most oxidised sample (Fe-O=1.85 Å) indicates that Fe^{3+} is in tetrahedral coordination. For these glass compositions, going from reducing to oxidising condition results in higher fraction of network forming $[4]Fe^{3+}$, thus increasing the polymerisation of the tetrahedral network.Alkali content has been found to have a very strongly effect on the Fe oxidation state: at a given oxygen fugacity, Fe oxidation state increase noticeably with increasing alkali content. A direct proportionality has been found between the S^{2-}/Fe^{2+} molar fractions. As Fe oxidation state is known to affect the solubility of S^{2-} species in silicate melts, Alkali content is expected to play a major role together with oxygen fugacity in the S geochemical behaviour in silicate magmas.

Redox dynamics resulting from chemical and physical fluxes in surficial permeable sediments

B.T. GLAZER[1]*, J. FRAM[1,2], J.L. MURPHY[1], K. FOGAREN[1] AND F. J. SANSONE[1]

[1]University of Hawaii, Department of Oceanography, 1000 Pope Rd., Honolulu, HI 96822; (*correspondance: glazer@hawaii.edu)

[2]College of Oceanic and Atmospheric Sciences, Oregon State University, 104 COAS Administration Bldg

The upper layers of nearshore permeable sediments are dynamic, active sites of intense redox cycling. Previous research and our preliminary results indicate that vertical redox oscillations in these sediments can be driven by biogeochemical or physical variability, or by episodic events such as severe storms and their associated terrestrial runoff. Further, it can be assumed that each of these forcings operate on different and distinctive time and vertical scales. The current work focuses on central goals of calculating the fluxes of redox-sensitive chemical species in surficial permeable coastal sediments, and understanding the transformations within the highly responsive "zone of reactivity" in the upper centimeters of these sediments.

We have made extended deployments of a custom physical and chemical sensor package in nearshore permeable sediments, as part of a cabled seafloor observatory. Instrumentation includes a multi-channel high-resolution miniature thermistor chain, an in situ electrochemical analyzer (ISEA-III, AIS Inc.), a profiling micromanipulator, oxygen optrodes (Aanderaa), independent temperature loggers (RBR), and a seafloor visualization system, all integrated into the existing physcial sensor network observatory (Kilo Nalu Nearshore Reef Observatory, Oahu, Hawaii, USA). Here, we describe on-going work aimed at: (i) improving our understanding of the interaction between these active, carbon recycling sediments and the overlying water column; (ii) examining in detail the temporal and spatial variability of key redox-reactive chemical species; (iii) quantifying the relative contributions of benthic photosynthesis, sand ripple position, currents and waves to redox oscillations; and (iv) integrating fine-scale chemical measurements with porewater velocity modeling to calculate biogeochemical fluxes.

Mercury stable isotopic variations in Arctic Ocean pelagic sediment

JAMES D. GLEASON[1], JOEL D. BLUM[1], TED C. MOORE[1], LEONID POLYAK[2] AND MARTIN JAKOBSSON[3]

[1] University of Michigan, Dept. of Geological Sciences, Ann Arbor, MI 48109, USA (*correspondence: jdgleaso@umich.edu)
[2] Ohio State University, Byrd Polar Research Center, Columbus, OH 43210, USA (polyak.1@osu.edu)
[3] Stockholm University, Dept. of Geology and Geochemistry, Stockholm, Sweden (martin.jakobsson@geo.su.se)

Mercury isotopic compositions were measured in 14 samples of Arctic Ocean pelagic sediment from three sites: Lomonosov Ridge, Yermak Plateau and Mendeleev Ridge. Holocene-age sediment from 4 piston cores shows highly negative and variable mass dependent isotopic fractionation (δ^{202}Hg = -1.06 to -2.98; +/-0.15‰). Surface sediment at two localities (Lomonosov Ridge and Yermak Plateau) shows small deviations from mass dependence recorded as Δ^{201}Hg = -0.11 to -0.14 (+/-0.10‰). In piston core 96/12-1pc (Lomonosov Ridge; 1003 m water depth; 87°05.9'N; 144°46.4'E), δ^{202}Hg appears to decrease with depth in the core from surface (δ^{202}Hg = -2.22) down to MIS 5.3 (~100 ka; 2 meters depth; δ^{202}Hg = -2.98). Mercury concentrations (~3 ppb to 114 ppb) are not well correlated with Hg isotopic composition, and neither of these parameters appears to be correlated with the Mn-rich/Mn-poor cyclic banding in core 96/12-1pc, which is thought to record variations in Quaternary ventilation and/or ice conditions of the Arctic Ocean. Overall, the sediment Hg isotopic compositions likely reflect a variable provenance signal of mixed terrestrial and atmospheric Hg reservoirs supplying the Arctic Ocean. The enhanced negative Δ^{201}Hg signature in the modern Arctic sediments could be due to the influence of anthropogenic Hg from coal combustion, or from enhanced photochemical reduction and loss of Hg from modern Arctic surface waters due to reduced sea-ice cover.

Sulfate reduction and microbial abundance in saline, alkaline Lake Van (Turkey)

CLEMENS GLOMBITZA*, JENS KALLMEYER AND PALEOVAN SCIENTIFIC PARTY

University of Potsdam, Institute of Earth and Environmental Sciences, Karl-Liebknecht-Str. 24, 14476 Potsdam, Germany
(*correspondance: clemens.glombitza@geo.uni-potsdam.de)

Lake Van is the fourth lagest terminal lake in the world. It is located on the Eastern Anatolia High Plateau (Turkey) and surrounded by two semi-active vulcanos (Nemruth Dagi and Syphan Dagi). Evaporation processes, chemical weathering of vulcanic rocks and hydrothermal activity have created an environment of extreme alkalinity (155 m eql^{-1}, pH 9.81) and salinity (21.4 ‰) [1]. Kempe and Degens [2] proposed an ancient Ocean with high alkalinity, a high pH and low Ca and Mg concentrations, analogous to modern soda lakes like Lake Van. This theory was and still is discussed controversly, e.g. Hardie [3] suggested that the post-Hadean ocean was never a soda ocean but instead a neutral-halide ocean. Recently, Shibuya *et al*. reportet evidence for high alkaline fluids in an Archean subseafloor hydrothermal system resultling in reactive mixing zones between alkaline fluids and neutral seawater [4]. A detailed study of the currently ongoing microbial processes in Lake Van may provide the information necessary to interpret the signals from fossil ecosystems. Independent from the different opinions about early Ocean chemistry, this study explores an ecosystem that deviates considerably from typical freshwater or marine systems with regard to porewater chemistry and biogeochemical processes.

We here report the first results from microbiological investigations (porewater chemistry, cell abundance and sulfate reduction rates) in samples from two sites (Northern Basin and Ahlat Ridge) at Lake Van, retrieved during the ICDP drilling campaing in summer 2010. Although located in relatively close proximity (7 km) sulfate reduction rates reveal unexpected differences between the two sites, indicating a high sensitivity of microbial activity to changes in hydrological conditions and organic matter input. Overall cell abundances deviate considerably from what is commonly observed in marine sediments.

Land use control of groundwater chemistry in the Pyosun Watershed, Jeju Island, Korea

YOUNG-HWA GO[1], SEONG-TAEK YUN[1]*, KYUNG-GOO KANG[2], BERNHARD MAYER[3], KYOUNG-HO KIM[1] AND HAE-NAM HYUN[4]

[1]Department of Earth and Environmental Sciences, Korea University, Seoul 136-701, South Korea (*correspondence: styun@korea.ac.kr)
[2]Jeju Special Self-Governing Province Development Corporation, Korea
[3]Department of Geoscience, University of Calgary, Calgary, Alberta, Canada T2N1N4
[4]Department of Bioscience and Industry, Jeju National Universityi, Jeju 690-756, South Korea

As groundwater from basaltic aquifers is a unique source of water supply in the volcanic Jeju Island, Korea, a better understanding of the current status of groundwater is important for a sustainable future water supply. For this study of the Pyosun Watershed located at the southeastern part of the island, we collected 90 groundwater samples from 45 existing wells and 41 soil water samples using porous cups installed at various depths at two sites. Hydrochemically, well groundwater was dominantly of the Na(-Mg-Ca)-HCO_3(-Cl) type, while soil water varied between Na(-Mg-Ca)-Cl-HCO_3(-SO_4) type at an upgradient forested area to a Na(-Mg-Ca)-Cl type at a downgradient agricultural (orchard) area. Most ions in groundwater, especially NO_3, Cl, SO_4, Na, Ca and Mg, increased in concentrations in aquifers at low altitudes (about <150 m a.s.l.) where land use is dominated by orchards and rural developments. Nitrate concentrations of groundwater ranged from 0.4 to 23.3 mg/L (median 4.7 mg/L). The results of a Principal Component Analysis (PCA) of hydrochemical data indicates that two major processes (i.e., anthropogenic contamination and water-rock interaction) control the groundwater chemistry. Water-rock interactions were dominated by silicate weathering (as indicated by the increases of HCO_3 and silica) with minor ion exchange and sorption. Combined with hydrochemical data, nitrogen and oxygen isotopes of groundwater nitrate (n=43) showed the systematic change of major nitrate sources, from nitrification in soil organic matter at upgradient forested and grassland areas to chemical fertilizers at the orchard areas to minor contributions of manure and sewage-derived nitrate at low altitudes. Thus, careful control of fertilizer use is highly recommended for a sustainable management of future groundwater quality in the Pyosun Watershed.

Hydrochemical characteristics of Bigadiç (Balikesir) geothermal area, Turkey

GÜLER GÖÇMEZ[1] AND ERDOĞAN ÖLMEZ[2]

[1]Department of Geology Engineering, Selcuk University, (gulergoçmez@selcuk.edu.tr)
[2]Directorate of Mineral Research and Exploration of Turkey (erdogan_olmez@yahoo.com)

The study area is located in 57 km southwesthern of Balıkesir, West Anatolia, Turkey. The stratigraphy of the area is characterized by the presence of ophiolites of Mesozoic basement, covered by Tertiary aged Dedetepe Formation (riodacite, dacite, tuff, agglomerate) and Quaternary covers. Major visible tectonic lines that control fluid flow in region is represented by faults approximately trending in N-NE direction; it determined the main morphological structure of the region.

The chemical composition of water discharges clearly shows that the Bigadiç geothermal system produces similar types of fluids having travelled distinctly different pats. A plume of high HCO_3 and SO_4 waters feeds discharge area, bordered by two strike slip faults. EC values of hot and mineral water in region are range between 2100 and 3040 μS/cm, temperature is between 24 and 98 ºC, total mineralization ranges from 2646 to 3537 mg/l, and pH values range from 6.4 to 8.3 and show generally the acidic character. Four wells in region were opened (HK-1; T=47 ºC and Q=0.5 l/s: HK-2; T=98 ºC and Q=60 ºC: HK-3; T=98 ºC and Q=40 l/s; HK-4; T=94 ºC and Q=10 l/s) to use in balneological purposes, space and greenhouse heating.

The hot and mineral waters have “Rav waters” properties according to Giggenbach diagramme. The reservuar rock temperature is calculated due to geothermometers as 100 to 110 ºC. The hot and mineral water is classified as B-F-Na-HCO_3-SO_4 according to AIH. High content of boron in fluids produced from the geothermal system throughout the volcanic environment, thought to be associated with extentional tectonics and volcanic hosted rocks leachings from the Bigadiç area appear to repr. All of these extentional type discharges from the Bigadiç area appear to represent geothermal fluids most directly derived from an environment dominated by riolitic/andesitic magmatism.

Recent advances in first principles based modeling and simulations of the physics and chemistry of large, complex atomistic systems

WILLIAM A. GODDARD, III

Charles and Mary Ferkel Professor of Chemistry, Materials Science, and Applied Physics Director, Materials and Process Simulation Center (MSC) California Institute of Technology (139-74) Pasadena, CA 91125

Advances in theoretical chemistry, computational chemistry, materials science, physics, and supercomputers are making it practical to consider first principles (de novo) predictions and simulations of the atomistic level physics and chemistry of complex systems and processes in the Chemical, Biological, and Materials Sciences. Our approach is to build a hierarchy of models each based on the results of more fundamental methods but coarsened to make practical the consideration of much larger length and time scales. Connecting this multi-paradigm multi-scale hierarchy back to quantum mechanics enables the application of first principles to the coarse levels essential for practical simulations of complex systems.

We will highlight some recent advances in multi-paradigm multi-scale methodology selected from: · The ReaxFF reactive force field for prediction of reactive processes in complex systems · The eFF method for electron dynamics of highly excited complex systems · PBE-lg and XYGJ-OS quantum mechanics methods for accurate intermolecular interactionsat modest cost ·The 2PT method for fast accurate calculations of entropy from molecular dynamics that we will illustrate with recent applications to Energy, Catalysis, Nanotechnology, and Materials selected from:

Applications of Multiparadigm, Multiscale Methodologies to high velocity impact ·EOS and phase transitions of materials from 2PT analysis of ReaxFF-lg reactive dynamics simulations Spin-coupling and superexchange in ferroelectrics ·Mechanism of superconductivity in cuprates; strategies for increased Tc ·Copper-Indium-Gallium-Selenide (CIGS)/CdS photovoltaics ·Hydration and hydrolysis processes in concrete (Ettringite) Functionalizing MOF, COF, ZIF Materials for storage and partitioning of H_2, CO_2, CH_4 ·Mechanisms of fuel cell catalysts including the oxygen reduction reaction ·Solid acid, Solid oxide, alkaline, and ceramic electrolytes ·simulations of transport in dye synthesized photovoltaics including electrodes, ionic liquid,and reluctant · New anodes and electrolytes for Li batteries · ReaxFF-Monte Carlo methods for resolving partial occupations from Rietveld analyses into supercells with whole atoms; application to Mixed metal oxide catalysts for ammoxidation of propane

Characterization of Saharan dust from red rain precipitated over Athens, Greece

A. GODELITSAS[1]*, P. NASTOS[1], T.J. MERTZIMEKIS[1], K. TOLI[1], A. DOUVALIS[2] AND R. SIMON[3]

[1]University of Athens, Greece (*correspondence: agodel@geol.uoa.gr)
[2]University of Ioannina, Greece
[3]ANKA Synchrotron Facility, KIT, Germany

Aeolian transport of Saharan dust influences significantly the rain acidity and furthermore the climate of the Mediterranean, causing among others, intense “red (or mud) rain” and even “red snow” episodes. During these episodes geological material from Sahara is deposited to the aquatic, terrestrial and urban environment [e.g. 1-3]. The Saharan dust samples were collected on membrane filters after intense “red rain” episodes over Athens megacity, Greece. Initial characterization by means of XRD, SEM-EDS and laser micro-Raman showed quartz, calcite and dolomite as major phases as well as phyllosilicates (mostly clays), rutile, zircon and goethite as minor constituents [4]. Preliminary analyses of metals using bulk XRF indicated Fe, Sr, Mn, Zn, Pb, Cr, Ni and Cu whereas gamma-ray spectroscopic measurements showed very low natural radioactivity and absence of human-produced nuclides. Detailed Synchrotron micro-XRF studies proved the presence of very hazardous elements, such as Pb and As, which had not been located on the samples by preliminary conventional investigation using SEM-EDS. It was also confirmed that many trace elements are intercorrelated (e.g. Fe-Mn-V-Cu) in other minor phases, of potential anthropogenic origin, hosted into the carbonate-silicate matrix. Subsequent Mössbauer spectroscopic study showed abundant Fe^{3+}-containing constituents and less Fe^{2+} phases. Moreover, sequential leaching experiments, using appropriate acids and ICP-MS analyses, revealed a high percentage of extractable Fe (and also Zn, Mn and Pb) due to carbonate phases comprising ~60% of the material. The above data can be important [see e.g. 5] for the geoavailability and bioavailability of aerosol-derived useful and harmful metals in southern Greece and generally in the entire semi-closed low-nutrient / low-chlorophyll marine ecosystem of eastern Mediterranean.

Isotope fractionation due to temperature gradients: Molecular dynamics simulation

GAURAV GOEL[1,2], DANIEL J. LACKS[2], JAMES A. VAN ORMAN[1,2], CRAIG C. LUNDSTROM[3], CHARLES E. LESHER[4]

[1]Department of Geological Sciences, Case Western Reserve University, Cleveland, OH 44106
[2]Department of Chemical Engineering, Case Western Reserve University, Cleveland, OH 44106
[3]Department of Geology, University of Illinois, Urbana, IL 61801
[4]Department of Geology, University of California, Davis, CA 95616

Experimental studies show that large isotope fractionation can occur along temperature gradients in silicate melts [1-3]. This thermally induced isotope fractionation can be much larger than the equilibrium fractionation between minerals and melts, In particular, lighter isotopes are found to be enriched in the hotter regions, and heavier isotopes are enriched in the colder regions of experimental charges, with the magnitude of the fractionation depending on the type of atom. The effect may be important in places such as at the edges of magma chambers and in other regions with sustained thermal gradients.

We have carried out molecular dynamics simulations to determine the factors that control the thermal fractionation of isotopes. The simulations are run for magnesium silicate melts (50-70% SiO_2), with non-equilibrium molecular dynamics techniques used to produce the temperature gradient. The results of the simulations are in good agreement with experimental observations [e.g. 2, 3], both in terms of the absolute magnitude of the fractionation and the relative magnitudes for different types of atoms.

The simulations are carried out as a function of pressure, to predict the behavior under conditions deep inside the earth, which experiments have not yet addressed. Increasing pressure change the magnitude of the isotope fractionation per temperature change for atoms that form part of the network structure (Si, O), but its effects are insignificant for atoms that are not part of the network (Mg).

Pb and Zn distribution in stalagmites

J. GÖTTLICHER[1]*, S. MARKS[2], R. SIMON[1], R. STEININGER[1] A. PLATTE [3] AND S. NIGGEMANN[4]

[1]Karlsruhe Institute of Technology, Institute for Synchrotron Radiation, Eggenstein-Leopoldshafen, Germany (*correspondence: joerg.goettlicher@iss.fzk.de)
[2]Münster, Germany
[3]Letmathe, Germany
[3]Dechenhöhle, Letmathe, Germany

The impact of atmospheric emission on carstwaters and carst bedrocks is investigated by analyzing speleothems (here: stalagmites of $CaCO_3$) for metals that have been set free during the early years of industrialization. Letmathe in the Sauerland (one of the low mountain ranges in Germany) was chosen as a suitable area because two caves (Dechenhöhle and Hüttenbläser) are located in the main wind direction about 1 km away from a Pb and Zn smelter operating from 1862 to 1925. Additionally, slices from beech trees (≈155-165 y old) close to the cave were available for measuring their metal contents. Evidence for airborne Pb and Zn in this area came from analyses of gypsum encrustations at a nearby rock formation [1] and from deer antlers [2].

The young zone of the stalagmites is grey colored compared to the beige inner and therefore older part. X-ray fluorescence (XRF) spectra of the stalagmites measured at the SUL-X and FLUO beamline of the synchrotron radiation source ANKA show discrete peaks for Pb and Zn in the gray zone, highest contents at the boundary grey/beige and almost no Pb and Zn in beige zone. Pb and Zn are partly correlated. XRF spectra of beech trees exhibit a few spikes of Pb but they are not concentrated in the older part as expected. Zn is represented by a large number of peaks of different heights and frequencies with time. In both types of samples (stalagmite, wood) a discrete occurrence of Pb and Zn have been found rather than a homogeneous elevation during the time when atmospheric emission was most intensive. For the stalagmites the Pb and Zn pattern could be explained by particular entry or by enrichments at grain boundaries of crystallites which has to be proven. For the nature of metal distribution in trees no explanation has been found so far

We thank ANKA for beamtime in the projects ENV-163 and ENV-186, and the forest officials of Letmathe for providing us slices of trees.

Plant impoundments as habitats for methanogenesis in tropical rainforest canopies

S. GOFFREDI[1]* AND W. USSLER III[2]

[1]Occidental College, Los Angeles, CA 90041, USA (*correspondence: sgoffredi@oxy.edu)
[2]Monterey Bay Aquarium Research Institute, Moss Landing, CA 95039, USA (methane@mbari.org)

Tropical epiphytes within the family Bromeliaceae possess foliage arranged in compact rosettes capable of retaining water. This creates an unusual environment suspended in the rainforest canopy; acidic and anaerobic, with decomposition of impounded material. Archaeal communities within the tanks were dominated by methanogens (~90% of archaeal ribotypes) and community structure, although variable, was generally dominated by the hydrogenotropic *Methanoregula*, with *Methanocella*, a specific clade of the acetoclastic *Methanosaeta*, rice cluster II, and *Methanosarcina* also present. Close relatives were recovered previously from peat bog, acidic fens, and anoxic rice fields, all areas of similarly high organic content and low pH. All tanks (n = 63, comprised of 6 plant species, sampled over a two year period) showed presence of methanogens, as long as they exceeded ~22 cm in plant height or ~7 cm tank depth. Soil was negative for methanogens (n=8), except in one case, in which the dominant methanogen, related to *Methanosarcina*, was different from nearby bromeliads. Archaeal methyl coenzyme M reductase A copy numbers correlated with both plant height and light levels, suggesting that these environmental parameters affect conditions for methanogenesis. Methane-specific isotopes ranged from -45 to -63‰, and direct methane production rates, comparable to emissions measured for pasture and peat bogs, were measured in microcosm experiments. These results suggest that bromeliad-associated archaeal communities may play an important role in the cycling of carbon in tropical forests.

Osmium isotopic tracing of atmospheric emissions from an aluminum smelter

J. GOGOT*[1], A. POIRIER[1] AND A. BOULLEMANT[2]

[1]GEOTOP-UQAM, CP. 8888, Succ. Centre-ville, Montréal, Qc, Canada. H3C 3P8 (*correspondence: julien.gogot@gmail.com, poirier.andre@uqam.ca)
[2]RIO TINTO ALCAN, CRDA, 1955 bld Mellon CP 1250, Jonquiere (QC), G7S 4K8, Canada (amiel.boullemant@riotinto.com)

In this study, we use osmium (Os) isotopes as a tracer of the environmental footprint of an aluminum smelter in Saguenay (Canada). This prebaked technology smelter transforms alumina (extracted from bauxite) in primary aluminum via carbon anodes. These latter are almost entirely consumed during the electrolytic process and are emitted as CO2 when reducing Al_2O_3 to Al(l). Such large gas emissions entrain inevitably some particulate matter (dust) at the stacks, despite gas and dust scrubbers demonstrate a more than 99.5% efficiency.

Heavy metals found in atmospheric emissions from this type of industry may have an isotopic composition significantly different from the local natural environment. The results of isotopic analysis of a sample of anode have revealed the presence of very radiogenic Os ($^{187}Os/^{188}Os$= 2.393 $\pm$ 0.005) compared to typical eroding continental crust (~1.2) and to usual anthropogenic sources (0.1-0.2). This suggested that Os might be a good candidate to follow a smelter's environmental impact. The main objective of this study is to determine the isotopic composition of real emissions from an aluminum smelter for metals of geochemical interest (variable isotopic composition) and compare them with the natural surrounding environment.

During this meeting, we present Os results for a wide range of analyzed samples: carbonaceous material (anode); filters of emissions from the plant; samples of soils and sediment collected in the surrounding environment of the plant; and sedimentary sequence including pre-anthropogenic levels to characterize the natural background.

Insights into short-term changes in local and global seawater redox conditions during Cretaceous OAE 2

T. GOLDBERG[1]*, S.W. POULTON[2], T. WAGNER[2] AND M. REHKAMPER[1]

[1]Imperial College London, SW7 2AZ London, UK, (*correspondence: t.goldberg@imperial.ac.uk)
[2]Newcastle University, NE1 7RU, Newcastle upon Tyne, UK

The mid Cretaceous was a time of extreme greenhouse conditions. Related to this were a series of major black shale deposition events associated with global perturbations of the carbon cycle (ocean anoxic events; OAEs). These units potentially document periods of rapid climate change where the redox state of the Cretaceous ocean repeatedly fluctuated between oxic, anoxic and euxinic depositional conditions, linked to orbital-driven natural processes. Understanding these short-term cycles is essential for improving our knowledge of how future rapid climate warming may affect ocean chemistry.

Global seawater $\delta^{98/95}$Mo is reflected in euxinic environments, and differs accordingly to the extent of oxic and anoxic sinks [1]. To recognise short-term changes and relationships in the local, regional, and global redox state of seawater, high-resolution (millennial – centennial) Fe, S and redox sensitive trace elements (Mo, V, U, Cr) were paired with Mo isotopes ($\delta^{98/95}$Mo). The study site was a low latitude Palaeo-North Altantic shelf region, deposited ~ 94 Ma ago.

In terms of local conditions, iron-sulphur systematics and biomarker evidence point to a predominantly sulphidic water column with short, periodic intervals of ferruginous conditions. Severe trace element depletion is mainly connected to sulphidic intervals, whereas ferruginous intervals show elemental recovery via continental input. A steady Mo isotopic composition is identified during local euxinia, indicating a reduction of the oceanic oxic sinks during OAE 2. During ferruginous conditions $\delta^{98/95}$Mo is affected by regional Mo uptake mechanisms. Conspicuous is an ~10-15 ky decrease in $\delta^{98/95}$Mo during euxinic deposition, coinciding with the peak of the positive carbon isotope excursion. This could be indicative of a massive increase in the spatial extent of ocean anoxia/euxinia in the Cretaceous oceans.

Clouds and the Faint Young Sun Paradox

COLIN GOLDBLATT[1] AND KEVIN J. ZAHNLE[2]

[1]Astronomy Department, University of Washington, Seattle, WA 98195, USA (cgoldbla@uw.edu)
[2]Space Science and Astrobiology Division, NASA Ames Research Center, Moffett Field, CA 94035, USA (kevin.j.zahnle@nasa.gov)

We investigate the role which clouds could play in resolving the Faint Young Sun Paradox (FYSP). Lower solar luminosity in the past means that less energy was absorbed on Earth (a forcing of $-50 Wm^{-2}$ during the late Archean), but geological evidence points to the Earth having been at least as warm as it is today, with only very occasional glaciations. We perform radiative calculations on a single global mean atmospheric column. We select a nominal set of three layered, randomly overlapping clouds, which are both consistent with observed cloud climatologies and reproduced the observed global mean energy budget of Earth. By varying the fraction, thickness, height and particle size of these clouds we conduct a wide exploration of how changed clouds could affect climate, thus constraining how clouds could contribute to resolving the FYSP. Low clouds reflect sunlight but have little greenhouse effect. Removing them entirely gives a forcing of $+25 Wm^{-2}$ whilst more modest reduction in their efficacy gives a forcing of +10 to $+15 Wm^{-2}$. For high clouds, the greenhouse effect dominates. It is possible to generate $+50 Wm^{-2}$ forcing from enhancing these, but this requires making them 3.5 times thicker and 14K colder than the standard high cloud in our nominal set and expanding their coverage to 100% of the sky. Such changes are not credible. More plausible changes would generate no more than $+15 Wm^{-2}$ forcing. Thus neither fewer low clouds nor more high clouds an provide enough forcing to resolve the FYSP. Decreased surface albedo can contribute no more than $+5 Wm^{-2}$ forcing. Some models which have been applied to the FYSP do not include clouds at all. These overestimate the forcing due to increased CO_2 by 20 to 25% when pCO_2 is 0.01 to 0.1 bar [1, 2].

Scaling of critical zone processes in the Praire Pothole region, USA

MARTIN GOLDHABER[1]*, CHRISTOPHER MILLS, JEAN MORRISON AND CRAIG STRICKER

[1]USGS, Denver, CO, USA, (*correspondence; mgold@usgs.gov, cmills @usgs.gov, jmorrison@usgs.gov, cstricker@usgs.gov)

The Prairie Pothole Region, which occupies 750,000 km^2 of the north central U.S. and south central Canada is one of the most important ecosystems in North America. It contains millions of small wetlands underlain by glacial till that are internally drained within discrete, km-scale basins. We studied the geochemistry of soils, sediments, wetland water, and groundwater in the 92 hectare Cottonwood Lakes (CWL) area of North Dakota. The CWL area includes upland groundwater recharge wetlands with compositions similar to rainwater (TDS 150 mg/l), and a discharge wetland at a local topographic low only 200m from the recharge wetlands. Oxygenated water interacting with pyrite in surficial glacial till has oxidized the till to depths >10 m. Coupled fluid flow and chemical reaction modeling shows that this oxidation process has taken $>10^3$ years. The resulting SO_4^{2-}-enriched fluids have migrated from upland recharge areas and accumulated in the discharge wetland which has >2500mg/l SO_4^{2-}. The drastic variability in recharge and discharge wetland chemistry is reflected by fauna and flora. Sulfur isotope data support the conclusion that isotopically light pyrite, origionally from marine shale (mean $\delta^{34}S_{SO4}$ =-16‰) is the source of groundwater sulfate ($\delta^{34}S_{SO4}$=-7.5 to -15.9‰). Heavier $\delta^{34}S_{SO4}$ values within discharge wetlands (maximum +4‰) is evidence that bacteria are reducing SO_4^{2-} to sulfide, a process that drives the precipitation of high Mg calcite.

Our evaluation of literature data on water compositions of 178 wetlands throughout a 10^3 km^2 area surrounding the study site document that oxidation of pyrite and formation of SO_4^{2-} enriched wetlands has occurred over a large area in North Dakota.

Oxygen isotope variations in the Allende CV3 meteorite

A. GOLDMANN[1,2], A. PACK[2], M. GELLISSEN[3], N. ALBRECHT[2], J. ZIPFEL[4] AND H. PALME[4]

[1]Leibniz-Universität Hannover;
[2]Georg-August-Universität Göttingen;
[3]Christian-Albrechts-Universität Kiel;
[4]Senckenberg Forschungsinstitut und Naturmuseum, Frankfurt

Introduction

The Allende (CV3) carbonaceous chondrite consists of mm-sized chondrules, fine-grained matrix, Ca- and Al-rich inclusions (CAIs), dark inclusions (DI) and amoeboid olivine aggregates (AOA). Various components of the Allende meteorite fall on a mixing line in the $\delta^{17}O$ vs. $\delta^{18}O$ space [1].

In this study, we investigate isotope variations of small bulk samples (~0.3 – 1.1 g) and compare the variations with chemical data of the same aliquots.

Samples and Measurement techniques

37 of 39 samples of a 22.5 mm^2 large and 4 mm thick slice of the meteorite were analyzed. One sample (C4) contained a macroscopically visibly CAI, one (F3) a large DI. Oxygen isotopes were analyzed in Göttingen using IR laser fluorination in combination with GC-irmMS using a MAT 253 gas source mass spectrometer. The $\Delta^{17}O$ is calculated relative to the rocks- and minerals-defined TFL (N > 700) with a slope of $\beta = 0.5151 \pm 0.0007$ (1σ) and an intercept of $\gamma = -0.0014 \pm 0.008$ (1σ). The accuracy and precision of a single isotope analysis is ~0.15 ‰ and $\delta^{18}O$ and ±0.04 ‰ in $\Delta^{17}O$.

The chemical analyses were obtained by XRF in Cologne.

Results

The O-isotope data fall on the AML. The $\Delta^{17}O_{TFL}$ shows a spread from –4.6 ‰ to –2.3 ‰. The lower limit is marked by sample C4 (CAI) and the upper limit by the DI in sample F3. Excluding these 2 samples, a spread in $\Delta^{17}O$ of –4.1 to –3.0 ‰ is observed. For the remainig samples, no correlation between chemical composition (e.g. Al content) and $\Delta^{17}O$ is observed. The Al_2O_3 concentrations range from 2.6 – 4.3 wt.%, with constant Ca/Al-ratios..

Discussion

A correlation between $\Delta^{17}O$ and chemistry is expected if variations in Al (and other refractory elements) is caused by addition of CAI-like material. Such a correlation is not observed. This suggests the existence of an oxygen component, independent of the chemical variability. Implications with respect of the correlation between O- and Cr-isotopes [3] will be discussed.

Nanoparticles of X-ray amorphous mineralogical substances

YE.A. GOLUBEV

Institute of Geology, Syktyvkar, 167982, Russia
(golubev@geo.komisc.ru)

Representations about the particular ultradisperse structural state of x-ray amorphous mineralogical substances (mineraloids), distinct from atomic-molecular are developed [1-4]. For mineraloids it are find out and in details described submicro-nanoscale structures of natural solid bitumens, fossil resins, of some inorganic metacolloids by HRTEM, STM, AFM, SEM. This has allowed revealing various species of superstructural orderings in mineraloids, to define its mechanisms, to allocate key value of influence of the heating factor for the sizes nanoparticles in organic mineraloids.

Results of studying submicro-nanoscale structures and mechanisms of their ordering are important for modifying technological properties of natural substances, making of geomaterials. Special interest cause mineraloids with periodically-ordered nanoscale structures like noble opal has aroused. The similar regular structures are characteristic for a row organic and inorganic mineraloids.

Statistical evaluation of the Holocene climate parameters in the NE of European Russia (from palynological data)

YU.V. GOLUBEVA* AND YE.A. GOLUBEV

Institute of Geology, Komi Science Centre, Ural Division of RAS, 167982 Syktyvkar, Russia,
(*correspondence: bratushchak@geo.komisc.ru)

In the given work present paleoclimatic investigation included palynological and statistical analyses, radiocarbon dating of the Holocene lake, alluvial (oxbow lake) and swamp sediments in middle and northern taiga subzones of the Komi Republic. On the basis of cores of four boreholes and fourteen outcrops, synchronous spectra correlation and Holocene separation were accomplished [1].

Mean annual and July temperatures were estimated by zonal method of the Holocene paleoclimates reconstruction [2], based on palynological assemblages for characteristics of environmental changes during the interval. It has been established that the sediments accumulated during the Preboreal–Subatlantic interval, when repeated climatic changes occurred.

To determine the main trends of paleoclimate changes climatic curves have been drawn. The curves show deviations of the mean annual and July temperatures during the Holocene from their current values. For this purpose, the statistical weight of mean temperature values are taken into account in paleoclimatic curves approximating, as the temperature ranges in certain intervals of the Holocene vary considerably.

According to the palynological data and statistical analyses three periods with warmer climatic conditions (Early Boreal, Middle Subboreal and Late Atlantic) were estimated. It is established, that climatic optimum have developed at the end of the Atlantic period to what distribution of the most thermophilic tree species (oak, elm, hazel and maple) and the highest temperatures testifies. The Atlantic period is characterized by mean July temperature on 2.5–3.5 °C and mean annual temperature on 2–3 °C warmer, than at the present time. The Boreal and Subboreal temperature maxima had the subordinated value. Thus, from the Preboreal period the increase tendency of temperatures up to the maximal values at the end of the Atlantic period is observed. Then reduction of temperatures to the present has followed.

This research was supported by grant by the Program of Presidium RAS n. 14.

Stability of Cu adsorbed onto clay surfaces: An experimental and computational study

MÁRIO A. GONÇALVES[1], DAVID MARTINS[1] AND STEPHEN C. PARKER[2]

[1]Departamento de Geologia and CREMINER/LA-ISR, Faculdade de Ciências U. Lisboa, Lisboa, Portugal (mgoncalves@fc.ul.pt, dmmartins@fc.ul.pt)
[2]Department of Chemistry, University of Bath, Bath BA2 7AY, United Kingdom (s.c.parker@bath.ac.uk)

The stability of adsorbed metals onto mineral surfaces is an essential property in controlling their ultimate fate in the environment. This study addresses this problem with the analysis of batch and flow-through (kinetic) experiments using Cu and illite, complemented with ab-initio and molecular dynamics studies. Experiments were performed at pH 4.5 to 6.5, and 10^{-4}M – 10^{-3}M ionic strength.

Batch and kinetic experiments gave consistent results on total adsorbed Cu per gram of adsorbent: 6.4 – 9.1 × 10^{-5} mol/g for pH 4.5, and 9.0 – 13.0 × 10^{-5} mol/g for pH 5.5. Results follow a Langmuir-type adsorption isotherm, but at pH 6.5 surface Cu precipitation occurs.

Desoprtion rates were measured with the results from flow-through experiments, and ranged between 1.0 – 2.4 × 10^{-10} mol/m^2/min. The amount of desorbed Cu ranged between 6 and 54% of the total adsorbed Cu. These results indicate that Cu surface stability is favoured for high pH/low ionic strength solutions, also lending support on the Eigen-Wilkins-Werner mechanism [1]. Metal adsorption on edge surface sites of clays is shown by spectroscopic studies [2].

We are also investigating the edge surface sites further by calculating the different modes of adsorption of Cu complexes at edge sites and comparing them to adsorption on (001) surface using atomistic simulation techniques. Initially, the static simulation code METADISE [3] was used to explore the structure and the stability of the different surface cuts for the (010), (100), and (-110) edge surfaces of an idealised pyrophyllite structure. Inner and outer-sphere Cu complexes are currently being optimised using DFT within the VASP code [4] to aid in the interpretation of the experimental results.

Redox state of lithospheric mantle in central Siberian craton: A Mössbauer study of peridotite xenoliths from the Udachnaya kimberlite

A.G. GONCHAROV[1,2]*, D.A. IONOV[2], L.-S. DOUCET[2] AND I.V. ASHCHEPKOV[3]

[1]IPGG RAS, Saint-Petersburg, Russia (
*correspondence: ag.goncharov@ipgg.ru)
[2]Université J. Monnet, Saint-Etienne 42023, France
[3]Inst. Geology & Mineralogy, Novosibirsk 630090, Russia

Redox state in a vertical profile of lithospheric mantle in central Siberian craton (Russia) was determined based on peridotite xenoliths from the 360 My old Udachnaya kimberlite. Equilibration temperatures (*T*) and pressures (*P*) for garnet peridotites are 860-1340°C [1]; P values for spinel peridotites were estimated from *T* (760-965°C) projections to a conductive geotherm defined by the gar peridotites. Mössbauer spectroscopy was used to obtain $Fe^{3+}/\Sigma Fe$ ratios in garnet from 15 samples (9–23%) and spinel from 7 samples (6-22%). Oxygen fugacity (f_{O2}) was calculated using oxygen thermobarometry. The f_{O2} decreases with pressure, hence depth. Low-T samples (750-1000°C; *P* = 2.6-5.3 GPa) yield f_{O2} *(ΔFMQ)* = (0.0) to (-1.8) log units whereas high-T (1200-1350°C; 5.4-6.8 GPa) samples have f_{O2} *(ΔFMQ)* = (-2.4) to (-3.1) log units. The low-T peridotites overlap the graphite and carbonate stability fields; the high-T gar peridotites plot in the diamond stability field. Speciation of hypothetical C-O-H fluids coexisting with the rocks was assessed from the T, P and f_{O2} data. Fluids for the high-T, hence the deepest, samples mainly consist of methane and water indicating that these "craton roots" are not likely to contain partial melts because of high T's of peridotite solidus in the presence of reduced C-H compounds.

Influence of thiol-containing ligands for the aggregation and dissolution of metallic silver nanomaterials

ANDREAS P. GONDIKAS[1], BRIAN REINSCH[2], GREG LOWRY[2] AND HEILEEN HSU-KIM*[1]

[1]Duke University, Civil and Env. Eng., Durham, NC, USA (*correspondence: hsukim@duke.edu)
[2]Carnegie Mellon University, Civil and Env. Eng., PA, USA

The environmental fate and mobility of metallic nanoparticles (NPs) in natural waters will be strongly influenced by reactions between the particle surfaces and metal-binding organic ligands that are prevalent in natural waters. Thiol- containing organics are known to dominate the speciation of soft-sphere metals such as ionic silver (Ag^+) in the environment [1]. Furthermore, the type and reactivity of the synthetic coating that is used during the synthesis of the nanomaterials will be a key factor controlling interactions with thiol-containing organic ligands. The objective of this work was to examine how thiols can modify particle surfaces and their reactivity during aggregation and dissolution of the nanoparticles. We studied zero valent silver (Ag) NPs with two types of coatings: citrate (CIT) and polyvinylpyrollidone (PVP). Our studies involved cysteine (CYS) and N-acetyl-cysteine (NAC), two low molecular weight thiol ligands that we utilized as analogues for the natural organics that are expected to bind dissolved Ag^+ in the aquatic environment.

Aggregation and dissolution experiments with CIT- and PVP-coated Ag NPs demonstrated that thiol-containing ligands increased aggregation rates of the particles, depending on solution ionic strength and type of thiol. The increase in aggregation was greater for the PVP-coated Ag NPs relative to the CIT-coated NPs. The addition of cysteine to Ag NP suspensions also increased the dissolved Ag concentration. These results indicated that cysteine was simultaneously sorbing to the Ag NPs and promoting their dissolution, resulting in surface modifications that increased aggregation rates. These results were supported by silver L-III-edge and sulfur K-edge X-ray absorption spectroscopy measurements that showed oxidation of the silver and the formation of Ag(+I)-CYS bonds for Ag NPs that were exposed to CYS.

Overall, our study highlights the importance of the coating and Ag^+-binding organic ligands for modifying the surface of silver nanomaterials in environmental settings. Sorption of natural organics alters the aggregation and solubility of the nanomaterials, and ultimately, will influence their persistence in the environment.

The isotope evidence of ore-forming materials of the Erdaogou gold deposit in Beipiao Liaoning deriving from magmatic rocks mixed by the crust and mantle source

GONGLI[1] , MAGUANG[1]*, ZHANG GUIPING[2] AND CHEN KUI KUI[1]

Henan Polytechnic University, Heana 454001, China (*correspondence: maguang5678@163.com)
[2]China Geological Library, Beijing, 100083

The isotope characteristic value is one of most effective methods recognized to solve petrogenetic question. Because of its tracing function, more and more geologists home and abroad pay attention to it in recent years.

Initial ratio of strontium isotope ($^{87}Sr/^{86}Sr$) varied greatly in Mesozoic volcanic rock in western of Liaoning area (basalt is 0.70474~0.70875, andesite is 0.70496~0.70595, trachyte-andesite is 0.70496~0.70595, dacite is 0.7076, liparite is 0.7081~0.7199) (Wanglaichun,1985); but initial ratio of strontium isotope in Duimiangou rock-mass is between the range of 0.704~0.708, indicated that the granitic magma coming from the upper mantle, and was contaminated by Si-Al layer of crust. The strontium isotopes ($^{87}Sr/^{86}Sr$) <0.710 and $\delta^{18}O$ <10 ‰, it is in line with the characteristics features of crust and mantle source.

From the figure of lead isotope ^{206}Pb / ^{204}Pb -^{207}Pb / ^{204}Pb in main alteration and mineralization rock (figure 1), we can see: a great number of the sample points of lead isotope fall within a wide range of the upper mantle and crust line, this reflects that lead in mineralization fluid comes from the magmatic rock of a mantle-crust mix, but majored in crust origin.

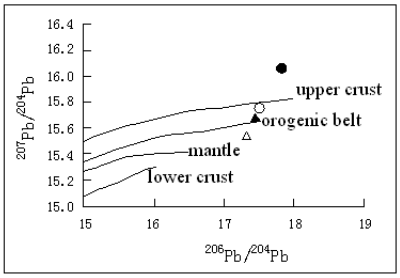

Figure 1: The Graphic of lead isotope ^{206}Pb / ^{204}Pb -^{207}Pb / ^{204}Pb in main alteration and mineralization rock

Mantle-to-surface magma dynamics at Mauna Loa and Kīlauea, Hawai'i

H.M. GONNERMANN[1]*, M. POLAND[2], J.H. FOSTER[3], B. BROOKS[3], C.J. WOLFE[3,4] AND A. MIKLIUS[2]

[1]Department of Earth Science, Rice University, Houston, TX 77005 (*correspondence: helge@rice.edu)
[2]U.S. Geological Survey, Hawai'ian Volcano Observatory, Hawai'i National Park, HI 96718
[3]Department of Geology and Geophysics, SOEST, University of Hawai'i, Honolulu, HI 96822
[3]Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, DC 20015

In 2002 Mauna Loa Volcano, Hawai'i, began a nearly decade long period of inflation. Almost simultaneously, inflation and heightened activity occurred at neighboring Kīlauea Volcano. We address the question if and how both volcanoes are dynamically linked.

We model asthenospheric and crustal magma flow and pressure using a numerical model that integrates kinematic models of volcano deformation with a lumped parameter flow model. The model is constrainted by continuous global position system (GPS) measurements of deformation at both volcanoes. The past decade of summit deformation at Kīlauea and at Mauna Loa can both be explained by coupling crustal magma flow and storage to a common permeable asthenospheric melt zone beneth both volcanoes. Each volcano's shallow crustal magma system is connected to the asthenospheric melt zone by a lithospheric magma plumbing system through which changes in magma pressure can be transmitted. Consequently, pore pressure diffusion within the porous zone produces a dynamical linkage between both volcanoes and increased activity at one volcano may or may not be correlated with activity at its neighbor, depending on the interplay between deep and shallow magmatic processes.

A characteristic pore pressure diffusion time between both volcanoes of approximately ½ year explains the time-delayed onset of inflation at Mauna Loa relative to Kīlauea during 2002. Moreover, magma flow paths within the asthenospheric melt zone capture compositionally distinct magma from different parts of the asthenospheric melt source over long periods of time, consistent with geochemical observations. Because the time required for melt flow within the porous layer between both volcanoes is about three orders of magnitude slower than pore pressure diffusion. Consequently, significant redistribution of melt by porous flow requires time scales of 100s to 1,000s of years, so that decadal changes in surface activity are unlikely to affect long-term trends in magma geochemistry.

Oxidation of Fe(II) in natural waters at high nutrient concentration

ARIDANE G. GONZÁLEZ, J. MAGDALENA SANTANA-CASIANO*, NORMA PÉREZ AND MELCHOR GONZÁLEZ-DÁVILA

Departamento de Química, Facultad de Ciencias del Mar, Universidad de Las Palmas de Gran Canaria, Campus de Tafira, 35017 Las Palmas, Spain

The Fe(II) oxidation kinetic was studied in seawater enriched with nutrients as a function of pH (7.2-8.2), temperature (5-35ºC) and salinity (10-36.72) and compared with seawater media. The effect of nitrate ($0\text{-}1.77\cdot10^{-3}$ M), phosphate ($0\text{-}5.80\cdot10^{-5}$ M) and silicate ($0\text{-}2.84\cdot10^{-4}$ M) was studied at pH 8.0 and 25ºC. The Fe(II) oxidation is faster when a high nutrient concentration is present, decreasing the $t_{1/2}$ and compromising the permanence of Fe(II) in nutrient rich waters. The most important nutrient affecting the oxidation rate is silicate. A kinetic model was applied to the experimental results in order to follow the speciation of each Fe(II) species and to compute the fractional contribution to the overall rate constant as a function of pH. The speciation was controlled by Fe^{2+} from pH 6 to 7.9 and $FeCl^{+}$ from pH 6 to 7.6. $FeH_3SiO_4^{+}$ was the most important species for pH higher than 7.6, when the concentration of total silicate was 1.41 10^{-4} M. The $Fe(OH)^{+}$ controlled the kinetic process at pH lower than 8.1, while the $Fe(OH)_2$ began to control the oxidation rate constant at higher pH values.

Microbial induced mineralization in Co-rich ferromanganese crusts from the Scotia Sea

F.J. GONZÁLEZ[1]*, L. SOMOZA[1], A. MALDONADO[2], T. TORRES[3] AND J.E. ORTIZ[3]

[1]Geological Survey of Spain (IGME). Madrid, Spain (*correspondence: fj.gonzalez@igme.es)
[2]Inst. Andaluz Ciencias Tierra, (IACT: CSIC/UG). Spain
[3]Lab. Estratigrafía Biomolecular (LEB/UPM). Madrid, Spain

Co-rich ferromanganese crusts were collected at 2000-2500 m water depth in oceanic ridges and seamounts from the Scotia Sea during the SCAN-2004 and SCAN-2008 oceanographic cruises. Fe-Mn crusts form botryoidally pavements up to 50 mm thick on tholeiitic oceanic basalts.

According to data of X-ray diffraction and petrographic observations the crusts are essentially composed by poorly crystalline feruginous-vernadite (δ-MnO_2), and goethite and detrital quartz and phyllosilicates as accessory minerals. The Mn/Fe ratio in bulk samples is 1.1, indicating precipitation from cold ambient of seawater onto hard rock substrates. All the studied Fe-Mn crusts concentrate strategic elements (Co, Ni, Tl, REE or PGE) several orders of magnitude above the mean concentration in the Earth´s crust.

Fe-Mn crusts occur as fine laminated manganese oxides structures. SEM imagings reveal abundant like-microbe tubular sheaths (less than 1μm in diameter and 10-200μm long). These textural features can be due to the Mn-biomineralization action of chemolithoautotrophic microorganisms (*Leptothrix* spp.?, *Metallogenium*?). We interpret these filaments as fossilised bacteria (mineralised biofilms) according to their morphology, size ranges and textural features of colonial associations, similar to modern bacteria. They could be easily formed by action of Mn-oxidizing bacteria forming sheaths stained by vernadite, precipitated within extracellular structures. EDX-SEM and Electron Microprobe analyses show the chemical composition of fossilised bacterial biofilms with enrichments in strategic elements with respect to the bulk sample: 22.6% Mn, 22.4% Fe, 1.6% Ti or 1.5% Co and also 7.6% C and 6.8% F. Biomarkers like n-alkanes (n-C_{18}) and nitrogen compounds, detected by GC-MS analysis, could be related to the bacterial mineralization. These findings suggest a link between the microbial and the mineralization. The microbes could have played a critical role in the accumulation of metals through sorptive, catalytic and oxidative processes forming Fe-Mn crust deposits with economic potential. It also remarks the high scavenging efficiency of vernadite for remediation or recovery of trace metal contamination.

Arsenic biomineral formation leads to partial encrustation of thermoacidophilic archaea

P. GONZALEZ*, J. WEIJMA AND C.J.N. BUISMAN

Wageningen University, Sub-dept. of Environmental Technology.Bornse Weilanden 9, 6708 WG Wageningen, The Netherlands,P.O. Box 17, 6700 AA Wageningen (*correspondence: paulaa.gonzalezcontreras@wur.nl)

Acidophilic iron oxidizing *Sulfolobales* spp. mediate the formation of jarosite nanoprecipitates and bioscorodite precursors [1]. In batch experiments, scorodite biomineral formation by *Sulfolobales* spp. was induced at a pH of 1 and 75°C [2]. At these conditions, we observed formation of precursors (nuclei) of scorodite on the cell surface. This suggests that the mechanism of scorodite formation begins with the sorption of ferric iron and arsenate onto the cell surface, followed by the formation of ferric arsenate nuclei from the adsorbed metal species. By growth of the nuclei and ageing of the precipitates, scorodite crystals were formed on the cell surface, which led to a partial encrustation of the cells. In the absence of arsenic , jarosite precipitates were found on the cell surface, but this did not result in encrustation.

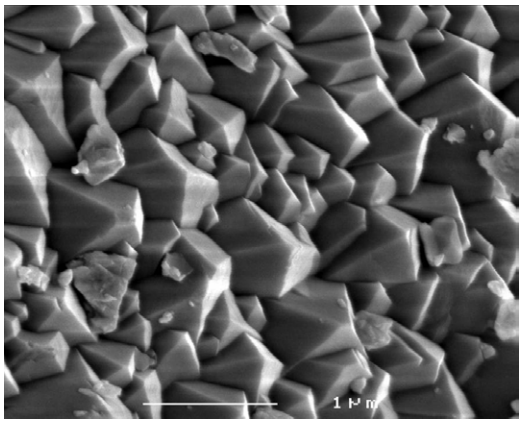

Figure 1. SEM photograph of the biomineralized scorodite by *Sulfolobales*. Photograph with 30000 magnification and SE detection at 3.5 KV.

Weathering intensity in the Mesoproterozoic and modern large-river systems: A comparative study in the Belt-Purcell supergroup

I. GONZÁLEZ-ÁLVAREZ[1,2]* AND R. KERRICH[2]

[1]CSIRO, Australian Resources Research Centre, Earth Science and Resource Engineering, Kensington, WA 6151, Australia,
(*correspondence: i.gonzalez.alvarez@gmail.com)
[2]Department of Geological Sciences, The University of Saskatchewan, 114 Science Place, Saskatoon SK, S7N 5E2

River systems are the main contributors of continental siliciclastic sediments to ocean basins, and potentially preserve a record of weathering conditions across the catchment areas. Proterozoic rivers have been viewed as mostly braided systems due to the lack of influence of rooted vegetation that produces fast channel lateral migration, high run-off rates, and low bank stability. Many large-scale Proterozoic siliciclastic basins are preserved, formed by river systems up to pan-continental scale. However, their significance as archives of continental weathering intensity remains under explored.

This study evaluates secular weathering variations for the Mesoproterozoic based on the Chemical Index of Alteration (CIA), accounting for post-depositional K addition and specifically for siliciclastic units of the Belt-Purcell Supergroup (BPS). BPS CIA values throughout the succesion span 60-85, averaging ~70. These values could be linked to CO_2 emissions from magmatism accompanying rifting of Columbia at ~1.4 Ga. The new data, along with K-corrected CIA data from the literature, could be interpreted as recording a rising trend from ~50 at ~2.5 Ga to ~75 at 1.6 Ga, a low of 50 at ~1.5 Ga, and ~50-60 from 1.4 Ga to 1.0 Ga. However, CIA link to global geodynamic events remains challenging due to scarcity and lack of space-time resolution of data sets.

BPS CIA values of ~70, are commensurate with modern large river systems such as the Orinoco, Nile and Amazon rivers. The Appekunny and Grinnell formations (Lower BPS succesion) display two intense weathering periods (~80±5) equivalent to humid-dry tropical conditions in modern rivers such as the Orinoco, Parana, Mekong and Amazon rivers, with a arid-template climate period in between.

This study suggests that BPS CIA values reflect a more aggressive chemical weathering, since Proterozoic rivers had less sediment residence time due to lack of vegetation cover, and therefore, faster transport time than their modern counterparts. To achieve high CIA values in shorter periods of time without vegetation cover, higher chemical weathering conditions need to be invoked.

Geodynamic implications of >1 Ga Re-Os model ages in PGM from the Dobromirtsi Ultramafic Massif, Central Rhodope, Bulgaria

J.M. GONZÁLEZ-JIMÉNEZ[1] W.L. GRIFFIN[1], F. GERVILLA[2], T. KERESTEDJIAN[3], S.Y O´REILLY[1] AND N.J. PEARSON[1]

[1] GEMOC ARC National Key Centre, Sydney, Australia. (jose.gonzalez@mq.edu.au.; bill.griffin@mq.edu.au; sue.oreilly@mq.edu.au; npearson@mq.edu.au).
[2] Dpt. Mineralogy & Petrology, University of Granada, Spain. (gervilla@ugr.es).
[3]Geological Institute, Bulgarian Academy of Sciences, Bulgaria. (thomas@geology.bas.bg).

The Dobromirtsi Ultramafic Massif is a relic of meta-ophiolitic mantle, located in the Central Rhodope Dome in southern Bulgaria. The ultramafics have been trust over Paleozoic (470-450 Ma; [3]) para-gneisses and are unconformably covered by Tertiary volcano-sedimentary rocks. The massif consits of strongly metamorphosed (greenschist to amphibolite facies) harzburgite and dunite, containing several chromititite pods, and cross cut by pyroxenite veins [2].

Os-rich laurite $(Ru,Os)S_2$ ± Os-Ir alloys ± pentlandite constitute the PGM assemblage in unaltered chromite. In altered zones, Os-poor partially desulfurized laurite, sometimes replaced by Ru-rich base-metal sulfides + Os-Ir alloys is the common assemblage [1].

In situ Re-Os analyses reveal that unaltered laurite has a small spread in T_{RD} (300-600 Ma). In contrast, 11 out of 36 of the altered grains yield T_{MA} (and T_{RD}) model ages > 1Ga and up to 2.2 Ga ($^{187}Os/^{188}Os$ = 0.1124- 0.1206; average = 0.1173 ± 0.003; 2σ). These unradiogenic Os signatures requiere a mantle source that underwent differentiation processes in the Proterozoic; we suggest tha this source lies in the ultramafic rocks surronding the chromitites and that hydrothermal fluids sequester this signature when it infiltrate the peritotite. The referred source would correspond to the sub-continental mantle beneath Gondwanaland. To the best of our knowledge, this is the first Os-isotope evidence of Gondwanaland terrains in Central Rhodope, as has been argued but not proved by Cherneva & Georgieva [4].

Multiphase magmatic history of the Oman-UAE ophiolite

K.M. GOODENOUGH[1]*, M.T. STYLES[2], R.J. THOMAS[2], D.I. SCHOFIELD[3], Q.G. CROWLEY[4] AND I.L. MILLAR[2]

[1]British Geological Survey (BGS), West Mains Road, Edinburgh EH9 3LA (*correspondence: kmgo@bgs.ac.uk)

[3]BGS, Columbus House, Tongwynlais, Cardiff, CF15 7NE
[4]Dept. Of Geology, Trinity College, Dublin 2, Ireland

The Oman-United Arab Emirates (UAE) ophiolite is the largest ophiolite complex in the world. The majority of the ophiolite lies in Oman, but it has a northerly extension into the UAE. This has been mapped and studied in detail by the BGS since 2002, funded by the UAE's Ministry of Energy.

The Oman-UAE ophiolite was traditionally interpreted as a classic mid ocean-ridge ophiolite, but more recently it has been recognised that a second, voluminous phase of magmatism is superimposed upon the early MORB-like ophiolite sequence. In the UAE, our field mapping has shown that this later magmatic phase forms extensive intrusions including large gabbro plutons, tonalite bodies and mafic dyke swarms throughout the crustal sequence and the mantle transition zone. The later magmatism has been dated at 96.4 to 95.2 Ma [1], coeval with similar magmatism in the Oman sector of the ophiolite [2]. The age of the early magmatism is not yet known.

Petrology and mineralogy of the early magmatic phase are consistent with formation at a spreading ridge, but the magmas of the later phase were more hydrous. Dykes and lavas from the early magmatic phase have MORB-like geochemistry, whereas those from the later magmatic phase show geochemical features of subduction-related magmatism, such as lower Ti/V and Zr/Y. Whole-rock Pb isotope data also distinguish the two phases, and support a supra-subduction zone setting for the later phase.

The youngest, volumetrically minor magmatism, recorded in the UAE sector of the ophiolite as localised mafic dykes, has geochemical and isotopic signatures more like those of ocean island basalts, and may be associated with an extensional, post-obduction event. This magmatism is tentatively dated at about 91 Ma.

Vadose zone controls on weathering intensity and depth: Observations from granitic and basaltic saprolites

B.W. GOODFELLOW[1]*, G.E. HILLEY[1], O.A. CHADWICK[2], M.S. SCHULZ[3] AND E. SHELEF[1]

[1]Department of Geological and Environmental Sciences, 450 Serra Mall, Stanford University, Stanford, CA 94131, USA. (hilley@stanford.edu; shelef@stanford.edu; *correspondence: bgood@stanford.edu)
[2]Department of Geography, University of California Santa Barbara, CA 93106, USA (oac@geog.ucsb.edu)
[3]US Geological Survey, 345 Middlefield Rd. MS-420, Menlo Park, CA 94025, USA (mschulz@usgs.gov)

An investigation of vadose zone weathering processes has been undertaken on saprolites developed in Californian granitoids and Hawaiian basalts. Granitoid observations have been made across a drying gradient (declining precipitation, increasing temperature), from the coast inland to the Sierra Nevada foothills. Observations of basalt weathering have been made across strong precipitation/hydrological gradients on Kauai and Hawaii and along a chronosequence of weathering profiles developed on lava flows ranging from ~10–40 ka on Hawaii to >4 Ma on Kauai.

Results indicate strong climatic control, through infiltration, on the depth and intensity of weathering in both lithologies. Dry, lower infiltration sites display only thin saprolites, strongly influenced by rock texture. At wet, higher infiltration, sites, the vadose zone is comprehensively altered to saprock and saprolite. In both granitoids and basalt, vadose zone and weathering depth appear to be governed by local base level. This is demonstrated by weathering to just above sea level, sharp contrasts between unweathered bedrock in perennial streams and weathered rock on adjacent slopes, and the presence of deep saprolites on steep slopes.

In addition, laboratory analyses of granitoids indicate that vadose zone hydrology exerts a fundamental control on the effective operation and relative dominance of the key weathering reactions. In zones of matrix permeability, oxidation of Fe-bearing phases comprehensively disaggregates the rock but results in minor mass loss and clay mineral formation. Conversely, the higher transient flow rates that characterize zones of fracture permeability result in plagioclase hydrolysis, significant mass losses and accompanying clay mineral formation. A variable hydrological regime may also contribute to high partial pressures of O_2 in vadose zone pore waters and pore spaces, thereby enhancing the oxidative environment and predisposing grussic saprolite formation in granitoids.

Mn/Cr systematics in carbonaceous chondrites: Mineral isochrons versus stepwise dissolution

C. GÖPEL[1]*, J.- L. BIRCK[1] AND B. ZANDA[2]

[1]IPGP- Géochimie et Cosmochimie, 1 Rue Jussieu, 75238 Paris Cedex 05, France (*correspondance: gopel@ipgp.fr)
[2]MNHN & CNRS, 61 rue Buffon, 75005 Paris, France

The Mn/Cr isotope systematics of meteorites holds a double information: the ^{53}Cr-^{53}Mn system may be used for dating while ^{54}Cr isotope systematics yields information on the mixing of nucleosynthetically distinct components of the solar system. We present Mn/Cr data on two recently discovered carbonaceous meteorites. Sequential dissolution steps of bulk rock powder were performed but also for the first time for carbonaceous meteorites the Mn/Cr systematics were measured on separated minerals.

Tafassasset is equilibrated and recrystallized. Its minerals are metal, olivine, low Ca pyroxene, feldspar with accessory chromite and phosphate. Tafassasset's classification as a CR chondrite or a primitive achondrite is still debated [1, 2]. Chromite, olivine and bulk rock define an isochron whose slope corresponds to ^{53}M/^{55}Mn= 3.07 x10^{-6} and $\varepsilon^{53}Cr_i$ = 0.07 translating into an absolute age of 4563.4 ±0.4 x10^6 y using the LEW Cliff 86010 anchor [3]. With the exception of the first leaching step, all dissolution steps fall on a linear array. The age obtained by this procedure, 4563.6 ±1.3 x10^{6}y, is identical to the age of the mineral isochron. All samples exhibit an excess of ^{54}Cr= 1.37ε which allows us to consider Tafassasset as a metamorphosed CR chondrite.

Paris is the less altered CM chondrite known to date with affinities to CO chondrites. It contains more chondrules, refractory inclusions and metal but less matrix than the others. Forsterite, fayalite, a separate of fine-grained material attached to chondrules (presumably FGR) and an aliquot of the bulk rock were analyzed for Mn/Cr systematics. All samples fall on a line with a slope of ^{53}M/^{55}Mn = 5.582 x10^{-6} and $^{53}Cr_i$ = -0.179. This slope corresponds to an age of 4566.54 ± 0.55 x10^{6}y based on the LEW Cliff 86010 anchor [3]. All mineral fractions as well as the bulk rock of Paris exhibit a positive ^{54}Cr anomaly. In contrast, the sequential dissolution pattern is similar to that of Murchison.

The ^{54}Cr values of both meteorites fall on the correlation line that has been established between ^{54}Cr and Δ^{17}O for carbonaceous chondrites [5]. In conclusion, the ^{53}Cr and ^{54}Cr isotope systems represent an efficient tool to decipher the origin and classification of meteorites.

Intra-cratonic lithospheric deformations — Heterogeneities, faulting and Rayleigh-Tylor instabilities

WERONIKA GORCZYK[1], BRUCE HOBBS[1], GUIZHI ZHU[2], KLAUS GESSNER[2] AND ALISON ORD[2]

[1]School of Earth and Environment, The University of Western Australia, Perth, Australia.
[2]Dept. of Geosciences, ETH-Zurich, Switzerland.

The seismological structure of the Earth's lithosphere is identified to be strongly heterogeneous in terms of thermal and rheological properties. Lithospheric discontinuities are thought to be long lived and are mostly correlated with major tectonic boundaries that commonly have been reactivated and are subsequently the foci of magma intrusion and major mineralization. The occurrence of such variations may be caused for instance by amalgamation of micro-continents such as is thought to be characteristic of the Yilgarn, Western Australia or parts of South Africa.

This paper explores the control that 3D lithospheric heterogeneity exerts on the thermal and chemical evolution during deformation subsequent to the development of the heterogeneity, as well as periodicity and lateral distribution of phenomena such as Rayleigh-Taylor instabilities and fluid transport from the mantle through the crust. Exploration of the parameters controlling the 3D distribution of focusing mechanisms is crucial for understanding the distribution of major ore deposits along main structures. Empirical observations in Kalgoorlie area (Western Australia, Yilgran craton) show that spacing of major gold deposits is approximately 30km along major lithospheric heterogeneities. This spatial distribution may result from periodic development of Rayleigh-Taylor instabilities along the contact zone, which results in fluid transfer in areas where delamination has occurred. From numerical experiments it appears that the yield strength of the weak zone is one important parameter controlling the spatial distribution of deformation

Above the site of localised delamination of the mantle lithosphere, a series of deep crustal faults develop that may extend into the upper mantle. These deep structures can act as the pathways for mantle derived CO_2 ± H_2O fluids and alkaline igneous complexes.

Geochemical features of the fluvial plain sediments from the riverbank profiles of the metallogenic area of Eastern Serbia– Ecological significance

V. GORDANIC[1]*, M. VIDOVIC[1], D. JOVANOVIC[2] AND A. CIRIC[2]

[1]The University of Belgrade, IHTM, Dep. Ecol., Serbia (corresp:gordanicv@gmail.com; mivibgd@yahoo.com)
[2]Geological Institute of Serbia, Belgrade, Serbia (dramar@sezampro.rs; abciric@eunet.rs)

During the geochemical mapping of the Eastern Serbia region (in scale 1:1.000.000) samples from the river bank profiles of the drainage areas of several rivers were gathered. Samples (181) were taken from the A-horizons, overbank sediments and stream sediments of the different localities (56). Geochemical features of the area are preserved in the investigated river bank profiles. Significant Cu and Au deposits and smaller deposits of U, Fe and W exist in the area. The anomaly concentrations of the same metals are noted in the investigated river bank sediments.

Well preserved geochemical inscription in the river bank profiles is in good correlation with metallogenic features of this part of the Carpatho-Balkan geochemical province. Sampling network is adjusted to the hydrographical features and mapping scale. The most interesting results are presented in the table 1.

locality	level	**Pb**	**Zn**	**Cu**	**Au**	**Sb**
Mali Timok	A	160	357	1610	0.20	7
	OB	311	1065	3500	0.22	15
	S	148	984	5444	0.25	8
	level	**As**	**Cd**	**Cr**	**V**	**U**
Mali Timok	A	20	3.0	60	140	-
	OB	65	2.1	40	30	3.5
	S	20	5.1	20	60	-

A= A-horizon; OB=overbank sediment); S =stream sediment

The results of gamma spectrometric analyses for ^{238}U, ^{232}Th and ^{40}K reflect radiation burden of selected localities.

Geochemical inscription from the river bank profiles are significant for geochemical prospecting and for rmineral raw material exploration, as well as for definition of anomalous concentrations areas of toxic and other elements.

This work has been financed by the Ministry of Science and Technology of the Rep. of Serbia, project OI 176018.

Partial melting and its role in elemental recycling: Insight from Pamir metasedimentary xenoliths

S.M. GORDON[1]*, P. KELEMEN[2], B.R. HACKER[3], P. LUFFI[4] AND L. RATSCHBACHER[5]

[1]Geological Sciences, University of Nevada, Reno, NV 89557, USA (*correspondence: staciag@unr.edu)
[2]Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, 10964, USA
[3]Earth Research Institute, University of California, Santa Barbara, CA, 93106, USA
[4]Earth Science, Rice University, Houston, TX 77005, USA
[5]Geowissenschaften, Technische Universitat Bergakademie, Freiberg, D-09599 Freiberg, Germany

Elemental recycling during subduction has played a key role in the geochemical evolution of the Earth, with recycling efficiencies as high as >75–80% for some elements (e.g., Th). Tracking the fluids and/or melts responsible for recycling, and understanding the *P-T* conditions at which recycling occurs, are more difficult as access to these conditions is limited to experiments. Crustal xenoliths erupted in Tajikistan record temperatures ranging from 875–1100 ºC at pressures of 19–29 kbar. Garnet–kyanite–sanidine gneisses have a meta-sedimentary protolith and represent dehydration-melting residua based on their bulk composition trend of Al_2O_3 > (CaO + K_2O + Na_2O) and that micas are only found as inclusions within garnet and kyanite. Because the metasedimentary xenoliths record a range of temperatures and reached conditions at which melting occurred, they are key samples to investigate the conditions at which recycling occurs. A LA-ICP-MS was used to measure the trace-element composition of all major and minor phases to determine where the key trace elements (e.g., Th, Sr) are stored at different temperatures. Here we highlight three of the samples that range in attaining maximum temperature from 875 ºC to 1000 ºC. In all samples, sanidine contains the large-ion lithophile elements, garnet the heavy rare-earth elements, rutile hosts Nb and Ta, and zircon contains Zr and Hf. In the granulite-facies (plagioclase-stable) gneiss, plagioclase stores Sr but less Ba and Rb, whereas sanidine stores Ba and Rb at all temperatures and Sr at high temperatures. The bulk compositions of the samples indicate that Th, La, and Ba were not depleted until temperatures >900 ºC, even though all three samples appear to have experienced melting. Thus, melting does not seem to have been directly responsible for the depletion, as only the high-*T* samples show depletion. Instead, high-temperature fluids most likely facilitated the recycling of elements from the subducted crustal material.

Redox conditions in infiltration basins of a large scale soil aquifer treatment (SAT) of effluent

O. GOREN[1]*, I. GAVRIELI[1], A. BURG[1], I. NEGEV[2], J. GUTTMAN[2], T. KRAITZER[2], H. CHIKUREL[2], W. KLOPPMANN[3], C. GUERROT[3] AND M. PETTENATI[3]

[1]Geological Survey of Israel, Jerusalem, Israel (*correspondence: orly.goren@gsi.gov.il)
[2]Mekorot National Water Company, Tel Aviv, Israel
[3]BRGM, Water Department, Orléans, France

Soil Aquifer Treatment (SAT) is considered to be an efficient and reliable effluent tertiary treatment system, in which the vadose zone and the aquifer serve as mechanical, geochemical and biological filters. In the SAT system of the Shafdan reclamation plant, Israel, large volumes of secondary effluent (about 130 million m^3 annually) are recharged into the Costal Plain Aquifer and are recovered for irrigation after residence time of a few months in the aquifer.

A severe degradation of the reclaimed water quality occurs due to a sharp increase of the Mn concentrations. This enrichement is the result of sedimentary Mn-oxides reduction under suboxic conditions within the aquifer. Such conditions prevail in the aquifer due to the intensive organic matter oxidation and nitrification that take place in the upper part of the vadoze zone and consume the dissolved oxygen from the recharged effluent [1].

The present work focuses on the redox reactions that occur in the infiltration basins as well as in the upper few meters below the basins, and aims to determine their sensitivity to different conditions, such as sunlight, temperature and recharge regime.

The preliminary results point to diurnal changes in the intensity of different redox reactions in the basins which have a significant impact on the redox conditions of the infiltrating effluents. The dissolved oxygen (DO) increases during the day to over-saturation values and decreases during night to under-saturation due to net photosynthesis and respiration, respectively. Unlike the DO, the dissolved organic carbon (DOC) in the effluents is quite stable during the 24-hour period. Moreover, the DOC concentrations in the water in the upper one meter of the vadose zone are higher than those in the basin. This implies that significant part of DOC oxidation takes place downward in the vadose zone. A combination of nitrogen mass balance and isotopic composition of oxygen and nitrogen in nitrates point to nitrogen removal by both NH_3 volatilization and denitrification.

An electrochemical approach to determine the redox properties of iron-bearing clay minerals

CHRISTOPHER A. GORSKI[1], MICHAEL SANDER[2], MICHAEL AESCHBACHER[2], LAURA E. KLÜPFEL[1] AND THOMAS B. HOFSTETTER[1,2]

[1]Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland
[2]Institute of Biogeochemistry and Pollutant Dynamics (IBP), Swiss Federal Institute of Technology, ETH Zurich, Switzerland

Clay minerals often contain redox-active structural iron (Fe) that can participate in electron transfer reactions with several environmental constituents, including bacteria, biological nutrients, and pollutants. Despite significant work, the electron accepting/donating capacities and Fe^{2+}/Fe^{3+} reduction potential(s) remain difficult to access due to the lack of reactivity between clay minerals and electrodes.

In the current study, we have overcome this challenge by using organic electron transfer mediator compounds that rapidly react with both the clay mineral and the working electrode. Our approach uses chronoculometry, where a fixed potential is applied (E) to the working electrode in a solution containing the mediator. The current (I) is then monitored after the addition of a known amount of clay mineral to quantify the number of electrons transferred. Electrochemical studies were complemented by batch experiments, where a solution of mediator at a set potential (E) is spiked with an alloquot of smectite and the change in potential is measured over time.

For these experiments, we have used an Fe-rich model clay mineral (ferruginous smectite, SWa-1). Highly reducing (E = -0.64 V, SHE) and highly oxidizing (E = +0.61 V, SHE) potentials led to the complete reduction and oxidation of the structural Fe of the smactite, respectively. At intermediate potentials, the Fe^{2+}/Fe^{3+} ratio has been measured as a function of E, pH, and the reduction/re-oxidation cycles of the smectite. We find that the redox properties of structural Fe cannot be described by a single standard reduction potential (E^o); instead, the properties can be explained by either capacitor-like behavior or a distribution of local structures of octahedrally bound Fe with distinct $E°$ values. Addtionally, the reduction/re-oxidation cycles of the smecite appears to strongly influence the Fe(II)/Fe(III) versus E relationship and the electron accepting/donating capabilites during Fe reduction and oxidation. The outcome of our study will help to address the biogeochemical implications of Fe redox reaction involving clay minerals.

Forensic analysis of surface fallout from low yield surface nuclear tests

RICHARD C. GOSTIC*, KIM B. KNIGHT, GREG SPRIGGS AND IAN HUTCHEON

Lawrence Livermore National Laboratory, Livermore, CA 94551, USA (*correspondance: gostic2@llnl.gov)

Five decades after the last US atmospheric test, fallout samples from low yield surface and near surface events are being re-examined for their forensic value using a combination of radiometric (counting) and mass spectrometry based techniques. Preliminary data from these studies indicate that soil samples collected along historical fallout plumes contain easily accessible information about key components of each test such as fuel isotopics and the elemental composition of structural components.

The distribution of fuel, activation product and fission product signatures as a function of soil grain size and distance from ground zero has been found to be nearly uniform among larger grain sizes of fallout soil (> 0.1 mm). Anthropogenic glasses extracted from the fallout soil samples constitute <5% of the bulk soil mass, yet contain >50% of the total activity. Order of magnitude increases in the concentrations of actinides such as ^{235}U or ^{239}Pu are observed in the glass relative to the soil. By gamma spectroscopy ^{235}U concentrations are estimated to be >60 μg/g and ^{239}Pu concentrations >20 μg/g in glasses recovered from two different tests. Preliminary analysis of the U bearing glasses by ICP-MS indicates a fuel with a minimum enrichment of 84% ^{235}U. Analysis of the stable isotope signal from ICP-MS measurements shows that Be is present in the glass at concentrations 4 times higher then the bulk soil, and that Cr, Co and Mo are present in the U bearing glasses at 3-20 times the bulk soil concentration.

These results demonstrate that fallout from low yield surface nuclear tests collected as surface deposits long after the detonation contains valuable information about device characteristics. This information is relevant to characterizing historical activities from surface based nuclear test programs and is applicable to nuclear forensics research. This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-480552

Rapid esterifications for compound-specific stable isotope analysis of fatty acids

A.S. GOTO AND T. KORENAGA

Department of Applied Chemistry, Tokyo Metropolitan University, Tokyo 192-0397, Japan (*correspondence: akigoto@tmu.ac.jp)

Fatty acids are frequently found as abundant lipid molecules in biological and geological samples, and therefore have been employed as biomarkers in a number of studies particularly for organic geochemistry. However, to reduce polarity and enhance volatility of fatty acids, and resultingly to improve the shape and resolution of fatty acid peaks on gas chromatograms, derivatization such as esterification or silylation are generally required for identification and quantification as well as compound-specific stable isotope analysis (CSIA) of fatty acids.

Here we evaluate methyl (MCF) and ethyl chloroformate (ECF) derivatizations as a rapid and simple esterification for CSIA of fatty acids. These derivatizations are generally prepared with an admixture of MCF/H_2O/methanol/pyridine or ECF/H_2O/ethanol/pyridine at room temperature for 5 min (Fig. 1). In this study, we used 0.1M HCl aq., H_2O, 0.1M NaOH aq., or organic alcohol (methanol or ethanol) instead of H_2O to evaluate the efficiency of derivatization.

For both MCF and ECF derivatizations, fatty acids are esterified very rapidly (within 5 min) even at room temperature, and accuracy of the carbon isotope measurements is always less than 0.3‰ (1σ). Although the yield of derivatives would depend on the chemical constituents and pH of derivative reagents as well as on the carbon-chain length of fatty acids, quantitative esterification is observed by using ECF/ethanol/pyridine (2/60/5, v/v). Thus we conclude that these derivatizations are potentially suitable as a rapid and simple esterification tool for CSIA of fatty acids.

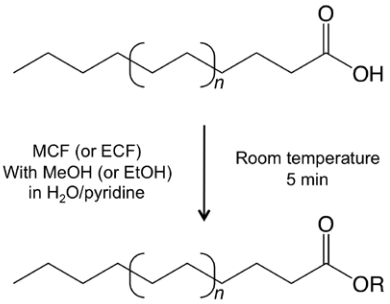

Figure 1: MCF or ECF derivatization of fatty acids.

U-Pb zircon geochronological, geochemical and Sr-Nd-Hf isotopic studies of granitoids in Muzhaerte River, Southwest Tianshan UHP belt (NW China), and their tectonic implications

L.L. GOU AND L.F. ZHANG*

The Key Laboratory of Orogenic Belt and Crustal Evolution, MOE; School of Earth and Space Sciences, Peking University, Beijing 100871, China
(*correspondence: Lfzhang@pku.edu.cn)

Two granitic intrusions, Changawuzi and Alasan plutons, in Muzhaerte River of Southwest Tianshan UHP belt (NW China) were studied, with the purposes of determining their ages, petrogenesis and implications for the evolution of South Tianshan orogenic belt. A SHRIMP zircon $^{206}Pb/^{238}U$ age of 333±3 Ma was obtained for the Changawuzi pluton and LA-ICP-MS zircon U-Pb dating gave three $^{206}Pb/^{238}U$ ages of 296±4 Ma, 292±2 Ma and 287±8 Ma for the Alasan pluton respectively. The Changawuzi pluton is formed in a continental marginal setting by fractional crystallization from the partial melting of juvenile mafic continental marginal arc rocks, which later assimilated ancient continental crustal material to the extent of 10-15% during emplacement as suggested by the Sr-Nd isotope mixing modelling. The elemental and Sr-Nd-Hf isotopic geochemical studies indicate that the Alasan pluton was the products of fractional crystallization of magma, which were generated by partial melting of mixture of crustal juvenile medium-to-high K intermediate-to-basaltic rocks and 10-30% ancient continental crustal material. As the closure of paleo-South Tianshan ocean (319 Ma), the lithospheric tearing with localized upwelling of asthenosphere occurred at the beginning of slab breakoff because of the localized deformation. This induced the syn-collision magmatisms (317-301 Ma) in the Middle Tianshan terrane. Afterwards, the extensive upwelling of hot asthenosphere induced the partial melting of the crust and formation of voluminous granitic rocks in the early Permian (300-270 Ma) in the South Tianshan orogenic belt. These results imply successive stages of late subduction and closure of paleo-South Tianshan ocean, as well as the collision and post-collision between Tarim plate and Yili-Central Tianshan block happened in Late Paleozoic period.

Geochemical composition of recent sediments and subrecent variability of the last 500 years for the SW Adriatic Sea and the Gulf of Taranto (Southern Italy)

M-L.S. GOUDEAU *AND G.J. DE LANGE

Department of Earth Sciences–Geochemistry, Faculty of Geosciences, Utrecht University, Utrecht, Netherlands
P.O. Box 80.021 3508 TA Utrecht
(*correspondence: m-l.goudeau@geo.uu.nl)

Previous studies from the Gallipoli shelf, Gulf of Taranto, S. Italy, indicate that continuous sedimentation at high accumulation rates and low bioturbation [1] permit high-resolution paleoclimate studies. Measurements of carbonate contents, thermolumuniscens, oxygen and carbon isotopes, [2,3] and reconstructed sea surface temperatures [4] display cyclic frequencies similar to those known for solar cycles. Origin and processes related to these patterns, however, remain unclear. To study these cycles in more detail, a multi-proxy approach is needed to reconstruct e.g. changes in run-off, and productivity in the past. The Gulf of Taranto however is located in a coastal area, influenced by rivers, ocean currents, and eolian dust sources, affecting the geochemical composition of the in situ sediments [5-8]. Assessing input and geochemical fingerprints of all different sources to the Gulf of Taranto in the present system, will permit changes in these sources to be reconstructed. Here, we present details and interpretation for a compositional study of core top samples from the S. Adriatic and the Gulf of Taranto and terrestrial samples from the Italian Adriatic coastal area. Results are then used to reconstruct e.g. run off in the Gulf of Taranto for the last 500 years.

Isotopic variations in mafic volcanic rocks from the western branch of the East African Rift

D. GRAHAM*[1], T. FURMAN[2], J. BLICHERT-TOFT[3], J. LUPTON[4], C. EBINGER[5] AND N. ROGERS[6]

[1]College of Oceanic & Atmospheric Sciences, Oregon State University, Corvallis, OR 97331, USA (*correspondence: dgraham@coas.oregonstate.edu)

[4]NOAA/PMEL, Hatfield Marine Science Center, Newport, OR 97365, USA
[5]Department of Earth and Environmental Sciences, University of Rochester, Rochester, NY 14627, USA
[6]Department of Earth Sciences, Open University, Milton Keynes, MK7 6AA, UK

Isotopic variations in lavas from regions of low tectonic extension, such as the western branch of the East African Rift (EAR), can be used to probe regional variability in the underlying continental lithospheric mantle. Volcanic rocks from the western branch of the EAR are isotopically among the most extreme young samples on Earth. Pb, Hf, Nd and Sr isotope compositions for mafic, undersaturated alkalic lavas from Rungwe, Kivu, Virunga and Toro-Ankole all show large variations over short lateral distances, indicating extensive isotopic heterogeneity in the continental lithospheric mantle source for these lavas, mostly due to ancient metasomatism associated with African orogenic events. Trends in the isotopic data show a convergence near values of $^{206}Pb/^{204}Pb$=18.9-19.2,$^{207}Pb/^{204}Pb$=15.63-15.67, $^{208}Pb/^{204}Pb$=39.3-39.7, ε_{Nd}=0, ε_{Hf}=3 and $^{87}Sr/^{86}Sr$=0.705. The isotopic variation within each volcanic province extends away from these values to distinct compositions. In contrast, $^{3}He/^{4}He$ within each province shows a restricted range; 7.5-9.0, 5.0-6.5, 6.7-7.5 and 5.6-6.8 R_A for Rungwe, Kivu, Virunga and Toro-Ankole, respectively. There is no evidence for the presence of high $^{3}He/^{4}He$ plume material such as that beneath the Ethiopian Rift and Afar. The convergence of the Pb-Hf-Nd-Sr isotopes suggests that primary magma is derived from a common mantle source beneath the western branch of the EAR, such as the lithosphere/asthenosphere boundary. In contrast, the distinct isotopic variations within each volcanic region represent the shallower, provincial characteristics of the underlying lithosphere and crust.

Electron shuttle production by *Shewanella oneidensis*

JEFFREY A. GRALNICK* AND NICHOLAS J. KOTLOSKI

Department of Microbiology and BioTechnology Institute, University of Minnesota, St. Paul, MN, USA, (*correspondence: gralnick@umn.edu)

Extracellular Respiration

Many dissimilatory metal reducing bacteria have evolved mechanisms to transfer electrons from the cytoplasmic membrane quinone pool to insoluble substrates (e.g. oxide minerals and electrodes) located beyond their outer membranes [1, 2]. *Shewanella oneidensis* strain MR-1 is the best understood model system for extracellular respiration. While biochemical evidence supports a direct mechanism for electron transfer to insoluble substrates, there is also strong physiological evidence for electron shuttling [3, 4]. Flavins (riboflavin and flavin mononucleotide (FMN)) were identified as the primary electron shuttle compounds produced by *Shewanella*. Our work seeks to define the contribution of electron shuttles to the reduction of insoluble substrates by *S. oneidensis* and understand the molecular mechanism underlying the production and processing of flavin shuttles produced by these bacteria.

Discussion of Results

We designed a mutagenesis screen in *S. oneidensis* to isolate strains that no longer accumulated flavins in culture supernatants. This work led to the identification of UshA, a 5'-nucelotidase involved in the processing of periplasmic flavin adenine dinucleotide (FAD) to FMN and adenosine monophosphate [5]. Strains defective in *ushA* accumulated FAD in culture supernatants instead of FMN or riboflavin. We repeated our mutagenesis screen in an *ushA* deletion mutant background to identify additional components involved in electron shuttle processing and secretion. This secondary screen identified mutants defective in flavin export and in regulation of flavin secretion. Here, we present the characterization of the two new components related to electron shuttle export by *S. oneidensis*. We have generated the first strain of *S. oneidensis* that is fully defective in electron shuttle secretion, allowing us to conclude that electron shuttling accounts for ~75% of the electron transfer activity to insoluble substrates. Moreover, electron shuttling mutants have no defect in respiration of soluble organic electron acceptors or chelated iron.

Deciphering mafic and felsic lunar magmatic events: Insight from zircon

M.L. GRANGE[1]*, A.A. NEMCHIN[1], N. TIMMS[1], R.T. PIDGEON[1] AND C. MEYER[2]

[1]Dept. of Applied Geology, Curtin University, GPO Box 1987, Perth, Western Australia 6845. (*correspondence: m.grange@curtin.edu.au)

[2]NASA Johnson Space Center, Houston, TX 77058, USA.

Microstructural studies of zircon grains from lunar breccia samples, combining high resolution imaging together with in-situ U-Th-Pb analyses, has allowed us to distinguish primary zircon, formed by igneous crystallisation in plutonic rocks, and secondary, impact-related, features in zircon grains. Dating of these grains can be used to identify multiple igneous and impact events. For example, a single impact melt breccia from the Apollo 17 landing site contains grains that record more than 3 igneous events in addition to 3 distinct impact events, indicating that the region sampled by this breccia probably significantly exceeds the area of the landing site. As a result, the study of primary zircon ages in the available samples can be used to investigate the temporal distribution of plutonic magmatism on the Moon, even though these samples were collected from the relatively small areas covered by the lunar landing missions.

The study of primary zircons containing inclusions of rock-forming minerals or zircons preserved in lithic clasts found in lunar breccias also provides an opportunity to place temporal constraints on the different types of plutonic magmatism on the Moon. U and Th concentrations of these zircon grains vary systematically allowing clear separation of zircons formed in mafic rocks, such as anorthosite, norite, and gabbro-norite, from those formed in felsic rocks (i.e. granophyre and felsite). This chemical variation can be used to determine plutonic hosts of zircon grains found as mineral clasts in the breccia samples and as loose grains in lunar soils, expanding significantly the number of zircons with known origin.

A comparison of ages of zircons originating from mafic and felsic host rocks suggests a possible age difference between these two chemical rock groups. If confirmed by further analyses this would indicate that the two current explanations for the formation of felsic rocks on the Moon, (i) as residual melt left after extreme fractionation of basaltic magma or (ii) as a result of liquid immiscibility during late stages of fractionation of basaltic melts, are incorrect. Both mechanisms imply close temporal relationships between mafic and felsic rocks, which does not appear to be supported by the available U-Pb ages.

Silicon isotopes as a tracer for silicate utilization in the Peruvian upwelling

PATRICIA GRASSE*, CLAUDIA EHLERT, LOTHAR STRAMMA, EVGENIYA RYABENKO, JASMIN FRANZ AND MARTIN FRANK

IFM-GEOMAR, Wischhofstr. 1-3, 24148 Kiel, Germany (*correspondance: pgrasse@ifm-geomar.de)

Natural stable isotopes are a powerful tool in marine sciences to investigate biological processes, such as present and past nutrient utilization. In this study we present the first dissolved silicon isotope data in the upwelling area off Peru, where one of the world's largest Oxygen Minimum Zones (OMZ) is located. Samples were recovered during "FS Meteor" cruises M77/3 and M77/4 in 2009. Silicic acid is the most important component required for the growth of diatoms, which dominate the primary productivity in this region. Stable silicon (Si) isotopes are fractionated during diatom growth in that the lighter isotopes are preferentially incorporated into diatom frustules with a fractionation factor of -1.1‰. The Si isotope composition of dissolved silicic acid of the corresponding surface waters is therefore left isotopically heavier. The silicon isotope composition, $^{30}Si/^{28}Si$ is given relative to a reference standard (NBS28) and expressed in the $\delta^{30}Si$ notation. Dissolved Si isotope signatures of seawater provide a measure for the degree of utilization of silicic acid but are also influenced by water mass mixing. Surface waters on the shelf off Peru are mainly fed by the Peru Chile Undercurrent ($\delta^{30}Si$=1.5‰), which consists of water masses ultimately originating from the western and Central Pacific. In areas and during phases of intense upwelling the fractionation of Si isotopes was observed to be weaker due to upwelling driven supply of less fractionated Si ($\delta^{30}Si$=1.8‰) from water depths of 50 to 150m, whereas under weak upwelling conditions the surface waters are heavier ($\delta^{30}Si$=2.8‰) due to more complete utilization of the available dissolved silicic acid. The distribution of the dissolved silicon isotope compositions correlates strongly with particulate biogenic silicate (opal) concentrations in that the highest opal concentrations in surface waters on the shelf reflect the lowest $\delta^{30}Si$ values thus the strongest upwelling intensity. The most extreme $\delta^{30}Si$ values in surface waters ($\delta^{30}Si$=3.2‰) are observed offshore where silicic acid is limited. Furthermore we compare $\delta^{30}Si$ data with the dissolved nitrogen isotope distribution, which, in addition to nitrate utilization, is also influenced by denitrification and annamox processes in the OMZ. Combined silicon and nitrogen isotope compositions can thus help to disentangle different fractionation processes within the nitrogen cycle.

Chemical modification of airborne mineral dust

VICKI H. GRASSIAN

Department of Chemistry, University of Iowa, Iowa City, IA 52246, USA (vicki-grassian@uiowa.edu)

Introduction

Mineral dust aerosol, i.e. suspended soil particles, can impact a wide range of global processes including the chemistry of the Earth's atmosphere and the Earth's climate. Atmospheric processing of mineral dust through heterogeneous chemical and photochemical reactions will modify the properties of the dust particle and thus alter how these particles impact global processes [1-3].

Approach

Using a combined approach of applying state-of-the-art surface sensitive probes, aerosol instrumentation and reactivity studies provides for an understanding of reactions on dust particles and how these reactions can alter the global impacts of mineral dust aerosol. These laboratory studies can provide a conceptual framework from which to understand the details of chemical processes that modify the properties of mineral dust aerosol as these particles are transported through the atmosphere [4].

Discussion of Results

The importance of mineralogy, the link between interfacial chemistry and climate and the specificity of mineral dust aerosol chemistry will be discussed. Examples will be shown that clearly provide evidence to show that mineral dust modifies the chemical balance of the atmosphere through heterogeneous reactions and that heterogeneous reactions modifies the physicochemical properties of mineral dust particles.

Stable isotopes of organics and inorganics of Aptian lacustrine sediments in North-Eastern Brazil

R. GRATZER[1]*, V.H. NEUMANN[2], W. VORTISCH[1], D. ROCHA[2] AND A. BECHTEL[1]

[1]Montanuniversität Leoben, 8700 Leoben, Austria, (*correspondence: gratzer@unileoben.ac.at)

[2]Universidade Federal de Pernambuco, Recife, Brazil (neumann@ufpe.br, dunaldson@msn.com)

The Jatobá Basin is located in the Pernambuco-Alagoas massif, NE Brazil. The elliptical basin, orientated NE-SW, is characterized by a semi-graben structure with tilted blocks toward NW direction. The analysed section [1] consists of shales, marls, sandstones, limestones and dolostones.

Stable isotope analysis was carried out on carbonates and organic matter. TOC content varies from 0.5-13 wt%, Hydrogen and Oxygen Indecies from 6 to 715 and 4 to 44 respectively. The organic matter is immature (R_o % 0.28) and is represented by kerogen Type I in the lower section. In the upper section it is modified by the addition of terrestrial organic matter. A ~3 m thick clay-rich shale seperates the the sections.

	Lower section	Upper section
$\delta^{13}C$ Carbonates	-8.72 to -3.65	-3.57 to +2.47
$\delta^{18}O$ Carbonates	-8.09 to -4.98	-8.67 to -4.11
$\delta^{13}C$ Pr + Ph	-28.25 to -31.66	-31.66 to -30.28
$\delta^{13}C$ C_{29} Steranes	-26.39 to -30.12	-30.12 to -28.08
$\delta^{13}C$ C_{30} Hopanes	-27.40 to -32.96	n.d.

Table 1: Variation and trends in $\delta^{13}C_{PDB}$ ‰ and $\delta^{18}O_{PDB}$ ‰ of carbonates and $\delta^{13}C_{PDB}$ ‰ organic compounds.

$\delta^{18}O$ of carbonate minerals (Table 1) indicates fresh water conditions throughout the sediment column. In the deepest part of the lower section dolomite occures together with high TOC contents. Here $\delta^{13}C$ suggests intense microbial activity during carbonate formation. In contrast, $\delta^{13}C$ shift to more positive values in the upper part, indicating less microbial influence. The upward trend of organic $\delta^{13}C$ is towards lighter values in the lower section and heavier values in the upper section (see Table 1). This is interpreted as the result of changing environmental conditions and enhanced terrigeneous organic matter input.

Hydrogeochemical survey of CO_2 geological leakage using noble gases: Application to the Furnas Caldera (Azores, Portugal)

C. GREAU[1,2]*, M. MOREIRA[1], P. AGRINIER[1], V. LAGNEAU[2], H. SCHNEIDER[3], P. MADUREIRA[4] AND L. RUZIE[1]

[1]Institut de Pysique du Globe de Paris (IPGP), 1 rue Jussieu, 75005 Paris, France (*correspondence : greau@ipgp.fr)
[2]École des Mines de Paris, Centre de Géosciences, 35, rue Saint Honoré, Fontainebleau, 77305 Cedex, France
[3]EDF R&D, Site des Renardières, Route de Sens, Écuelles, Moret-sur-Loing, 77818 Cedex, France
[4]Universidade de Évora, Centro de Geofísica de Évora, Departamento de Geociências, 8 Rua Romão Ramalho, 59, 7000-671 Évora, Portugal

Significant natural CO_2 emissions have been measured across the caldera of Furnas (São Miguel Island, Azores) allowing us to consider the area as a CO_2 leakage analogue.

During two field trips, we have collected twenty springs in purpose to measure CO_2 contents (Dissolved Inorganic Carbon and $\delta^{13}C$) and noble gas isotopic compositions (He and Ne) and for seventeen water samples, major ions chemistry. The corrected $^3He/^4He$ ratios (normalized to air ratio R_A) range from 1.46 to 5.17, the carbon contents (DIC) range from 0.57 to 41,41 mmol/l and most of the waters have a $\delta^{13}C$ about -4 ‰.

With field observations and waters chemistry, we have characterized seven different types of water springs through the caldera, resulting from various mixing rates between three sources : soil equilibrated meteoritic water, gas emanations (CO_2, He…) from a magmatic intrusion and hydrothemal waters coming from a shallow depth aquifer. Saturation indexes and geothermometers indicate a trachytic aquifer at a temperature of about 145°C.

In order to confirm that noble gases are good tracers of CO_2 leakage, we are building a first mixing model using noble gases and carbon isotopes and a second one based on major ions chemistry with CHESS hydrochemical modelling software. Preliminary mixing models seem to be consistent thus confirming that noble gases can be used as tracors of CO_2 leakage.

Comparison of Diviner Lunar Radiometer Observations of Apollo sites and Apollo soils measured in simulated Lunar environment

B.T. GREENHAGEN[1]*, I.R. THOMAS[2], N.E. BOWLES[2], C.C. ALLEN[3], K.L. DONALDSON HANNA[4], E.J. FOOTE[5], AND D.A. PAIGE[5]

[3]NASA Johnson Space Center, Houston, TX 77058, USA
[4]Brown Univ., Providence, RI 02912, USA
[5]Univ. of California, Los Angeles, CA 90095, USA

The Diviner Lunar Radiometer (Diviner), onboard NASA's Lunar Reconnaissance Orbiter, has made the first direct global measurements of lunar silicate mineralogy using multispectral thermal emission mapping [1]. Diviner has three spectral channels near 8 μm designed to characterize the Christiansen feature (mid-infrared emissivity maximum) [2], which systematically shifts to shorter wavelengths with increasing silicate polymerization [e.g. 3,4].

Only laboratory experiments conducted in simulated lunar environment (SLE) are directly comparable to Diviner data. The Lunar Thermal Environment Simulator at University of Oxford's Atmospheric, Oceanic, and Planetary Physics Laboratory is uniquely capable of measuring thermal emission of samples in SLE [5]. In the lunar environment, large thermal gradients develop in the top few hundred microns of the surface, driven by the difference in the solar and thermal skin depths (i.e. the surface is heated to greater depth than the infrared emitting layer). The thermal gradients generally result in a significant enhancement of Christiansen feature spectral contrast and significant decreases in Reststrahlen Bands spectral contrast.

Diviner observations include all six Apollo sites at approximately 200 m spatial resolution. Spectral differences between the Apollo sites caused by composition and space weathering are apparent in Diviner data [1]. Since the compositions of Apollo soils are known, the Apollo sites are important calibration points for the Diviner dataset. This presentation will include the first comparison of Diviner observations of Apollo sites and spectra of Apollo soils measured in SLE.

Surface modifications of engineered nanoparticles and their impacts on cytotoxicity

KELVIN B. GREGORY[1,2], ZHIQIANG LI[1,2] AND GREGORY V. LOWRY [1,2]

[1]Carnegie Mellon University, Civil and Environmental Engineering, Pittsburgh, PA, 15213, USA
[2]Center for Environmental Implications of Nanotechnology

The interactions of engineered nanoparticles (ENP) with the natural environment will have a deterministic affect on their fate and transport, yet the impacts of environmental tansformations of ENP are poorly understood. For example, previous work in our laboratory demonstrated that bare particles of nanosized zero-valent iron exhibited toxicity towards bacterial cells at concentrations as low as a few mg/L, yet oxidation of the iron surfaces or the presence of natural or engineered coatings may eliminate the toxic effects of NZVI. We examined the impact of surface transformations on the bacterial toxicity of ENP through the application of natural and/or engineered coatings on the particles. We selected particles with different mechanisms of expressing cytotoxicity; 1) NZVI- requires direct contact with cells, 2) TiO_2- produces reactive oxygen species, and 3) AgNP- produce toxic metal cations. Our findings show that both natural and engineered surface coatings on NP may greatly reduce or eliminate the cytotoxicity of NP. However, the ability and mechanism of interference with toxicity is dependent on both the type of particle well as the coating. While engineered coatings of NZVI induced electrostatic or electrosteric repulsion between the NP and cell that prevented toxicity, in the case of TiO_2, the natural organic matter coatings scavenged reactive oxygen species. Interestingly, engineered polyaspartate coatings did not prevent the toxicity of TiO_2. The coating of AgNP with engineered and natural polymers has little impact on toxicity, but oxidation of the surface through sufidation greatly reduced toxicity. Our studies imply that surface modifications may be engineered to minimize cytotoxicity and that the potential for detrimental impacts of ENP in the environment is lessened by coatings on which arise in natural systems.

Physical versus chemical non-equilibrium model for simulating U(VI) adsorption

JANEK GRESKOWIAK[1,2,*], MICHAEL B. HAY[3], HENNING PROMMER[2], CHONGXUAN LIU[4], VINCENT E. A. POST[5], RUI MA[6], CHUNMIAO ZHENG[6], JAMES A. DAVIS[3] AND JOHN M. ZACHARA[4]

[1]University of Oldenburg, 26111 Oldenburg, Germany (*correspondence: janek.greskowiak@uni-oldenburg.de)
[2]CSIRO Land and Water, Wembley, Australia
[3]USGS, Menlo Park, USA
[4]Pacific Northwest National Laboratory, Richland, USA
[5]Flinders University, Adelaide, Australia
[6]University of Alabama, Alabama, USA

Surface complexation reactions and diffusional mass-transfer between mobile pore water and immobile water associated with the intra-grain pores have been found to play an important role for the overall U(VI) transport behaviour in the US DOE Hanford 300A aquifer. Several laboratory- and field-scale scenario simulations have been carried out to investigate the behaviour of two alternative model approaches for the simulation of coupled intra-grain diffusion and surface complexation of U(VI) under dynamic groundwater flow and hydrochemical conditions.

The physical non-equilibrium approach explicitly calculates aqueous speciation and surface complexation in the intra-grain pore spaces as instantaneous recations and simulates the diffusional mass-exchange between the mobile and immobile domains by a set of multiple 1^{st}-order rates. The chemical non-equilibrium approach approximates the diffusion-limited surface complexation by a multiple 1^{st}-order kinetic reactions, which makes it computationally efficient compared to the physical non-equilibrium approach. While for linear sorption scenarios the two model approaches are equivalent, they show differences when the sorption process becomes non-linear, for example as a result of surface complexation reactions under varying hydrochemical conditions.

Under the Hanford 300A field scale hydrological and hydrochemical conditions, the two model approaches predicted largely similar U plume behaviour. In contrast, simulated U(VI) mass discharge into the Columbia River that is adjacent to the 300A was noticeably higher in the physical model due to a higher degree of non-equilibrium in the plume fringe located at the river-groundwater interface. However, compared to other effects, such as that of calcite dissolution on U(VI) mass discharge, the choice of the non-equilibrium model approach appeared to be less important.

Experimentally determined standard properties for $MgSO_4 \cdot 4H_2O$ (starkeyite) and $MgSO_4 \cdot 3H_2O$; A revised internally consistent thermodynamic dataset for magnesium sulfate hydrates

K.-D. GREVEL[1,2]*, J. MAJZLAN[1], A. BENISEK[3], E. DACHS[3], M. STEIGER[4], A. D. FORTES[5] AND B. MARLER[2]

[1]Inst. of Geosciences, Friedrich-Schiller University, Jena, Germany (*correspondence: Klaus-Dieter.Grevel@rub.de)
[2]Inst. for Geology, Mineralogy and Geophysics, Ruhr-University, Bochum, Germany
[3]Dept. of Materialscience & Physics, Mineralogy Division, University Salzburg, Austria
[4]Dept. of Chemistry, University of Hamburg, Germany
[5]Dept. of Earth Science, University College London, UK

A number of different hydrated forms of $MgSO_4 \cdot nH_2O$ ($1 \le n \le 11$) are known to exist on Earth and also on Mars. Recently, the enthalpies of formation from the elements ($\Delta_f H^0_{298}$) of kieserite ($n = 1$), sanderite ($n = 2$), hexahydrite ($n = 6$), and epsomite ($n = 7$) were measured [1]. Now, we have obtained $\Delta_f H^0_{298}$ of synthetic $MgSO_4 \cdot 3H_2O$ and $MgSO_4 \cdot 4H_2O$ (starkeyite) by solution calorimetry in water at $T = 298.15$ K. The resulting values are –2210.3 ± 1.3 and –2498.7 ± 1.1 $kJmol^{-1}$ for the trihydrate and starkeyite, respectively.

The standard entropy of starkeyite was derived from low-temperature heat capacity measurements using a PPMS® system [2] in the temperature range 5 K < T < 300 K resulting in S^0_{298} (starkeyite) = 254.5 ± 2.0 $J \cdot K^{-1} mol^{-1}$.

Additionally, DSC measurements with a Perkin Elmer Diamond DSC in the temperature range 280 K < T < 295 K were performed to check the reproducibility of the PPMS® measurements around ambient temperature.

All Mg sulfate hydrates change their hydration state in response to the local temperature and humidity conditions. Based on recently reported equilibrium relative humidities [3] and the new standard properties described above, the internally consistent thermodynamic database for the $MgSO_4 \cdot nH_2O$ system [1] was refined.

Ore deposits and the SCLM

W.L GRIFFIN[1]*, G. BEGG[1,2], SUZANNE Y. O'REILLY[1], AND N.J. PEARSON[1]

[1]GEMOC/CCFS, Earth and Planetary Sciences, Macquarie Univ., NSW 2109 Australia (*correspondence: bill.griffin@mq.edu.au)
[2]Minerals Targeting Intl., 26/17 Prowse st., W. Perth 6005, Australia (graham@mineralstargetting.com.au)

The single largest influence on the formation of Earth's ore deposits has been the generation of the Archean subcontinental lithospheric mantle (SCLM). Geological and geochemical evidence suggests that subduction-like processes, and the progressive depletion of the convecting mantle, began at least 3.8-4.0 Ga ago, but there are few large ore deposits older than ca 3 Ga. Re-Os data suggest that the formation of the Archean cratonic SCLM began ca 3.5 Ga ago, and reached a peak around 3 Ga. This primitive SCLM was much more depleted than is commonly recognised; it was essentially a magnesian dunite, the residue after large-scale extraction of crustal material from rising plumes/mantle overturns. Since its formation it has been progressively refertilised by fluids and melts from the asthenosphere and subducting slabs. At present ≥70% of continental crust is underlain by Archean-aged SCLM. The coming of the SCLM has had major effects on the types of ore deposits and their distribution in space and time. (1) *Preservation:* The Archean SCLM is buoyant relative to the asthenosphere and resists subduction, giving its overlying crust a "life raft"; the more fertile SCLM beneath younger terrains is denser, and can be delaminated and recycled, leaving its overlying crust unprotected from the convecting mantle. Ore deposits generated in juvenile arcs, some continental arcs and rifted-margin basins thus are unlikely to survive subsequent orogenies. (2) *Lithospheric architecture*; the deep roots of old continents focus fluid flow toward their margins, and act as physical guides for plume melting. (3) *A durable metasomatic reservoir*; the refertilisation of the ancient SCLM has built up the concentrations of metals, which can be tapped by ascending magmas. There are many komatiites, but those fertile in Ni-Cu-PGEs are limited to ages <2.9 Ga, and lie along ancient craton margins. Kimberlites may be generated by low-degree melting of SCLM, but only those that intersect previously metasomatised SCLM during their ascent will carry many diamonds. (4) *New ore-forming environments*. The coming of the SCLM provided tectonic settings that did not previously exist, allowing the generation of new types of ore deposit: large foreland basins (banded iron formations), craton margins (Ni-Cu-PGE), back-arc/pericratonic basins and passive margins (granular iron formations, Pb-Zn, Mississippi Valley-type deposits).

The geogenic impact on groundwater composition in the Netherlands

JASPER GRIFFIOEN[12]*, SOPHIE VERMOOTEN[2] AND BAS VAN DER GRIFT [2]

[1]TNO Geological Survey of the Netherlands, Utrecht, the Netherlands (*correspondence: jasper.griffioen@tno.nl)
[2]Deltares, Utrecht, the Netherlands

The quality of groundwater is vital for both its natural function and anthropogenic use. Surprisingly, the geogenic control on groundwater composition has received little attention while the petrological composition of the rock matrix forms a major factor on groundwater composition. We have systematically investigated the geogenic control on both major groundwater composition and a series of trace elements at a national scale for the Netherlands. Several thousands of existing groundwater analyses were classified on geological formation. Additionally, the samples were grouped into 26 unique geographical regions. Regional statistics were created for all solutes of interest. An interpretation was established in terms of salinity, pH and carbonate status, redox status and nutrients. Interesting regional differences are noted within both the Pleistocene part of the Netherlands where phreatic aquifers are dominant, and the Holocene part where a reactive layer of clay and peat lies at the surface. This holds both for the major groundwater composition as well as for trace elements. These differences can partly be related to the sedimentary origin of the deposits, where marine deposits are more reactive than fluvial deposits. Upon result, the buffering capacity of marine deposits is larger but the natural contamination with arsenic, nutrients and salinity, too. This buffering capacity is monitored by an additional field and laboratory campaign, which establishes regional statistics on reaction capacities of sediment.

The crystal chemistry of (As,Sb,Bi)-bearing dumortierite

L.A. GROAT[1]*, R. JAMES EVANS [1], E.S. GREW[2] AND A. PIECZKA[3]

[1]University of British Columbia, Vancouver, British Columbia V6T 1Z4, Canada (*correspondence: lgroat@eos.ubc.ca)
[2]University of Maine, Orono, Maine 04469-5790, U.S.A
[3]University of Science and Technology, 30-059 Kraków, Poland

Dumortierite [c. $(Al,\square)Al_6(BO_3)Si_3O_{13}(O,OH)_2$] and holtite [c. $(Ta,\square,Al)Al_6(BO_3)(Si,Sb,As)_3O_{12}(O,OH,\square)_3$], are isostructural minerals found in a few granitic pegmatites. Dumortierite may contain several wt.% of Sb_2O_3, As_2O_3, Ta_2O_5, thereby blurring compositional distinctions between the two, although generally As > Sb in dumortierite. For this study we investigated the effect of minor amounts of Sb and As on the crystal structures of dumortierite samples D21 (Rats quarry, Hartmannsdorf, Saxony), D31 (Tonagh Island, Enderby Land, Antarctica) and D27 (Uval'dy Lake, Il'men Mountains, southern Urals, Chelyavinskaya Oblast', Russia). Average electron microprobe compositions for sample D21 show 2.32 wt.% As_2O_3 (0.14 atoms per formula unit) and 0.57 wt.% Sb_2O_3 (0.02 Sb apfu); for D31, 2.85 wt.% As_2O_3 (0.18 apfu) and 1.03 wt.% Sb_2O_3 (0.04 apfu); and for D27, 1.69 wt.% As_2O_3 (0.10 apfu) and 0.68 wt.% Sb_2O_3 (0.03 apfu). Analyses of samples D21 and D27 show no appreciable Ta, whereas sample D31 contains on average 1.62 wt.% Ta_2O_5 (0.04 apfu). Sample D27 also contains Bi (1.07 wt.% Bi_2O_3, 0.03 apfu).

Crystal structure refinements of single-crystal X-ray diffraction data converged to R1 values 1.92, 1.62, and 3.04% for samples D21, D31, and D27 respectively (all D27 crystals investigated were twinned in the normal fashion for dumorterite, with three twin individuals related by 120° rotation about a threefold twin axis parallel to a). For all three samples the results suggest that the As and Sb atoms are at the Sb1 and Sb2 sites, as is the case for holtite. However in the dumortierite samples the atomic displacement parameters (ADPs) associated with the atoms at these sites are unusually large, with U_{eq} Sb1 values of 0.03 Å^2, 0.02 Å^2, and 0.09 Å^2, and U_{eq} Sb2 values of 0.02 Å^2, 0.03 Å^2, and 0.06 Å^2, for samples D21, D31, and D27, respectively (for holtite these values are generally less than or equal to 0.01 Å^2). Atomic displacement parameters for the coordinating oxygen atoms are no larger than in holtite and dumortierite with no As or Sb.

The reason for the large ADPs remains under investigation but may be a function of the small amounts of As and Sb at these sites, or perhaps indicates the presence of both trivalent and pentavalent As and Sb (and perhaps Bi, or Bi^{3+} and Bi^{5+}) at the Sb1 and Sb2 positions.

Reconstruction of permanent thermocline temperatures in the Atlantic during Heinrich Stadial 1

J. GROENEVELD[1]*, C. M. CHIESSI[2], A. MACKENSEN[3] AND R. TIEDEMANN[3]

[1]Marum Excellence Cluster, Alfred Wegener Institute, Bremerhaven, Germany (*correspondence: Jeroen.Groeneveld@awi.de)
[2]School of Arts, Sciences, and Humanities, University of São Paulo, São Paulo, Brazil
[3]Alfred Wegener Institue for Polar and Marine Research, Bremerhaven, Germany

Changes in Atlantic Meridional Overturning Circulation (AMOC) have been modeled to lead to a global adjustment of the depth of the thermocline via the propagation of Kelvin waves, particularly in the North Atlantic with warming during AMOC slowdown. The aim of this study is to test for significant warming during AMOC shutdown by reconstructing permanent thermocline temperatures for the Deglaciation at key locations in the Atlantic. Therefore, we used Mg/Ca-paleothermometry on the deep-dwelling foraminifer *Globorotalia inflata*.

We established a new Mg/Ca-temperature calibration for *G. inflata* based on core top samples from the South Atlantic. The reconstructed apparent calcification depth for dominantly non-encrusted specimens is 350-400 m making *G. inflata* ideal to reconstruct temperature changes in the permanent thermocline.

First results from core GeoB9508-5 off northwest Africa, which is close to the boundary between the predicted thermocline warming (to the north) and cooling (to the south), show a significant warming during HS1 of ~4°C supporting the prediction of subsurface warming in the North Atlantic during AMOC slowdown. Interestingly, this warming occurs after the actual start of HS1.

Temporal dynamics of arsenic-bearing phases during the suspended transport

C. GROSBOIS[1]*, A. COURTIN-NOMADE[2], E. ROBIN[3], H. BRIL[2], N. TAMURA[4], J. SCHÄFER[5] AND G. BLANC[5]

[1]Université François Rabelais de Tours. UMR 6113 CNRS ISTO. Tours, France (*correspondence : cecile.grosbois@univ-tours.fr)
[2]Université de Limoges. EA GRESE IFR 145 GEIST. Limoges, France

[5]Université de Bordeaux 1. UMR 5805 CNRS EPOC. Talence, France

In a former gold mining district (Isle river basin, France), arsenic-bearing phases have been characterized in suspended particulate matter by in-situ techniques (EPMA, SEM-EDS/ACC system and synchrotron based μXRD) in order to describe the temporal dynamics of As at a particle scale during the solid transport.

The most frequent As-bearing phases but the least As-concentrated (0.10-1.58 wt% As) were aggregates of various fine clay particles (chlorite-phlogopite-kaolinite assemblage during the high flow and chlorite-illite- muscovite assemblage during the low flow). They were also associated to Fe-coatings and nano- to micro- particles of Fe oxyhydroxydes like goethite (0.18 - 0.45 wt% As, Fig. 1).

Iron and Mn oxyhydroxydes were the 2 other types of As-bearing phases (0.12-2.80 wt% As and 0.14-1.26 wt% As respectively), present as discrete particles. Their occurrence and in-situ concentrations varied throughout the hydrological cycle, according to their detrital or newly formed origins.

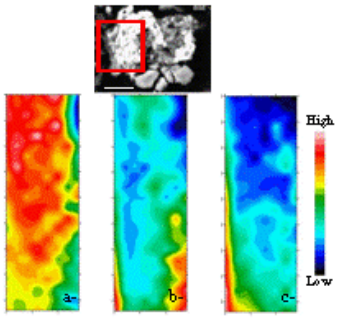

Figure 1: BSE image of a grain of Fe oxyhydroxyde associated to μ-XRD maps representing the relative abundance of a- goethite (4.18 Å), b- chlorite (7.07 Å) and c- muscovite (9.9 Å).

Birefringence mapping: A new *in situ* mass-loss technique for determining mineral solubilities

JULIANE GROSS[1]*, MICHAEL BURCHARD[2] AND WALTER V. MARESCH[3]

[1]Lunar and Planetary Institute, Houston TX 77058, USA (*correspondence: gross@lpi.usra.edu)
[2]Ruprecht-Karls Universität, 69120 Heidelberg, Germany
[3]Ruhr-Universität Bochum, 44801 Bochum, Germany

Data for the solubility of minerals in aqueous solutions at high pressures and temperatures are essential for our understanding of fluid properties, mass transport and growth/dissolution processes of minerals in Earth's crust and upper mantle. [e.g. 1-4].

Although a fairly extensive dataset is now available on the solubility of minerals in aqueous fluids at high pressures, most of the data above 0.5 GPa have been obtained by *ex situ* weight-loss quench methods in piston-cylinder presses [e.g. 5-7]. However, the uncertainties are generally large and difficult to quantify, because the resulting phase assemblages and product textures are characterized at post-experimental conditions. This can be problematic for the interpretation of the results if phase transitions, quench crystallization, incongruent dissolution or mechanical fragmentation occured.

We developed a new *in situ* mass-loss technique for hydrothermal diamond anvil cell experiments that uses the fact that crystals show birefringence in polarized light. Birefringence depends on the crystal's phase difference and its thickness. By measureing the phase difference at every point on a crystal, the thickness of the crystal at every such point can be determined and its surface area mapped. By multiplying the thickness of the crystal with its surface area its volume can be calculated. The mass of a crystal is then given by its volume multiplied by its density. With this method crystal masses less then a few µg can be determined

This new method combines the advantages of *ex situ* and *in situ* approaches, such as direct observation of the reaction path of the sample while circumventing their obvious disadvantages, such as quench problems.

Antimony and arsenic behaviour upon microbial dissolution of mining waste

M. GRYBOS*[1], J. KIERCZAK[2], O. RAKOTOARISOA[1], A. COURTIN-NOMADE[1] AND H. BRIL[1]

[1]University of Limoges, GRESE Laboratory, FST, 123, avenue A. Thomas, 87060 Limoges Cedex, France (*correspondence: malgorzata.grybos@unilim.fr)
[2]University of Wroclaw, W. Cybulskiego 30, 50205 Wroclaw, Poland

In surface and sub-surface environment, microorganisms mediate dissolution and precipitation processes of minerals, and thus affect geochemical cycling of elements. Antimony (Sb) and arsenic (As) are considered to have comparable geochemical behavior and toxicity, both are redox sensible and toxic even at low concentrations. In natural environment, weathering of mining waste is one of the major source of contamination by metal(oid)s including Sb and As. Determination of biotic factors influencing Sb and As mobility is crutial to understand geochemical behaviour of these elements in environement.

In this study, we performed controlled incubations of mine tailings containing > 0.2% and 0.06% of Sb and As respectively under abiotic and biotic (phylogenetically divers heterotrophic bacteria) conditions to assess the role of bacteria on As and Sb release upon dissolution process. Role of microbes (biotic factor) was evaluated by comparing the amount of a given element released during biotic incubation to the amount of the same element released during abiotic incubation at the same pH value.

The results shown that all used bacteria were able to weather highly contaminanted solids. For a given pH value, the amount of released Sb and As varied between the strains and was from half-fold less to three-fold greater than under abiotic conditions. This indicates that complexing metabolites produced by bacteria play an important role in the overall dissolution process and may have accelerating or inhibiting effect on Sb and As release. Positives correlation coefficients of biotic factors between Sb and Fe ($R^2 = 1$), Ca ($R^2 = 0.58$), and Al ($R^2 = 0.999$) as well as negative correlation coefficients of biotic factors between As and Fe ($R^2 = 0.58$), Ca ($R^2 = 0.98$), and Al ($R^2 = 0.57$) sugest its different behaviour upon microbial dissolution.

In conclusion, heterotrophic bacteria influence Sb ans As geochemical pathway and mobility in environement.

Features of the pyrites in black shale series in Southern Anhui Province

YOUFEI GUAN[1,2], YONG ZHAN[1,2], HAIJIAO YOU[1,2], GUODONG SHI[2] AND MAOYAN MA[2]

[1]China Gezhouba Group Corporation, P.R. China (631677428@qq.com)
[2]Anhui University of Architecture, P.R. China

Black shale series in southern Anhui Province are located widely and belong to Lower Yangtze depression area, mainly developing the Sinian and Early-Middle Triassic sedimentary cover, late Yanshanian intrusions, and Indosinian-Early Yanshanian NE Jura-type folds and a series of the NE thrusting (sliding) nappe structure.

According to the crystal habit of the pyrite crystals in black shale series in southern Anhui Province, the pyrites can be divided into five crystal forms: {100} cube, {100}+{200} cube and pyritohedron combination, {111} octahedron, {210} pyritohedron and {210}+{111} pyritohedron and octahedron combination. The Co/Zn ratios of pyrites with various crystal forms are relatively low, mostly less than 0.15. The As content of the pyrite with {100} + {200} crystal form is the highest (120 ppm), and that of the pyrite with {111} crystal form is about 32 ppm on average that is many times higher than claystone's (6.6 ppm).

The Co/Zn ratios of sediments can distinguish their different sources. The Co/Zn ratio for hydrothermal origin is relative low, with value of 0.15 on average, and that in iron-manganese crust or concretion is about 2.5 in general. Therefore, the Co/Zn ratios can be used as a sensitive indicator to distinguish the source of sediments. The Co/Zn ratios of the pyrites from black shale series in southern Anhui Province suggests that the pyrites are derived from submarine hydrothermal fluid. As is an active element of hydrothermal fluid, so the As anomaly in sediments can be used as an indicator of submarine hydrothermal activity. The As values of the pyrites from black shale series in southern Anhui Province indicates that the pyrites have features of strong hydrothermal deposit.

Many studies suggest that hydrothermalism is the key for the formation of noble metal deposits in black shale series. This conclusion has been proved in Hunan-Guizhou. The pyrite's features and genesis indicate that the noble metals may enrich and even form deposit in black shale series in southern Anhui Province.

Mineral paragenesis and textural features of gneisses and amphibolites from Daday-Devrekani (Kastamonu, Turkey) Massif: Preliminary results

M.A. GUCER[1]* AND M. ARSLAN[2]

[1]Dept. of Geol. Eng., Gümüşhane Univ., 29100-Gümüşhane, Turkey (*correspondence: maligucer@gmail.com)
[2]Dept. of Geol. Eng., Karadeniz Tech. Univ., 61080-Trabzon, Turkey (marslan@ktu.edu.tr)

The Daday-Devrekani (Kastamonu, N Turkey) massif contains various metamorphic rocks ranging from Precambrian to Early Cretaceous in age [1]. NE part of the massif contains medium to high grade metamorphic rocks, called Devrekani Metamorphics [2], and divided into two sub-units; gneissic rocks of the lower parts and calcite marbles of the upper parts. In this study, gneissic and amphibolitic rocks of the massif were examined in terms of mineral assemblages and textural evidence of metamorphic P-T conditions. The gneissic rocks are biotite-hornblend, cordierite-biotite, sillimanite-biotite, sillimanite-cordierite-mica, sillimanite-garnet-mica, sillimanite-cordierite-garnet-mica, microcline-biotite, muscovite-microcline-biotite and sillimanite-garnet-cordierite-microcline-biotite gneisses. They contain quartz, K-feldspar (orthoclase, microcline), plagioclase, biotite, muscovite, sillimanite, cordierite, garnet, hornblend, sericite, Fe-Ti oxide, ±apatite, ±hematite, ±zircon, ±hercynite (?). The amphibolitic rocks contain hornblende, oligoclase-andesine, Fe-Ti oxide and ±orthoclase. The rocks exhibit grano-, lepidograno-, fibrolepidograno-, nemato-, nematograno-, lepidonemato- and porphyro- blastic textures. In some gneiss, there are pre-kinematic and syn-kinematic mineral growth, and cordierite porphyrpblasts containing sillimanite, hercynite (?) and garnet inclusions.

Possible mineral reactions in gneissic rocks are as (1) Muscovite + quartz → K-feld. + sillimanite + H_2O, (2) chlorite + muscovite (or chloritoid) + quartz → garnet + biotite + H_2O, (3) garnet + sillimanite + quartz → cordierite, (4) sillimanite + garnet → cordierite + hercynite, (5) biotite + sillimanite + plagioclase + quartz→garnet + cordierite + K-feld. + H_2O. Possible mineral reaction in amphibolites is albite + actinolite + epidote + chlorite → plagioclase (An>17) + hornblende. All these features suggest amphibolite facies P-T conditions.

Dissolution rates of plagioclase feldspars as a function of solution composition

S. GUDBRANDSSON[1]*, D. WOLFF-BOENISCH[2], S.R. GISLASON[2] AND E. H. OELKERS[1]

[1]GET-Université de Toulouse-CNRS-IRD-OMP, 14 Avenue Edouard Belin, 31400 Toulouse, France (*correspondence: snorgud@hi.is)

[2]Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavik, Iceland

Feldspars are the most abundant mineral in the Earth's crust and plagioclase is the most abundant of these feldspars. Plagioclase dissolution is therefore a major, and at times dominant, contributor to global weathering rates. It is therefore remarkable how little work has been performed to systematically characterize the dissolution rates of this mineral as a function its composition and the composition of the fluid phase.

Towards the improved characterization of the dissolution behaviour of the plagioclases in natural processes, the steady-state dissolution rates of 5 distinct plagioclase feldspars, spanning the compositional range from albite to anorthite, have been measured in mixed-flow reactors at 25 ºC as a function of pH from pH 2 to 11. Rates tend to exhibit a typical U-shape behaviour; rates decrease with increasing pH at acidic conditions, then increase with increasing pH at basic conditions. Similar to past work [1, 2] plagioclase dissolution rates increase with increasing An content at acidic conditions. In contrast, preliminary work suggests little effect of An content at basic pH.

Interpretation of the dissolution rates of the plagioclase feldspars is challenging because this mineral tends to consist of finely intergrown albite rich and anorthite rich phases. To address this challenge, measured rates have been interpreted assuming the dissolving plagioclase is a mechanical mixture of two distinct end-member feldspars similar to that done recently for the dissolution of crystalline basalt [3].

^3H – ^3He isotopic tracer for age estimating of the ground waters (Aquifers of the Khibiny slopes, Kola Peninsula)

ANTON GUDKOV[1]*, IGOR TOLSTIKHIN[1] AND STANISLAV IVANOV[2]

[1]Russian Academy of Science, Kola Science Center, Geological Institute (*correspondence: Gantoris@rambler.ru, igor.tolstikhin@gmail.com)

[2]Russian Academy of Science, Kola Science Center, Institute of the North Industrial Ecology Problems (etostas@mail.ru)

To introduce the ^3H - ^3He method samplers of stainless steel and degassing of water, using the flow of water vapor through the capillary as a gas – carrier have been developed and made. When being pumped through the capillary almost all helium and neon (over 95%) is collected in the trap. At the same time gets not more than 0.5 grams of water (i.e. approximately 0.3% of the sample mass, Beyerle *et al*., 2000) gets in the trap. The extraction and purification processes take approximately 30 minutes. The water samples were taken from the bores located at the southern slope of the Khibiny mountains (the Kola peninsula). The picture shows the measured relations of ^3He / ^4He and ^{20}Ne / ^4He in the samples from water inlets "Centralniy" (the grey squares, the figures are numbers of the bores Kamensky *et al*., 1991) and "Klyuchevoy" (the grey circles). In these coordinates the mixture of young waters (the corresponding points, the square and the circle are located above the coordinates of the air saturated water, ASW) and the deep ancient waters (in the lower left corner of the graph, the radiogenic He is formed in enclosing rocks, and migrating from them, is accumulated in ground waters) is expressed in the straight line. Regression line extrapolation of the samples from the water inlet "Centralniy" (the black line on the graph) to the trend APB + $^3He_{TRI}$ gives ^3He / ^4He = 3, 65 × 10^{-6}. Concentration of the $^3He_{TRI}$ in the young water, $[^3He]_{TRI} = [^3He]_{MEASURED} \times \{(^3He / ^4He)_{YOUNG} - (^3He / ^4He)_{ASW}\}$ и $[^3H]_{MEASURED}$ = 30 TE gives 3H - 3He the age of 16. The intersection of the regression line and the line of accumulation of radiogenic helium (the black square in the circle) gives the parameters of ancient water, whose age is estimated as40,000 years old (Kamensky *et al*, 1991). In the case of water inlet "Klyuchevoy" ^3He / ^4He relations in ground waters are close to those in the ASW whereas ^{20}Ne / ^4He is slightly lower which indicates to an admixture of ancient waters. Supposing that these isotopic relations in ancient waters of the Khibiny southern slopes are close, one can build a line passing through the points corresponding to the ancient waters and waters from the water inlet "Klyuchevoy" (the black dotted line). Extrapolation of this line to the trend ASW + $^3He_{TRI}$ gives $(^3He / ^4He)_{YOUNG}$ = 1,65 × 10^{-6} a slightly higher value than the value of ASW.A small excess of ^{3}HeTRI along with a relatively low [3H] MOD = 12, TE correspond to the water age.

The use of magnetic susceptibility in forensic soils analyses

A. GUEDES*, H. RIBEIRO, H. SANT'OVAIA, A. RODRIGUES, B. VALENTIM, S. LEAL AND F. NORONHA

Centro de Geologia da Universidade do Porto e Departamento de Geociências, Ambiente e Ordenamento do Território, Faculdade de Ciências, Universidade do Porto, Rua do Campo Alegre 687, Porto, Portugal, (*correspondence: aguedes@fc.up.pt)

Magnetic parameters such as magnetic susceptibility (MS) are important in characterizing materials, and detectable quantities of magnetic and paramagnetic minerals are almost always found in soils, the magnetic susceptibility being the sum of all contributions from the forming minerals, and varying due to concentration and composition of those minerals. The MS measurements of soils at room temperature are non-destructive. Therefore, the same material is available for further analysis with any other technique. Additionally, does not require sample preparation, and can be used as a simple and fast method which may be operable in small samples. So, MS is an excellent tool for studies of soils being used as trace evidence in forensic investigations.

Magnetic susceptibility measurement methodology, discriminatory power, reproducibility and accuracy in analysis were tested on soil samples for its use in forensic applications. Seventeen soil samples were collected on several Portuguese sites surrounded by different lithologies. At each site, samples were manually collected from the surface soil with a plastic spade. The magnetic susceptibility was measured applying an external magnetic field of 300 A/m to the sample, and a Kappabridge, model KLY-4S of Agico balance equipped with the Sumean software was used. Tests were performed on each sample to establish the discriminatory power between similar and different geological and geographical origins; the measurement reproducibility within samples and along the time; the variation with sample quantity, size fractions and presentation method. Before each measurement, the equipment was calibrated, and regularly calibrated along the measurement period due to the repeated nature of the measurements carried out. Magnetic susceptibility was calculated in m^3/kg. It was observed that magnetic susceptibility can enable discrimination between soil samples, measured values are reproducible over time, and the analysis can be carried out in samples as small as 0.5 g.

Chemical and isotopic properties of airborne particles in industrial, urban and rural areas of the Rhine Valley

F. GUÉGUEN[1,2], P. STILLE[1], V. DIETZE[3] AND M. MILLET[2]

[1]Laboratoire d'Hydrologie et de Géochimie de Strasbourg, Université de Strasbourg/EOST, CNRS; 1 rue Blessig, F-67000 Strasbourg

[2]Equipe de Physico-Chimie de l'Atmosphère, Laboratoire des Matériaux, Surfaces et Procédés pour la Catalyse, Université de Strasbourg/ECPM, CNRS; 1 rue Blessig, F-67000 Strasbourg

[3]German Meteorological Service, Research Center Human Biometeorology; Stefan-Meier-Str.4. D-79104 Freiburg

In order to evaluate the past and actual air pollution, tree barks (biomonitoring) and airborne particulate matter (dp >2.5 μm) were collected around and within the industrial area of the cities of Strasbourg (France) and Kehl (Germany) situated on both sides of the river Rhine. Theses cities suffer from emissions of traffic and industries (steel plant, thermal power plant and waste incinerators) located in the industrial harbour.

Sr, Nd and Pb isotopic ratios measured on barks allowed to distinguish between various sources of pollution. Traffic emissions are the main contaminants in the urban areas of the cities, whereas local industrial emission plumes are distinguishable around and within the industrial harbour.

Organic and inorganic emissions were monitored during 9 months by Sigma-2 passive samplers as well as by passive air samplers with XAD-2 resin for PCB collection for actual air quality measurement in these environments. Sample sites were located in remote, rural and in urban areas, where different industrial emission plumes have been detected by tree bark biomonitoring.

Ambient aerosol collected in these different environments have similar trace element concentrations but the mass deposition rate is highest in the industrial zone. Enrichment factors (EF) $((X/Nd)/(X/Nd)_{UCC})$ are particularly high in Mn, Cr, Zn, Mo, Cd, and similar to EF measured in tree barks.

Isotopic ratios of the collected particles from different sampling sites allowed to distinguish between anthropogenic and natural sources. The dominating emission source in the industrial area is the steel plant as also demonstrated by the aerosols trace metal concentrations. Both organic and trace metal emissions are correlated, which allows the Sr and Nd isotopes to be a powerfull tool to trace the polluting sources.

Isotope fractionation during Fe translocation in plants grown with an artificial chelate

M. GUELKE-STELLING[1]* AND F. VON BLANCKENBURG[2]

[1]KIT, Inst. for Mineralogy and Geochemistry, D-76131 Karlsruhe (*correspondence: monika.stelling@kit.edu)
[2]GFZ Potsdam, D-14473 Potsdam (fvb@gfz-potsdam.de)

The determination of the plant-induced Fe-isotopic fractionation with multiple-collector ICP-MS is a promising tool to better quantify their role in the geochemical Fe cycle and possibly to identify the physiological mechanisms of Fe uptake and translocation in plants.

We show here that half of the entire range of Fe isotope variations detected to date on this planet (-2.5‰ in δ^{56}Fe) ocurrs when Fe is moved *within* a single plant. This finding extends that of an earlier study in which we found that strategy I plants, which rely on reduction of iron before uptake, were enriched in stable ^{54}Fe relative to ^{56}Fe when grown on soil. In contrast strategy II plants (grasses), which rely on chelation of Fe(III) by phytosiderophores before uptake, were slightly enriched in the heavier iron isotopes [1,2].

In our new study bean plants (strategy I) and oat plants (strategy II) were grown in a nutrient solution supplemented with Fe(III)-EDTA, and were harvested at three different ages. All parts of the plants during all growth stages were quantified for Fe amounts and isotope composition. Total bean plants, regardless of their age, were found to be enriched in the light iron isotopes by -1.2‰ relative to the growth solution throughout. However, during growth plants internally redistributed isotopes where young leaves increasingly accumulated the lighter isotopes whereas older leaves and the total roots were simultaneously depleted in light iron isotopes. For bean fruits, mass balance indicates that these obtain ca. 40% of their Fe from translocation within the plant (with δ^{56}Fe = -2.65‰), and 60% from the roots. Given that not all of this fruit Fe can be supplied by older leaves, the roots apoplast plays a major role as intermediate Fe store. Both apoplast Fe and tissue-bound Fe is remobilised by reduction – preferring the light Fe isotopes. In contrast, during growth of the oat plants the initial isotope ratio obtained during uptake is maintained in all organs at all growth stages, including the roots. Hence it can be assumed that both uptake and translocation of Fe in strategy II plants maintains the irons' ferric state, or that Fe is always bound to high-mass ligands, so that isotope fractionation is virtually absent in these plants.

The nitrogen isotopic composition of a Proteozoic microbial community

NUR GUENELI* AND JOCHEN J. BROCKS

Research School of Earth Sciences, The Australian National University, Canberra, A.C.T. 0200, Australia (*correspondence: nur.gueneli@anu.edu.au)

Nitrogen is an essential element for life, incorporated into fundamental components such as amino acids and DNA. The isotopes of nitrogen can be used to trace biogeochemical processes, yet, the use of this tool to reconstruct Precambrian environments is still in its infancy. Recent studies on nitrogen isotope fractionation in microorganisms [1,2] have significantly improved interpretations of paleorecords [3-5] and the use of nitrogen isotopes in combination with established biomarker techniques has now the potential to yield novel information about the succession of predominant primary producers through deep time.

The 1.64 Ga Barney Creek Formation (BCF), northern Australia, represents a marine succession deposited below wave base in the intracratonic McArthur Basin. The dolomitic shales of the BCF bear the oldest preserved, clearly indigenous molecular fossils [6]. Based on these biomarkers, the upper BCF marks a marine basin with anoxic, sulphidic, sulphate-poor and stratified waters inhabited by green and purple phototrophic sulphur bacteria (PSB) [7]. Evidence for these PSB disappears in deeper successions. However, it is currently under debate whether the lack of PSB derives from biological or thermal degradation, or a shift in ecological settings. Here, we will present ^{15}N and ^{13}C data in combination with biomarker analysis to test whether regime changes caused a shift in predominant primary producers in the McArthur Basin.

Fluid inclusion analysis by laser ablation ICPMS: How consistent are element ratios?

MARCEL GUILLONG[1]*, THOMAS PETTKE[2] AND LEONID DANYUSHEVSKY[1]

[1]CODES, ARC Centre of Excellence in Ore Deposits, University ofTasmania, Private Bag 79, Hobart, TAS, 7001, Australia
(*correspondence: marcel.guillong@utas.edu.au)
[2]Institute of Geological Sciences, University of Bern, Baltzerstrasse 1 + 3, CH-3012 Bern, Switzerland

Analysis of fluid inclusions is a commonly used technique to obtain insights into fluid evolution and ore forming processes. Laser ablation ICPMS offers the possibility to analyse individual inclusions for a wide range of elements and certain isotope ratios, with low detection limits. Quantification of inclusion composition is commonly performed by normalising measured element signals to those of Na or Cl, which are used as internal standards, with their concentrations determined via micro thermometry.

Using a Resonetics M-50 laser probe which allows for analysis of fluid inclusion at depths up to several hundred microns, we observed that values of some element signal ratios change between shallow inclusions and deep inclusions by up to a factor of 2.5. This limits the accuracy of inclusion analysis at larger depth from the sample surface. The Cl/Na and the Pb/Na ratios were found to be affected the most. Ablating a scapolite sample with homogeneous Na, Pb and Cl concentrations showed very similar behaviour. Such strong fractionation behaviour of chlorine has not been reported to date for LA-ICPMS analysis. This may account for some of the scatter observed when analysing a series of individual fluid inclusions, as inclusions are commonly located at a range of depth below the surface. Results from two different brine assemblages will be presented and discussed.

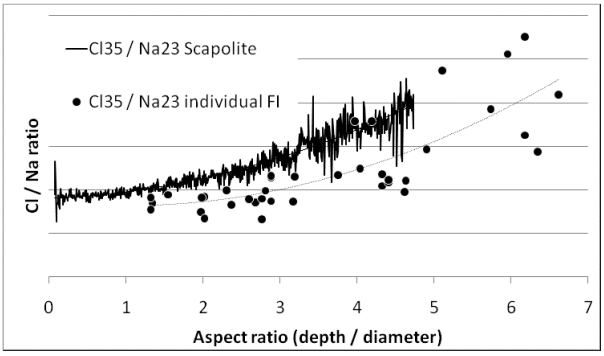

Figure 1: Aspect ratio dependent Cl/Na ratios for scapolite mineral and a fluid inclusion assemblage.

U-Pb SHRIMP and geochemical data of granitoids characterizing the evolution of shear zones in NE Brazil

I. P. GUIMARÃES[1]*, A.F. SILVA FILHO[1]; F.M.V. SILVA[2] AND R. ARMSTRONG[3]

[1]Depto de Geologia –UFPE
(*correspondence: ignez@ufpe.br)
[2]Geologia - UFPE, Petrobrás (francismiller@hotmail.com)
[3]RSES - Australian National University
(richard.armstrong@edu.edu.au)

A large volume of granitic magmatism associated with large scale shear zone and metamorphism under high-T conditions, characterize the Brasiliano/Pan African Orogeny in the Borborema Province, NE Brazil. Granitoids from two plutons and later dykes intruded along a large dextral sense E-W trending Shear Zone show distinct crystallization ages and geochemical signature. The oldest studied granitoids (U-Pb SHRIMP age of 618 ± 5 Ma), Serra de Inácio Pereira Pluton (SIPP), show high Ba (4440 to 6654 ppm) and Sr (2358 to 2962 ppm) and medium to high Zr (321 a 378 ppm), low Y (19 a 25 ppm) and Nb (14.7 to 17.0 ppm) contents. Their REE patterns are characterized by small or no negative Eu anomalies (Eu/Eu*= 0.92 – 1.15) and $(Ce/Yb)_N$ ratios ranging from 28.34 to 40.09. In contrast, the granitoids showing crystallization age of 563 ± 4 Ma, the Serra do Marinho Pluton (SMP) have low Sr (238 to 272 ppm), and high Zr (755 to 846 ppm) contents. The contents of Y (40 to 75 ppm) and Nb (9.0 to 51.0 ppm) are higher and the Ba (1660 to 1680 ppm) contents lower compared to the values recorded in the SIPP granitoids. Their REE patterns are characterized by negative Eu anomalies (Eu/Eu*= 0.39 – 0.59) and $(Ce/Yb)_N$ ratios ranging from 6.62 to 20.25. Later dykes of subvolcanic granitoids have crystallization ages of 527 ± 6 Ma and A-type geochemical signature. The SIPP granitoids are coeval with the peak of regional metamorphism and originated by melting of a paleoproterozoic source. The SMP show geochemical signature of post-collisional A-type granites and the later dykes have signature of A-type post-orogenic extension-related granitoids coeval with the deposition of small sedimentary basin.

Microbial diversity in Oylat Cave and their roles on biogeochemical cycling

YASEMIN GULECAL* AND MUSTAFA TEMEL

Istanbul University, Istanbul, Turkey
(*correspondence: ygulecal@istanbul.edu.tr)

The subsurface of the Earth is one of the major habitats and contains a significant proportion microbial life [1, 2]. However, our overall knowledge about the life forms and biogeochemical processes contained within it is rather scarce, mainly because of the difficulties in approaching this habitat. One relatively easy way to approach this habitat is to investigate karst terrains, which expand over ~20% of the Earth's subsurface [3]. Since caves are one of the most prominent features of karst terrain, they may serve as noteworthy entries and virtual "windows" into subsurface habitats [4]. Recent work has revealed interesting insights into the diversity and resilience of different life forms in caves may be revealed and how to recognize biosignatures for subsurface life on other planetary bodies [for example,5-6].

Our studying area which is Oylat Cave in Bursa (Turkey) has been developed at the intersection of two fault zones striking along WNW-ESE and NE-SW directions in recrystalized limestone unit of Permian-Triassic age. Clastics and carbonate sediments are in the Oylat Cave developed due to karstification. The aim of study was to investigate the microbial diversity and their roles of biogeochemical cycling.We have not only used the geochemical analyses but also genetic tools. In addition, this study reports the first microscopic investigations on the microbial communities encountered in the microbial biofilm Oylat Cave.

Geochronology of Cenozoic intrusive rocks of NW Anatolia: Topkaya-Eskişehir, Turkey

B. GÜLLÜ* AND Y.K. KADIOĞLU

Ankara Univ., Department of Geol., Eng., & YEBIM Ankara, Turkey (*correspondence: bgullu@ankara.edu.tr)

The intrusive rocks of Northwest Anatolia mainly exposed at Sivrihisar, Karakaya and Topkaya region of Eskisehir in Sakarya continent. Topkaya (Eskişehir) Granitoid is intruded into the metamorphic basement and obducted ophiolitic suite in the composition of granodiorite, monzogranite and cutting by felsic and mafic dykes. They have MME ranging from 1cm up to 60cm in sizes [1].

The ^{40}Ar /^{39}Ar age data reveal 44.30 ± 0.47 Ma for granodiorite of Topkaya granitoid. The isotopic ratio of granitoids and mafic dykes of the Topkaya have almost same $(^{87}Sr/^{86}Sr)_i$ and $\varepsilon_{Nd\ ratio}$ ($(^{87}Sr/^{86}Sr)_{i\text{-granodiorite}}$=0.705593-0.706133, $\varepsilon_{Nd\text{-granodiorite}}$= -0.6, -0.7; $(^{87}Sr/^{86}Sr)_{i\text{-mafic dyke}}$ =0.705677-0.705706, $\varepsilon_{Nd\ mafic\ dyke}$= -0.39, -0.4).

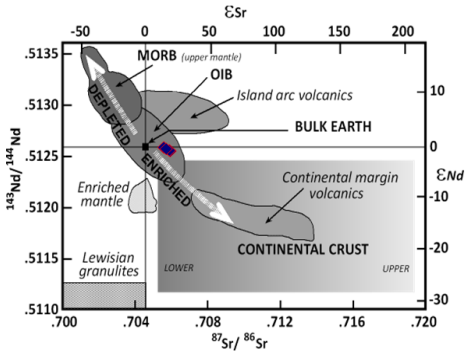

Figure 1: Isotope correlation diagram. The positions of the main tectonic environments and isotopic reservoirs taken from [2], [3], [4].

Discussion and Results

The ^{40}Ar /^{39}Ar age and geochemistry may be interpreted to reflect the time of magmatism since the level of emplacement was shallow enough such that rapid cooling would have occurred.

The granitoid exhibited initial rates $^{87}Sr/^{86}Sr$ always less to 0.708, suggesting represent I-type granites [5]. Sm-Nd data show distinct isotopic signatures, to the granitoid and mafic dykes. Both units exhibited εNd initials values clear negative, suggesting crustal contribution with mantle products in the source.

Hydrochemical properties of thermal waters in the Eastern Black Sea section

FATMA GULTEKIN*, ARZU FIRAT ERSOY AND ESRA HATIPOGLU

Karadeniz Technical University, Depaertment of Geological Engineering, 61080, Trabzon, Turkey (*correspondence: gultekinftma@hotmail.com)

The Ilıca (Artvin), Ayder and İkizdere (Rize) and Sarmaşık (Ordu) thermal waters are located Eastern Black Sea section. Thermal springs and thermal wells have temperatures ranging from 37 to 70°C. The pH values of the thermal waters change between 6.32 and 8.92. Thermal waters display various chemical compositions and high temperature waters have Na-SO_4, Na-HCO_3 and Na-Cl type. In the Ordu and Artvin area Late Cretaceous and Eocene aged volcanic rocks constitute reservoir and cap rocks. Late Cretaceous aged granite, granodiorite and monzonite rocks are reservoirs and cap rocks in the Rize geothermal system. The water-rock interaction has been investigated in this study. The thermal waters located rocks dominate region in the Gibbs Diagram. The chemistry of thermal water is controlled by weathering of minerals containing the rocks. According to chemical analysis basaltic rocks have higher Co, Sr, V, Cu, Pb, Zn, Ni and As content than granitic rocks. Especially Ilıca, İkizdere and Sarmaşık thermal waters have high As, B, Ba, Br, Fe, Li, Rb, Cs and Zn concentration. Compare with Rare Earth Elements (REE) content rocks and thermal waters La, Ce, Nd and Pr are immobile elements for Ayder and Sarmasık thermal waters. Ilıca and İkizdere thermal waters are similar to REE content.

Duofuton mafic volcanic suite at northeastern margin of the Qing-Tibet plateau: Its age, geochemistry and tectonic implications

A. GUO, X. HU, Y. GUO, C. ZHANG AND L. ZHANG

State Key Lab of Continental Dynamics/Department of Geology, Northwest University, Xian 710069, China (anlingxb@nwu.edu.cn)

Located at the northeastern margin of the Qinghai-Tibet Plateau, the Duofuton volcanics belong to a Na-rich and mafic volcanic suite. The suite has yielded an age of 96.21±2.10 Ma by the whole-rock $^{40}Ar/^{39}Ar$ method, indicating a magmatic product in early Late Cretaceous time.

The rocks are characterized by the (La/Yb_N) ratios of 6~11, ΣREE of 117, enrichment in incompatible elements. The Nb/U and Ce/Pb ratios are 30 and 17 on average, respectively.

The $^{87}Sr/^{86}Sr$ ratios of the samples are 0.7041~0.7069, $^{143}Nd/^{144}Nd$ =0.5129 ($\varepsilon_{Nd(t)} = 6$) and $\Delta^{207}Pb/^{204}Pb$ and $\Delta^{208}Pb/^{204}Pb$ =11 ~ 19 and 73~84. Coupled with high $^{87}Sr/^{86}Sr$ ratios, they show Dupal anomalies. The rocks are OIB-like in nature and their source region exhibits mixture between DM and EMII, while some samples are contaminated by continental crust. The complexity of the OIB-like rocks may have inherited from the proto- and paleo-Tethyan mantle in the region and is possibly not related to materials of eastward extrusion from the plateau. Compared with the contemporaneous volcanics in the area, it can be inferred that the mantle region below at the northeastern margin is heterogeneous. The development of the volcanic activity in the area could be triggered by the distance effect from the initial collision between the Eurasian Plate and a microcontinent in northwest Indian Plate.

Using Mössbauer spectra to characterize and differentiate tourmaline crystals from China

Y. GUO[1], S.Y. YANG[2]*, J.H. MIN[1], L.J. WANG[1] AND Y.B. XIA[1]

[1]School of Materials Science and Engineering, Shanghai Uni., Shanghai 200072, China,
[2]State Key Lab. of Marine Geology, Tongji Uni., Shanghai 200092, China (*correspondence: syyang@tongji.edu.cn)

Tourmaline is a valuable crystalline raw material notable for its piezoelectric and pyroelectric properties. It is also regarded as precious stones in jewlry industry. Tourmaline occurs in almost all types of geologic circumstances and coexists with numerous minerals. Consequently, chemical variation of tourmaline is tightly related with its crystal structure and physical properties which provides important constraints on the origin of tourmaline. Mössbauer spectra analysis has been playing an important role in the detailed study of isomorphic substitutions in tourmaline crystal by Fe^{2+} and Fe^{3+} and the distribution of these ions over distinct crystallographic positions. Nevertheless, the traditional researh on Mössbauer parameter of tourmaline crystals has great uncertainty in the determination of the valance states and occupation types by the expecience values.

In this contribution, the multi-statistic method of cluster analysis was used to effectively determine the Mössbauer spectra and examine microscopic structures of Fe ions in different tourmaline crystals from Guangxi, Hebei, Neimeng and Xingjiang Provinces where have much variable geologic background. The determined assignment corresponds well with previous documented results. We observed four kinds of distribution styles of iron (Fe) ion in the measured tourmaline samples, which distinctly occupy four zones in the diagram of isomer shift and quadrupole splitting. The tourmaline crystals from Guangxi, Hebei and Neimeng are characterized by similar Mössbauer spectra bearing three doublets, which correpand to Fe^{2+}(Y), Fe^{2+}(Z) and Fe^{3+}(Y) sites with two kind of valances respectively. In comparison, only two doublets appear in the Mössbauer spectrum of Xinjiang tourmaline, and the Fe ions having bivalence states occupy Fe^{2+}(Y) and have a neighborhood effect in the Y-Z site. Our study on Mössbauer spectra together with scanning electronic microprobe analysis clearly suggests these tourmaline crystals sourced from different areas have variable compositions and crystalline structures indicative of their different origins.

Long term aerosol trends over large global urban centres

PAWAN GUPTA[1,2]*, MAUDOOD N. KHAN[2] AND ARLINDO DA SILVA[1]

[1]NASA Goddard Space Flight Center, Greenbelt, MD, USA (*correspondence: pawan.gupta@nasa.gov)
[2]Universities Space Research Association, Huntsville, AL, USA (maudood.n.khan@nasa.gov, arlindo.dasilva@nasa.gov)

Aerosol Optical Depth (AOD) retrieved from MODIS and MISR sensors onboard EOS Terra satellite over the last decade (2001-2010) has been utilized to analyze aerosols trends over global megacities. Analysis provides an assessment of retrieval capabilities of these sensors. Level 2 data sets have been carefully analyzed over selected urban centers to understand the retrieval capabilities of these two sensors over complex urban surfaces. Areas over each urban center have been identified, where MODIS operational algorithm is unable to retrieve AOD due to limitation of dark target approach. MISR aerosol product has been used to identify dominating aerosol size distribution and type, as function of seasons. Spatial gradient in AOD within and around the city has been estimated as well. Impact of spatial and temporal averaging over long term trends will also be addressed.

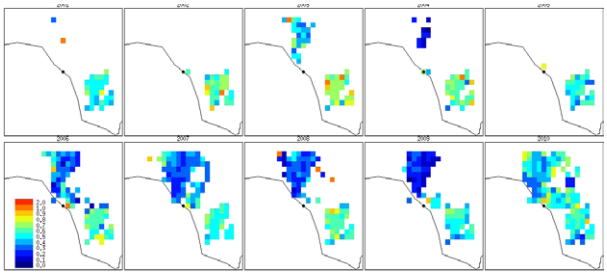

Figure 1: Annual mean aerosol optical depth from MODIS (Terra) over Karachi, Pakistan for 2001 to 2010.

Conduit-scale to localized degassing in ascending magmas: Insights from Cl measurements in Vesuvius 79AD pumice

L. GURIOLI[1], T. SHEA[1]*, E. HELLEBRAND[1] AND J.E. HAMMER[1]

[1] LMV, Univ. Blaise Pascal, Clermont-Fd, France
[2]SOEST, Univ. Hawaii, 1680 East-west rd., Honolulu, HI, 96822, USA (*correspondence tshea@hawaii.edu)

During the ascent and decompression of magmas that fed the 79AD eruption, melts experienced a complex vesiculation history [1]. Both textural evidence from tephra and conduit ascent modelling suggest that velocity gradients affect the ascending magma column and cause spatial variations in degassing [2]. Localized shearing is one of the dominant mechanism through which these velocity gradients can be accommodated during ascent [3]. These shear zones can enhance bubble connectivity and provide pathways for volcanic gases. Here, we present chemical evidence for spatial degassing variations at the scale of the conduit as well as at localized scale. Because Cl diffuses slower than H_2O during ascent, it records a different portion of the magma's history. Figure 1 below shows Cl increases within denser more degassed zones in 79AD pumice clasts. Through textural observations of vesicles as well as Cl and H_2O measurements within pumice glass from various phases of the 79AD eruption, we derive a general conduit model that involves the birth, development, and death of shear-zones.

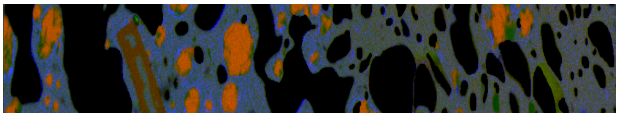

Figure 1: Compositional map (Cl=blue, K=red, Si=green) made in 79AD pumice. Cl increases towards the denser zone richer in large collapsed vesicles (left) likely due to degassing of H_2O. Image width ~ 0.5mm.

Soil source contribution estimation mation of Arsenic and Lead in atmospheric precipitaion at urban industrial area, Raipur, Central India

BALAKRISHNA GURUGUBELLI AND SHAMSH PERVEZ

School of Studies in Chemistry, Pt. Ravishankar Shukla University, Raipur, INDIA. 492010

The components and quantities of atmospheric dust fallout have been reported to be the pollution indicator of large urban areas. The multiplicity and complexity of sources of atmospheric dusts in urban regions has put forward the need of source apportionment of these sources indicating their contribution to specific environmental receptor. The study presented here is focused on investigation of soil source contribution estimates of Arsenic and lead in urban dust fallout in an urban-industrial area, Raipur, India. Source-receptor based representative sampling plan using longitudinal study design has been adopted. Source apportionment has been done using Chemical Mass Balance (CMB 8). Dominance of coal fired industries sources on arsenic levels measured at selected ambient residential receptors compared to line sources has been observed. Road-traffic has shown highest contribution of dust at indoor houses and out door-street automobile exhaust has shows highest contribution for arsenic. The results of CMB output and regression data of source-receptor dust matrices have shown comparable pattern.

Calcium isotopes in Martian meteorites

N. GUSSONE[1], T. MAGNA[1] AND K. MEZGER[2]

[1]Universität Münster, Germany (Nikolaus.Gussone@uni-muenster.de, tomas.magna@uni-muenster.de)
[2]Universität Bern, Switzerland (klaus.mezger@geo.unibe.ch)

Mass-dependent fractionation of Ca isotopes at high temperatures has long been considered minor; consequently, Ca isotopes have mostly been used to study low-temperature processes [1,2]. Here we report high-precision Ca isotope data for a suite of Martian meteorites revealing a $\delta^{44/40}$Ca variation of ~0.4‰ among shergottites, nakhlites, chassignites and orthopyroxenite. Calcium isotope ratios of Martian crust generally fall into the range of terrestrial basalts but tend to be slightly heavier than Earth's crust. $\delta^{44/40}$Ca exhibits no clear relationship with modal contents of olivine, plagioclase and/or pyroxene although pyroxene is the main Ca carrier in the mantle [3]. No systematic behavior is observed between individual groups of shergottites, despite the range in element depletion/enrichment, suggesting a lack of Ca isotope fractionation imparted by different degrees of melting. $\delta^{44/40}$Ca of 1.06 in orthopyroxenite ALH 84001 is in the mantle range whereas low $\delta^{44/40}$Ca in NWA 2737 may reflect the presence of carbonate minerals. Nakhlites mostly have distinctive $\delta^{44/40}$Ca similar to terrestrial plume basalts [4], supporting the derivation of nakhlites from a Martian mantle plume. Whether this difference is directly linked to the dominance of clinopyroxene (with generally lower $\delta^{44/40}$Ca) in nakhlite lavas or is an intrinsic feature of nakhlite mantle source remains to be solved. Nevertheless, Ca appears to evolve distinctively different isotope ratios in plumes and mantle rocks, providing evidence for resolved Ca isotope fractionation at magmatic temperatures.

Collectively, the new data suggest $\delta^{44/40}$Ca ~1.0–1.1 for the bulk silicate Mars. This is identical to an estimate of the Earth's upper mantle [3] and suggests broadly similar processes for mantle melting in the interiors of Mars and Earth, independent of time constraints on the activity of mantle dynamics. Unlike other stable isotope systems, the bulk Ca isotope composition of Earth and Mars differs from enstatite chondrites [5,6]. Thus, they are probably not the major building material for Earth and possibly also not for Mars.

Lead(II) sorption to soil materials – Binding heterogeneity and influence of phosphate

J.P. GUSTAFSSON[1], C. TIBERG[2], A. EDKYMISH[1] AND D.B. KLEJA[3]

[1]KTH (Royal Institute of Technology), Department of Land and Water Resources Engineering, Teknikringen 76, 100 44 Stockholm, Sweden. (gustafjp@kth.se)
[2]Swedish University of Agricultural Sciences, Department of Soil and Environment, Box 7014, 750 07 Uppsala. (Charlotta.Tiberg@slu.se)
[3]Swedish Geotechnical Institute, Kornhamnstorg 61, 111 71 Stockholm. (Dan.Berggren.Kleja@swedgeo.se)

Lead (Pb) is a common pollutant, but still the environmental behaviour of lead is incompletely known. Attempts to simulate the binding of lead(II) to soils by use of geochemical models have usually underestimated lead binding with about one order of magnitude.

Here, new evidence will be presented about some key mechanisms that can explain the failure of most previous modeling attempts. First, the adsorption of Pb^{2+} to ferrihydrite, an important Pb^{2+} sorbent in soils, is shown to be very strong, particularly at low Pb^{2+} / ferrihydrite ratios. Second, the sorption of Pb^{2+} to ferrihydrite is greatly enhanced in the presence of phosphate. The effect is stronger than that predicted by electrostatic interactions only. The mechanisms involved are being studied with spectroscopic methods.

Third, data will be presented that show that the sorption of Pb^{2+} to solid-phase organic matter, especially mor layer material, is much stronger than that of fulvic or humic acid, which are often used as model compounds for solid-phase organic matter. Apparently, Pb^{2+} is strongly bound to a non-humic organic fraction of the solid-phase organic matter, but the mechanism by which this occurs remains obscure. Taken together, these observations may explain the often observed deviation between model and reality concerning lead(II) binding.

Lack of a late deglacial carbonate compensation signal in the intermediate depth Amundsen Sea

M. GUTJAHR[1,2]*, D. VANCE[1], J.W.B. RAE[1], G.L. FOSTER[2], C.D. HILLENBRAND[3] AND G. KUHN[4]

[1]Bristol Isotope Group, Department of Earth Sciences, University of Bristol, Queens Road, Bristol BS8 1RJ, UK (*correspondence: marcus.gutjahr@noc.soton.ac.uk)
[2]School of Ocean and Earth Science, National Oceanography Centre, Southampton, UK
[3]British Antarctic Survey, High Cross, Madingley Road, Cambridge CB3 0ET, UK
[4]Alfred Wegener Institute for Polar and Marine Research, Am Alten Hafen 26, 27568 Bremerhaven, Germany

The Southern Ocean (SO) is an important component in deglacial ocean circulation- and climate change. Ice core-derived temperature and atmospheric pCO_2 records show a deglacial rise as early as 17.9 ka [1, 2], thereby leading Northern Hemisphere warming by about three thousand years [3]. The atmospheric CO_2 rise occurred alongside increasing bioproductivity around Antarctica, providing evidence that reinvigorated upwelling of Circumpolar Deep Water (CDW) around Antarctica led to large-scale degassing of Dissolved Inorganic Carbon (DIC) stored in the glacial deep ocean [4].

Changing CDW circulation patterns should also find their expression in variable CDW DIC/alkalinity relationships. In broad terms, the release of previously deep-sea stored DIC to the atmosphere should leave deglacial CDW more alkaline until the excess alkalinity is removed from the water column. To test this hypothesis we have measured the boron isotopic composition (expressed in $\delta^{11}B$) of calcitic scleraxonian cold-water corals sampled in intermediate water depths in the Amundsen Sea (~123°W, ~69°S, 2500 m to 1430 m water depth). We will present an assessment of the genus-specific biological fractionation (c.f. [5, 6]) alongside fossil-coral $\delta^{11}B$ values dating back to the Antarctic Cold Reversal. Our corals appear to be internally homogenous and modern samples have only slightly elevated $\delta^{11}B$ compared to that of ambient intermediate water borate ion. We find that modern and early Holocene coral display fairly constant $\delta^{11}B$ compositions, whilst deglacial coral $\delta^{11}B$ are slightly elevated. This suggesty that the deglacial evolution of the deep Southern Ocean carbonate system is more complicated than a simple degassing and carbonate compensation model may indicate.

The emergence of metabolism: Prebiotic simulations of shallow sea hydrothermal vents

MARCELO I. GUZMAN

Department of Chemistry, University of Kentucky, Lexington, KY 40506, USA (marcelo.guzman@uky.edu)

The origin of metabolism has been one of the most challenging and intriguing issues in the origin of life research. All known carbon fixation pathways used by living organisms, including the reductive tricarboxylic acid cycle, share at least one common intermediate [1]. The implications are that 1) all carbon fixation mechanisms are linked, and 2) a prebiotic mechanism of carbon fixation should have used some of the key organic compounds that participate in central anabolism today. The prebiotic system should have implemented the core reactions involved in central metabolism abiotically and nonezymatically [2]. The model is based on sulfur-containing semiconductor minerals, *in situ* produced in a shallow sea hydrothermal vent [3]. The advantage of the model is to use free energy from sunlight photons to drive otherwise unviable reactions in the absence of enzymes using photocatalysts.

Current work examines the origin of metabolism in a simulated prebiotic shallow water hydrothermal vent. Zinc sulfide (ZnS, sphalerite) was used as a candidate mineral to jumpstart the origin of metabolism in chemoautotrophs. Photochemical reactions of simple organic compounds with carbon dioxide occur at the semiconductor interface. The experimental results show the production of C2, C3, C4, C5, and C6, intermediates of central metabolism [4]. Starting from CO_2, and by consecutive reactions, we observed formate, acetate, oxalate, glyoxylate, glycolate, lactate, pyruvate, succinate, α-ketoglutarate, and isocitrate. The mechanism provides a way to capture energy from the environment while producing carbon feedstock useful in anabolism. The results of this study suggest that central metabolites could have participated in a viable enzyme-free cycle for carbon fixation in a shallow sea hydrothermal vent, where light, sulfide minerals, carbon dioxide, and other organic compounds interacted on the prebiotic Earth to generate an autonomous chemical cycle [5].

Melt inclusions in coexisting perovskite, nepheline, magnetite and clinopyroxene in pyroxene melilitolite from Kerimasi Volcano, Tanzania

T. GUZMICS[1]*, R.H. MITCHELL[2], M. BERKESI[1], C. SZABÓ[1] AND R. MILKE[3]

[1]Lithosphere Fluid Research Lab, Institute of Geography and Earth Sciences, Eötvös University Budapest, 1117 Pázmány Péter sétány 1/C, Budapest, Hungary (correspondence: tibor.guzmics@gmail.com)
[2]Lakehead University, Thunder Bay, ON P7B 5E1, Canada
[3]Free University, Habelschwerdter Allee 45, 14195 Berlin, Germany

We studied melt inclusions in pyroxene melilitolite from Kerimasi volcano, Tanzania. Primary silicate melt and fluid inclusions were entrapped in perovskite, magnetite, nepheline and clinopyroxene, however, perovskite usually enclosed multiphase melt inclusions containing both silicate and carbonatite melt (Fig. 1).

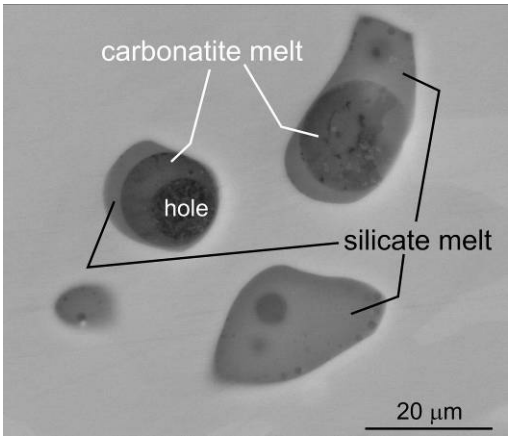

Figure 1: Quenched melt inclusions containing immiscible melts in perovskite after heating to 1050 ºC.

High temperature heating experiments on melt inclusions show minimum homogenization temperatures at 1040 ºC in clinopyroxene and at 1050 ºC in nepheline and perovskite, which correspond to actual crystallization temperature. Nevertheless, in many cases, heterogeneous entrapment of melts and fluid prevented complete homogenization of melt inclusions. We applied furnace technique in order to produce homogenous melt(s). Melt compositions indicate an earlier formation of this rock than Kerimasi calciocarbonatite.

CO_2 sequestration and hydrothermal basalt alteration at 40-250 °C

A. P. GYSI* AND A. STEFÁNSSON

Institute of Earth Sciences, University of Iceland, 101 Reykjavik, Iceland (*correspondence: apg2@hi.is)

In order to gain insight into the geochemical processes associated with CO_2 mineralization and sequestration in basalts, a series of CO_2-water-basaltic glass reaction path experiments and numerical simulations were performed at 40-250 °C and initial pCO_2 of 0-20 bar, and the water chemistry and the secondary minerals studied as a function of reaction progress.

At 40-75 °C, the addition of CO_2 changes the water-basalt reaction path considerably. At low reaction progress (pH <6.5), the pH was buffered by CO_2 ionization, consumption of protons (H^+) by the dissolving basaltic glass and proton consumption-release upon secondary mineral formation. The stable mineralogy consisted of Ca-(Mg)-Fe clays, amorphous SiO_2 and Ca-(Mg)-Fe-(Mn) carbonate (ankerite) solid solutions. The moles of carbonates and SiO_2 per moles dissolved basaltic glass was observed to increase at elevated pCO_2, whereas the amount of clays forming decreased. At high reaction progress (pH >8), the pH was buffered by the basalt alteration and secondary mineral formation and dissolved silica ionization. The stable mineral assemblages consisted of Mg-Fe clays, zeolites and Ca-Mg carbonates.

At 150-250 °C, the secondary mineral assemblages formed during the experiments where similar to those observed in natural geothermally altered basalts, and consisted of amorphous SiO_2, mixed Mg-Fe smectites/chlorite, zeolites and calcite. The amount of clays and a basaltic glass surface alteration layer increased in thickness with temperature, coating sometimes the entire basaltic glass surface. At 250 °C, the clay compositions were generally closer to chlorite and the basaltic glass completely altered after ~50 days, whereas at 150 °C a thin alteration layer was observed after ~125 days reaction time.

The dissolution of basaltic glass in CO_2-rich waters was found to be incongruent with the overall water composition and secondary mineralogy depending on pH, reaction progress and temperature. Competing reactions between clays (Ca-Fe smectites) and carbonates at low pH, and zeolites and clays (Mg-Fe smectites) and carbonates at high pH, control together the availability of Ca, Mg and Fe, playing a key role for CO_2 mineralization and sequestration into basalts [1, 2].

Sediment melt flux into the melting zone of the Northernmost Tonga island arc

KARSTEN M. HAASE, MARCEL REGELOUS AND CHRISTOPH BEIER

GeoZentrum Nordbayern, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany (haase@gzn.uni-erlangen.de)

The lavas from the northernmost islands Tafahi and Niuatoputapu in the Tonga island arc are long known to differ in terms of composition from rocks from the central and southern volcanoes of this arc. The differences are believed to reflect either the influence of plume-type mantle from Samoa or the subduction of OIB-material from the Louisville Seamount Chain. Although the distance between the two islands is only 8 km we find significant differences between the lavas. Compared to lavas from the central Tonga arc the Tafahi-Niuatoputapu basaltic lavas have relatively high SiO_2 contents at a given MgO but are highly depleted in heavy rare earths, Ti and Zr, thus resembling boninites. This implies a highly depleted mantle wedge composition beneath the northern Tonga arc.

Radiogenic isotope variations indicate that binary mixing of different slab components occurs in the melting zones beneath each island. The Niuatoputapu lavas have slightly U-shaped REE patterns with significant negative Ce anomalies that are less pronounced in the lavas from Tafahi. The Ce anomaly probably reflects a prevailing influx of sedimentary components. Most samples also show superchondritic Nb/Ta indicating residual rutile in the sedimentary component. This component also has relatively high Pb isotope ratios and most likely represents a partial melt of subducted volcaniclastic sediments from the Louisville Seamount Chain. The sedimentary component mixes with a hydrous fluid from altered mid-ocean ridge basalts. Seismic studies show that the slab beneath the northern Tonga arc is only about 70 km deep which may lead to the prevailing influence of sediment melts relative to fluids from altered basaltic crust.

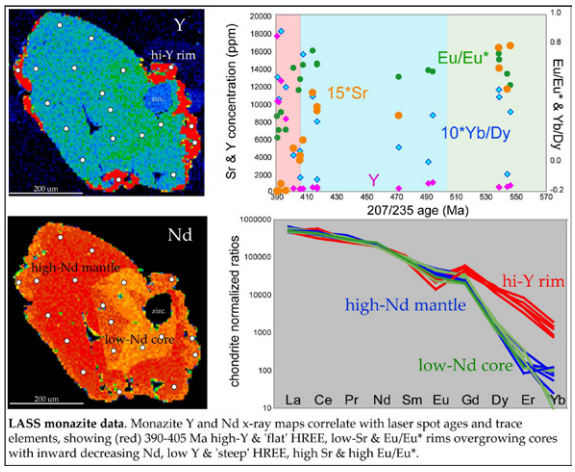
Subduction and exhumation of the UHP Western Gneiss Region: Petrology, structural geology, and LASS petrochronology

BRADLEY R. HACKER* AND ANDREW R.C. KYLANDER-CLARK

University of California, Santa Barbara, 93106-9630 (*correspondence: hacker@geol.ucsb.edu)

The Western Gneiss Region of Norway is one of Earth's two giant UHP terranes, with eclogites distributed across an area ~150 x 200 km. A new LASS petrochronology dataset of more than 200 samples now rivals structural, petrological, and $^{40}Ar/^{39}Ar$ datasets in richness and information content. The half of the WGR that is close to the foreland shows weak Caledonian deformation and preserves Precambrian Sm-Nd garnet ages, Precambrian U-Pb zircon ages, partially reset U-Pb titanite ages, 398–397 Ma U/Th-Pb monazite ages, and muscovite $^{40}Ar/^{39}Ar$ ages that decrease monotonically away from the foreland from 400 to 390 Ma.

The hinterland portion is variably deformed and preserves three distinct UHP domains that are marked by 420–400 Ma Lu-Hf and Sm-Nd eclogite ages, 418–407 Ma Sm-Nd garnet ages from HP gneiss, 425–405 Ma monazite U/Th-Pb ages from garnet-stable gneiss, 430–415 Ma U-Pb zircon ages from HP gneiss, 407–392 Ma U-Pb zircon ages from exhumation-related leucocratic intrusions, 405–394 Ma U/Th-Pb monazite ages from post-UHP gneiss, 400–398 Ma U-Pb zircon ages from post-UHP gneiss, 395–381 Ma U-Pb rutile ages, and 390–375 Ma muscovite $^{40}Ar/^{39}Ar$ ages. In general, coherence among the age gradients defined by the different isotopic systems indicates simple east-directed exhumation. In detail, however, differences among the ages within the three UHP domains indicate juxtaposition of the central and northern UHP domains against the southern UHP domain after titanite and rutile closure and prior to muscovite closure.



LASS monazite data. Monazite Y and Nd x-ray maps correlate with laser spot ages and trace elements, showing (red) 390-405 Ma high-Y & 'flat' HREE, low-Sr & Eu/Eu* rims overgrowing cores with inward decreasing Nd, low Y & 'steep' HREE, high Sr & high Eu/Eu*.

Sources and sinks of acetate in an acidic peatland

ANKE HÄDRICH[1], VERENA HEUER[2], MARTINA HERRMANN[1], KAI-UWE HINRICHS[2] AND KIRSTEN KÜSEL[1]

[1]Aquatic Geomicrobiology Group, Dept. Ecology, University of Jena, D-07743 Jena, Germany, (kirsten.kuesel@uni-jena.de)

[2]Organic Geochemistry Group, Dept. of Geosciences and MARUM Center for Marine Environmental Sciences, University of Bremen, P.O. Box 330 440, D-28334 Bremen, Germany, (vheuer@uni-bremen.de)

Acetate in anoxic environments originates from fermentation of organic matter or the reduction of CO_2 using the acetyl-CoA pathway (acetogenesis). As a key intermediate acetate is consumed by various anaerobic microorganisms which complicates unraveling its turnover in pore waters. This study aimed to i) determine proportions of acetate forming processes via stable carbon isotope analysis of acetate and ii) to identify the acetogens in an acidic fen (pH ~4.8) located in northern Bavaria, Germany. Assessing the functional *fhs* gene involved in the acetyl-CoA pathway revealed sequences of potentially novel acetogens like a phylotype related to *Eggerthella* present only in surficial soil layers. The presence of active acetogens in peat soil was suggested by ^{13}C-depleted acetate (-37‰ vs VPDB) in H_2/CO_2 supplemented microcosms compared to acetate with -14‰ vs VPDB in an unsupplemented control. Peat pore water profiles showed acetate concentrations from 0-170 μM with δ^{13}C values of -17.4‰ up to -3.4‰ vs VPDB. The ^{13}C-enrichment of acetate relative to peat TOC (-26‰ vs VPDB) suggested the predominance of sinks which are preferentially consuming ^{12}C-acetate. Depth profiles of $\delta^{13}C_{CH4}$ point towards acetoclastic methanogenesis as a sink for acetate prevailing mainly in the upper fen soil layers. Additionally, iron and sulphate reduction appeared to play a role in acetate turnover at this acidic fen.

The variability in formation water composition and the implications for CO_2 storage conditions

R.R. HAESE[1]* AND M. PREDA[2]

[1]CO2CRC and Geoscience Australia, GPO Box 378, Canberra ACT 2601, Australia (*correspondence: ralf.haese@ga.gov.au)

[2]Geological Survey of Queensland, Department of Employment, Economic Development and Innovation, Brisbane QLD, Australia (micaela.preda@deedi.qld.gov.au)

Background and motivation

The prediction of CO_2 storage conditions and safety requires a range of informtion. The emphasis of this study is the composition of formation water and its control on the long-term distribution of injected CO_2 and the different CO_2 trapping mechanisms in the reservoir. Formation water composition was compiled for basins from the USA, Canada, Norway, Germany and Australia and the data was then used to make inferences on a) the density-driven convection of fluid due to differences in the CO_2 concentration, b) CO_2 solubility (fluid trapping) and c) long-term fluid-rock reactions leading to the immobilization of CO_2 (mineral trapping).

Preliminary results

The reported formation water composition is highly variable between basins with total dissolved solid (TDS) concentrations ranging from 340 to 355,000 mg/L. The lowest TDS concentrations are in the drinking water range and are found in Australian basins, while the highst concentrations are found in formations in near proximity to salt deposits. The CO_2 solubility decreases by approximately 50% from lowest to highest TDS concentrations. The fluid density increase due to CO_2 saturation follows an exponential function with the highest density increase in freshwater. The latter leads to significantly more rapid convective mixing. The combined effect of higher solubility and more rapid convection means a more effective CO_2 trapping in the fluid and its downward transport in reservoirs with low TDS fluids. The prediction of CO_2 mineral trapping capacity is dependant on the water and mineral composition in the reservoir. Examples for differences in mineral trapping capacity with variable water and mineral composition will be given.

Effect of process conditions on the biological selenate reduction and selenium particle production

S.P.W. HAGEMAN*, R.D. VAN DER WEIJDEN, J. WEIJMA AND C.J.N. BUISMAN

Wageningen University, Sub-dept. of Environmental Technology. Bornse Weilanden 9, 6708 WG Wageningen, The Netherlands, P.O. Box 17, 6700 AA Wageningen (*correspondence: Simon.Hageman@wur.nl)

Objective and methods

Diverse microorganisms can reduce selenate to elemental Se. Elemental Se particle properties are determined by the Se production mechanism and kinetics. The effect of the used bacterial mixed culture, temperature, Se oxyanion and electron donor concentration on Se particle size, shape, sedimentation rate, and purity was investigated.

Experiments were performed in a pH and T controlled fed-batch system. The feed contained 25mM Se oxyanions and the electron donor was lactate or ethanol.

Results and discussion

SEM pictures of the Se precipitates showed that it was possible to affect the Se particle properties (needles to spheres) by varying process parameters.

The mechanism of Se precipitation was also investigated to determine whether the reaction is direct bio-mineralization or a combination of direct and indirect bio-mineralization. A possible two step mechanism is suggested.

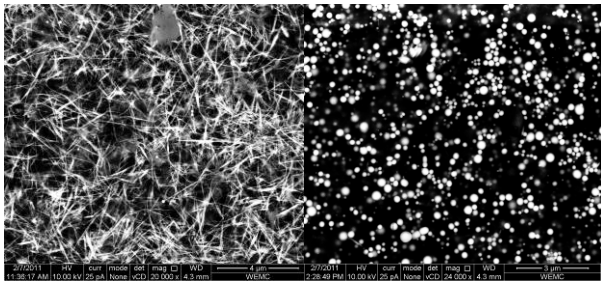

Figure 1: SEM-photos of the Se precipitates. The picture on the left shows Se needles, the scalebar in the lower right corner is 4μm. The picture on the right shows Se spheres, the scalebar in the lower right corner is 3μm.

Atomic environment of Y in silicate melts from molecular dynamics and x-ray absorption spectroscopy

V. HAIGIS*, S. SIMON, M. WILKE AND S. JAHN

German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany (*correspondence: haigis@gfz-potsdam.de)

Trace element partitioning strongly depends on major element composition of the involved phases. Whereas the influence of crystal chemistry is well described by the lattice strain model [1], the role of melt composition and structure is still poorly understood. In experiments with immiscible silicate melts, Schmidt *et al*. [2] observed partitioning of Y and rare earth elements into the more depolymerized (silica-poor) melt, where the tetrahedral network is partially destroyed. An explanation of these findings in terms of atomic-scale structure is still missing.

We performed molecular dynamics (MD) simulations to investigate the local environment of Y as a trace element in different silicate melts of the system CaO-Al_2O_3-SiO_2. The interactions between atoms were described by a new polarizable ion model which also captures many-body effects and was parametrized non-empirically, using density functional theory data as a reference. As a result, we found a systematic dependence of the atomic-scale structure around Y on melt polymerization, which can be quantified by means of the ratio of non-bridging oxygen to the network forming cations Si and Al (NBO/(Si+Al)): Upon increasing NBO/(Si+Al) from 0.0 to 1.9, the coordination of Y by O drops from 7.7 to 6.2, and the average Y-O distance decreases from 2.56Å to 2.46Å. Moreover, using the method of thermodynamic integration, we obtained first results for the exchange coefficient (ratio of partition coefficients) $D_Y^{melt1/melt2}/D_{Al}^{melt1/melt2}$ of Y and Al between two melts.

To validate our structural findings, we performed a joint theoretical and experimental study on extended x-ray absorption fine structure (EXAFS) spectra of Y in silicate melts. These spectra contain information about the coordination of Y and distances to neighbouring atoms. Traditionally, a structural model is refined until the measured spectrum is satisfactorily reproduced. However, for amorphous systems it is often difficult to make an appropriate guess for the structure, and hence we propose a converse approach. We modelled EXAFS spectra by averaging over many MD snapshots, and the agreement with experimental spectra confirms that our model faithfully reproduces the atomic-scale environment of Y.

A deglacial ^{14}C budget

M.P. HAIN[1]*, D.M. SIGMAN[1] AND G.H. HAUG[2]

[1]Department of Geosciences, Guyot Hall, Princeton University, Princeton, New Jersey 08544 (*correspondence: mhain@princeton.edu)
[2]Geological Institute, Department of Earth Sciences, ETH Zürich, Zürich 8092, Switzerland

Using the simplest possible model, an ocean split into upper (32%) and deep (63%) plus biosphere/atmosphere (5%), we construct a best estimate LGM ^{14}C budget based on ocean and atmospheric $\Delta^{14}C$ measurements. This budget is consistent with the estimates for the production-based global ^{14}C inventory during the LGM. Since the inferred ^{14}C ventilation ages for the mid-depth and deep ocean are significantly older than pre-industrial, some combination of sluggish LGM ocean overturning and greater surface reservoir ages is implicated. However, this budget leaves little room for a sizable, severely ^{14}C deplete Mystery Reservoir in the deep LGM ocean.

Given this preliminary LGM budget, it is very difficult, yet possible, to explain some of the deglacial observations by simple redistribution of ^{14}C from the upper ocean into the deep ocean. Specifically, the modest deglacial $\Delta^{14}C$ decline of southern-sourced mid-depth waters [1,2] can be accounted for by rising $\Delta^{14}C$ in the deep Southern Ocean [3]. However, for the Heinrich stadial 1, most records show constant or modestly decreasing planktic-benthic $\Delta^{14}C$ difference, suggesting a decline in the absolute $\Delta^{14}C$ of the deep ocean [4-6]. If these observations collectively reflect global deep ocean $\Delta^{14}C$, then (a) an imbalance between deglacial production and decay of ^{14}C, (b) the addition of ^{14}C-dead geologic carbon, and/or (c) a substantial deepening of the thermocline are required to close the deglacial budget. These alternative mechanisms would also significantly contribute to the deglacial 190‰ decline in atmospheric $\Delta^{14}C$.

The lithium isotopic signature of carbonatites

R. HALAMA[1,2]*, W.F. MCDONOUGH[2], R.L. RUDNICK AND K. BELL

[1]SFB 574, University of Kiel, 24105 Kiel, Germany (*correspondence: rh@min.uni-kiel.de)
[2]Department of Geology, University of Maryland, College Park, MD 24072, USA
[3]Department of Earth Sciences, Carleton University, Ottawa, Canada, K1S 5B6

Carbonatites are mantle-derived intraplate magmas that provide a means of monitoring the chemical secular evolution of the Earth's mantle [e.g., 1]. Speculations that mantle-derived rocks may record secular lithium (Li) isotopic variations as Li is progressively recycled into the mantle [2] have been fueled by the diverse Li isotopic composition of subducted sediments and basaltic ocean crust. The Li isotopic composition of carbonatites reflects their mantle source because there is no, or very little, Li isotope fractionation during their differentiation [3] and partial melting. A correlation is expected between recycled materials and Li isotopic anomalies, if a) non-mantle-like Li is introduced to the mantle through subduction [2], or b) Li isotopic heterogeneities are generated kinetically in the mantle by diffusion from subducted, Li-rich materials [4]. Li isotopic compositions of Archean to Recent carbonatites from several continents (δ^7Li = +4.1±1.3; n=23) overlap the range typical for modern mantle-derived rocks (MORB and OIB) and show no variation with time [5]. If the mantle sources of carbonatites are related to subduction and recycling of oceanic lithosphere, as suggested by some studies [e.g., 6], we see no evidence for this in terms of their Li isotopes, suggesting that neither of the two conditions above hold and that one or both of the following is true: a) the bulk composition of subducted material does not deviate greatly from the average mantle value (δ^7Li = +4±2), in agreement with a bulk δ^7Li of +3.1 for a typical subducting oceanic slab [7], b) crustal Li is effectively homogenized upon subduction into the mantle [5]. Alternatively, carbonatites may derive from primitive or depleted mantle sources, which have not been influenced by crustal recycling.

Origin of vesuvianite-bearing ultramafic layers from the Raspas Complex, Ecuador

R. HALAMA[1]*, I.P. SAVOV[2], D. GARBE-SCHÖNBERG[1] AND T. TOULKERIDIS[3]

[1]SFB 574, University of Kiel, 24098 Kiel, Germany (*correspondence: rh@min.uni-kiel.de)
[2]School of Earth and Environment, University of Leeds, Leeds LS2 9JT, United Kingdom
[3]Center of Geology, Volcanology and Geodynamics, Escuela Politécnica del Ejército, Quito, Ecuador

Serpentinized ultramafic rocks from the Raspas Complex (Ecuador) are spatially associated with eclogites and high-pressure metapelites and assumed to have experienced similar peak P-T conditions (1.8-2.0 GPa at 600 °C) [1,2]. Their compositions vary from low Al_2O_3 (<1wt.%) typcial for harzburgites to high Al_2O_3 (up to 15 wt.%) and CaO (up to 16 wt.%) contents. Some of the Ca-rich ultramafic layers contain pargasitic amphibole, vesuvianite and, very rarely, relicts of Ca-rich garnet. The aim of this study is to test whether the hydrous ultramafic assemblages can provide P-T estimates that confirm, or disprove, peak P-T conditions similar to the associated eclogites. Moreover, the origin of the layers in terms of mantle processes vs. fluid influx during subduction zone metamorphism will be evaluated.

Pseudosection calculations using the THERIAK software reveal that vesuvianite has, for most compositions, a wide stability field in P-T space. However, to stabilize Ca-rich garnet in the garnet-bearing sample, temperatures in excess of 550°C are required. This points to peak P-T conditions overlapping those of the eclogites and hence a similar subduction path.

For the Ca-rich ultramafic layers, the elevated Al_2O_3 and CaO contents and correlations between Ni and MgO are similar to pyroxenite layers in orogenic ultramafic massifs [3]. Chondrite-normalized REE patterns have La_N/Yb_N ratios <1, suggesting derivation from a depleted source, similar to the Al-poor peridotites [2]. Initial Sr isotope ratios (0.7025-0.7028) also point to a depleted mantle signature without significant effects of alteration or subduction zone metasomatism. These observations, combined with up to 10x chondritic REE abundances, indicate that these ultramafic layers represent former pyroxenite layers within an orogenic peridotite massif.

En echelon volcanic chains at hotspots as probes of the deep mantle

P.S. HALL[1]*, S. HUANG[2] AND M.G. JACKSON[1]

[1]Department of Earth Sciences, Boston University, Boston, MA 02043, USA (*correspondence: phall@bu.edu)
[2]Department of Earth and Planetary Sciences, Harvard University, Cambridge, MA 02138, USA

Systematic differences have been identified in the isotopic composition of lavas from the geographically distinct Loa and Kea trend volcanoes at Hawaii, with lavas from the southern (Loa) trend having higher $^{208}Pb^*/^{206}Pb^*$ and lower ε_{Nd} than lavas from the northern (Kea) trend [1,2]. This inter-trend difference has been interpreted as reflecting geochemical zonation within the conduit of the Hawaiian plume. Here we report on the existence of similar inter-trend isotopic differences in lavas from both the Samoa and the Marquesas hotspots. As with Hawaii, both of these hotspots are located on the Pacific plate and feature volcanism organized into en echelon trends. In Samoa, lavas from the southern (Malu) trend are found to have higher $^{208}Pb^*/^{206}Pb^*$ and lower ε_{Nd} than lavas from the northern (Vai) trend. Similarly, lavas from the southern (Motu) trend in the Marquesas have higher values of $^{208}Pb^*/^{206}Pb^*$ at a given value of ε_{Nd} than lavas from the northern (Nuku) trend volcanoes. In addition, the average isotopic compositions of lavas from these three hotspots show a geographic variation on a large scale that is consistent with the inter-trend. In particular, the southernmost hotspot (Samoa) has the highest $^{208}Pb^*/^{206}Pb^*$ and lowest ε_{Nd} while the northernmost hotspot (Hawaii) has the lowest $^{208}Pb^*/^{206}Pb^*$ and the highest ε_{Nd}.

Geodynamic models have demonstrated that the azimuthal distribution of heterogeneity within the thermal boundary layer (TBL) at the base of a plume is preserved within the plume conduit itself [3]. We propose that the observed inter-trend and inter-hotspot isotopic variations reflect the large-scale distribution of heterogeneities within the TBL at the base of the mantle, from which the respective plumes originate. Comparison of the observed isotopic compositions to seismic shear-wave velocity (v_s) in the lowermost mantle [4,5] at these locations reveals that the high $^{208}Pb^*/^{206}Pb^*$, low ε_{Nd} component correlates well with the large region of low v_s known as the Pacific superplume.

Hydrogen, carbon, nitrogen and xenon depletion in terrestrial planets

ALEX N. HALLIDAY

Department of Earth Sciences, Oxford University, South Parks Road, Oxford, OX1 3AN, UK (alexh@earth.ox.ac.uk)

The $^{40}Ar/^{36}Ar$ of MORB, OIB and well gases can be used to calculate the degree of degassing of primordial ^{36}Ar from the total mantle as sampled, which can be shown to be >95% and was probably nearer to 99% given evidence for ^{36}Ar recycling. On this basis a minimum primordial ^{20}Ne budget of $(2\text{-}7)\times10^{13}$ kg can be calculated from upper mantle estimates assuming the lower mantle is if anything less degassed, and this is close to the atmosphere's 6×10^{13} kg. A similar calculation for Xe using upper mantle estimates yields minimum degassing of 3×10^{10} kg primary ^{130}Xe, again close to the atmosphere's 9×10^{10} kg. There is no evidence that the atmospheric pattern is fractionated relative to mantle. The primordial ^{3}He budget can be calculated in the same way and an overall composition derived for the bulk silicate Earth's noble gases (BSE = total Earth minus core). When combined with updated budgets for ^{1}H, ^{12}C, ^{14}N, Earth's composition correlates with that in chondrites. The noble gases ^{3}He, ^{20}Ne, ^{36}Ar and ^{84}Kr in particular are in chondritic proportions and provide evidence against models based on fractionated solar components. Relative to CI chondrites they are more abundant by 1 to 2 orders of magnitude than ^{1}H, ^{12}C, ^{14}N and ^{130}Xe. Normalised to CI chondrites carbon and nitrogen are the most depleted elements in the BSE. Venus and Mars display a similar primordial pattern (excluding ^{1}H and ^{3}He). This reproducible feature cannot be explained with combinations of diverse protolith materials. For example, enstatite and CI chondrites have similar relative proportions of volatiles. Therefore, it appears that there was early removal of ^{1}H, ^{12}C, ^{14}N and ^{130}Xe relative to ^{3}He, ^{20}Ne, ^{36}Ar and ^{84}Kr. The present day budgets of carbon and nitrogen in Venus and Earth are strikingly similar, and similar in C/N to the budgets in Mars and CI chondrites providing evidence that they were subsequently replenished as veneers in proportion to planetary mass. More than half of Earth's water predates this veneer assuming a CI hydrogen budget. The mechanisms for preferential removal of ^{1}H, ^{12}C, ^{14}N and ^{130}Xe are unclear. They might all be depleted by core formation. Carbon, nitrogen and xenon also form low temperature species with first ionization potentials less than that of hydrogen. Therefore, depletion and possibly also xenon isotopic fractionation may relate to ionisation from solar EUV in the inner circumstellar disk [1].

Partitioninig of hydrogen between plagioclase and basaltic melt

M. HAMADA, M. USHIODA AND E. TAKAHASHI

Dept. Earth & Planet. Sci., Tokyo Institute of Technology, Tokyo 152-8551, Japan (hamada@geo.titech.ac.jp)

The hydrogen in nominally anhydrous minerals (NAMs) can be an indicator of H_2O in silicate melts if the partitioning behavior of hydrogen between NAMs and melts is known. Plagioclase is one of the NAMs and igneous plagioclase accommodates hydrogen as OH [1]. We will report preliminary experimental results on the partitioning of hydrogen between Ca-rich plagioclase and arc basaltic melt.

Hydrous melting experiments of basaltic magma were carried out at 350 MPa using internally-heated pressure vessel. Starting material was powdered hydrous basaltic glass (50.5% SiO_2, 18.1% Al_2O_3, 4.9% MgO) with 1 to 4 wt.% H_2O. A grain of Ca-rich plagioclase (about 1 mg, An_{95}) and 10 mg of powdered glass were sealed in a $Au_{80}Pd_{20}$ alloy capsule and kept at temperature slightly above crystallization temperature of plagioclase as a liquidus phase, in order to attain near equilibrium between plagioclase and melt. Oxygen fugacity during the experiments was estimated to be 3 log unit above Ni-NiO buffer. Experiments were terminated after 24 hours, which is long enough to attain equilibrium partitioning of hydrogen between plagioclase and melt. Concentration of H_2O in melt and concentration of OH in plagioclase was analyzed using FT-IR [2].

Linear correlation between H_2O concentration in melt and OH concentration in plagioclase is recognized. Obtained partition coefficient is ≈ 0.008 in molar basis, which is higher than the estimated partition coefficient using H_2O in dacitic melt inclusions and hydrogen in their host plagioclase, ≈ 0.004 [3]. This difference in partition coefficients between basaltic system and dacitic system may be explained by difference in crystallization temperature of plagioclase; we suggest that partition coefficient of hydrogen is higher at higher temperature. We are conducting further experiments to prove this hypothesis.

Microbial arsenic transformation associated with soda lake in Khovsgol, Mongolia

N. HAMAMURA[1]*, T. ITAI[1], N. DAMDINSUREN[2], A-L. REYSENBACH[3] AND W.P. INKEEP[4]

[1]CMES, Ehime Univ., Matsuyama, Ehime 790-8577, Japan (*correspondence: nhama@ehime-u.ac.jp)
[2]Nat. Univ. of Mongolia, Ulaanbaatar, 14201, Mongolia
[3]Portland State Univ., Portland, OR 97201, USA
[4]Montana State Univ., Bozeman, MT 59717, USA

Soda lakes are extreme habitats characterized by high pH, high salt content, and elevated concentrations of trace elements from volcanic origin. To gain insight regarding the role of microorganisms in the geochemical cycling of arsenic (As), we characterized the bacterial community associated with a soda lake in northern Mongolia. Geochemical analysis of the salt evaporites present in lakeshore soils showed elevated concentrations of Se, As, phosphate and nitrate (pH >8.5). Microbial populations present in the same samples were investigated using molecular methods (16S rRNA and functional genes involved in As transformation) and culturing approaches to isolate relevant organisms involved in As transformation. Bacterial 16S rRNA gene sequences recovered from soda lake sediments and soils were affiliated with halophilic alkaliphiles, including *Bacillus* and *Halomonas* spp. Dissimilatory arsenate reductase genes (*arrA*) were detected, and formed a distinct phylogenetic clade suggesting the presence of unique arsenate-reducing bacterial populations. Pure cultures of *Alkaliphilus*- and *Halomonas*-related organisms were obtained and both showed capabilities for As transformation. The *Halomonas*-related isolate contains a gene similar to anaerobic arsenite oxidase (*arxA*) recently identified in the haloalkaliphilic, arsenite-oxidizing *Alkalilimnicola ehrlichii* strain MLHE-1. These results demonstrate that indigenous microorganisms associated with soda lake environments are capable of As cycling and contribute to the speciation and mobility of As *in situ*.

A new depleted mantle end-member revealed by high resolution sampling along the Mid-Atlantic Ridge

[3]CNRS, UMR 6538, IFREMER, 29280 Plouzané, France (laure.dosso@univ-brest.fr)

New samples from the center of Lucky Strike segment along the Mid-Atlantic Ridge define an atypical correlation, significantly different from the mantle array. This trend is characterized by radiogenic values of $^{177}Hf/^{176}Hf$ for a given $^{143}Nd/^{144}Nd$. Similar anomalous $^{177}Hf/^{176}Hf$ data have already been reported along Mohns and Knipovich ridge [1], and near Ascension Island [2]. In order to explain this atypical signature, these studies have proposed respectively: a disequilibrium melting during garnet breakdown and an anomalous mantle source created by an ancient melting event with residual garnet. Based on our new sampling, we propose a simple petrogenetic model for Lucky Strike basalts. This model allows us to reconsider the two hypotheses for Hf isotopes anomalous values. It reveals an unusual refractory component in the mantle near the Azores.

Developments in Noble Gas mass spectrometry

D. HAMILTON*, J.B. SCHWIETERS, D. TUTTAS, M. KRUMMAN, M. DEERBERG, N.S. LLOYD

Thermo Fisher Scientific, Hanna-Kunath-Str. 11, 28199 Bremen, Germany
(*correspondence: Doug.Hamilton@ThermoFisher.com)

Recent advances in ion optics and electronic design have added features to the new range of Noble Gas mass spectrometers from Thermo Fisher Scientific that will enable the scientific community to resolve a number of existing analytical limitations.

The first development relates to detector technology. Because instrument transmission and ion source efficiency can be very high, detector noise can be the limiting factor for ultra-small sample analysis. Faraday cup detectors are the detectors of choice for high accuracy and high precision isotope ratio measurements because of their unmatched stability and linearity and because of the electronic cross calibration network available to precisely and accurately cross calibrate the multiple Faraday detector channels against each other.

Today, most IOMS systems are equipped with current amplifiers using a 10^{11} Ohm resistor coupled to the feedback loop of a high stability and temperature-stabilized operational amplifier.

In this paper we will describe our latest investigations in Faraday cup measurements utilising 10^{12} & 10^{13} resistors for signal intensities in the range of 1 pA to 1 fA.

The second development relates to a new beam deflection technology added to the new ARGUS VI mass spectrometer that enables a fixed collector array to be given some of the properties of a mechanically adjustable array. This enables multi-dynamic multi-collector measurements to be taken utilising a fixed array thus enabling the end user to perform vital detector cross-calibrations “in run”.

Lastly we will describe early results on a new high resolution platform and the capabilities of this platform to finally deal with certain isotopic interferences in both the Argon and Neon spectra.

Martian surface geochemistry from MGS TES: Evidence of global-scale dissolution of olivine from basalts

VICTORIA E. HAMILTON[1]* AND A. DEANNE ROGERS[2]

[1]Southwest Research Institute, Boulder, CO 80302, USA; (*correspondence: hamilton@boulder.swri.edu)
[2]Stony Brook University, Stony Brook, NY 11794-2100 USA

Previous studies of MGS TES-derived major element oxides have found relatively high SiO_2 abundances, interpreted as being due to the presence of high-silica weathering phases in basaltic materials [e.g., 1]. Our derivation of major element chemistry from TES is not substantially different than that obtained in previous studies. However, we have applied new and different approaches to analyzing the data in terms of primary and secondary compositions and draw additional conclusions for the weathering history of the Martian surface.

The molar proportions of Al_2O_3, $CaO+Na_2O+K_2O$, and FeO+MgO can be indicative of weathering trends and the global TES data plot along a line that is consistent with the trend measured in Gusev crater. In Gusev, this trend is attributed to olivine dissolution at low water-to-rock ratios [e.g., 2]. On this diagram, however, the same trend also could reflect primary igneous variation, for which there is evidence on Mars [e.g., 3]; we are in the process of examining trends on regional scales to distinguish between these in TES data.

To evaluate primary igneous trends, we excluded all likely weathering phases and recalculated the bulk oxides. As a result, SiO_2 is reduced relative to prior studies, and overlaps the basaltic field on a total alkalis vs. silica classification diagram to a greater degree than shown previously. On a plot of FeO*/MgO vs. SiO_2, however, our data still largely plot in the calc-alkaline field. This suggests that the igneous phases represent: 1) a non-tholeiitic composition, 2) weathering of a tholeiitic composition that enriches the residual material in relatively higher SiO_2 phases, and/or 3) a weathered tholeiitic composition depleted in FeO relative to MgO. In the absence of evidence for abundant calc-alkaline compositions on Mars, we suggest that olivine dissolution could produce both 2 and 3 above, offering a plausible explanation for the observed trends. We are recalculating compositions with added olivine to constrain how much olivine could have been removed to produce the observed compositions.

A sulfidic driver for the Late Ordovician extinction

E.U. HAMMARLUND[1,2]*, T.W. DAHL[1], D.A.T. HARPER[3], D.P.G. BOND[4], C.J. BJERRUM[5] AND D.E. CANFIELD[1]

[1]Nordic Center for Earth Evolution (NordCEE) and Institute of Biology, University of Southern Denmark, 5230 Odense M, Denmark (*correspondence: emma@biology.sdu.dk)

[4]School of Earth and Environment, University of Leeds, LS2 9JT, UK
[5]Institute of Geography and Geology, Copenhagen University, Øster Voldgade 10, 1350 Copenhagen K, Denmark

The first of three major Phanerozoic extinctions occurred during the late Ordovician Hirnantian stage when 86% of marine species and up to 24% of families perished in two phases. The extinction has been linked to cooling, glaciation and transgression but the exact kill mechanism(s) remain enigmatic because the timing of events and environmental changes are unclear. We analyzed sediments from the Dobs Linn (Scotland), the Billegrav (Denmark), and the Carnic Alps (Austria). These record a positive excursion in the isotopic composition of pyrite sulfur of up to 40‰ during the early to mid-Hirnantian, with maximum $\delta^{34}S$ values close to those of modern rivers. Similar excursions have previously been noted from the Hirnantian of China. The positive $\delta^{34}S$ shift is interpreted to reflect a drop in seawater sulfate concentration promoted by enhanced pyrite burial during expanded global ocean euxinia.

We examined changes in local depositional environments during the late Ordovician extinctions using multiple redox indicators: reactive iron, molybdenum, organic nitrogen and carbon isotopes, and pyrite framboid size distributions. The emerging picture is of deep ocean euxinia, prevailing before the initiation of the first phase of Hirnantian extinction. We argue that both phases of the extinction, and especially the second, were linked to marine euxinia.

During the first phase of extinction, a sea level fall of up to 150 meters decreased shelf area and accompanying euxinia further compressed the habitable oxic zone of the upper ocean, foremost affecting nektonic species. The second phase occurred in the aftermath of the Hirnantian glaciation when ice caps retreated, leading to transgression and the invasion of shelves by deep sulfidic waters, killing mid and shallow water fauna.

Bench scale experiments modeling the effects of a phytostabilization strategy for arsenic and lead containing mine tailings in the semi-arid Southwestern United States

CORIN M. HAMMOND*, ROBERT A. ROOT, SCOTT WHITE, RAINA M. MAIER AND JON CHOROVER

Department of Soil, Water, and Environmental Science, University of Arizona, Tucson, AZ 85721, USA (*correspondance: schowalt@email.arizona.edu)

The Iron King Mine-Humboldt Smelter Site in Dewey-Humboldt, Arizona, U.S.A. is characterized by high iron oxyhydroxide content, acidic pH, and concentrations of arsenic and lead in the top 35 cm averaging about 4,010 mg kg^{-1} and 2,390 mg kg^{-1}, respectively. In the semi-arid climate, human exposure to contaminated tailings particulate matter occurs primarily by aeolian dispersion and water erosion. Consequently, the site was added to the National Priorities (*Superfund*) List by the United States Environmental Protection Agency (EPA) in 2008.

The overall research goal is to develop a cost effective phytostabilization strategy to remediate the Iron King Mine tailings by amending the tailings with compost, lime, mycorrhizal fungi, irrigation, tilling, and seed of native halotolerant plant species. ICP-MS analysis reveals variation in contaminant "solubility" (defined here as <0.2 μm diameter) as a function of dissolved organic matter (DOM) from dairy compost additions. Both arsenic and iron exhibited significant reductions in concentrations in the aqueous phase with increased DOM (Figure 1). This trend is attributed to decreased surface charge of suspended oxyhydroxide colloids with sorbed DOM enhancing flocculation. The colloids (<200 nm) were further investigated with synchrotron XAS and the arsenic species was shown to be As(V) associated with ferric hydroxides.

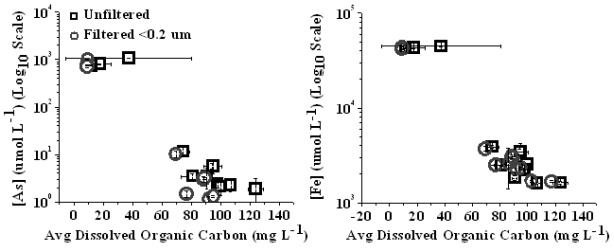

Figure 1: Arsenic (left) and iron (right) supernatant concentrations from batch experiments show similar trends with respect to dissolved organic carbon concentration.

The deep carbon cycle confronted to mantle electrical conductivities

TAHAR HAMMOUDA[1], FABRICE GAILLARD[2], BERTRAND GUILLOT [3], DIDIER LAPORTE[1], PASCAL TARITS[4], NICOLAS SATOR[3], MATTHIEU MICCOULAUT[3] AND SOPHIE HAUTOT[4]

[1]LMV, Clermont-Ferrand, France (t.hammouda@opgc.univ-bpclermont.fr)
[2] ISTO, Orléans, France, (gaillard@cnrs-.orleans.fr)
[3] LMPTC, Paris, France, (guillot@lptl.jussieu.fr)
[4] UBO, Brest, France, (tarits@univ-brest.fr)

The deep carbon cycle is tightly related to (i) subduction processes that injects in the mantle oxidized carbon species, (ii) deep redox processes that traps carbon as graphite or diamond, and (iii) volcanic degassing that transfers carbon form the mantle into the atmosphere. The rate at which such a transfer operates is slow with time-scale comparable to the age of the Earth if it is rate-controlled by solid state mantle convection. Carbonatite melts, however, the oxidized and molten form of mantle carbon, are likely to shortcut these slow processes provided that large scale connected paths exist at depth, and that carbonatite stability is allowed by appropriate redox conditions. Our proposal is that such channels could indeed be revealed by mantle electrical conductivity as deduced from magnetotelluric methods. This approach allows imaging the deep volatile cycling, which has so far relied essentially on petrologically-based models.

Petrologically-based models predict an increasingly reduced mantle with increasing depth, with the possibility that the asthenosphere could be saturated with metallic iron. This should prevent carbonate stability at depth exceeding 200-250 km. Water activity should also be reduced due decomposition into hydrogen. However, there is geochemical evidence for carbonate-rich melts formed at depth exceeding 250 km. This requires redox heterogenities at depth such as oxidized regions within a globally reduced mantle. Similarly, electrical mapping of the mantle images conductive regions surrounded by a globally more insulating mantle. Some conductive mantle regions appear to be spatially connected to subduction regions, which could indicate release of carbonatite at depth, due to melting of subducted carbonates. This process requires that those deep regions are oxygen-enriched and subduction of oxidized material can provide the excess oxygen. In upwelling regions (MOR), underneath volcanic zones that experience CO_2 degassing, electrically conductive zones seems to be deeply rooted suggesting that the deep mantle source regions of those volcanic emissions are more oxidized than the surrounding mantle. We will define the oxygen/carbon ratios required at such depth to reconcile high conductivity and oxidizing conditions.

Tectono-geochemistry exploration and the ore-finding discovery – A case study of the Zhaotong Zn-Pb deposit, Yunnan, China

HAN RUN-SHENG[1]*, WANG XUE-KUN[1] AND WANG FENG[2]

[1]Kunming University of Science and Technology; Southwest Institute of Geological Survey, Geological Survey Center for Non-ferrous Mineral Resources, 650093, P.R.C.; (*correspondence: hrs661@yahoo.com.cn)
[2]Yunnan Chihong Zn Ge Co., Ltd., 655011, P.R.C.

The Zhaotong Zn-Pb deposit is one of the typical deposits in northeast Yunnan rich Zn-Pb-Ge deposit district, and is located in the sagged Yunnan basin at the middle end of the Yangtze Platform. It lies in a structurally compounding position of NE-, SN- and NW-trending fault-fold belts. The ore-bodies occur in the Zaige Formation of Upper Devonian and the Baizuo Formation, which are mainly composed thick layer coarse-grained dolomite, is strictly controlled by the interstratified faults. The length of ore-body is 325 m and its depth is more than 500m, its average thickness is about 16m. The ore grade of Pb and Zn is high up to 20%-35% principally with compact lump shape. In the ores there are other elements including Ag, Ge, Cd. Mineral composition in the ores mainly includes sphalerite, galena, pyrite, ferro-calcite, calcite, dolomite and quartz. The dolomitization is widely observed in wall-rock alteration.

Based on studying the structural ore-controlling laws, M-2, M-4 and A-2, A-3, D-2, F-1 tectono-geochemical anomalies in the mining area were delineated by tectono-geochemical mapping for 1:5000, 1:2000 measuring scale. The main anomalies extend in NE-SW-trending, and superimposed anomalies of Zn-Pb-Cd-Mn-Ge-Ba and Mo-U-W element groups are significant. By the IP and TEM geophysical exploration techniques, two positioning targets were proposed. The one parallels the SW-NE-trending mineralized zone of No.1 orebody group, the other is at the depth of No.1 orebody at the southwest end, concealed orebody may extend from 95 exploration lines to 80 lines. By engineering verifying, more concealed orebodies had found. NO.1-6 orebody is one of the largest, its thickness is 15.6-54.2m, its content of Pb and Zn is 25 % - 35 %. The increase of the Pb-Zn metal reserves by near 1.0 million tones so that the deposit changes into a large-type lead-zinc deposit. This discovery is a successful example after an important breakthrough had made by tectono-geochemical exploration technology in the Huize Pb-Zn deposit.

Spatio-temporal variation of total mercury concentrations in Antarctic snowpack

YEONGCHEOL HAN[1], YOUNGSOOK HUH[1], SUNGMIN HONG[2]; SOON DO HUR[3] AND HIDEAKI MOTOYAMA[4]

[1]School of Earth and Environmental Sciences, Seoul National University, Seoul, Korea (hanlove7@snu.ac.kr; yhuh@snu.ac.kr)
[2]Department of Oceanography, Inha University, Incheon, Korea (smhong@inha.ac.kr)
[3]Korea Polar Research Institute, Incheon, Korea (sdhur@kopri.re.kr)
[4]National Institute of Polar Research, Tokyo, Japan (motoyama@nipr.ac.jp)

Investigation of mercury in the shallow snowpack is helpful for interpreting its deep ice core data and for understanding the mercury dynamics in polar regions. The total mercury concentration (Hg_T) was determined in surface snow (n=44) along a ~1500 km transect from the coast to Dome Fuji in east Dronning Maud Land and from two 4-m snow pits collected during the Japanese-Swedish IPY Antarctic Expedition (Nov 2007 – Jan 2008). The Hg_T of surface snow samples were low (<0.4 – 10.8 pg g^{-1}) and exhibited spatial and/or temporal heterogeneity. However, high Hg_T above the third quartile (>1.7 pg g^{-1}) were observed only in the inner Plateau (>570 km from sea-ice, >3500 m altitude). The Hg_T in two snow pits ranged between <0.3 and 2.4 pg g^{-1} (n=160) with eposodic peaks. The average Hg sequestration rates were estmated to be 1.3±0.9 pg cm^{-2} yr^{-1} for ~52 years and 2.8±0.6 pg cm^{-2} yr^{-1} for ~36 years. These are comparable to the interglacial mercury deposition rate of ~6 pg cm^{-2} yr^{-1} recovered from the deep ice core at Dome C [1].

Our Hg_T determination may underestimate the actual amount in the snow by a factor of 2-5, since additional experiments revealed some loss of volatile mercury from snowmelt samples which had been kept frozen in the dark. Even allowing for potential underestimation, no depositional enhancement that should accompany photo-oxidation of atmospheric elemental mercury in austral mid-summer [2, 3] was observed in surface or pit snow samples. Our Hg_T values could represent the particle-bound refractory fraction that has survived post-depositional reduction within the sunlit snow layer and sequestered on the Antarctic Plateau.

Study on the geochemical characteristics of noble gasses in groundwater in Beishan, Gansu Province, China

YONG HAN[1], GUANGCAI WANG[1] AND YONGHAI GUO[2]

[1]School of Water Resources and Environmental Science, China University of Geosciences, Beijing 10083, China (hanyongzh@163.com)
[2]CNNC Beijing Research Institute of Uranium Geology, Beijing 100029, China (guoyonghai@163.net)

Beishan, located in the Nouthwest of China, has been considered as one of the candidate areas for sitting disposal repository for high level radioactive waste. Groundwater activities is one of most important concerns for such a site. A preliminary hydrogeological investigation has been conducted to understand the groundwater flow systems in the area. The methods regarding noble gases and their isotopes in groundwater were involved in the investigation in an attempt to understand the groundwater recharge, circulation and flow modes. A total of 16 gas samples in situ deaerated from groundwater and 9 groundwater samples by copper tubes were collected. Concentrations and isoptoes of noble gases were determined by mass-spectrometer VG5400.

The values of N_2/Ar range from 45.76 to 81.23 for all groundwater samples, suggesting groundwaters have close relations with atmosphere and atmospheric precipitation. This can be proved by the relationship between δD and $\delta^{18}O$ of groundwater samples, which shows all groundwaters originate from meteoric rainfall. $^3He/^4He$、$^4He/^{40}Ar$ indicate that noble gases in groundwater maily derived from atmosphere and crust with different extent of water-rock interaction and rate of water circle. The excess air in four samples exceed 100% suggesting the relatively larger recharge rate from precipitation. Based on the noble gasses in groundwater, groundwater recharge temperature was estimated by using a computing program, Noblegas [1]. In combination with the age of groundwater, the recharge temperature in the deep borehole BS02 is 5.9°C indicating colder groundwater recharge conditions. According to the analysis above and the hydrogeological conditions, five water circulation modes were generalized, such as Precipitation-Deep or Lateral Recharge, Local Precipitation Recharge-Evaporation and so on.

Supported by the Fundamental Research Funds for the Central Universities of China (No.53200959016) and NSFC project (No.40930637).

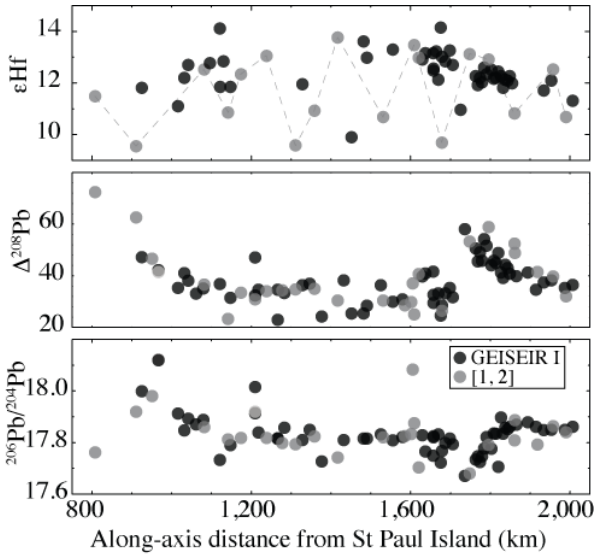
[4] CNRS-OMP, BGI, 31400 Toulouse, France
[5] COAS, Oregon State University, Corvallis, OR 97331, USA

This investigation is designed to constrain mantle melting conditions and composition at high resolution. Fresh basalt glass was recovered from ~130 localities along ~1200 km of the Southeast Indian Ridge (SEIR) axis between 89.5° and 99.3°E during the GEISEIR I expedition. From 89-96° the sampling density was 0.1 km^{-1} and for 96-99° it was 0.2 km^{-1}.



The new data are consistent with the bimodal Hf isotope distribution and presence of ancient compositional streaks along the SEIR [1]. The Pb isotope variation is highly structured, similar to [2], likely reflecting variable melting of an isotopically heterogeneous mantle.

Characterization of pedogenic Mn concretions and coatings in redoximorphic soils

M. HÄNDEL*, T. RENNERT AND K.U. TOTSCHE

Institute of Earth Sciences, Friedrich Schiller University of Jena, Burgweg 11, 07749 Jena, Germany (*correspondence: matthias.haendel@uni-jena.de)

Secondary Mn minerals play an important role in many soil chemical processes such as sorption of metal ions and degradation of organic contaminants. Redoximorphic soils such as Gleysols and Stagnosols are characterized by spatially separated enrichment and depletion zones of pedogenic (hydrous) Fe and Mn oxides, which appear as a result of the periodic change between reducing and oxidizing conditions.

We investigated stagnic and gleyic subsoil horizons developed from loess, Early Triassic sandstone, calcareous gravel and Middle Jurassic loamy sediments with pH values from 3.7 to 7.3. The concretions, coatings and parts of the surrounding matrix were characterized by electron microprobe analysis and polarizing microscopy on thin sections, XRD, FTIR spectroscopy and analyzed for their total element contents and their oxalate- and dithionite-extractable fractions. Diffractograms and FTIR spectra often showed a signal overlapping of clay and Mn minerals. Nevertheless, birnessite [$Na_4Mn_{14}O_{27}$•$9H_2O$] was detected in a gleyic horizon (pH 7.3). We further assume todorokite [$(Mn^{II},Ca,Mg)Mn_3^{IV}O_7$•$H_2O$] in an acidic stagnic horizon (pH 3.7).

Backscattered electron images and EDX measurements showed that Mn phases in stagnic horizons always occur together with clay minerals in a matrix. Iron precipitates are partly present in a clay matrix like Mn phases and also as pure Fe precipitates at the edges of pores inside the concretions. Single particles cannot be discerned and are thus <500 nm. Concretions formed in Middle Jurassic sediments showed a shell-like structure, which suggests a periodic genesis. In contrast, concretions developed in stagnic horizons from sandstone were formed by the flow of the soil solution into the interior of aggregates, where Mn phases precipitated. All pedogenic Mn precipitates were enriched in Co (360 μg/g) and Ni (480 μg/g). The presence of Ni in the Mn precipitates was confirmed by EDX.

Further studies with TEM and EXAFS are required to clarify the detailed mineralogy of the Mn precipitates.

Evolution of a mantle wedge: Basalts from the Colville and Kermadec Ridges

M.R. HANDLER[1]*, R.J. WYSOCZANSKI[2] AND E.M.F. BURGER[1]

[1]SGEES, Victoria University of Wellington, New Zealand (*correspondence: Monica.Handler@vuw.ac.nz)
[2]NIWA, PO Box 14901, Wellington, New Zealand

The Kermadec Arc intra-oceanic arc system has been active for at least the last 17 Ma. Volcanic rocks extracted from much the same location over this period allow the composition and fluxing of the mantle wedge to be investigated over a prolonged period of subduction.

The Southern Kermadec Arc consists of the active Southern Kermadec Arc volcanic front and the Havre Trough back-arc system bound by two sub-parallel ridges, the Colville Ridge to the west and Kermadec Ridge to the east. These ridges represent the proto-Kermadec volcanic arc split by the opening of the Havre Trough at c. 6 Ma. Here, we will present the first major and trace element data, Sr and Pb isotopic data and mineral chemistries of lavas from this remnant arc and compare them with the currently active Southern Kermadec Arc and Havre Trough back arc basin.

The ridge samples comprise highly porphyritic basalts. The crystal cargoes of the ridge crest samples are dominated by plagioclase that span the compositional range observed in the modern arc, extending to very primitive compositions (An ≤ 98). By contrast, samples dredged from a knoll on the Kermadec Ridge contain abundant olivine (Fo ≤ 94; NiO ≤ 0.5 wt%) and pyroxene phenocrysts. Preliminary trace element data suggest a mantle wedge source that was less depleted than the modern wedge (e.g. N-MORB normalised HREE concentrations ~ 0.6 – 1.0), and already polluted with both fluid-mobile element enrichments (e.g. Ba/Nb = 84 – 300) and a sediment melt component (e.g. (La/Sm)N = 1-2). These data suggest that the fluid flux into the mantle wedge has been broadly similar through the life of the arc system, however the mantle wedge has become more depleted and has had less of a sediment melt component added with time.

Insights into the Galápagos plume from uranium-series isotopes of recently erupted basalts

HEATHER K. HANDLEY[1], KIM BERLO[2], CHRISTOPH BEIER[3], SIMON TURNER[1] AND ALBERTO E. SAAL[4]

[1]GEMOC, Department of Earth and Planetary Sciences, Macquarie University, Sydney, NSW 2109, Australia.
[2]Department of Earth Sciences, University of Oxford, Oxford OX1 3PR, UK.
[3]GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Schlossgarten 5, D-91054 Erlangen, Germany.
[4]Department of Geological Sciences, Brown University Providence, Rhode Island 02912, United States.

Uranium-series isotopes (^{238}U-^{230}Th-^{226}Ra-^{210}Pb), major element, trace element and Sr-Nd isotopic data are presented for recent (< 60 years old) Galápagos archipelago basalts and are interpreted in terms of chemical fractionation by magmatic processes. Volcanic rocks from all centres (Fernandina, Cerro Azul, Sierra Negra and Wolf volcano) display ^{230}Th excesses (4-15%) and steep rare earth element patterns indicative of residual garnet during partial melting of the mantle source. Rare earth element (REE) modelling suggests that only a few percent of garnet is involved. Correlation between ($^{238}U/^{232}Th$), radiogenic isotopes and Nb/Zr ratio suggests that the U/Th ratio of Galápagos volcanic rocks is primarily controlled by geochemical source variation and not fractionation during partial melting. Unexpectedly, the lowest ($^{230}Th/^{238}U$) is not observed at Fernandina (supposed centre of the plume) but at Wolf volcano on the 'periphery' of the plume. Small radium excesses are observed for all samples with ($^{226}Ra/^{230}Th$) ranging from 1.107 to 1.614. ^{226}Ra-^{230}Th disequilibria do not correlate with other U-series parent-daughter nuclide pairs or geochemical data, suggesting modification at shallow levels on timescales relevant to the half-life of ^{226}Ra (1600 years). ^{226}Ra and ^{210}Pb excesses are inconsistent with interaction of magma with cumulate material unless decoupling of ^{210}Pb (or an intermediate daughter, such as ^{222}Rn) occurs prior to modification of Ra-Th disequilibria. The intriguing correlation of $(^{210}Pb/^{226}Ra)_0$ with Nb/Zr and radiogenic isotopes requires further investigation but may suggest possible control via magmatic degassing and accumulation related to source heterogeneities.

The uptake of radionuclides into nanoparticulate hydroxyapatite

S. HANDLEY-SIDHU*, J. C. RENSHAW, B. STOLPE, J.R. LEAD AND L.E. MACASKIE

The University of Birmingham, Edgbaston, Birmingham B15 2TT, UK
(*correspondence: s.handley-sidhu@bham.ac.uk)

Hydroxyapatite (HAp) is a potential material for the remediation of metal contaminated waters [1, 2] and as a radionuclide waste storage material [3]. *Serratia* sp. cells bio-manufacture nanophase hydroxyapatite (Bio-HAp) from the substrates glycerol 2-phosphate and Ca^{2+} [4]. Varying the manufacturing conditions influenced Bio-HAp properties (e.g. organic content, Ca/P ratio, specific surface area (SSA), and crystallite size).

The uptake of key radionuclides was investigated: Eu^{3+} (as an analogue for trivalent actinides), U^{6+}, Sr^{2+} and Co^{2+}. All the Bio-HAp (n=10) tested in this study were more efficient than commercially available HAp. For Eu^{3+}, Co^{2+}, Sr^{2+} the main Bio-HAp properties that increased metal uptake were: decreasing crystallite size, increasing SSA and organic content. However U^{6+} uptake showed no relationship to these properties. Figure 1 shows the relationship of crystallite size and Eu^{3+} uptake (mmol per 100g).

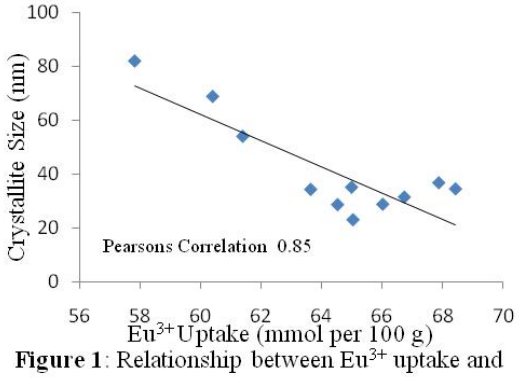

Figure 1: Relationship between Eu^{3+} uptake and crystallite size.

Overall, Bio-HAp shows promise for the remediation of aqueous metal waste especially since Bio-HAp can be synthesized for optimal metal uptake properties.

Petrogenetic implications from PGE in the layered mafic Dufek intrusion and related sills of the Ferrar large igneous province, Antarctica

RICARDA HANEMANN[1], LOTHAR VIERECK-GOETTE[1] AND SAMUEL MUKASA[2]

[1]Inst. f. Geowiss., FSU Jena, Burgweg 11, 07747 Jena
[2]College of Engineering and Physical Sciences, University of New Hampshire, Durham, N.H. 03824, USA

The Jurassic Ferrar large igneous province extends in a >3000 km long, linear belt along the western margin of the East Antarctic craton and comprises numerous sills, dikes and lava flow sequences as well as the layered mafic Dufek intrusion. According to previous studies, the strikingly uniform crust-like trace element and isotope data have been interpreted to indicate a single magma source within the subcontinental lithospheric mantle characterised by crustal enrichment due to Palaeozoic subduction processes.

The goal of the present study is to further describe the petrogenesis of the Ferrar magmatic rocks by investigating the fractionation behaviour of platinum-group elements (PGE) during magmatic evolution. Therefore, we studied the stratigraphic distribution of PGE throughout both the Dufek intrusion and selected Ferrar sills from Northern Victoria Land by analysing the abundances of Ir, Ru, Rh, Pt and Pd by ID-ICP-MS after NiS-fire in about 130 rock samples.

Considering the lithological and geochemical variablity, the studied rocks also exhibit highly variable PGE compositions; PGE totals range from 4 to 138 ppb within Ferrar sills and reach up to ~800 ppb for analysed rocks from the Dufek intrusion. In general, the combined PGE are dominated by Pt and Pd with the Ir-PGE often being near or below detection limits indicating a strong fractionation between the single PGE. The samples analysed do not show clear variations of PGE as a function of stratigraphy or modal rock composition. Obviously, only Fe-Ti oxide-rich rocks from upper parts of both the sills and the Dufek intrusion exhibit significantly elevated PGE concentrations.

The PGE characteristics obtained are attributed to an extensive pre- and post-emplacement differentiation history under mainly sulphur-undersaturated conditions resulting in PGE enrichment until the onset of Fe-Ti oxide fractionation at advanced stages of low-pressure magma evolution. The inferred very low level of S-saturation during differentiation processes of the Ferrar magmas is in agreement with an origin of their primary magmas by high-degree partial melting of a refractory, sulphur-depleted subcontinental lithospheric mantle source proposed beneath this province.

Origin of early hydrothermal fluids associated with the Sudbury structure deduced from individual fluid inclusion Sr isotope analysis

JACOB HANLEY[1]*, FELIX OBERLI[2] AND THOMAS PETTKE[3]

[1]Saint Mary's University, Dept of Geology, Halifax, Canada, B3H3C3 (*correspondence: jacob.hanley@smu.ca)
[2]ETH Zurich, Institute of Geochemistry and Petrology, CH-8092 Zürich, Switzerland
[3]University of Bern, Institute of Geological Sciences, CH-3012 Bern, Switzerland

Early quartz-epidote-calcite-sulfide veins and stockworks in the Archean footwall of the Sudbury Igneous Complex contain inclusions of ore metal-bearing (Cu-Ag-Pt-Bi-Au) aqueous brine (Ca-Na-Cl) with high Sr and relatively low Rb bulk concentrations (4400 μg/g Sr; 110 μg/g Rb; Sr/Rb = 40; n = 18) in addition to wt% concentrations of K, Fe, Mn, Zn, Pb and Ba[1]. Inclusions were trapped in the veins at ~ 0.5 kbar; 200-250ºC[1]. We have determined initial (at 1.85 Ga[2]) $^{87}Sr/^{86}Sr$ ratios in individual brine inclusions by LA-MC-ICP-MS to constrain the source of this fluid that circulated prior to magmatic sulfide deposition.

Analyses of 62 brine inclusions yielded an average initial $^{87}Sr/^{86}Sr$ = 0.70308 ± 0.00020 (1SE). Tentatively, we suggest that the data are most consistent with this early, metalliferous hydrothermal fluid containing a significant endowment of regional Proterozoic seawater ($^{87}Sr/^{86}Sr$ = 0.70296[3]) which covered the target area at the time of impact and subsequent formation of the melt sheet. Suspected major crustal reservoirs in the area had initial $^{87}Sr/^{86}Sr$ too radiogenic to have been an exclusive source for the Sr in the inclusions; these include the gneissic country rocks hosting the veins and their associated groundwaters (initial $^{87}Sr/^{86}Sr$ = 0.71008-0.71092[3]) and magmatic fluids derived from the main igneous units of the Sudbury Igneous Complex itself (initial $^{87}Sr/^{86}Sr$ = 0.70710-0.70742[3]). However, some individual inclusions of assemblages show significant variation in composition (e.g., for 3 inclusions: initial $^{87}Sr/^{86}Sr$ ranges from 0.7018 to 0.7046). A standard deviation for all inclusions analyzed (1σ on mean) of ± 0.001540 suggests the inclusions have trapped pulses of a poorly mixed fluid involving mainly seawater, and a minor component from an additional source, either magmatic and/or groundwater. Scatter due to analytical bias is also being investigated.

Pairing Re-Os geochronology and biostratigraphy – Dating fossils

J. HANNAH*[1,2], H. STEIN[1,2], G. YANG[1] AND J. MALETZ[1]

[1]AIRIE Program, Dept Geosciences, Colorado State University, Fort Collins, CO 80523-1482, USA (*correspondence: jhannah@cnr.colostate.edu)
[2]Geological Survey of Norway, 7491 Trondheim, Norway

With hard-earned insights in sampling strategies and improvements in analytical precision, Re-Os geochronology of organic material in sedimentary rocks is now an established method for placing time pins in the stratigraphic record. Age uncertainties better than 1% are routine, and as low as 0.5% not uncommon. We are now able to address a range of questions using Re-Os geochronology where age constraints were previously lacking. For example, Re-Os shale geochronology can assist uncertain biostratigraphic correlations, and provide ages where biota are absent. We have established the timing of tectonic events in the southern Superior province with a 2695 ± 14 Ma age in a supracrustal sequence [1]. We have confirmed correlation of Anisian-Ladinian (Middle Triassic) biozones between Boreal and Tethyan terranes, where there are no common fossil assemblages and U-Pb geochronology is limited to the Tethyan realm [2]. Further work on the Boreal Triassic section (Xu *et al*., this meeting) affirms the proposed "Alternate" Triassic time scale. Similarly, tight time constraints on the Permo-Triassic extinction were previously limited to the Meishan area in Tethys. We have extended that extinction timeline to the Boreal, with remarkably precise Re-Os isochrons from opposing sides of the Norwegian Sea [3].

An obvious next step is direct dating of fossil organic remains. The Lower and Middle Ordovician sections in western Newfoundland display sequences of well-defined graptolite zones, but lack radiometric age constraints. Re-Os analysis of *Archiclimacograptus* sp., hand-picked from Table Cove Fm shales (Table Head Group) yields 11.4 ppb Re and 0.540 ppb Os. Isotopic ratios are reasonable for the proposed biostratigraphic age. Detailed age constraints from multiple graptolite horizons can delimit durations of biozones, refine the Ordovician time scale, and confirm global correlations. Ultimately, we can assign absolute ages to stratigraphic key surfaces and system tracts, reflected in environmentally sensitive graptolite assemblages, to improve precision of the sea-level curve for the Lower and Middle Ordovician.

The role of aluminum in ferrihydrite preservation

C.M. HANSEL

School of Engineering and Applied Sciences, Pierce Hall, Room 118, Harvard Univerisity, Cambridge, MA 02138 (hansel@seas.harvard.edu)

The poorly crystalline Fe(III) (hydr)oxide ferrihydrite is considered one of the most important sinks for (in)organic contaminants within the environment. In sedimentary environments, the oxidation of carbon and hydrogen is constrained by microbial reduction of Fe(III) (hydr)oxides, of which ferrihydrite is considered the most biologically available. Yet, pure ferrihydrite ripens rapidly to more crystalline Fe phases, such as goethite, leading to diminished sorption capacities and bioavailability. This ripening is accelerated by surface reactions between ferrihydrite and aqueous Fe(II) and can also lead to ferrihydrite conversion to magnetite at higher Fe(II) levels. While ferrihydrite within most natural systems contains high levels of adsorbed or co-precipitated cations, particularly aluminum (Al), little is known regarding the impact of these cations on the capacity for ferrihydrite to ripen to more stable Fe(III) phases or serve as an effective electron acceptor. Accordingly, we explored the impact of adsorbed and substituted Al on the microbial reduction and abiotic Fe(II)-induced secondary mineralization of ferrihydrite over a wide range of Al levels.

Here, we show that Al substituted within (6-24 mole %) or adsorbed on (0.1 to 27% Γ_{max}) ferrihydrite results in diminished microbial reduction and abiotic Fe(II)-induced secondary mineralization resulting, in both cases, in the preservation of ferrihydrite even at low Al levels. The preservation of ferrihydrite increases linearly with the amount of Al adsorbed on or co-precipitated within ferrihydrite. In fact at Al substitution levels exceeding 17 mole %, the rate of microbial Fe(III) reduction is lower for ferrihydrite than for the more crystalline (and hence considered less bioavailable) phase goethite. Furthermore, formation of magnetite is completely inhibited at Al substitution levels greater than 17 mole %, levels that are frequently observed within natural ferrihydrites. Interestingly, the secondary minerals formed upon reaction with different Fe(II) levels (0.2 and 2.0 mM) varies not only with the concentration of Al, but also the mode of Al incorporation (adsorption versus co-precipitation). These findings provide insight into the mechanisms that may be responsible for ferrihydrite preservation and low levels of secondary magnetite typically found in sedimentary environments. The findings also have large implications for constraints on carbon oxidation in sedimentary systems containing compromised ferrihydrites.

Lithium isotope perspective on the Iceland mantle plume

H.-E. HANSEN[1], T. MAGNA[2,3], J. KOŠLER[1] AND R.-B. PEDERSEN[1]

[1]University of Bergen, Norway
[2]Universität Münster, Germany
[3]Czech Geological Survey, Prague, Czech Republic

The Iceland mantle plume represents a quest of searching for the individual mantle end members as well as other components that may have contributed to the observed elemental and isotope variability. Here we present Li contents and isotope compositions in samples from two distinct volcanic centres in Iceland, Krafla and Theistarykir, that show a considerable range in Li and δ^7Li extending that reported previously [1–3]. Pristine Theistareykir basalts (MgO>7%) have consistently low Li contents and range in δ^7Li (+4.2 to +8.1‰) that mimics "depleted" lavas of [1], thought to be variously contributed by an old altered oceanic crust that underwent prior extraction of Li-rich arc magmas at convergent boundaries. Chemically evolved rocks from Krafla (MgO<2%) have similarly invariant δ^7Li pattern coupled with high Li enrichments as reported in [2]; this suggests that magmatic differentiation does not impart resolved Li isotope fractination in juvenile crust derived from plume basalts. The radiogenic Sr–Nd isotope data appear to follow bi-modal distribution akin to [1] and no influence of magmatic evolution on either Sr or Nd in Li-rich rhyolitic and dacitic magmas which may mean a rapid formation of silicic rocks from parental basalts. The new and published data show a strong negative correlation between Li and Mg which shows a significant coupled data density gap between 2 and 5% MgO and 10 and 20 ppm Li, respectively, suggesting a lack of andesitic lavas between basalts and chemically evolved dacites and rhyolites. This may have petrogenetic consequences for formation of new crustal material through magmatic differentiation of rising plume magmas.

A possible mantle plume source in the lower mantle; Evidence from Polynesian HIMU

T. HANYU[1]*, Y. TATSUMI[1], R. SENDA[1], T. MIYAZAKI[1], Q. CHANG[1], Y. HIRAHARA[1], T. TAKAHASHI[1], H. KAWABATA[1], K. SUZUKI[1], J.-I. KIMURA[1] AND S. NAKAI[2]

[1]Institute for Research on Earth Evolution, Japan Agency for Marine-Earth Science and Technology, Yokosuka 237-0061, Japan (*correspondence: hanyut@jamstec.go.jp)
[2]Earthquake Research Institute, The University of Tokyo, Bunkyo-ku, Tokyo 113-0032, Japan

One of the major issues of mantle geochemistry is to decipher heterogeneous nature of the mantle through the studies of ocean island basalts (OIBs) related with mantle plumes. In this study, we focus on OIBs from Polynesia, with unique geochemical characteristics referred to as HIMU. Combined Pb-Sr-Nd-Hf-Os-He isotope analyses using mineral separates provide reliable isotopic information of the basalt source. Coherent isotopic systematics in multi-isotope spaces defined by the HIMU basalts are best explained by recent mixing of melts derived from the HIMU reservoir and the local shallow mantle. The HIMU reservoir has high Pb isotope ratios ($^{206}Pb/^{204}Pb \geq 21.5$), low Nd isotope ratios (epsilon Nd $\leq$ +4), low Hf isotope ratios (epsilon Hf $\leq$ +3), low He isotope ratios ($^{3}He/^{4}He \leq 6$ Ra), and moderately high Os isotope ratios ($^{187}Os/^{188}Os$ = 0.14-0.15). Low $^{3}He/^{4}He$ is consistent with involving recycled materials, most probably, the oceanic crust in the source. However, moderately high Os isotope ratios suggest that the HIMU reservoir is not a recycled oceanic crust itself, but a metasomatised mantle by subducted oceanic crust-derived melt. Such the metasomatism can occur at various settings in the recycling process. These would include (a) wedge mantle metasomatism beneath subduction zones by melting of subducted slab, (b) metasomatism of the upper mantle by melting of stagnant slab, and (c) metasomatism of the lower mantle by melting of deep slab near core-mantle boundary. The parent-daughter element fractionation in Sm/Nd, Lu/Hf and U/Pb deduced from the present day Nd, Hf and Pb isotopes of the HIMU reservoir, respectively, should constrain when and where the subducted oceanic crust melted and subsequent metasomatism occurred. We demonstrate a possibility that melting of the oceanic crust in the lower mantle at 2-3 Ga leaving Mg-perovskite as the residual phase adequately fractionates these parent-daughter element ratios. If this is the case, the oceanic crust was subducted and melted to metasomatize the lower mantle to generate the HIMU reservoir.

Sorption mechanism of dilute fluorine in wastewater using aluminium hydroxide coprecipitation method

D. HARAGUCHI*, C. TOKORO AND S. OWADA

Waseda university, Tokyo 169-8555, Japan (*correspondence: d.haraguchi@suou.waseda.jp)

Hydroxide coprecipitation method is widely used in a treatment of wastewater containing dilute toxic anions. But now detail mechanism or quantitative characteristic is not well understood and also demanded. This study discussed a sorption mechanism of fluorine (F(-I)) in wastewater using aluminum hydroxide coprecipitation method by analyzing filtrates and precipitates using artificial wastewater.

Sorption mechanism of F(-I) coprecipitation with aluminium hydroxide was investigated using 4 kinds of experimental methods: (i) sorption instherm, (ii) zeta potential mesurement, (iii) XRD analysis, and (iv) FT-IR analysis. We compared between coprecipitation experimental results and simle adsorption ones in which F(-I) was just adsorbed on the sysnthized aluminum hydroxide.

Sorption isotherms of F(-I) on aluminum hydroxide exhibited a BET type isotherms and sorption densities abruptly increased when the initial F/Al molar ratio was more than 3. And zeta potential hardly changed even if sorption densities increased when the initial F/Al was more than 3. But results of XRD and FT-IR suggested that precipitates between F(-I) and Al (i.e., AlF_3 and $AlF(OH)_2$) were not formed in all cases [1]. In other words, sorption of F(-I) to aluminum hydroxide was always achieved by simple adsorption. In particular, FT-IR spectra indicated the amount of F(-I) adsorbed to Al-O bonding increased when initial F/Al was more than 3. Therefore, these results exhibited that F(-I) was adsorbed as complex ions between F(-I) and Al (i.e., AlF_3^0 and AlF_4^-) and sorption densities of F(-I) abruptly increased when initial F/Al molar ratio was more than 3. There was little to distinguish coprecipitation experimetnal results from simple adsorption ones in all kinds of experiments.

For summary, All of experimental results showed that F(-I) was adsorbed as F^- when the initial F/Al molar ratio was less than 3 whereas F(-I) was adsorbed as complex ions between F(-I) and Al (i.e., AlF_3^0 and AlF_4^-) when the initial F/Al molar ratio was more than 3.

Dating crocidolite deposits using the argon-argon-method

M. HÄRING[1]*, J.A. PFÄNDER[1] AND J. GUTZMER[2]

[1]Institut für Geologie, TU Freiberg, Germany (*correspondence: maria.haering@student.tu-freiberg.de)
[2]Institut für Mineralogie, TU Freiberg, Germany

Understanding the mechanisms and geological framework of crocidolite formation is a matter of debate and often hampered by a precise knowledge of its formation age. To address this issue, we have dated a series of crocidolite (amphibole asbestos) samples from the Asbesheuwels Subgroup (Griqualand West, South Africa) using the Ar-Ar technique. At very low K-contents (0.01 – 0.20 wt% K), between 6 and 30 mg of fiber bundles were measured by laser induced step wise heating on a ARGUS noble gas mass spectrometer.

Resulting ages span a large range between 2.13 and 1.22 Ga at relatively well developed plateaus, from which some of them indicate diffusive Ar loss. The crocidolite ages therefore did not reflect a single event, but a series of post-formation thermal overprints that may have disturbed the K-Ar system. Although no closure temperature is reported for crocidolite, we assume it to be similar to other amphiboles (~500-550°C) and thus interpret the oldest age (2.13 ± 0.02 Ga) as formation age of the crocidolite deposit. This is slightly younger than the age of the banded iron formation (2.5 - 2.4 Ga). Several of our Ar-Ar ages range between 1.63 ± 0.02 and 1.87 ± 0.02 Ga (4 samples) and are most likely related to the Kheis event, during which the Congo Craton collided with the Kaapvaal Craton [1]. The youngest age preserved by one sample (1.22 ± 0.02 Ga) most likely reflects a thermal resetting during the Namaqua-Natal-orogeny at about 1.4 - 1.0 Ga [1].

In conclusion, crocidolite is a suitable phase to be dated by the Ar-Ar technique. Interpretation of ages, however, is hampered by the fact that the retentivity behavior of Argon in crocidolite during thermal overprints is unknown and that the conditions of crocidolite formation itself are poorly understood.

Sr isotopic composition of manganese nodules: Recorder of Cambrian ocean

Y. HARLAVAN[1]*, M. BAR-MATTHEWS[1] AND A. MATTHEWS[2]

[1]Geological Survey of Israel, 30 Malkhe Israel St., Jerusalem 95501, Israel (*correspondence: y.harlavan@gsi.gov.il)
[2]Institute f Earth Sciences, Hebrew University of Jerusalem

The rapid increase in seawater Sr isotopic composition at the start of the Paleozoic era is attributed to the onset of intensive weathering of the Pan-African orogen. A potential recorder of this significant change is found in Cambrian Mn ores in southern Israel. However, because these ores experienced several stages of dissolution, mobilization and alteration, the timing of their formation is in dispute. Two different generations of Mn nodules (types A and B) were recognized in previous studies [1]. Sr isotope measurements reveal that Type A Mn nodules have a constant value of the $^{87}Sr/^{86}Sr$ ratio (0.7089 ± 0.0005), whereas type B Mn nodules show a wide range (0.709 to 0.716). A composite seawater Sr isotope curve [2] places the Type A Mn nodule values in the lower Cambrian period (*ca*. 550Ma), and hence reinforces their Cambrian origin. This finding agrees with field observations, metal ratios and Eh-pH calculations, which show that Type A Mn nodules formed at the sediment-water interface under oxidizing conditions [1]. In contrast, the high $^{87}Sr/^{86}Sr$ ratios of Type B nodules indicate post-deposition processes that involved radiogenic solutions. The current study indicates that Mn nodules can retain oceanic Sr isotopic ratios, even where they experience complex alteration events. It is, however, essential that the field, petrographic and mineralogical relations are determined.

Experimental high-grade alteration of zircon using alkali- and Ca-bearing solutions

DANIEL E. HARLOV[1] AND DANIEL J. DUNKLEY[2]

[1]GeoForschungsZentrum Telegrafenberg, D-14473 Potsdam Germany

[2]National Institute of Polar Research, 3-10 Midori-cho, Tachikawa-shi, Tokyo-to 190-8518 Japan

Natural alteration of zircon takes place either via partial dissolution coupled with overgrowth or via fluid-aided coupled dissolution-reprecipitation [1, 2]. Coupled dissolution-reprecipitation results in the zircon being partially to totally replaced by compositionally re-equilibrated zircon, a new mineral phase or both. In this study, fragments (50 - 200 μm) from an inclusion-free, relatively non-metamict euhedral zircon (nepheline syenite pegmatite, Seiland magmatic province, northern Norway) were experimentally reacted in 20 mg batches with a series of alkali- and Ca-bearing fluids plus 5 mg (ThO_2 + $ThSiO_2$ + SiO_2) in sealed Pt capsules at 900 °C and 1000 MPa for 6 to 11 days (piston cylinder press, CaF_2 setup, cylindrical graphite oven). Fluids included 5 mg 2 N NaOH, 5 mg 2 N KOH, 10 mg $Na_2Si_2O_5$ + 5 mg H_2O, 1 mg NaF + 5 mg H_2O, and 1 - 5 mg $Ca(OH)_2$ + 5 mg H_2O. In each experiment, the fluid reacted with the zircon. This reaction took the form of partial replacement of the zircon with compositionally altered zircon via coupled dissolution-reprecipitation plus varying amounts of overgrowth. The reacted zircon is characterized by a sharp compositional boundary between the altered and original zircon as well as, in some cases, by a micro-porosity and/or inclusions of ZrO_2 or $ThSiO_4$. SIMS analysis of the replaced zircon indicates that it is strongly enriched in Th + Si, heavily depleted in U, and heavily to moderately depleted in (Y+REE). If YPO_4 replaces (Th + Si) in the system, the altered zircon is enriched in YPO_4 and heavily depleted in Th and U. In all experiments radiogenic ^{206}Pb (3 to 5 ppm in the unaltered zircon) is strongly depleted in the altered zircon. Hf concentrations in the altered zircon retain the same value as in the original zircon. The results from these experiments indicate that zircon can be compositionally altered via alkali- and Ca-bearing fluids via coupled dissolution-reprecipitation processes under high-grade conditions and that their internal geochronometer can be reset due to the massive loss of radiogenic Pb.

Pyrrhotite oxidative dissolution: A microstructural perspective by FIB-TEM and surface topometry

D. HARRIES[1]*, K. POLLOK [1] AND F. LANGENHORST [2]

[1]Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany (*correspondence: dennis.harries@uni-bayreuth.de)

[2]Institut für Geowissenschaften, Friedrich-Schiller-Universität Jena, D-07749 Jena, Germany

Pyrrhotite is non-stoichiometric iron sulfide ($Fe_{1-x}S$ with x < 0.125) and abundant in the Earth's crust. Due to variable Fe deficiency many structural variants arise from the ordering of Fe vacancies within the NiAs-based structure [1]. The resulting superstructures show different physicochemical and magnetic properties, bearing on pyrrhotite's contribution to rock magnetisation and many issues in geochemistry, petrology, and technical mineral processing (e.g., [2]). In the processing of Ni ores, pyrrhotite needs to be separated and is usually discarded to the tailings, where interaction with meteoric waters may lead to oxidation and formation of acid mine drainage.

In order to study differences in reactivity of pyrrhotite varieties, we conducted oxidative dissolution experiments on carefully polished pyrrhotite surfaces containing crystallographically coherent intergrowths of 4C- and NC-pyrrhotite (N = 4.81-4.87). The intergrowths, sharing the same crystallographic orientations, offer the possibility to eliminate the effect of crystal anisotropy, which is significant. Experiments were conducted at 30-50 °C using Fe^{3+} and H_2O_2 as oxidants in acidic solution of pH<3.0. From the reacted samples, surface cross sections in form of electron transparent lamellae were prepared using the FIB technique and studied using analytical TEM. The surface topography of the reacted pyrrhotites was recorded by vertical scanning confocal microscopy and used to deduce individual reaction rates of the intergrown pyrrhotite varieties.

Our results show, that reaction rates strongly and abruptly decrease as pH become larger than 2.65 (close to the iso-electric point [3]). At pH<2.65, NC-pyrrhotite oxidises and dissolves faster than 4C-pyrrhotite and abundant elemental sulfur precipitates. At pH>2.65, 4C-pyrrhotite reacts faster and sulfur appears to be absent. We are continuing to search for S-enriched sulfides (e.g., FeS_2) at the reaction interface by TEM, but until now, no such phases have been found.

O-isotope evidence for a hydrothermally altered volcanic roof to the Bushveld Complex

CHRIS HARRIS*AND DUANE FOURIE

Dept of Geological Sciences, University of Cape Town, Rondebosch 7701, South Africa (*correspondence: chris.harris@uct.ac.za)

The preserved rocks of the Bushveld Complex are mainly plutonic, and intrusion culminated in the production of > 90 000 km^3 of granite and granophyre. We present mineral $\delta^{18}O$ values that suggest that these granitic magmas assimilated hydrothermally altered material, presumably from a once substantial volcanic edifice. In the granites and granophyres, high-temperature equilibrium O- isotope fractionations are preserved between quartz and zircon, but not between quartz and feldspar, with many samples having -ve values for $\Delta_{quartz\text{-}feldspar}$. Quartz separated from four granite samples, showed no significant difference in core and rim $\delta^{18}O$ values. These data indicate that quartz was not significantly affected by the alteration that raised feldspar $\delta^{18}O$ values. Quartz is, therefore, a reliable proxy for magma $\delta^{18}O$ values in these rocks, leading to estimates of 6.8‰ (assuming $\Delta_{quartz\text{-}magma}$ = 1.18‰), and 6.9‰ (assuming $\Delta_{quartz\text{-}magma}$ = 0.66‰) for the granites and granophyres, respectively. Similar magma $\delta^{18}O$ values (6.6‰) were obtained from zircon data, assuming $\Delta_{zircon\text{-}magma}$ = -1.3‰. The similarity in $\delta^{18}O$ value between granites and granophyres from the three major lobes of the complex suggests a common origin.

Whereas the mafic and ultramafic rocks of the Rustenburg Layered Suite (RLS) have abnormally high $\delta^{18}O$ values (7.1‰) compared to other layered intrusions, the Bushveld granites have abnormally low $\delta^{18}O$ values compared to granites worldwide. Both the RLS and the granitic rocks have similar crustal ε_{Nd} values (mean = -6.4 and -5.3, respectively). Granitic magma derived from mafic magmas similar to those that produced the RLS would have had a magma $\delta^{18}O$ value of about 7.7‰, 1‰ higher than observed. We therefore suggest that the granite magmas assimilated a significant quantity of hydrothermally altered volcanic material with low $\delta^{18}O$ value as has been postulated for Yellowstone.

Cloud processing measured with sulfur isotopes during HCCT 2010

E. HARRIS[1]*, B. SINHA[1], P. HOPPE[1], J. CROWLEY[1], S. BORRMANN[1], S. FOLEY[2], T. GNAUK[3], D. VAN PINXTEREN[3] AND H. HERRMANN[3]

[1]Max-Planck-Institut für Chemie, Becherweg 27, 55128 Mainz, Germany (*correspondence: eliza.harris@mpic.de)

[2]Institute for Geosciences, University of Mainz, Becherweg 21, 55128 Mainz, Germany

[3]Leibniz-Institute for Tropospheric Research, Permoserstrasse 15, 04318 Leipzig, Germany.

Processing of aerosol by clouds has been shown to modify the CCN spectrum, leading to important climatological effects [1, 2]. In-cloud SO_2 oxidation and uptake of sulfate play a large role in this processing, causing both mass increases and hygroscopicity changes. However, the uptake of sulfate and SO_2 is not well constrained or resolved for different particle types and sizes [3, 4].

This study uses isotopic measurements to investigate the uptake of sulfur to particles in an orographic cloud during the HCCT campaign. The campaign took place at the Schmücke mountain in Germany and used connected flow conditions between measurement sites to study the evolution of air masses due to cloud processing. The FEBUKO campaign at the same site saw in-cloud mass production of up to 0.38 μg m^{-3}, 5% of the upwind aerosol mass [5]. Upwind, downwind, cloud droplet residue and interstitial particles were collected during HCCT, as well as SO_2 and H_2SO_4 gases at upwind and downwind sites. NanoSIMS isotopic analysis was then used to constrain the formation and uptake of sulfate in the cloud.

Clear changes were seen in the isotopic composition of the samples between the different sites. Sulfuric acid was depleted in ^{34}S following the cloud. Fine particles were enriched in ^{34}S, consistent with H_2SO_4 condensation as the dominant process. Coarse droplets were also enriched in ^{34}S following the cloud, however SO_2 oxidation to sulfate appeared to be the dominant process. In two out of three measured events, SO_2 gas was enriched while coarse mineral dust sulfate was depleted in ^{34}S, showing a reaction other than aqueous oxidation by H_2O_2 or O_3 had dominated overall SO_2 removal. Laboratory studies are being carried out to identify this 'missing' in-cloud oxidation pathway.

Accelerated carbon sequestration in mine tailings using elevated pCO_2

A.L. HARRISON*, I.M. POWER AND G.M. DIPPLE

The University of British Columbia, Vancouver, BC V6T 1Z4, Canada (*correspondence: aharriso@eos.ubc.ca)

Mineralization of atmospheric CO_2 within hydrated Mg-carbonate minerals occurs passively in ultramafic mine tailings via weathering of Mg-silicates [1]. If this process were accelerated, large mines may have the capacity to sequester millions of tonnes of CO_2 annually, providing the potential to offset the greenhouse gas emissions of mining. Recent evidence from laboratory experiments and reactive transport modelling indicates uptake of atmospheric CO_2 into solution is rate limiting [2]. An increase in CO_2 partial pressure may accelerate carbon sequestration by increasing dissolved inorganic carbon (DIC) and enhancing primary mineral dissolution due to increased acidity.

The effect of elevated pCO_2 on carbonation rate was examined experimentally to mimic process water chemistry and temperature conditions in tailings at the Mount Keith Nickel Mine (MKM), Western Australia. N_2 and CO_2 mixtures, ranging from 10% to 100% CO_2, were sparged into 3.0 L alkaline slurries containing 5% brucite [$Mg(OH)_2$]. Subsequent experiments will examine carbonation of serpentine, which is more abundant in MKM tailings but dissolves more slowly in aqueous solutions. System mass, pH, temperature and gas composition were monitored throughout the experiment. Samples were analyzed for DIC, Mg concentration, mineralogy and carbon content of solids. Nesquehonite [$MgCO_3 \cdot 3H_2O$] completely replaced brucite within 10 hours with 100% CO_2 gas and within 100 hours with 10% CO_2 gas. This corresponds to an increase in brucite carbonation rate from ~0.007 to ~0.07 g CO_2/g brucite/ hour. PHREEQC geochemical modelling using experimentally derived mineral dissolution rates indicates that serpentine dissolution would exhibit a similar acceleration at elevated pCO_2 conditions. Modelling of experimental conditions indicates that equilibrium between the gas and aqueous phases is not attained during sparging of CO_2-rich gas. Thus there is potential to further accelerate carbonation.

Brucite dissolution provided sufficient buffering capacity for carbonate mineral formation despite a significant pH shift to near neutral conditions in response to CO_2 injection. The carbonation process therefore not only sequesters CO_2, but also neutralizes process water alkalinity. At the mine scale, complete carbonation of brucite at MKM would sequester a total of 1.2 to 3 Mt CO_2.

Jack Hills zircon Lu-Hf revisited

T.M. HARRISON AND E.A. BELL

Dept. of Earth and Space Sciences, UCLA, Los Angeles, CA 90095 USA; (tmh@oro.ucla.edu, ebell21@ucla.edu)

Our in situ Lu-Hf analyses of Hadean zircons [1,2] revealed surprising results, including the presence of unradiogenic $^{176}Hf/^{177}Hf$ close to solar system initial (Hf_o) and those with highly positive $\varepsilon_{Hf(T)}$ suggestive of their origin from a long-term depleted source. The latter population, however, was not observed in our follow-up study (or even later efforts by others). As these results have profound implications for the early history of BSE, we have revisited these issues with new in situ Lu-Hf analyses of Hadean zircons from Jack Hills (JH), Western Australia. These analyses were undertaken on an expanded suite of rocks from the region, including a paragneiss adjacent the 'Blob' granite. In situ Lu-Hf analyses using a NEPTUNE LA-ICPMS-MC confirm the presence of large negative $\varepsilon_{Hf(T)}$ deviations and re-open the possibility of significant positive deviations. Specifically, we re-analyzed zircon ANU125 11.3, earlier found to be within error of Hf_o, at multiple locations and replicated the earlier datum within uncertainty. Using currently adopted CHUR parameters, these data collectively require the source of this zircon to have separated from BSE by 4.45 Ga at the latest (assuming Lu/Hf=0) and more likely by 4.5 Ga ($^{176}Lu/^{176}Hf$=0.015). The paragneiss zircons displays uniform $^{176}Hf/^{177}Hf$ but Hadean grains contain younger domains such that matching of age to Lu-Hf systematics is less certain. If the Hadean ages and measured $^{176}Hf/^{177}Hf$ reflect closed system behaviour, then $\varepsilon_{Hf(T)}$ deviations up to +18 are possible. Alternatively, these data could be evidence for the homogenisation of zircon $^{176}Hf/^{177}Hf$ within the source rock. Focussed Lu-Hf studies of 3.9-3.5 Ga JH zircons show a general diminution of $\varepsilon_{Hf(T)}$ deviations by ~4 Ga, suggestive of vigorous continental crust-mantle re-cycling, although evidence of highly negative $\varepsilon_{Hf(T)}$ continues to 3.6 Ga. We thus infer that a geochemical reservoir resembling the modern continental crust formed by ca. 4.5 Ga, perhaps leaving a depleted signature in a sufficiently large portion of the upper mantle to be later sampled by other JH zircons. Numerous geochemical investigations of Hadean zircons reveal their origin in a continental crust-like environment. Thermo-barometric results for Jack Hills zircons and their inclusions imply low conductive heat flows suggestive of their formation under a suppressed heat flow condition. Thus the single most compelling model for their formation is also the simplest: re-working of an initially tonalitic flotation crust by a process similar to that operating at modern convergent margins.

The Mantle Zoo: New species, endangered species, extinct species

STAN HART

Woods Hole Oceanographic Institution, Woods Hole, MA (shart@whoi.edu)

It has been 29 years since Allegre introduced the field of Chemical Geodynamics, and 25 years since Zindler and Hart formalized the concept of geochemical mantle components, with an attendant, to some odious, concoction of acronym soup. Work on this marriage of mantle geochemistry and mantle dynamics continues unabated to this day, with many Sisyphean heroes along the way. In 1986, we had a chondritic Earth model that we believed (give or take a minor problem with oxygen), and plumes ruled the dynamics of the mantle. Today we don't know what Earth is made of, and there is a vocal (albeit misguided) faction that repudiate plumes! We know unequivocally that the mantle is chemically heterogeneous, but we do not know the scale lengths of these heterogeneities. We know unequivocally that these heterogeneities have persisted for eons (Gy); we don't know where they were formed or where they are stored.

The most accessible and well understood mantle reservoir is the upper depleted MORB mantle (DMM). Classically, this mantle was depleted by extraction of oceanic and continental crust from a "chondritic" bulk silicate Earth. In this post-Boyet and Carlson world, the complementary enriched reservoir may instead be hidden in the deepest mantle. If the Earth is non-chondritic, DMM will be an endangered species. It is widely believed that the DMM is a mixture of peridotitic and mafic lithologies; I think this is an open question.

Radiogenic Pb mantle (HIMU) was argued by Hofmann and White (1982) to be re-cycled ocean crust, and this is still the most viable of existing models. It does require some *ad hoc* chemical manipulations during subduction to satisfy the isotopic constraints (e.g. Th/U fiddling). Given 2 Gy of likely aggregate mantle strains, the mafic component in HIMU will be of small scale length (< 50 m), possibly subsumed into the dominant peridotitic lithology. This mantle species is widespread (Atlantic, Pacific and Antarctic hotspots).

Enriched mantles (EM1 and EM2) almost certainly reflect recycling of enriched continental material. This was verified spectacularly by Jackson *et al* (2007), with the report of EM2 Samoan lavas with $^{87}Sr/^{86}Sr$ up to 0.721. The lithology and scale length of EM1 and EM2 is unconstrained. EM1 is present in Atlantic, Pacific and Indian hotspots; EM2 is confined to the SW Pacific hotspots.

In 2007, FOZO was split into 2 new subspecies (A and B). Many would like to see both become extinct!

Enhanced weathering – Not only CO_2-consumption

JENS HARTMANN[1]*, PETER KÖHLER[2] AND DIETER WOLF-GLADROW[2]

[1]Institute for Biogeochemistry and Marine Chemistry, Universität Hamburg, Germany (*correspondence: geo@hattes.de)

[2]Alfred Wegener Institute, Bremerhaven, Germany

Artifically enhanced weathering at the terrestrial surface by spreading olivine powder on land is one posibillity to contribute to the drawdown of CO_2 from the atmosphere. However due to limitations it is assumed that possibly not more than 1 Gt C a^{-1} can be sequestered by this technique .[1]

Further "effects", which may contribute additionally to the CO_2-sequestration by this technique, have been less analysed, and quantified.[2] At the same time as CO_2-is bound in the water, in the form of bicarbonate or carbonate, silica is released into the aqueous system. In case the propoposed technique would be excersised to its limits, the release of dissolved silica would be a multiple of the natural dissolved silica fluxes from the terrestrial system to the river systems and thus of the land-ocean fluxes.

Dissolved silica is a beneficial nutrient to many crop species, and harvest as well as biomass of these plants are likely to increase significanlty.[3] Additional biomass of plants due to additional silica uptake could be used in strategies to recarbonize the soil-carbon pool. In addition, increased levels of dissolved silica will likely increase the biomass of silica uptaking species in limnic systems, specifically in those, which are eutrophied, and/or are characterised by low silica concentrations. Some proportion of the biomass is sedimented and stored in the river systems, like in lakes or flood plains, and it is not known how much this could be. Further, instead of the mineral olivine one could use less soluble, grinded rocks, which contain significant amounts of phosphorus. In this case P-limited ecosystems might increase their biomass and add to the CO_2-sequestration by artifically enhanced weathering.

New approaches to analyze the preferential loss of elements from the continental crust

JENS HARTMANN *AND NILS MOOSDORF

Institute for Biogeochemistry and Marine Chemistry, Universität Hamburg, Germany (*correspondence: geo@hattes.de)

Lithological information can be combined with geochemical data to estimate differences between the terrestrial surface and the upper continental crust[1]. In addition, lithological characteristics influence the evolution of the continental crust and its differentiation because they control global chemical weathering. The preferential depletion of elements of the terrestrial surface by chemical weathering can be estimated spatially explicitly using information on lithology, climate and further Earth surface properties[2].

Application of models based on recent available geodata suggest that a large proportion of land-ocean dissolved element fluxes originate from small, highly active areas, which represent only a minor part of the Earth's surface[3]. It is found that the accurate quantification of the fluxes from these areas is crucial to explicate the influence of chemical weathering on the chemical differentiation of the upper continental crust. Specifically the estimation of land-ocean fluxes of Ca and Mg relies on adequate lithological information. To represent relevant, but small areas adequately at the global scale, new global geodata, like improved lithological maps (e.g. the global lithological map, GLiM), are needed. GLiM consists of more than one million polygons, assembled from more than 65 geological maps. In combination with recently developed weathering models it can be used to quantify the preferential loss of elements from the surface of the upper continental crust.

Influence of soil shielding on local to global chemical weathering rates

JENS HARTMANN*, NILS MOOSDORF AND RONNY LAUERWALD

Institute for Biogeochemistry and Marine Chemistry, KlimaCampus, Universität Hamburg, Germany (*correspondence: geo@hattes.de)

Chemical rock weathering rates vary spatially, following lithological and hydroclimatic patterns, which have been identified as important controls on chemical weathering rates at the local to global scale. Chemical weathering rates of tropical-continental or permafrost regions can, for comparable runoff and lithological conditions, be lower than than those of island arcs with relatively young rocks and/or "young" terrestrial surfaces.

One of the factors leading to a decrease in chemical weathering rate is the shielding effect of deeply weathered soils above the bedrock [1]. Further, permafrost- or peatland-areas can shield the underlaying bedrock, leading to lower weathering rates if compared to those of island arcs like the Japanese Archipelago.

To quantify this shielding effect at the local to global scale, multi-lithological weathering-functions [2] were applied to river catchments in tropical and permafrost regions. Some of these regions were proposed to yield high chemical weathering fluxes [3].

For comparable lithologies and runoff conditions a reduction of chemical weathering rates by ~50% relative to the weathering rates of island arc regions was identified for certain soil types overlaying the bedrock (Gleysols, Histosols, and deeply weathered tropical soils like Ferrasols). A large regional variability of the reduction factor can be observed.

Evolution of the LUSI mud volcano: Fluid chemistry and remote sensing

H.E. HARTNETT*, L. VANDERKLUYSEN AND A.B. CLARKE

Sch. of Earth & Space Exploration, Arizona State Univ., Tempe, AZ 85287 (*correspondence: h.hartnett@asu.edu)

The LUSI mud volcano near Sidoarjo in East Java, Indonesia has been erupting since May 2006. It discharged as much as 180,000 m^3/d at the peak of its activity [1, 2], destroyed thousands of homes, and displaced tens of thousands of people. The solids in the mud can be traced with some certainty to the blue-gray clays of the Upper Kalibeng formation, found 1600-1800 m beneath the LUSI main vent. The erupting fluid is a mixture of water, clay, and other minerals at near-boiling temperatures that is accompanied by venting of hot gases, primarily H_2O vapor, CO_2, and CH_4 [2]. The origin of the LUSI fluids remains a matter of speculation.

LUSI is an evolving and complex dynamic system, thus, we take a multi-disciplinary approach to assess both the fluid provenance and erpution behaviour. Our effort includes both geochemical analyses of aqueous and solid-phase components (elemetal and isotopic composition) as well as ground-based (FLIR) and satellite-based (MODIS, ASTER) thermal remote sensing data for the LUSI main-vent region. Preliminary geochemical results (IC, ICP-MS, Sr isotopes) indicate the water in the LUSI mud may have multiple sources (Fig. 1). Solid-phase analyses (XRD, ICP-MS) confirm the mud has an elemental composition and mineralogy very similar to that of the Kalibeng formation. The satellite-based thermal remote sensing data are used to calculate the radiant heat-flux from LUSI over time. We compare these estimates with ground-based flow rate and thermal flux estimates to establish and calibrate a remote-sensing proxy for mud emission rate.

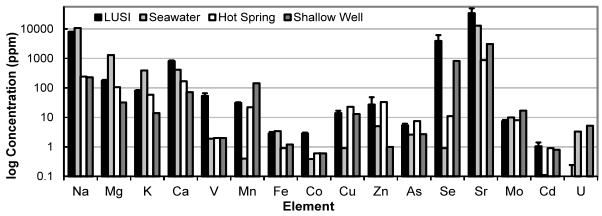

Fig. 1. Metals (ppm) in LUSI fluid (black), and a selection of potential source fluids; LUSI fluid is likely a mixture of multiple water sources that may include hydrothermal fluids.

The leaching of arsenic and heavy metals from pyrite slags depots in the upper banks under conditions of highly dynamic groundwater-surfacewater interaction

N. HARTOG[1]*, P. VAN GAANS[1], K.-J. VERMEULEN[2] AND M. JANSEN[2]

[1]Soil and Groundwater Systems, Deltares, Utrecht, The Netherlands (*correspondence: niels.hartog@deltares.nl)
[2]Dutch Railways Foundation for Soil Remediation (SBNS), Utrecht, The Netherlands

Pyritic waste slags from mining activities in Germany were used "*free-of-charge*" in The Netherlands This occured in the 1970's to fill former clay pits in the largely unsaturated upperbank deposits within the drainage area of the river Rhine. The original clay pits in part extended down to the confined sandy aquifer beneath. The present-day groundwater flow patterns within this aquifer are highly dynamic. Variation in surface water levels, causing alternating infiltration and drainage periods, in combination with hydraulic heterogeneity are the main controls. The flow dynamics are reflected in the erratic temporal evolution in groundwater observation wells of both contaminant concentrations (arsenic and heavy metals) and main elements. While weathering of the pyritic slags is the controls the release of contaminants, secondary reaction strongly influence overall contaminant behavior. High arsenic concentrations appear to be associated with the occurrence of drainage conditions, when arsenic mobility is probably enhanced by reductive dissolution of secondary ironhydroxide precipitates at to redox and pH boundaries below the pyritic slags. Mobility of zinc and nickel is probably controlled by pH-dependent adsorption to the sediment under the carbonate-buffered conditions. Geochemical modeling using PHREEQC corroborates that the oxidation of pyrite with oxygen and subsequent pH-buffering by carbonate dissolution are the main geochemical processes. In addition, acid buffering by K-feldspar under conditons in or close to the pyrite slags seems to occur when carbonate buffer is consumed. The extent to which nickel and zinc will be transported further off site will depend in particular on the depletion of sediment acid-buffering capacity, the concentrations of zinc and nickel evolving from the pyriteslags, and the adsorption capacity for nickel and zinc in the sediment. The main control for arsenic transport will be the development of redox conditions in the pyrite slag as well as future alteration of the hydrological situation.

Magma evolution and the formation of a 'Daly Gap' in the volcanic and plutonic rocks of Akaroa Volcano, New Zealand

EVA HARTUNG[1], CHAD DEERING[2], BEN KENNEDY[1], ALEYSHA TRENT[1], JONATHAN GANE[1], ROSE TURNBULL[3]

[1]Geological Sciences, University of Canterbury, Christchurch, 8140, New Zealand (eva.hartung@pg.canterbury.ac.nz)
[2]Earth and Space Sciences, University of Washington, Seattle, WA 98195-1310, USA (cdeering@u.washington.edu)
[3]GNS Science, Dunedin, 9016, New Zealand

The origin of compositional gaps in volcanic deposits remains controversial. In Akaroa Volcano (9.6-8.6 Ma), New Zealand, a dramatic compositional gap exists in both eruptive and co-genetic intrusive products between basalt and trachyte, and between gabbro and syenite respectively. Previously, the formation of more evolved magmas has been ascribed to crustal melting. However, the interpretation of new major and trace element analysis from minerals and bulk-rocks coupled with the mechanics of crystal-liquid separation offers an alternative explanation that alleviates the thermal restrictions required for crustal melting models.

Major and trace element trends can be reproduced by polybaric Rayleigh fractionation from dry melts (<0.5 wt.% H_2O) at the QFM buffer in a two-stage model. In the first stage, basalt and trachybasalt are produced by separation from an olivine-pyroxene dominant primitive mush at 50-80 vol. % crystallinity near the crust-mantle boundary (10-12 kbar). In the second stage, trachyte melt is extracted from the more evolved trachybasalt mush at mid-crustal levels (3-5 kbar) after the melt has reached 50 vol.% crystallinity. The fractioned assemblage of plagioclase, clinopyroxene, olivine, magnetite and apatite is left in a cumulate residue and corresponds to mineral assemblages of ultramafic enclaves. Trace element modeling of crystal fractionation using this extraction window is consistent with the concentration measured in trachyte (= liquid) and enclaves (= cumulate residue). Similar to the compositional gap observed in the eruptive products, feldspar data also show a distinct gap between the mineral compositions of basalt and trachyte. Yet, importantly, the feldspars from co-magmatic enclaves fill the feldspar compositional gap observed between the basalt and trachyte.

The results of these models indicate that the bimodal distribution of the volcanic products formed from punctuated melt extraction within an optimal crystal fraction window of 50 – 80 % at shallow depth.

Serpentinization and subsequent metamorphism in Mid-Atlantic Ridge peridotites from Hole 1268a, ODP Leg 209: Seawater vs. hydrothermal alteration

J. HARVEY*, I.P. SAVOV AND R.J. NEWTON

School of Earth & Environment, University of Leeds, Leeds LS2 9JT, UK (*correspondence: feejh@leeds.ac.uk)

Material recovered from Hole 1268a, ODP Leg 209, comprises heavily serpentinized peridotite. Subsequent serpentine-to-talc metamorphism and accompanying Si-metasomatism has been attributed to interaction with seawater modified by hot underlying gabbroic intrusions [1]. Sulphur abundances are elevated ([S] ≤2 wt %; [2]) and $\delta^{34}S$ in peridotite-hosted sulphides from talc-metamorphosed lithologies is significantly heavier than in nearby peridotites serpentinized at low-temperatures [3]. These values are consistent with high-temperature ultramafic-hosted hydrothermal vents elsewhere on the Mid-Atlantic Ridge [4] and suggests that the influence of high-temperature fluids from the nearby Logatchev hydrothermal field may extend to a radius of at least 15 km. Using a combination of radiogenic (Sr, Nd) and stable (B, S, O) isotopes this study aims to quantify fluid-rock ratios and chemical exchange, and the relative effects of seawater and hydrothermal fluids on the chemical and mineral evolution of peridotites from Hole 1268a. Preliminary results demonstrate Sr isotope ratios that are relatively uniform throughout the length of the borehole and indistinguishable from those of seawater This suggests particularly high (>100) fluid/rock ratios and contrasts with peridotites and gabbros from other, less altered ODP-drilled Holes nearby (e.g. Hole 1275). It is expected that this will be more precisely constrained with Nd and B isotopes.

Role of water in continental melting

P. HASALOVÁ* AND R.F. WEINBERG

School of Geosciences, Monash University, Clayton, 3800, Victoria, Australia
(*correspondence: pavlina.hasalova@monash.edu)

The Zanskar region, NW India, exposes the High Himalayan Crystalline (HHC) which is a sequence of medium- to high-grade rocks intruded by many granites. Rocks here underwent early dehydration melting that was later overprinted by water-fluxed melting producing extensive migmatites. Each event is recognizable in the field: early dehydration melting has produced leucosomes with peritectic garnet and sillimanite, in contrast to tourmaline-rich two-mica leucogranites associated with later water-fluxed melting. Potential water source here are the underlying cooler rocks that were heated and dehydrated by the thrusting of the hot rocks of the HHC. This water migrated upwards causing extensive melting of the overlying hot rocks. Water flowed into the hot system along a network of fractures. Melting took place at the fracture walls and as water diffuses a diffusion front was set up with a water content/activity gradient away from it. This gradient is preserved in the rock record as reflected in melt volumes produced and mineral composition. Garnets at the far end of the diffusion front reveal different composition and zoning pattern than garnet close to the diffusion front. Garnet close to the diffusion front reveals either no element zoning or Ca and Mg rich cores, in contrast to well preserved prograde zoning at the far end of the diffusion front. This means that rocks that underwent the same P-T history have preserved a mixed signal that is related to fluctuation in volume of water and/or water activity rather than to changes in P-T conditions. And we suggest that presence of water influnce diffusion rates in garnet.

Clay minerals deposit of Halakabad (Sabzevar- Iran)

SEYED MOHAMMAD HASHEMI

Department of Geology, Mashhad branch, Islamic Azad University, Mashad, Iran (dhashemi@mshdiau.ac.ir)

Clay minerals are expanded in south of Sabzevar. They are identified with light color in the filed. The XRD and XRF chemical and mineralogical studies on the Clay minerals indicated that their main clay minerals are Kaolinite, Illite and Dickite. Pyrophyllite is minor clay mineral. Quartz and Sanidine non clay minerals are present with clay minerals. Ratio of Al_2O_3 is about 40 per cent, it is very good for industrial minerals .Volcanic rocks are origin clay minerals. Their composition are basic to acidic. In south of Sabzevar town there is a small part of these rocks available which include volcanic and volcaniclastic rocks. Geochemical and petrographic studies showed that their compositions are generally acidic and intermediates and are of Dacite and Rhyolite and Andesite rocks type that have changed into clay minerals.

Meteoritic organics as a carrier of the oxygen isotope anomaly in the solar system

KO HASHIZUME[1], NAOTO TAKAHATA[2], HIROSHI NARAOKA[3] AND YUJI SANO[2]

[1]Dept. of Earth & Space Sci., Grad. School of Sci., Osaka Univ., Toyonaka, Osaka 560-0043, Japan; (kohash@ess.sci.osaka-u.ac.jp)
[2]Atmosphere and Ocean Research Institute, Univ. of Tokyo, Kashiwa, Chiba 277-8564, Japan.
[3]Dept. of Earth & Planet. Sci., Grad. School of Sci., Kyushu Univ., Fukuoka 812-8581, Japan.

It is generally accepted that Earth formed from building blocks that compose of metals, rocks, water and organics. The latter two are particularly important to characterize the surface of our planet covered by atmosphere, ocean, and lives, although their exact origins remain unresolved. The organic matter abundantly found in primitive meteorites may provide us precious clues to address this issue. Several pioneers [1-4] discovered that a tiny fraction of the meteoritic organics, opposed to the bulk of them which are likely homogenized by later planetary processes, may preserve primordial isotopic signatures acquired upon its birth in the space medium. The main target of this study is to search for the oxygen isotope anomalies among the meteoritic organics.

We report the detection of organic grains, extracted from an Antarctic carbonaceous chondrite Yamato-793495 (CR2), with the highest $^{17,18}O/^{16}O$ ratios ($\delta^{17,18}O_{SMOW}$~+500‰) [5] among all planetary materials besides the presolar grains. The isotopic composition is plotted in the O isotope diagram close to the slope-1 line, where the compositions for the planet-forming building-blocks are predicted to be plotted on, suggesting that the detected organic grain may represent one of the fundamental carriers responsible for the O isotope anomaly, i.e., the non-mass-dependent $^{17,18}O/^{16}O$ variations commonly observed among all available solid planetary materials. By the multi-isotope imaging analysis, we discovered that $^{17,18}O$ enrichments among the organics were correlated with ^{13}C enrichments. This correlation is naturally explained by the self-shielding effect of CO that occurred in a warm (>60 K) gas medium illuminated by UV light, such as the surface layer of the solar nebula.

Isotopic and geodynamic implications of progressive magmatism in W. Anatolia (Turkey)

A. HASOZBEK[123]

[1]New Brunswick Laboratory, SED, Argonne, IL 60439, USA (*correspondence: Altug.Hasozbek@ch.doe.gov)
[2]Institut für Geowissenschaften, Universität Tübingen, Tubingen, D-72074, Germany
[3]Technical Higher Education, Dokuz Eylul University, Torbali, Izmir, 35860 Turkey

In the Aegean region, complex geodynamic processes including subduction, continent continent collision, and back-arc extension occurred from the Eocene to the present time. In NW Anatolia (Turkey), the products of these events are widely exposed. During and after the closure of the Neo-Tethyan Ocean and progressive collision of the Tauride-Anatolide Platform with the Sakarya Continent, widespread magmatism occurred in NW Anatolia. This magmatism is manifested in a NW trending belt along the northern border of the Menderes Massif. Due to the complex geodynamic setting of this region, the exact emplacement mode of the granitoids is still a matter of debate.

In order to see whole progressive magmatic evolution of the Western Anatolia and to understand its tectono-magmatic position in the Aegean region, during and after the collision of the Anatolide-Tauride platform with the Sakarya Continent, magmatic associations from Eocene to Miocene time were examined and gathered together by detailed mapping, geochemical, isotopic and geochronological studies. According to our new results, the Eocene and Miocene granites are shallow seated bodies (4-7 km), granite-granodiorite and monzogranite in composition, and are I-type, calc-alkaline in nature. Their Sr-Nd-Pb-O isotopes are in line with derivation from lower-to middle crustal source lithology. It can be demonstrated that mantle to crustal assimilation during the magma generation played an important role. Within the emplacement natures and isotopic results of the Western Anatolian magmatic associations, considerable limitations are put forward regarding to previously suggested extensional related emplacement models. The magmatic associations in Western Anatolia were formed in two distinct separated phases; the first and the earliest phase resulted in progressive magmatism and formed the intrusive suites of the Western Anatolia during the Eocene- Miocene time long before the main extension phase started. The late phase is mostly associated with the extensional regime.

Tracking single coccolith dissolution with picogram resolution: Implications for CO_2 sequestration and ocean acidification

T. HASSENKAM, A. JOHNSSON, K. BECHGARRD AND S.L.S STIPP

Nano-Science Center, Department of Chemistry, Univeristy of Copenhagen, Denmark, (tue@nano.ku.dk, stipp@nano.ku.dk)

Coccoliths are micrometer scale shields made from 20 to 60 individual calcite ($CaCO_3$) crystals that are produced by some species of algae. Chalk deposits, the fossil remains of ancient algae, have remained remarkably unchanged by diagenesis. Even after 60 million years, the fossil coccolith crystals are still tiny (<1 μm), compared with inorganically produced calcite, where one day old crystals can be 10 times larger. This raises the question if the biogenic nature of coccolith calcite gives it different properties than inorganic calcite? And if so, can this protect coccoliths in CO_2 challenged oceans? By recording the changes in resonant frequency of a cantilever coccolith setup the dissolution of individual specimens, can be tracked with picogram (10^{-12} g) resolution.

The results show that the behaviour of modern and fossil coccoliths is similar and both are more stable than inorganic calcite. However, ancient and modern coccoliths, that resist dissolution in Ca-free artificial seawater at pH > 8, all dissolve when pH is 7.8 or lower. Ocean pH is predicted to fall below 7.8, by 2100, in response to rising CO_2 levels. Our results imply that at these conditions, the advantages offered by the biogenic nature of calcite will disappear, putting coccoliths on algae and in the calcareous bottom sediments at risk [1].

Online preconcentration ICP-MS analysis of rare earth elements in seawater

ED HATHORNE[1]*, TORBEN STICHEL[1,2], PATRICIA GRASSE[1] AND MARTIN FRANK[1]

[1]IFM-GEOMAR, Wischhofstr. 1-3, 24148 Kiel, Germany (*correspondance: ehathorne@ifm-geomar.de)

[2]SOEST, University of Hawaii 1680 East-West Rd, Honolulu, HI 96822, USA

The rare earth elements (REEs) with their systematically varying properties are useful tracers of continental inputs, particle scavenging activity and the oxidation state of seawater. However, their generally low (~pmol/kg) concentration and fractionation potential during chemical treatment makes them difficult to measure. Here we report initial results for GEOTRACES samples obtained using an automated preconcentration system, which separates the matrix and elutes the preconcentrated sample directly into the spray chamber of an ICP-MS instrument.

The commercially available SeaFAST system (Elemental Scientific Inc.) uses a resin with ethylenediaminetriacetic acid and iminodiacetic acid functional groups to preconcentrate REEs and other metals while alkali and alkaline earth elements are washed out. Importantly, time resolved analysis of the elution peaks demonstrates that this resin does not fractionate the REEs. The technique we developed for the analysis of REEs in seawater samples loads 4 mL of undiluted, filtered and acidified (pH ~2), seawater sample onto the column. The column is flushed with water and a pH 6 buffer solution for ~10 mins to wash the matrix away before the REEs are eluted with nitric acid into the ICP-MS for measurement. Using this technique each analysis takes about 15 mins and we obtain sub ppt limits of detection (3 times the standard deviation of blank measurements). Repeated measurements of a sample from 2000 m water depth in the Southern Ocean allows the external precision of the technique to be estimated at < 10% for all REEs and < 5% for many others. Comparison of Nd concentrations with isotope dilution measurements for 30 samples shows the techniques agree within 10%. To assess the accuracy of the technique for all REEs mine water standards have been diluted with NaCl matrix and analysed as unknowns. The results for most elements agree well with values in the literature. This makes the online preconcentration ICP-MS technique advantageous for the minimal sample preparation required and the relatively small sample volume consumed. Further development of the technique is underway to ensure accurate results even for the least abundant REEs in seawater samples.

Mineralogical and geochemical characteristics of Emet borate basin, Kütahya, Western Anatolia, Turkey

ZEYNEP NAZLI HATIPOGLU[1] AND ABIDIN TEMEL[2]

[1]Acme Analitik Laboratuar Hizmetleri LTD. STI. 21. Cadde 108/2, 06370, Yenimahalle/ Ankara, Turkey
[2]Hacettepe Üniversitesi Müh. Fak. Jeoloji Müh. Böl. 06800, Beytepe/ Ankara Turkey

The volcanosedimentary borate deposites in Emet, Kütahya have been studied to investigate the mineralogy and geochemistry of neoformation minerals (carbonate, clay, sulphate, borate minerals). For this purpose, 193 samples collected from 4 different locations (Espey, Hisarcık open pits and two drill holes) in Emet.

XRD whole rock analyses made on all samples show that, clay, feldspar, realgar, mica, carbonate (dolomite, calcite), sulphate (glauberite, gypsum, anhydrite), opal-CT and borate (colemanite, ulexite, probertite, hydroboracite, P-veachite) are the minerals detected. XRD clay fraction analyses made on 69 samples revealed that there are illite, smectite, kaolinite and chlorite minerals. ICP major element analyses applied on smectite minerals show that the trioctaedric smectites are saponite and stevensite in composition.

At the investigation area, an increase at the amount of smectite has been discovered from northern parts (Espey) to southern parts (Hisarcık). As the dolomite minerals are absent at Espey open pit and present at two drill holes and Hisarcık open pit, the Espey area can probably be the edge of the basin. Ca-borate→ Ca-borate + Na-borate→ Na-Ca-borate + Mg-Ca-borate mineralogical zoning show that the drilling area of two drill holes which are located between Espey and Hisarcık open pits, can be the center of the basin. Especially at the borate bearing zones Sr reaches high concentrations. Samples that have higher clay contents also have higher REE contents.

Chemical heterogeneities along the South Atlantic Mid-Ocean-Ridge (5-11°S): Shallow or deep recycling of ocean crust?

F. HAUFF[1]*, K. HOERNLE[1], T.F. KOKFELT[2], K. HAASE[3], D. GARBE-SCHÖNBERG[4] AND R. WERNER[1]

[1] IFM-GEOMAR, Wischhofstr. 1-3, 24148 Kiel, Germany (*correspondence: fhauff@ifm-geomar.de)
[2]GEUS, Øster Voldgade 10, 1350 Copenhagen K, Denmark
[3] GeoZentrum Nordbayern, University of Erlangen-Nürnberg, Schlossgarten 5, 91054 Erlangen, Germany
[4]Inst. Geosciences, Christian-Albrechts-Univ., Kiel, Germany

Between 5° and 11°S, the Mid-Atlantic Ridge displays anomalous crustal thickness and geochemical compositions, thought to be related to either small scale upper mantle heterogeneities or a weak, diffuse mantle plume. We report new high precision trace element and Sr, Nd and Pb (DS) isotope data for 72 ridge axis samples and 9 off-axis seamount samples along with U–Th–Ra disequilibria data for off axis seamounts at c. 9.7°S. At least four distinct components are needed to explain the geochemical variations along the ridge: 1) a common depleted (D-MORB-like) component near and north of 4.8–7.6°S, 2) an enriched component upwelling beneath Ascension Island and the northern A1 ridge segment (segment numbers ascend from north to south), 3) an enriched component upwelling beneath the A2 ridge segment, and 4) an enriched component upwelling beneath the line of seamounts east of the A3 segment and the A3 and A4 segments. The A1 and the A3+A4 segment lavas form well-defined mixing arrays from Ascension Island and the A3 seamounts respectively to the depleted D-MORB component. We propose that the enriched components represent different packages of subducted ocean crust and/or ocean island basalt (OIB) type volcanic islands and seamounts that have either been recycled through 1) the shallow mantle, upwelling passively beneath the ridge system or 2) the deep mantle via an actively upwelling heterogeneous mantle plume that interacts with the ridge system.

Arsenic and tungsten in groundwaters of West Bengal, India

T. JADE HAUG[1], ANDREW NEAL[2], NINGFANG YANG[1], KATHERINE TELFEYAN[1], SAUGATA DATTA[2] AND KAREN H. JOHANNESSON[1]

[1]Department of Earth and Environmental Sciences, Tulane University, New Orleans, LA 70118, (thaug@tulane.edu, kjohanne@tulane.edu)

[2]Department of Geology, Kansas State University, Manhattan, KS 66506, (sdatta@k-state.edu)

Arsenic (As) concentrations and speciation were measured along with tungsten (W) in groundwaters from Murshidabad, West Bengal, India ($6.91 \leq pH \leq 7.54$). Total dissolved As concentrations (As_T) range from < 1 to 4622 μg kg^{-1}, and As(III) predominates in solution accounting for between 54% to >98% of As_T. W concentrations range from 0.15 to 1.1 μg kg^{-1}. The W concentrations are low compared to alkaline groundwaters (pH > 8) from Nevada, USA, where W concentrations range from 0.27 to 742 μg kg^{-1} [1, 2]. Although W correlates with As in the Nevada groundwaters ($r^2 = 0.63$, $p < 0.05$ [1]), W is not correlated with As_T or As(III) in Murshidabad groundwaters ($r^2 = 0.075$, $p > 0.2$ and $r^2 = 0.085$, $p > 0.2$, respectively). These relationships suggest that As and W biogeochemistry differ as a function of pH and redox conditions. Both W and As are strongly desorbed from mineral surface sites at high pH and under oxidizing conditions [3], which explains, in part, the relationship between these two elements in groundwaters from Nevada. Under reducing conditions and neutral pH that characterizes Murshidabad aquifers, As(III), which occurs as the uncharged $H_3AsO_3^0$ species, is more mobile than the tungstate oxyanion, WO_4^{2-}. We hypothesize that both As(III) and W are mobilized by reductive dissolution of Fe(III) oxides/oxyhydroxides, but that WO_4^{2-} is strongly re-sorbed, whereas As(III) is relatively more mobile as the uncharged, $H_3AsO_3^0$ in Murshidabad.

The volatile content of primitive Lunar volcanic glasses

E.H. HAURI[1], A.E. SAAL[2], , M.J. RUTHERFORD[2] AND J.A. VAN ORMAN[3]

[1]DTM, Carnegie Institution of Washington, (ehauri@ciw.edu)
[2]Dept Geological Sciences, Brown University
[3]Dept Geological Sciences, Case Western Reserve University

The general consensus is that the Moon formed and evolved through a single or series of catastrophic heating events in which most of the highly volatile elements, especially hydrogen, were evaporated away. That notion has changed with new reports showing evidence of indigenous water in lunar volcanic glasses [1] and in lunar apatites from mare basalts [2, 3, 4]. These results represent the best evidence for the presence of a deep source within the Moon relatively rich in volatiles. We compiled volatile data (C, H_2O, F, S, Cl) for more than 360 individual Apollo 14, 15 and 17 lunar glasses with composition ranging from very-low to high-Ti contents. The glassy volcanic spherules range in size from ~100 μm to ~ 1 mm. We measure the volatile content by SIMS using a Cameca IMS 6F and NanoSIMS at DTM, CIW. Our new SIMS detection limits (~0.13 ppm C; ~0.4 ppm H2O, ~0.05 ppm F, ~0.21 ppm S, ~ 0.04 ppm Cl) represent at least 2 orders of magnitude improvement over previous analytical techniques.

Our data support the hypothesis that there were significant differences in the initial volatile content of lunar magmas, and/or the mechanism of eruptive de-gassing was different for different eruptions. Interestingly, a general correlation was found between the volatile enrichment and the incompatible trace elements. This suggests that eruptive degassing, although extensive, did not completely erase initial differences in volatile contents between the distinct compositional groups of volcanic glasses. Our results suggest not only a much wetter Moon's interior than previously thought [1], but also suggest that the KREEP component, either through shallow assimilation by the melt or deep hybridization of the LMO cumulate, may influence the volatile composition of erupted lunar magmas.

Use of pyrolysis-GC/MS combined with petrographic analysis to monitor changes of organic matter in coal and biomass derived materials

MARTINA HAVELCOVÁ*, IVANA SÝKOROVÁ AND HANA TREJTNAROVÁ

Institute of Rock Structure and Mechanics AS CR,v.v.i. V Holešovičkách 41, 182 09 Prague, Czech Republic (*correspondence: havelcova@irsm.cas.cz)

Charred solid organic residues produced during biomass and fossil fuel combustion are collectively referred as black carbon (BC). BC is ubiquitous and can be found in sediments, soils, and the atmosphere [1]. Because of the important role and effect of BC materials on the environment and biogeochemical cycles, different techniques have been used to study their chemical properties and structures [2].

In this study (project IAA300460804), pyrolysis of coal and biomass was studied under varying conditions of temperature and environment. The solid products, i.e. chars, were analysed by combination of optical microscopy and pyrolysis-GC/MS methods. The elemental composition was also determined and the chemothermal oxidation method [3] was employed to determine the BC content in the samples.

The composition of chars was dependent on the used conditions and indicated that incomplete combustion leads to the formation of aromatic structures and regions. Chars prepared in oxidative atmosphere created more condensed aromatic network at lower temperatures by comparison to chars prepared in inert atmosphere. Compounds typical for the BC presence like indene, benzonitrile, naphthalene, methylnaphthalenes, fluorene were found in all chars.

The results of BC determination were in good consensus with H/C atomic ratios and reflectance values. The found relation among identified organic compounds and BC corresponds with the results for carbonaceous matter in dust and lacustrine seidments from Prague [4].

LTD Phase I.: Long-term real-scale diffusion experiment results

V. HAVLOVA[1]*, A. MARTIN[2], J. EIKENBERG[3] AND F. SUS[1]

[1]NRI Rez plc., Husinec-Rez 130, 250 68 Rez, Czech Rep. (*correspondence: hvl@ujv.cz)

[2]NAGRA, Hardstrasse 73, 5430 Wettingen, Switzerland

[3]Paul Scherrer Institute, 5232 Villigen PSI, Switzerland

Matrix diffusion can significantly decrease the amount of radionuclides potentially released from deep geological repository of radioactive waste. A systematic reseach approach to understanding the diffusion process was applied within Phase I of the Long Term Diffusion Project (LTD) at the Grimsel Test Site, Switzerland (GTS, www.grimsel.com).

In workpackage 1 of the LTD project, a cocktail of ^{3}H, ^{22}Na, ^{131}I and ^{134}Cs tracers was circulated in a packed-off interval in a borehole drilled 8 m into undisturbed granitic matrix in GTS and left for 26 months in the contact with the rock. Tracer solution was regurarly sampled in order to obtain the pattern of radionuclide activity decrease in the test interval. Later the borehole was overcored and the rock segments were analysed for radionuclide content.

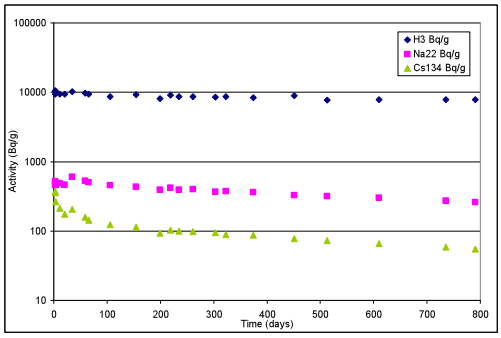

Figure 1: Radionuclide activity (Bq/g) decrease in the test interval.

The activity decrease in the circulation tank is shown in Fig. 1. ^{22}Na and ^{134}Cs were analysed in the rock samples, using γ-spectroscopy. Special care had been applied for ^{3}H analyses (modified LSC). Diffusion profiles within the rock segments clearly showed that ^{3}H had reached a distance of 17 cm from the borehole. ^{22}Na migrated up to 7 cm and ^{134}Cs up to 1.5 cm distance respectively. The results are under further evaluation.

The research was held in co-operation with NAGRA, NRI, Helsinki University, JAEA and AIST (2005-2009). NRI thanks to RAWRA and to to the Czech Ministry of Education, Youth and Sport (contract No. P05LA248) for funding.

The generation and evolution of the continental crust

CHRIS HAWKESWORTH[1]*, PETER CAWOOD[1] AND BRUNO DHUIME[1,2]

[1]Department of Earth Sciences, University of St. Andrews, St. Andrews KY16 9AL, UK (*correspondence: cjh21@st-andrews.ac.uk)

[2]Department of Earth Sciences, University of Bristol, Queens Road, Bristol BS8 1RJ, UK

There is increasing evidence for marked changes in the crustal record at the end of the Archaean, and that these reflect changes in both the generation and the evolution of the continental crust. The post Archaean crust has marked peaks in crystallisation ages that coincide with the development of supercontinents. These peaks appear to be an artefact of preservational bias, in that magmas generated in some tectonic settings may be preferentially preserved in the geological record, rather an indication of periods of unusually large volumes of crustal magmatism. The creation and destruction of supercontinents require some form of plate tectonics, and yet the rates of crust generation and destruction along modern subduction zones are strikingly similar.

In the Archaean, and by implication the Hadean, the continental lithosphere was thinner, mountains were more difficult to support, and perhaps there was less erosion. There is also less evidence for the development of peaks of ages globally. Material must have moved up and down in the uppermost mantle, and yet the magmatic record is different from that commonly associated with subduction. The zircon record yields little evidence for the development of depleted mantle in the Hadean, and on that basis for large volumes of continental crust. Granitic crust was generated by the remelting of mafic crust, and there is some evidence for a shift from mafic to more evolved source rocks with time. The Hadean crust appears to have had a bimodal silica distribution, as also characterizes the early Archaean rock assemblages. These at present characterise intraplate rather than plate margin settings, and yet most of the crust was generated by the end of the Archaean, and the average crust has a composition similar to that of destructive plate margin magmatism.

Hf isotopes require no subduction in the Hadean?

CHRIS HAWKESWORTH[1]*, A.I.S. KEMP[2], S.A.WILDE[3] AND J.D.VERVOORT[4]

[1]Department of Earth Sciences, University of St. Andrews, St. Andrews KY16 9AL, UK (*correspondence: cjh21@st-andrews.ac.uk)

[2] School of Earth and Environmental Science, James Cook University, Townsville, Australia

[3]The Institute of Geosciences Research, Curtin University of Technology, Perth, Australia

[4]School of Earth and Environmental Science, Washington State University, Pullman, USA

The Hf, Pb and O isotope data on results of an in situ isotopic study of 67 Jack Hills zircons (Kemp et al. 2010) are combined with Hf isotope data from zircons of the Narryer gneisses (3.65- 3.3 Ga) and from Neoarchaean granites that intrude the Jack Hills belt. The detrital zircons define a subchondritic ε_{Hf} – time array consistent with the protracted intra-crustal reworking of an enriched, dominantly mafic protolith that was extracted from primordial mantle at 4.4-4.5 Ga. There is no evidence for the existence of strongly depleted Hadean mantle, and on that basis for large volumes of continental crust. There is also no evidence for juvenile input into the parental magmas to the Jack Hills zircons.

This simple Hf isotope evolution is difficult to reconcile with modern plate tectonic processes, which generate magmas with both juvenile and reworked sources. Strongly unradiogenic Hf isotope compositions of zircons from several Archaean gneiss terranes, including the Narryer and Acasta gneisses, suggest that dominantly mafic Hadean source reservoirs were tapped by granitic magmas up to 1.8 billion years after the initial crust generation episode. This implies the presence of Hadean crust with a bimodal silica distribution, as also characterizes the early Archaean rock assemblages, but not modern arcs. It supports the notion of a long-lived and globally extensive Hadean protocrust that may have comprised the nuclei of many Archaean cratons. Such Hadean protocrust survived the postulated late heavy meteorite bombardment of the terrestrial planets at ca. 3.9 Ga and might not have endured if crust-mantle recycling processes like subduction were efficient in the Hadean.

The influence of boundary scavenging and particle composition on dissolved and buried ^{230}Th and ^{231}Pa in the subarctic North Pacific

CHRISTOPHER T. HAYES[1]*, ROBERT F. ANDERSON[1] AND RAINER GERSONDE[2]

[1]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, 10964 USA (*correspondence: cth@ldeo.columbia.edu)
[2]Alfred Wegener Institue for Polar and Marine Research, Bremerhaven, Germany (Rainer.Gersonde@awi.de)

The well-known production rates of insoluble ^{230}Th and ^{231}Pa in seawater via decay of soluble uranium make them useful tracers of scavenging processes in the modern ocean. Additionally, their half-lives (75.7 and 32.5 kyr, respectively) and preservation in the sediment record make them attractive tools for understanding the particle flux of the late Pleistocene ocean. Yet, multiple processes affect the distribution of these radionuclides in the ocean including particle flux, particle composition, advection and eddy diffusion. Based on the available, spatially-limited, modern ocean observations, it is often unclear which factor has the primary control on a particular seawater profile or surface sediment survey. This ambiguity hinders our understanding of the behavior of other trace metals that undergo scavenging (such as the micronutrient Fe) in addition to our ability to interpret sediment ^{231}Pa/^{230}Th records which have important paleoceanographic and paleoclimtologic consequences.

New observations of ^{230}Th and ^{231}Pa in the water column and in surface sediments are presented here from the Innovative North Pacific Experiment cruise (INOPEX, Jul-Aug 2009) which crossed large gradients in particle flux and particle composition. Boundary scavenging, or preferential removal at high particle flux sites, appears to have little impact on lateral gradients in the concentrations and ratio of dissolved ^{230}Th and ^{231}Pa. As well, concentrations in surface sediments compared with those in the immediately overlaying bottom water allow calculation of pseudo-distribution coefficients for the scavenged elements and fractionation factors for the ^{231}Pa/^{230}Th ratio. These parameters in light of sediment compositions demonstrate the relative importance that the chemical composition of particulate matter plays in scavenging. A new paradigm for understanding the removal of particle-reactive elements from the ocean may need to necessarily include the differential scavenging intensities of variable particle types as well as seafloor processes, which will also be investigated here through high depth-resolution profiles of water within 200 m of the bottom.

Mineral evolution: What's next?

R.M. HAZEN[1], R.T. DOWNS[2], J. GOLDEN[2], E.S. GREW[3], M. MCMILLAN[2], J.P. RALPH[4] AND D. A. SVERJENSKY[1,5]

[1]Geophysical Laboratory, Washington, DC 20015 USA (*correspondence: rhazen@ciw.edu)
[2]University of Arizona, Tucson, AZ 85721 USA
[3]University of Maine, Orono, ME 04469 USA
[4]mindat.org, 81 Woodcote Grove Rd, Surrey CR5 2AL, UK
[5]Johns Hopkins University, Baltimore, MD 21218 USA

The central thesis of mineral evolution is that the near-surface mineralogy of terrestrial planets and moons diversifies through time owing to processes such as planetary accretion and differentiation, the evolution of igneous rocks, fluid-rock interactions, and the influences of life. Studies of mineral evolution thus seek to frame mineralogy in an historical context by focusing on temporal changes in near-surface characteristics, including mineral diversity and associations, relative abundances of mineral species, ranges of chemical and isotopic compositions, and grain sizes and morphologies [1,2]. Mineral evolution also exemplifies aspects of other complex evolving systems, in that we observe complexification (i.e., diversification) through time and each stage of mineral evolution depends on the sequence of prior stages [3]. Recent efforts in mineral evolution research have focused on first reported appearances of mineral species containing specific chemical elements, e.g., U, Be, B, Hg and Mo through time [4,5]. These studies reveal striking increases in the diversity of mineral species, notably between 2.0 to 1.7 and 0.6 to 0.2 billion years ago. Other on-going studies correlate the relative abundances of minerals to geologic conditions, with special attention on changes in clay mineralogy, both in absolute and relative terms [6]. Variations in the extent of incorporation of non-essential elements in specific minerals through time, notably redox sensitive elements, represents a third promising avenue of research, e.g., reported increased incorporation of Re and W in molybdenite (MoS_2) during the past billion years. These efforts are being facilitated by development of a Mineral Evolution Database linked to the comprehensive mindat.org platform [7].

The Deepwater Horizon oil spill: Ecogenomics of the deep-sea plume

TERRY C. HAZEN

Lawrence Berkeley National Laboratory, Berkeley, CA USA (tchazen@lbl.gov)

The explosion on April 20, 2010 at the BP-leased Deepwater Horizon drilling rig in the Gulf of Mexico off the coast of Louisiana, resulted in oil and gas rising to the surface and the oil coming ashore in many parts of the Gulf, it also resulted in the dispersment of an immense oil plume 4,000 feet below the surface of the water. Despite spanning more than 600 feet in the water column and extending more than 10 miles from the wellhead, the dispersed oil plume was gone within weeks after the wellhead was capped – degraded and diluted to undetectable levels. Furthermore, this degradation took place without significant oxygen depletion. Ecogenomics enabled discovery of new and unclassified species of oil-eating bacteria that lives in the deep Gulf where oil seeps are common. Using 16s microarrays, functional gene arrays, clone libraries, lipid analysis and a variety of hydrocarbon and micronutrient analyses we were able to characterize the oil degraders. Metagenomic sequence data was obtained for the deep-water samples using the Illumina platform. In addition, single cells were sorted and sequenced for the some of the most dominant bacteria that were represented in the oil plume; namely uncultivated representatives of *Colwellia* and *Oceanospirillum*. The results provide information about the key players and processes involved in degradation of oil, with and without COREXIT, in different impacted environments in The Gulf of Mexico. This data suggests that a great potential for intrinsic bioremediation of oil plumes exists in the deep-sea and other environs in the Gulf of Mexico.

Silver nanoparticle-reactive oxygen species interactions: Application of a charging-discharging model

D. HE, A.M. JONES, S. GARG AND T.D. WAITE*

University of New South Wales, Sydney, NSW, Australia 2052 (di.he@student.unsw.edu.au, adele.jones@unsw.edu.au, s.garg@unsw.edu.au, *correspondence: d.waite@unsw.edu.au)

A complex interplay between AgNPs, Ag^+, superoxide and H_2O_2 exists with an understanding of these interactions potentially at the core of the bactericidal behavior of silver species [1-3]. This work is focused on obtaining a better understanding and, to the extent possible, quantification of the interaction between AgNPs and ROS.

The ability of these particles to catalytically decompose H_2O_2 was examined by measuring the decay of H_2O_2, the re-formation of AgNPs and the subsequent degradation of Ag^+ [4]. A kinetic model based on the concept of electron storage and subsequent discharge by AgNPs has been developed and found to adequately explain all results obtained [5-7].

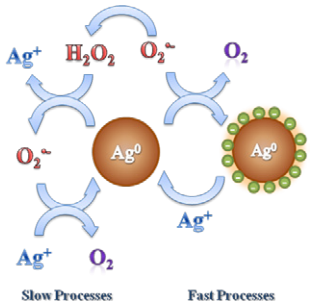

Figure 1: Schematic presentation of the action of AgNPs as electron pool in ROS reactions.

Effects of water on the thermal stability of hydrocarbons and the composition and isotope characteristics of the gas products

HE KUN, ZHANG SHUICHANG AND MI JINGKUI

Research Institute of Petroleum Exploration and Development, PetroChina, Beijing 100083, China

As ubiquitous inorganic agent in subsurface, water can react with hydrocarbons [1], although no consistent opinion about the effects of water on the stability of hydrocarbons were achieved[2].

In this paper, a series of isothermal gold-tube pyrolysis experiments using *n*-C_{16} and a marine oil were conducted to study the effects of water chemistry on gas yields and isotopes. It was revealed that the interaction between water and hydrocarbons lead to a relative high content of inorganic gas products. Water showed distinct effect on the cracking of hydrocarbons at lower and higher temperature. Meanwhile, the pH and dissolved salts type and concentration can affect the reaction rate of the organic-inorganic interactions.

The ^{13}C of hydrocarbon gas, especially for CH_4 and C_2H_6, was depleted in the presence of water. An enrichment of D for CH_4 and C_3H_8 can be evidently observed in hydrous pyrolysis using H_2O and *n*-C_{16}, whereas, a reverse phenomenon occur for C_2H_6. The increase of δD for all the hydrocarbon gases with the presence of D_2O demonstrates that water has provided hydrogen for generation of hydrocarbon gas in pyrolysis. In addition, the presence of smectite and calcite carbonate can remarkably promote the gas yields. The unique surface acid of clay mineral accelerated the decomposition of D_2O and the exchange of D between water and hydrocarbon gases, though its catalytic effect on generation of gas yields was weaker than the carbonate.

Interaction of synthetic manganite with antimony(III)

M.C. HE* AND X.Q. WANG

State Key Laboratory of Water Environment Simulation, School of Environment, Beijing Normal University, No. 19 Xinjiekouwai Street, Beijing 100875, China. (*correspondence: hemc@bnu.edu.cn)

Manganese oxides play an important role in many redox processes in the environment, such as oxidation of antimony (Sb) [1]. The kinetics of antimony transformation by synthetic manganite is examined in this study.

The kinetic experiment was carried out with a background electrolyte of 0.01 M $NaNO_3$ and 5 mM CH_3COONa at pH 4. Sb species were measured by hydride generation atomic fluorescence spectrometer (HG-AFS) (AFS 230, Haiguang Corp., Beijing).

The oxidation of Sb(III) by synthetic manganite is shown in Figure 1. Rapid uptake of Sb(III) by manganite is apparent as well as formation of Sb(V) at the initial period. Then, the Sb(V) in the solution is adsorbed by manganite and reduced gradually with the reaction time. Figure 2 shows the normalized Sb L-edge XANES spectra of reference materials ($KSb(OH)_6$ and Sb_2O_3) and the samples collected from the Sb(III)-manganite system. It is obvious from the spectra that the absorption edge of Sb(III) shift to higher energy at the Sb(V). This indicates that the adsorbed Sb species on the manganite surface is Sb(V).

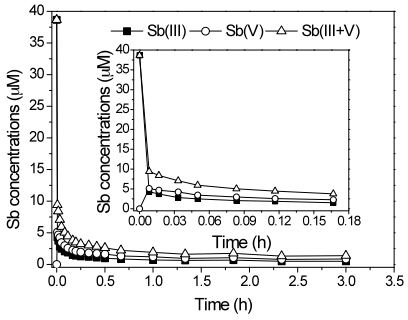

Figure 1: Speciation of dissolved Sb_{total}, Sb(III) and Sb(V) recovery during the reaction of 38.66 μM Sb(III) with synthetic manganite (0.12 g/L) as a function of time at pH 4.0.

LA-ICP-MS chronological study of Tongka gneissic granite in Northern Gangdise, Qinghai-Tibet Plateau

SHIPING HE, CHAO WANG AND PINGYANG GU

Xi'an Institute of Geology and Mineral Resources, Xi'an 710054, Shaanxi, China (xakeyi@163.com)

The Tongka gneissic granite, which locates in Jiayuqiao Block in the northern margin of Gangdise, intruded to the high-amphibolite facies metamorphic rocks of Kaqiong Rock Group of Meso-Neoproterozoic and developed intensive plastic deformation with band fabrics and crumpled texture. The CL imagines of the zircons from Tongka gneissic granite show that the zircons well developed oscillatory zoning core and dark growth rim. Two discordant lines can be obtained by LA-ICP-MS in-situ zircon U-Pb isotopic analysis (Fig. 1). The upper intercept age of the oscillatory zoning cores is (549±18)Ma (MSWD=0.02, Points=23), with the ^{207}Pb-^{235}U weighted average age, (550±10)Ma (MSWD=0.03). However, the dark growth rims yield an upper intercept age (416±23)Ma (MSWD=0.001, Points=8), and the ^{207}Pb-^{235}U weighted average age is (416±20)Ma (MSWD=0.001). The ratios of Th/U of the cores (0.39~1.59) are generally higher that of the rims (0.32~1.29), which proves that the age (549±18)Ma represents the crystallization time of the gneissic granite, equivalent to the time of Pan-Africa Movement (600-500Ma), and the age (416±20)Ma represents the time of an intensive tectonic-thermal event in late Caledonian. This study further confirmed that the Jiayuqiao block in the northern margin of Gangdise is Pan-African basement.

This study was supported by China territorial resources survey project(No. 1212010610102).

Global constraints on biogenic particles

COLETTE L. HEALD[1]*, DOMINICK V. SPRACKLEN[2] AND ALEX GUENTHER[3]

[1]Department of Atmospheric Science, Colorado State University, Fort Collins, CO, USA (*correspondence: heald@atmos.colostate.edu)

[2]School of Earth and the Environment, Leeds University, Leeds, UK (d.spracklen@see.leeds.ac.uk)

[3]Atmospheric Chemistry Division, National Center for Atmospheric Research, Boulder, CO, USA (guenther@ucar.edu)

The biosphere is a source of particles and their precursors to the global atmosphere, yet the magnitude and drivers of these emissions are poorly understood. Two key classes of biogenic particles are primary biological aerosol particles (PBAP) and secondary organic aerosol (SOA) from biogenic volatile organic compounds (VOCs). In this presentation I will discuss modeling efforts and field observations of PBAP, (with a focus on fungal spores) and SOA (including biogenic VOC precursors), highlighting challenges and recent progress.

Short magma residence times for Kilauea Volcano based on high-precision Pb isotope ratios

D.E. HEATON[1], A.J. PIETRUSZKA[1], M.O. GARCIA[2] AND J.P. MARSKE[2]

[1]Deptartment of Geological Sciences, San Diego State University, San Diego, CA 92182-1020, USA
[2]Department of Geological Sciences, University of Hawaii, Honolulu, HI 96822, USA

We present new high-precision Pb isotopic analyses of 46 historical Kilauea summit lavas (1823-2008). These data are used here to investigate the architecture of Kilauea's summit magma storage reservoir and the characteristics of the volcano's mantle source region. These lavas exhibit a temporal trend characterized by low $^{206}Pb/^{204}Pb$ ratios in 1823, a gradual increase to a maximum in 1921, an abrupt drop to relatively constant intermediate values from 1923 to 1959, and a rapid decrease to 2008. These variations indicate that Kilauea's summit reservoir is being supplied by rapidly changing parental magma compositions derived from a mantle source that is heterogeneous on a small scale. At least three components are required to explain two distinct mixing arrays on a plot of $^{206}Pb/^{204}Pb$ vs. $^{208}Pb/^{204}Pb$, where the 19th century lavas have a low $^{206}Pb/^{204}Pb$ at a given $^{208}Pb/^{204}Pb$ compared to the 20th century lavas. Analyses of multiple lavas from several individual eruptions reveal small but significant differences in $^{206}Pb/^{204}Pb$ ratios (~0.01-0.03). For example, the extra-caldera lavas from Aug. 1971 and Jul. 1974 display significantly lower Pb isotope ratios and higher MgO contents (10 wt. %) than the intra-caldera lavas (MgO ~7-8 wt. %) from the same eruption. These distinctions appear to be spatially delineated by the rim of the volcano's summit caldera. From 1971 to 1982, the $^{206}Pb/^{204}Pb$ ratios of the lavas define two separate decreasing temporal trends. Intra-caldera lavas from 1971, 1974, 1975, Apr. 1982 and the lower MgO lavas from Sep. 1982 have consistently higher $^{206}Pb/^{204}Pb$ ratios at a given time (compared to the extra-caldera lavas and the higher MgO lavas from Sep. 1982). Magma residence-time modeling of the high $^{206}Pb/^{204}Pb$ (low MgO) and low $^{206}Pb/^{204}Pb$ (high MgO) trends suggest that the intra- and extra-caldera lavas are being supplied from two distinct magma bodies, each with a volume of ~0.2 km^3. This volume estimate is more precise and much smaller than previous estimates of a single, ~2-3 km^3 magma body based on trace element ratios. Overall, these observations suggest that Kilauea's summit reservoir has a small volume that efficiently transfers the changing compositional signals of the mantle-derived parental magmas.

The calcite–water interface and its interactions with selenium IV and VI

FRANK HEBERLING, STEPHANIE HECK AND JÖRG ROTHE

Institute for nuclear waste disposal, Karlsruhe Institute of Technology (KIT), PO-Box 3640, 76021 Karlsruhe, Germany

Due to the reactivity of its surface, calcite may play an important role for the retention of contaminants in soils, lacustrine-, marine- and aquifer environments.

Selenium is on the one hand an important nutrient. On the other hand, if a certain concentration limit is exceeded, it is toxic. The chemical toxicity is highest for the oxidized selenium IV and VI species. These are also the species expected to be the most mobile in soils and aquifers. Selenium-79, is a long lived nuclear fission product formed in nuclear power plants. It is of special concern, as it is expected be able to diffuse through the technical and geological barrier systems around nuclear waste disposals and increase the radiotoxicity of groundwater in adjacent aquifers.

At calcite equilibrium conditions, tetravalent selenium shows only very weak adsorption at the calcite surface. At pH below 9, K_D values are about 0.001. Above pH 9 no adsorption is observed. In situ grazing incidence EXAFS measurements at the calcite(104) face show no contribution to the selenium(IV) spectra that could be assigned to the calcite surface. If the calcite saturation index is increased selenium(IV) starts coprecipitating with calcite. The ordering of the coprecipitated selenite ($Se(IV)O_3^{2-}$) ions corresponding to the orientation of the calcite carbonate ions becomes visible in polarization dependent grazing incidence XANES spectra. Coprecipitation of selenite with calcite is quantified in mixed flow reactor (MFR) experiments at steady state and low supersaturation (SI~0.8) conditions. Homogeneous partition coefficients range from 1 to 10. EXAFS spectra measured on selenite doped calcite from MFR experiments show that selenite is structurally incorporated into calcite onto a slightly distorted carbonate lattice site.

Selenium(VI) shows a slightly stronger adsorption to the calcite surface. Grazing incidence EXAFS spectra, measured in situ at the calcite(104) face, show clear contributions that can be assigned to two Ca^{2+} neighbours from the calcite surface, at about 3.5 Å distance. There are two non-equivalent adsorption sites at the calcite(104) face that could explain this result. The GIXAFS data however, cannot be used to distinguish between the two.

Coprecipitation of selenium(VI) with calcite in MFR experiments was below detection limit.

Metal attenuation in tailings

T. HEDLUND*, L. LÖVGREN AND T. KARLSSON

Department of chemistry, Umeå University, 901 87 Umeå, Sweden (*correspondence: tomas.hedlund@chem.umu.se)

Oxidation of sulphide mineral in mine waste can result in extensive release of metals, which may escape the waste via groundwater discharge. However, the metals may also be attenuated by various processes in which metal ions are re-associated with the solid matter within the tailings. The objective of our work is to identify the minerals in mining waste that are of significance for the attenuation in short and long term perspective of heavy metals release in mine waste by quantifying the metal retardation capacity of tailings of different properties or origin.

The metal uptake capacity has been studied for Cu, As, Zn and Cd in batch and column experiments on tailings sampled in four different locations: Kristineberg, Aitik, Zinkgruvan and Boliden. In order to distinguish between adsorbed metal and precipitation of metal oxide/hydroxide, the acid neutralization capacity of the tailing was neutralized before the batch and column experiments. The elemental composition of tailings and pore-water was analysed using ICP-AES/MS. Characterization of the mineralogical composition by using Mineral Liberation Analysis and the speciation and local structure of metal ions associated with tailings was investigated using X-ray Photoelectron Spectroscopy and synchrotron based X-ray Absorption Spectroscopy.

Our result for Cu shows that there is an initial uptake likely explain by precipitation of $Cu(OH)_2$ (supported by XANES analysis) follow by a slower process involving phase transformation e.g. formation of secondary copper sulphide. The copper uptake capacity was highest, up to 50 μmol/g of tailing, for Kristineberg and Zinkgruvan. Uptake of arsenic appears to be more strongly correlated to sulphide content of tailings with an uptake capacity similar to copper for tailings with high sulphide content. For cadmium no significant uptake could be observed.

Donnan equilibrium in Na-montmorillonite from a molecular dynamics perspective – Consequences for diffusional transport

M. HEDSTRÖM*, M. BIRGERSSON AND O. KARNLAND

Clay Technology AB, Ideon Science Park, SE-223 70 Lund, Sweden (*correspondence: mh@claytech.se, mb@claytech.se, ok@claytech.se)

Bentonite clay is proposed as buffer material in several concepts of High Level Radioactive Waste repositories, and a correct description of ion diffusion in this material is of vital importance for any quantification of the chemical evolution of the repository near field.

This study investigates the importance of ion equilibrium between montmorillonite interlayer space and an external solution for the diffusional behaviour of bentonite.

We present molecular dynamics simulations of the Donnan equilibrium principle in compacted montmorillonite with three hydration layers of water in the interlayer. This draws attention to the misconception, frequently seen in the literature, stating that anions cannot enter interlayer space due to electrostatic repulsion forces, sometimes referred to as anion exclusion. However, the calculations presented here show that excess salt, i.e., both anions and cations enter interlayer space to the extent predicted by Donnan equilibrium. Thus the excess salt concentration is reduced in the interlayer in comparison to the external electrolyte but not totally excluded [1].

Taking into account that anions can and will enter the interlayer space a general theoretical framework for describing through-diffusion in montmorillonite is developed [2]. By using a single pore space, the interlayers, cations and anions are treated symmetrically as opposed to conventional multi-porosity models where anions and cations follow different pathways. The validity of the presented approach is further justified in comparisons to experimental chloride tracer diffusion data [3].

Mineral alterations due to accessory gases in the geological storage of CO_2

K. HEESCHEN*, A. RISSE, S. STADLER AND C. OSTERTAG-HENNING

Federal Institute for Geosciences and Natural Resources (BGR), D-30655 Hannover, Germany (*correspondence: Katja.Heeschen@bgr.de)

To establish reliable numerical models that depict the geochemical processes caused by the storage of CO_2 in saline aquifers it is essential to have an applicable database. This has to include thermodynamic properties and kinetic data of those gas mixtures occurring in the captured CO_2 gas stream, which will contain minor amounts of gases such as O_2, N_2, NO_x, SO_x, CO, H_2S. However, quantitative measures of the chemical alterations due to these accessory gases are scarce at relevant conditions.

The COORAL project "CO_2 Purity for Capture and Storage", concentrates on the effects of accessory gases during all four processes: capture, transport, injection and storage. At BGR it is the storage that is in focus. High-pressure-high-temperature (HPHT) experiments are carried out using unstirred batch-reactor systems ($P \leq 590$ bar; $T \leq 350$°C) to elucidate mineral and fluid alterations and quantify kinetic rates for different mineral–fluid–CO_2–co-injected gas system.

A first set of experiments using pure CO_2 and carbonates allowed testing the laboratory set-up and adjusting the modelling environment (PHREEQC). Dolomite-brine-CO_2 experiments exhibited a very good reproducibility of the increase in cation concentrations at the different stages of the experiment. Release rates for both, Mg and Ca, vary between $2*10^{-10}$ mol s^{-1} cm^{-2} at the very beginning and $4*10^{-13}$ mol s^{-1} cm^{-2} just before approaching steady state. There is a tendency towards slightly higher rates for Ca release during the first stage of the experiment.

The main target of the running experiments is set on the effects of binary gas mixtures in the system mineral–fluid–CO_2–O_2 (this contribution) and mineral–fluid–CO_2–SO_2 [1]. The mineral phase consists of carefully crushed, sorted and cleaned natural mono-minerals while the natural saline water is represented by a Na-Cl solution of 150 g/l NaCl in most cases.

Comparison of land-based REE ore deposits with REE-rich marine Fe-Mn crusts and nodules

JAMES R. HEIN[1]*, TRACEY CONRAD[1] AND ANDREA KOSCHINSKY[2]

[1]USGS, Menlo Park, CA, 94025, USA (*correspondence: jhein@uss.gov)
[2]Jacobs University, Bremen, Germany (a.koschinsky@jacobs-university.de)

REEs are essential for a large variety of high-tech and green-tech applications. The global market has been supplied over the past 10 plus years, from a single source, China. China's domestic needs have meant that its export of REEs has and will continue to decrease significantly. Consequently, other land-based sources of REEs are being explored and mines developed. Deep-ocean deposits may offer a partial solution to this projected shortage, but marine deposits have not been evaluated. Here we compare data for the Clarion-Clipperton Mn Nodule Zone (CCZ) in the NE Pacific and the prime Fe-Mn crust zone (PCZ) in the central Pacific with the two largest land-based mines, Mountain Pass (MP) in USA and Bayan Obo (Obo) in China. The land-based deposits are lower tonnage deposits, but higher grade (MP $0.9x10^8$ tons at 5% total REEs as oxides (TREO); Obo, $8x10^8$ tons at 6% TREO), compared to the CCZ ($211x10^8$ tons at 0.10% TREO) and PCZ ($75x10^8$ tons at 0.3% TREO). These grades and tonnages correspond to tons of TREO of $4.9x10^7$ Obo, $0.45x10^7$ MP, $2.1x10^7$ CCZ, and $2.3x10^7$ PCZ. The land-based deposits have <1% heavy REEs, whereas the CCZ has 10% HREEs and the PCZ, 6.3% HREEs. An important environmental issue is the high Th contents in the land-based deposits (100s of ppm) in contrast to the low Th in marine deposits (mean 14 ppm CCZ; 11 ppm PCZ).

Stepwise C & O stable isotope shows no detectable CO_2-sequestration by cements in analogue for engineered storage

N. HEINEMANN[1]*, M. WILKINSON[1], A. E. FALLICK[2] AND R. S. HASZELDINE[1]

[1]School of Geosciences, The University of Edinburgh, The King's Buildings, West Mains Road, Edinburgh, EH9 3JW (*correspondence: n.heinemann@sms.ed.ac.uk)
[2]Scottish Universities Enviromental Research Centre, East Kilbride, G75 0QU

Geochemical models often predict a relatively rapid growth of carbonate minerals as the most secure form of long term, engineered, CO_2 storage. But validation of model-results remains difficult due to the long periods of time involved, 1000's of years. Natural analogue studies can bridge the gap between experiments and real-world storage.

The Fizzy field, a southern North Sea (UK) gas accumulation with a high natural CO_2 content (c. 50%) provides an ideal opportunity to study the long term effect of CO_2 related mineral reaction. However all such reservoirs contain 'normal' diagenetic dolomite, so that distinguishing sequestration related dolomite is a challenge. Previous petrographic work and comparison of stable carbon and oxygen isotopes from dolomite in the Fizzy field and dolomite in the Orwell field, an adjacent gas field with low CO_2 content, did not find major differences [1]. However, stable isotope measurements were only made on whole-rock samples such that internal zonations of crystals may have been masked.

We extracted CO_2 from dolomite from both the Fizzy and the Orwell gas field in a stepwise manner in order to reveal any zonation of the crystals which could be related to enhanced dolomite precipitation due to the high CO_2 concentration. The results do not match with the calculated isotopic equilibrium composition for the CO_2 which is currently present in the Fizzy field but are comparable with data from the adjacent low CO_2 Orwell field. We conclude that the dolomite present in the Fizzy field is not related to high CO_2 concentration but a product of earlier diagenetic events.

Investigation of organo-mineral interactions in artificial soil incubations by NanoSIMS

KATJA HEISTER[1]*, CARMEN HÖSCHEN[1], GEERTJE J. PRONK[1], CHRISTIAN POLL[2], ELLEN KANDELER[2], CARSTEN W. MÜLLER[1] AND INGRID KÖGEL-KNABNER[1]

[1]Lehrstuhl für Bodenkunde, Technische Universität München, 85350 Freising-Weihenstephan, Germany (*correspondence: heister@wzw.tum.de)
[2]Institute of Soil Science and Land Evaluation, Soil Biology, University of Hohenheim, Emil-Wolff-Str. 27, 70593 Stuttgart, Germany

Soils are complex mixtures of minerals, organic material (OM) and microorganisms. These components interact with each other, forming biogeochemical interfaces (BGIs). BGIs in soils are believed to be hot-spots where many important processes like sorption and microbial activity occur. Thus, depending on the components involved, various microhabitats for soil microorganisms are created.

In order to study the effect of mineral composition on the development of BGIs, we performed an artificial soil incubation experiment. The artificial soils are model systems, comprising of well-defined mixtures of various minerals like quartz, clay minerals and iron and aluminium hydroxide and sterilized manure as organic substrate that were inoculated with soil microorganisms and incubated over different time periods up to 18 months.

The microorganisms were active and OM turnover occurred in the soil systems. Phospholipid-derived fatty acid (PLFA) pattern showed that the initial composition of the artificial soils initiated the development of different soil microbial communities.

Selected samples after one year of incubation were investigated with nano-scale secondary ion mass spectrometry (NanoSIMS) to study BGI formation. NanoSIMS analysis demonstrated that patchy attachment of OM occurred to clay minerals. Up to now, no intact microbial cells were detected in the artificial soils using NanoSIMS, which is probably due to sample pretreatment or too low abundance of microorganisms in these samples.

Our data demonstrate that in these simple soil systems, depending on the mineralogical composition, microhabitats were created, and that NanoSIMS is a tool to visualize these hot-spots in soil at a relevant scale.

First high-resolution $\delta^{13}C$-records of the Early Aptian OAE 1a within the mid-latitudes of NW-Europe (Germany, Lower Saxony Basin)

M. HELDT [1]*, F.W. LUPPOLD [1], W. WEISS [1], J. MUTTERLOSE [2], U. BERNER [1] AND J. ERBACHER [1]

[1]BGR, 30655 Hannover, Germany (*correspondence: Matthias.Heldt@bgr.de)
[2]Ruhr-University Bochum, 44801 Bochum, Germany

Two mid-Cretaceous sediment cores (Hoheneggelsen 9 and Ahlum 1 cores) from the area south of Brunswick, North Germany, were investigated in detail on the base of biostratigraphy, $\delta^{13}C$-stratigraphy and geochemistry. Results suggest a latest Barremian to early Late Aptian age for the deposits. In both cores, three lithological units are recognized: a lower claystone unit including finely laminated black shale horizons ("Blättertone"), an overlying prominent black shale horizon ("Fischschiefer") and an upper marly section (*Hedbergella* marls). Isotope stratigraphy allows to subdivide the deposits into segments (C1-C7), which are used for high-resolution stratigraphy globally. These segments also allow to identify the Late Early Aptian Oceanic Anoxic Event 1a (OAE 1a). The present study represents the first high-resolution $\delta^{13}C_{carb}$ and $\delta^{13}C_{org}$ records across this event within the mid-latitudes of NW-Europe. Our results confirm that the regional sedimentary expression of the OAE 1a is the above-mentioned "Fischschiefer" horizon, a 2-3 m-thick laminated black shale layer known from NW Germany and the southern North Sea.

The main trends of the $\delta^{13}C$ isotope curves of both cores can be correlated with global curves. However, several bulk carbonate samples of the Early Aptian, including those of the OAE 1a, are considerably depleted in $\delta^{13}C$. This might be explained by authigenic carbonate formation, induced by microbial sulphate reduction and –in cases of extreme ^{12}C enrichment- also by microbial methane generation and oxidation processes. Such processes are confined to anoxic enironments. Consequently, strong ^{12}C enrichement mainly correlates with the black shales, including the "Fischschiefer" horizon (OAE 1a), which are associated with anoxic bottom water conditions. The overlying marls (*Hedbergella* marl unit), deposited under oxic seafloor conditions, show values closer to normal marine levels. The early diagenetic processes of the carbonates discussed above did not affect the $\delta^{13}C_{org}$ ratios of both cores to greater extent. These are close to normal marine levels and show variations in the range of a few permil only. Our study shows, that $\delta^{13}C_{org}$ data is better suited for stratigraphy in mid-Cretaceous anoxic sediments of the Lower Saxony Basin.

Causes and consequences of outer core compositional stratification

GEORGE HELFFRICH[1] AND SATOSHI KANESHIMA[2]

[1]Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK
[2]Earth and Planetary Sciences, University of Kyushu, 6-10-1 Hakozaki, Higashi-ku, Fukuoka 812-8581, Japan

We report on a detailed investigation of the structure of the topmost outer core using seismic waves travelling across it at depths between 60-700 km. The observations are regional array recordings of between 120-200 seismograms from the same earthquake using stations in Europe and Japan. The use of arrays allows high-precision measurements of differential SmKS travel times and slownesses for multiple (m) values up to 5. The study [1] yields a well constrained velocity structure for the topmost 500 km of the outer core. The uppermost 300 km is gradationally slower than the PREM model by up to 0.3%. Applying Birch's homogeneity test to the velocity profile shows that it differs at more than the 95% confidence level from compression of a simple liquid of fixed composition. Thus the outer core is stratified in its composition.

The thickness of the layer requires the layer's bulk to be derived from the core rather than from the core-mantle boundary given known diffusivity of core liquids. Consequently, the gradient must arise from light element addition within the core, probably from the growth of the inner core. A rough material balance may be made between the density jump at the inner core boundary and the thickness of the layer. Using a core liquid velocity model in the Fe-O-S system, the velocity change requires a 3-5 wt% light element concentration increase in the topmost core. Maintaining a 300 km thick layer against convective mixing in the outer core suggests that the shallowest core is stagnant. One way to suppress convection there is by making the outermost core isothermal, suggesting that there is not a significant thermal boundary layer at the base of the mantle.

Processes affecting iron solubility in the Tropical North Atlantic

M.I. HELLER[1] AND P.L. CROOT[2]

[1]IFM-Geomar, Kiel, Germany (mheller@ifm-geomar.de)
[2]Plymouth Marine Laboratory, Plymouth, United Kingdom (pecr@pml.ac.uk)

Iron (Fe) has been clearly shown to be a limiting nutrient for phytoplankton productivity in many different oceanic regions. A critical apsect underlying iron limitation is the low solubility, under ambient seawater conditions, of solid iron phases supplied as aerosols or riverine particles to the ocean. Processes which enhance the solubility of iron in seawater, either through redox reactions or organic complexation, are key to our understanding of the biogeochemical cycling of iron and its global distribution. In this work we combine information from a recent meridional cruise through the Atlantic (PS ANT XXVI-4) with sampling performed within the SOPRAN project at the TENATSO time series site located near Cape Verde to examine processes influencing iron solubility in the Tropical North Atlantic in the region under the Saharan dust plume.

A promising indicator of iron solubility in deep waters is marine humic fluorescence (ex 320/em 420), as work in the Pacific [1] has shown strong correlations with Fe solubility and AOU. This suggests that iron solubility in deep waters is scaled to the release of iron complexing ligands from the decomposition of sinking organic matter. During ANTXXVI-4 we observed a region of intermediate waters with strong humic fluorescence consistent with observations of elevated Fe concentrations [2]. The humic fluorescence signal however is sharply attenuated in surface waters due to bleaching, suggesting that other ligands or processes are important in the euphotic zone. Our work at TENATSO suggest that iron solubility is not significantly enhanced by reactions with superoxide [3] and is controlled by the presence of non-fluorescing colloids or siderophore type ligands consistent with earlier previous work in the Mauritanian upwelling [4].

Albite precipitation in mudstones – Comparison of natural and synthetic systems

HELGE HELLEVANG*, BRIT THYBERG AND JENS JAHREN

Department of Geosciences, Univ. Oslo, Pb. 1047, Blindern, Oslo, Norway. (*correspondence: helghe@geo.uio.no)

Closed system hydrothermal batch experiments on smectite (SWy-2, The Clay Minerals Society) and smectite + K-feldspar, reacted with NaCl solutions, were performed at 200 °C with each experiment runing for 2-3 weeks. The experiments show that dispersed albite readily forms from smectite in systems supersaturated with respect to albite. This compares well with observations from natural mudstones, where micro-sized authigenic albite (mAlb) is found together with authigenic 2-4 μm micro-crystalline quartz (mQtz) embedded in an illitized clay matrix (Fig. 1). The amount of authigenic mAlb formed in the natural systems are about 10-15% of the produced authigenic mQtz. The suggested reaction equation indicate that less than 2 wt % sodium and 2-3 wt % potassium is required to account for both the estimated mAlb and illite formation from smectite and K-feldspar.

The findings indicate closed system diagenesis predicted from the physical and chemical properties of fine grained siliciclastic rocks during burial, and that the source for necessary sodium, silica and aluminum for authigenic mAlb formation is smectite and K-feldspar dissolution resulting in mainly illite and quartz formation.

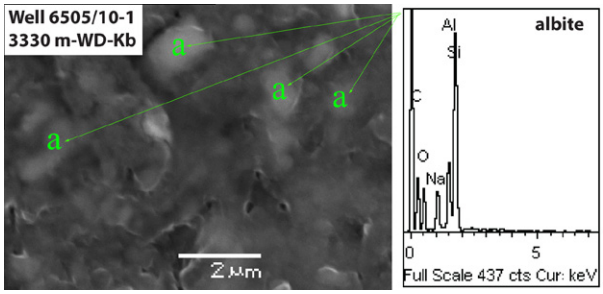

Figure 1: SEM image of natural mAlb (a) together with feldspar, quartz and clay from well 6505/10-1 sampled at 3330 m.

Arsenic, copper, and zinc leaching through preferential flow in mining-impacted soils

MARTIN HELMHART[1], PEGGY O'DAY[2], JAVIER GARCIA-GUINEA[3], SUSANA SERRANO[1] AND FERNANDO GARRIDO[1]

[1]Institute for Agricultural Sciences (CSIC) c. Serrano 115-dup, 28006 Madrid (Spain)
[2]School of Natural Sciences, Universtiy of California, 5200 North Lake Rd, Merced, CA 95344 (USA)
[3]National Museum of Natural Sciences (CSIC), Jose Gutierrez Abascal 2, 28006 Madrid (Spain)

The effect of preferential flow on the spatial distribution and chemical speciation of As, Cu and Zn in a metal(loid) polluted soil was studied within the river bed of a small stream that collects surface runoff from an arsenic-bearing, mainly as scrorodite (FeAsO4·2H2O), waste pile near an abandoned mine. Water flow domains, either preferential or matrix, were identified by staining techniques, a detailed soil sampling procedure, and statistical analysis. General soil properties were studied in each flow domain. In addition, total metal(loid) content and chemical distribution by means of sequential extraction procedure were done within each flow domain. Lastly, As speciation was studied by X-ray absorption spectroscopic (XAS) methods.

An upper river bed and its underlying subsoil were distinguished, and both were characterized by low pH and high As, Cu, Zn and Fe concentrations as compared to the adjacent soil. Metal(oid) concentrations were higher in the river bed than in the subsoil due to the accumulation of incoming material from the waste pile. In the river bed, higher metal(oid) concentrations were found in the preferential flow domain compared to matrix flow. Instead in the subsoil, preferential flow paths were characterized by a lower ion exchange capacity and lower Cu and Zn concentrations from acidic leaching, and higher concentrations of total organic matter attributed to high root content, compared to the soil matrix. Arsenic was mainly concentrated in the preferential flow paths as As(V). XAS analysis indicated As sorption on iron hydroxide phases as the primary retention mechanism in the subsoil, which may be a reversible process if geochemical conditions change. Preferential flow, acting as a by-pass connecting the highly contaminated river bed layer with deeper soil, has an impact on the distribution of metal(oids) at the study site and may increase the risk for groundwater contamination.

Mechanisms of light-induced flocculation of terrestrial dissolved organic matter and iron

JOHN R. HELMS[1], KLAUS SCHMIDT-ROHR[2], JINGDONG MAO[1] AND KENNETH MOPPER[1*]

[1]Department of Chemistry and Biochemistry, Old Dominion University, Norfolk, Virginia 23529 (jhelms@odu.edu; jmao@odu.edu; *correspondence: kmopper@odu.edu)
[2]Department of Chemistry, Iowa State University, Ames, Iowa 50011 (srohr@iastate.edu)

Dissolved organic matter (DOM) rich water samples from the Great Dismal Swamp (Virginia, USA) were filtered (<0.1 micron) and UV-irradiated (~290 nm lower cutoff) for 30 days. During the irradiation, particulate organic matter (POM) and particulate iron formed. Water samples before and after particle removal, as well as isolated particles, were analyzed by ultraviolet-visible absorption spectroscopy, high temperature combustion (TOC/DOC), solid-state ^{13}C nuclear magnetic resonance (NMR) spectroscopy, Fourier transform infrared (FT-IR) spectroscopy, and flame atomic absorption spectroscopy (for iron). After 30 days of UV light exposure, 7.1% of the original DOC was converted to particulate organic carbon (POC) while 75% was converted to inorganic photoproducts. Approximately 84% of the absorption in the 250-450 nm region was removed by photobleaching, while 8.3% was removed by photo-flocculation. About 87% of the iron was removed from the dissolved phase after 30 days of irradiation, but iron did not begin to flocculate until a considerable excess of DOM was removed by photodegradation and flocculation between 10 and 20 days of irradiation. These results suggest that, during the initial 10 days, there was still sufficient organic ligands present to keep iron in solution. NMR and FT-IR spectroscopies indicated that the photochemically flocculated POM is significantly more aliphatic than the irradiated DOM. Further, photo-flocculated POM was enriched in amide functional groups, while carbohydrate-like material was resistant to both photochemical degradation and flocculation. When photochemical flocculation is considered, the extent to which photochemistry may remove terrestrial DOM from the upper water column is revised upward by about 10%. Abiotic photochemical flocculation is therefore a heretofore-ignored phenomenon that significantly alters our understanding of sedimentation in humic lakes and the transport of DOM and POM in ocean margin environments such as estuaries.

PGE complexes at superliquidus temperature: Embryos for platinum-group minerals?

H.M. HELMY[1]*, C. BALLHAUS[2], C. WOHLGEMUTH-UEBERWASSER[3], R. WIRTH[4] AND M. TREDOUX[5]

[1]Minia University, 61519 Minia, Egypt (*correspondence: hmhelmy@yahoo.com)
[2]Steinmann Institut, Universität Bonn, Germany
[3]University of Johannesburg, PO Box 524, South Africa
[4]GFZ, Potsdam, Germany
[5]Univ of the Free State, 9300 South Africa

Even though As, Sb, Te, and Bi are mere trace elements in magmatic sulfide melts, minerals of the platinum-group elements (PGE) with these ligands are exceptionally common. Obviously, at subsolidus temperatures, there is a marked chemical preference of the PGE to bond with the chalcogenes and semimetals and form discrete arsenides, antimonides, tellurides, and bismuthinides. The question addressed here is if similar PGE-ligand preferences also exist at supersolidus and superliquidus temperature. Should such proposition be proven correct, we could argue that discrete crystalline PGE-chalcogene and PGE-semimetal phases have their chemical equivalents at superliquidus conditions in the form of PGE-As, Sb, Te, and Bi molecular associations, complexes or even poly-atomic clusters [1]. We could even go as far as proposing that the crystallization of a discrete PGE phase with a specific metal-ligand combination merely reflects the re-organization to larger units, of PGE-ligand molecules or complexes with the same PGE-ligand combination.

Experiments were carried out in an Ir-Pt-As-bearing, monosulfide (mss)-saturated Fe-Cu-S system at 950°C at minimum and maximum sulfur fugacities as bracketed by the Fe-FeS (metal-troilite) and $Fe_{1-x}S$-S_2 (mss-sulfur) equilibria. Copper was added to expand the two-phase (mss-melt) stability field such that mss grains coexisted with sulfide melt pools sufficiently large for contamination-free laser-ablation analysis. Platinum, Ir, and As were added to the sulfide matrix at the tens of ppm levels. The molecular As/PGE bulk ratios varied from 0, 1, 2, 3 and 5. In charges with high sulfur fugacity, i.e. when all As is present as cation [2], the partition coefficients of Pt, Ir and As are insensitive to the As/PGE atomic bulk ratio. At low sulfur fugacity, in contrast, when all As is dissolved as anions, the mss-sulfide melt partition coefficients of Pt and Ir decrease with increasing atomic As/Pt; DIr (mss/sulfide melt) slightly and DPt (mss/sulfide melt) sharply by almost one order of magnitude. The results can only be rationalized if PGE minerals such as $IrAs_2$ (iridarsenite) or $PtAs_2$ (sperrylite), and potentially many more discrete PGE phases with rare elements as ligands, have their equivalents at superliquidus temperature in the form of Ir-As, Pt-As etc. molecules, complexes or even poly-atomic clusters [1].

Geochemical roles of thioanions of the heavier metals and metalloids

G. R. HELZ

Department of Chemistry and Biochemistry, University of Maryland, College Park, MD, 20742, USA (helz@umd.edu)

Where sulfide replaces oxygen in sedimentary environments, many elements' aqueous geochemistry is altered profoundly. Among first row transition metals, the primary effect is reduction (e.g. $Cr^{VI} \rightarrow Cr^{III}$, $Mn^{IV} \rightarrow Mn^{II}$, $Fe^{III} \rightarrow Fe^{II}$, $Cu^{II} \rightarrow Cu^{I}$). Secondarily (i.e. at higher sulfide concentrations), sulfide complexes can form through replacement of O, N or Cl atoms in first coordination shells of the reduction products. In contrast, for many heavier metals and metalloids, the primary effect is ligand replacement, with reduction occurring secondarily, if at all. Thus thioanions may form with trace elements in their highest oxidation states (e.g. $Re^{VII}S_4^-$ $Mo^{VI}S_4^{2-}$, $As^{V}OS_3^{3-}$, $Sb^{V}_2S_6^{2-}$). In each of these known cases, the thioanion a) is stabilized at geochemically reasonable sulfide concentrations (10^{-6} to 10^{-4} M) at near-neutral pH and b) appears not to precipitate a binary sulfide solid phase under conditions ordinarily found in nature.

Owing to experience with first-row transition metals, geochemists have tended to attribute behavior of heavier metals and metalloids in sulfidic waters to reduction rather than ligand exchange. Although the determing role of ligand exchange in Mo's behavior in sulfidic waters has become accepted over the past 15 years, belief in Re's reduction in these waters still prevails. I will present a new, ligand-exchange model for Re's response to sulfide that is analogous to that recently proposed to explain Mo behavior in euxinic waters [1]. The model can explain important features of Re's geochemistry, including its precipitation exclusive of Mo in suboxic environments and its precipitation at a nearly constant ratio to Mo in sulfidic environments.

Because thioanions can act as multidentate, sulfur-donating ligands, they may influence the geochemistry of other trace metals. Both As^{III} and Mo^{VI} thioanions are now known to form extraoridinarily stable complexes with coinage metals (Cu, Ag, Au). It can be expected that the same will eventually be demonstrated for thioanions of other elements, especially Sb and Bi.

Rates and mechanisms of oxygen consumption by fresh volcanic material in the marine environment

D.J. HEMBURY[1]*, M.R. PALMER[1] AND G.R. FONES[2]

[1]School of Ocean & Earth Science, University of Southampton, Southampton, SO14 3ZH, UK (*correspondence: d.hembury@noc.soton.ac.uk)
[2]School of Earth & Environmental Sciences, University of Portsmouth, Portsmouth, PO1 3QL, UK

Volcanic sediments are ubiquitous in the marine environment, to the extent that almost a quarter of the Pacific Ocean sediments are believed to be of volcanic origin. Volcanic material from explosive volcanism is fresh, fine grained and highly reactive. Although longer term alteration of volcanic material in the marine environment is relatively well studied, and has been demonstrated to make a significant contribution to the global cycling of elements, early diagenetic alteration of volcanic sediment in the marine environment is less well understood. We may, therefore, be missing an important component in our understanding of global geochemical cycles.

The ongoing eruption of Soufriere Hills, Monsterrat, West Indies, provides an excellent case study for these processes. Oxygen microelectrode profiles were measured in cores collected from around the island, 18 months after the May 2006 dome collapse event deposited approximately 115 x 10^6 m^3 of non-dense rock equivalent of material into the ocean [1]. Profiles reveal that oxygen is typically depleted to zero within 0.5 cm of the sediment water interface in volcanic deposits, compared with up to 6.5 cm in unaffected sediments. Oxidation of all available organic carbon in the volcanic sediments is only sufficient to sustain the calculated rate of oxygen consumption for c. 25 days. Hence, there must be another mechanism for oxygen consumption in these sediments. Results from laboratory flow-through experiments with the volcanic sediment indicate that consumption of the dissolved oxygen is likely driven by a coupled charged transfer reaction involving oxidation of silicate bound Fe^{II}.

Intercalibration of Ar-Ar standards and samples at LDEO

SIDNEY R. HEMMING[1,2], KAORI TSUKUI[1,2], GARY T. MESKO[2], GULEED ALI[1,2], YUE CAI[12], ALEXANDER ADLER[1], SIOBHAN CAMPBELL[1], ELLEN CRAPSTER-PREGONT[1,2], CATHLEEN DOHERTY[1,2], JOEL GOMBINER[1], JOHN RUSSELL[1], JOHN TEMPLETON[1,2], MARISSA TREMBLAY[1] AND MARC VANKEUREN[1,2]

[1]Columbia University, New York, NY, (sidney@ldeo.columbia.edu)
[2]Lamont-Doherty Earth Observatory of Columbia University, 61 Rt 9W, Palisades, NY 10964

The Columbia University Spring 2011 Introduction to Geochronology and Thermochronology class is conducting an intercalibration experiment of Ar-Ar monitor standards in addition to some promising, well-behaved sanidine samples that have been analyzed multiple times in several labs. The goals are to document the intercalibration factors "R" (as defined by Renne *et al*., 1998, Chemical Geology) for the lab at Lamont-Doherty Earth Observatory and further to integrate research and education by providing a real introduction to EARTHTIME with a hands on exercise to examine the issues related to obtaining the highest quality Ar-Ar dates. This experiment will address the degree to which the Ar-Ar dates can be confidently compared between our lab and others that have reported on these samples, and will provide insights into potential sources of bias.

We have designed aluminium disks with 12 "unknown" pits, each surrounded by 4 "monitor" pits. Each unknown shares 2 of the 4 surrounding pits with an adjacent unknown. One package was irradiated for 4 hours, and another for 24 hours at the USGS TRIGA reactor in Denver, CO. Both irradiations contain several pits with Fish Canyon and Taylor Creek sanidine standards, which will result in 7 populations.

We examine data produced on samples recovered along three cruises along the CIR axis segment supposedly involved in the interaction process, off axis along two sections up to 800ky on both sides of the axis and on several off axis volcanic features on the African plate between the CIR and the hotpsot present surface expression, La Réunion island.

Trace elements are enriched along the spreading axis from the central part of the segment and northward to the Marie-Celeste fracture zone. Enriched samples occur also symmetrically off axis as spikes along the northern section at 19°10”S with a wavelength of about 200 ky. This is not the case along the southern section at 19°30”S on which enriched samples are found only in the axial trench. All off axis ridges and seamounts are depleted in trace elements.

Isotopically, the picture is quite complex. On axis samples fall on isotope trends that are compatible with mixing material from both an heterogeneous Réunion plume and the local Indian upper mantle. Off axis samples along the northen sections fall on a similar mixing trend showing that if Cordier *et al*. (2010) were right, the enriched material is intrinsically part of the local mantle. The enriched trace element trend to the north does exist in Sr, Nd and Hf isotopes but Pb isotopes reveal that the northern most samples fall together with samples from the next northern short segment on a separate mixing line. That reveals the potential existence of a distinct local component that is not drastically different but only a bit more radiogenic in 208 at a given 206. He isotopes (Füri *et al*. 2011) revealed that some ^{3}He enriched material also exist to the North of the segment and and they attributed it to the trace of the Réunion hotspot left behing within the upper mantle.This northern Pb mixing line points to two enriched samples in Pb isotopes, one coming from the Marie Céleste fracture zone and the other from an off shore seamout built on the southern slop of the Piton de la Fournaise. They may reveal the existence of a discrete Reunion component that does not survive when melts pass through large magma plumbing and/or magma chambers but appears when small melt bacthes can be preserved.

Quantifying fluxes of metals to surface waters of the South-East Atlantic

G.M. HENDERSON[1]*, E.P. ACHTERBERG[2], A.R. BAKER[3], R. CHANCE[3], W. GEIBERT[4], W.B. HOMOKY[2], Y.-T. HSIEH[1], M.B. KLUNDER[2], M.C. LOHAN[5], P. MARTIN[2], R.A. MILLS[2], A. MILNE[5], M.R. PALMER[6], R.J. SANDERS[2], A.L. THOMAS[1], B.D. WAKE[2], E.M.S. WOODWARD[7] AND THE UK-GEOTRACES CONSORTIUM.

[7]Plymouth Marine Laboratory

The UK-GEOTRACES Consortium aims to assess the balance of inputs of trace elements and isotopes from each of the four ocean boundaries (rivers, sediments, atmosphere, and volcanic) to the highly productive region along 40ºS in the Atlantic. Circumstances during the first UK-GEOTRACES cruise in late 2010 delayed completion of the full trans-Atlantic section, but allowed unexpected multiple occupation of key portions of the eastern third of the section, covering the Cape Basin. These multiple occupations significantly enhanced the realisation of one of the key objectives of the UK-GEOTRACES Consortium: observational quantification of the fluxes of trace metals to productive surface waters.

Vertical micro-profiler (VMP) measurements in the upper 500m of the water column provide constraints on both the vertical and off-shelf mixing of waters. Combined with measured gradients of trace elements, VMP data provide fluxes due to mixing. In the near-shelf, these can be compared with mixing derived from measurements of the Ra-isotope quartet in both surface and deeper waters.

Downward fluxes of trace elements were assessed using combined ^{234}Th and particle composition measurements, with repeat occupations allowing the commonly applied steady-state ^{234}Th approximation to be tested. Addition of trace elements from the atmosphere was also constrained by combining aerosol collection on ship, and relevant high resolution surface ocean chemistry (particularly ^{232}Th and Al concentrations).

In combination, these measurements provide an unusually firm set of constraints with which to quantify and balance the budget of trace elements, including the micronutrients, to the surface of a key open-ocean region.

Zinc and silicon isotope fractionation by deep-sea sponges

KATHARINE R. HENDRY[1], MORTEN B. ANDERSEN[2] AND LAURA ROBINSON[1,2]

[1]Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA 02540, USA

[2]Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queens Road, Bristol, BS8 1RJ

Dissolved Zn is an important micronutrient essential for the growth of marine phytoplankton, and exhibits a seawater depth profile similar to that of major nutrients, such as dissolved Si. Previous work has shown that diatoms Zn/Si ratios relate to the availability of free Zn^{2+} ions in surface seawater, and their Zn and Si isotopic composition relates to surface opal productivity and nutrient utilization. Conversely, the Zn/Si ratio of deep-sea sponge opaline spicules, among the earliest multicellular fossils to appear in the geological record, has been shown to related to the rain of Particulate Organic Carbon (POC). Here, we present a new calibration of sponge Si isotopes from different species and different ocean basins, showing a strong relationship between Si isotope fractionation and ambient dissolved Si concentrations. We also present new Zn concentration and isotope data from deep-sea sponges collected from the Southern Ocean. Our results highlight some species-specific differences in Zn uptake. The isotope data suggest, unlike for Si, sponges acquire some Zn from dietary sources, and some directly from seawater i.e. reflect both the dissolved and particulate pool of Zn. We discuss the consequences of these different uptake mechanisms for the use of sponge spicules as chemical palaeoenvironmental indicators.

Boron isotopes ($\delta^{11}B$) in coral: Energy budgets and pH control at the site of calcification

E. HENDY[1,2]*, T. MASS[3], I. BRICKNER[4] AND A. GENIN[5,6]

The rate of water flow around a coral colony has a dramatic effect on diffusive boundary layer thickness and thereby colony physiology and skeletal formation. A controlled flow rate experiment was used to test whether these responses to environmental conditions influenced skeletal $\delta^{11}B$ as a measure of the pH at the site of calcification. Coral nubbins of *Pocillopora verrucosa* were grown for 2 years on stages within a reef and exposed to one of two flow regimes; flow enhanced by underwater pumps (15-20 cm s^{-1}) or reduced-flow, near stagnant conditions (~ 1 cm s^{-1}). Colonies in the enhanced-flow condition developed a more compact morphology, denser skeleton and calcified faster, in addition they had significantly higher tissue protein and chlorophyll concentrations, a higher density of zooxanthellae and higher reproductive output in terms of both quantity of oocytes and their size. We will present MC-ICPMS $\delta^{11}B$ analyses of the skeletons to explore colony control of the pH at the site of calcification and the allocation of energy resources by coral to the fundamental processes of skeletogenesis, growth, maintenance and reproduction.

A key issue for reconstructing climate of the past is the need for accurate constraints on atmospheric concentration of CO_2. For timescales beyond the last 800 kyrs, further than the reach of the Antarctic ice cores, we have to rely on indirect proxy based estimates of CO_2. The boron isotope-pH proxy in foraminifera is gathering increasing momentum as a means to this end. This proxy has a firm theoretical grounding but tests of this understanding, with some recent exceptions [1], are restricted to a few culture based calibration studies (e.g. [2]). In this contribution we will present new attempts to calibrate the boron isotope pH proxy for *Globigerinoides ruber* – a surface dwelling tropical/subtropical species with symbiotic algae. We have cultured *G. ruber* at a range of pH values (8.2, 7.9, 7.6) and we will compare this data to published [3] and new core top data for this species. These data enable a determination of the pH sensitivity of $\delta^{11}B$ in *G. ruber* and provide valuable insights into the causes of "vital effects" that are known to influence the boron isotope system in planktonic foraminifera [2].

Comparison of XRF core scan data to conventional geochemical analyses: Usage in high resolution paleoenvironmental research

F.M. HENNEKAM* AND G.J. DE LANGE

Utrecht University, Faculty of Geosciences, Budapestlaan 4, 3508 TA, Utrecht, The Netherlands (*correspondence: hennnekam@geo.uu.nl)

Core scanning by X-ray fluorescence (XRF) is getting an increasingly common method to rapidly obtain paleo-environmental data from untreated (marine) sediments. A sediment surface is not an ideal substrate for XRF analysis; artifacts may occur relating to water content, grain size, surface roughness, water film formation, and sediment inhomogeneity. A high resolution analysis of an Eastern Mediterranean sediment core is used to get a grip on the signal-to-noise ratio of XRF core scan measurements. A suit of major elements (and elemental ratios), often used as paleoproxies, have been examined to indicate their relative correctness compared to 'real' data generated by both glass bead XRF and ICP-AES on distinct samples. Examples are shown to illustrate the consequences for the paleoproxy-interpretation.

XRF core scan data only reflects the chemical composition of a thin (few μm to hundreds of μm) layer of the sediment surface. The inhomogeneity in this surface can cause seemingly large paleoenvironmental variability. It is shown that (random) water rich spots can form underneath the Ultralene covering foil, having a substantial effect on the lighter elements with shallow response depths. This can create non-existing peaks in the XRF core-scan-produced paleoenvironmental record. Such deviations may especially occur for elemental ratios when elements are measured in different runs (e.g. other tube-voltage settings). This study promotes to verify certain high/low amplitudinal variability by means of a (destructive) conventional geochemical analysis prior to their interpretation.

Accidental release of radionuclides from mining activities, nuclear energy production, and radioactive waste storage sites requires research to predict the fate and mobility of these contaminants in the environment and more specific in organisms. To date, the interaction of actinides with biological systems is widely unkown, due to the lack of structural information on the molecular level. The aim of this presentation is to summarize recently explored coordination principles of tetravalent actinides with small carboxylic [1] and aminocarboxylic ligands as well as the interaction with proteins [2].

Tetravalent actinides form with carboxylate ligands in aqueous solutions at low pH values usually monomeric complexes. They show at the other hand a strong tendency toward hydrolysis already at low pH. As the pH reaches the onset of An(IV) hydrolysis, olation and oxolation occur as competing reactions to the carboxylate complexation. We observed under these circumstances the formation of several well-defined polynuclear species. The carboxylic group acts in such systems as a terminating ligand and stabilizes nanosized polynuclear clusters in solution and in the solid state [1]. It is important to note that this reaction prevents widely the formation of polynuclear hydrolysis species as well as the formation of An(IV) hydrous oxide colloids.

Geochemistry of cold seeps - Fluid sources and systematics

CHRISTIAN HENSEN[1]*, FLORIAN SCHOLZ[1], ANJA REITZ[1], VOLKER LIEBETRAU[1], MATTHIAS HAECKEL[1], MARK SCHMIDT[1], KLAUS WALLMANN[1] AND ROLF L. ROMER[2]

[1]Leibniz Institute of Marine Sciences, IFM-GEOMAR, Kiel, Germany (*correspondance: chensen@ifm-geomar.de)
[2]Deutsches GeoForschungsZentrum, Potsdam, Germany

Emanation of fluids at cold seeps, mud volcanoes, and other types of submarine seepage structures is a typical phenomenon occurring at continental margins worldwide. They represent pathways along which volatiles and solutes are recycled from deeply buried sediments into the global ocean, and hence they may be considered as a potentially important link in global geochemical cycles.

In this contribution we present geochemical data from various geological and tectonic settings such as the Gulf of Cadiz, the convergent margin off Central America, and/or the Black Sea and provide approaches how to systemize available data sets. Clay-mineral dewatering plays a central role in terms of fluid-mobilization from greater depth, however, resulting cold seep fluids are typically very different from each other and cover a large range of geochemical signatures. This is is due to variations in control parameters such as the type and thickness of the sediment cover, thermal conditions, extension of fluid pathways, and the potential for secondary overprinting. For example, freshened fluids emanating at cold seeps off Costa Rica indicate dewatering and related geochemical reactions in subducting sediments, while fluids sampled at mud volcanoes in the Gulf of Cadiz provide evidence for a high-temperature fluid source originating in the underlying oceanic basement. The latter finding provides evidence for a hydrological connection between buried oceanic crust and the water column even at old crustal ages.

Varius geochemical tracers were proposed in the past to decipher relevant processes in the subsurface. In a recent systematic study, Scholz *et al*. [1] demonstrated the general use of Li, reflecting the temperature-dependent isotope fractionation during early diagenetic Li uptake and burial diagenetic Li release from sediments. However, additional approaches are required in order to provide robust geochmical interpretations of cold seep fluids.

On organic synthesis reactions driven by serpentinization

M. HENTSCHER[1], W. BACH[1] AND F. KLEIN[2]

[1]University of Bremen, 28359 Bremen, Germany (hentscher@uni-bremen.de, wbach@uni-bremen.de)
[2]WHOI, Woods Hole, MA 02543, USA (fklein@whoi.edu)

Moderate temperature, alkaline fluids with high amounts of hydrogen and methane issue from the seafloor in oceanic core complexes [1]. These fluids contain low molecular weight organic molecules likely related to abiotic synthesis [2,3]. The amount of dihydrogen produced during serpentinization of mantle peridotite at elevated temperatures is the driver behind forming abiotic organic carbon species. Recent models of serpentinization [e.g., 4, 5] provide insights into the quantity of hydrogen which is produced at different temperatures and water-rock-ratios from variable lithologies. Based on these models, affinites for the synthesis of organic molecules during the serpentinization process were calculated.

Methane is predicted to be the dominate organic species, but its formation is known to be kinetically sluggish [6]. Preliminary results for different serpentinization scenarios show strong affinities in the overall reaction for hydrocarbons at low temperatures. These reactions are kinetically sluggish in aqueous solutions at low temperatures, and at higher temperatures, when rates are increased, the affinities decrease because less hydrogen is available from fluid-rock equilibrium. When the affinities of the overall reactions are normalized to electrons transferred, the highest affinities are predicted for formic acid, which is indeed elevated in fluids from the Lost City vent field [3].

Mixing of 350°C hydrothermal fluid from serpentinization systems with cold seawater also creates abundant driving force for organic synthesis [7l. As the time scales of mixing much exceed those at which abiotic organic synthesis reactions proceed, these environments generate an energetically feasible habitat for microbes. Affinity calculations for these environments allow an assessment of energy availability for catabolism, which can be coupled to anabolic energy demand to characterize the uniqueness of serpentinization systems.

Subsurface biogeochemistry of hydrothermal flow at the Hook Ridge, Bransfield Strait

L. HEPBURN[1]*, R.A. MILLS[1], A. AQUILINA[1], J.T. COPLEY[1], A. GLOVER[2] AND P. TYLER[1]

[1]National Oceanography Centre, Southampton, SO14 3ZH, UK (*correspondence: leh204@soton.ac.uk) (ram1@soton.ac.uk, aa@noc.soton.ac.uk, jtc@noc.soton.ac.uk, pat8@noc.soton.ac.uk)
[2] Natural History Museum, London, SW7 5BD, UK (a.glover@nhm.ac.uk)

Metalliferous sediments at active hydrothermal vent sites host significant populations of free-living and symbiotic chemosynthetic microorganisms associated with benthic fauna. Reduced hydrothermal fluids flow through the sediments and interact with oxic, overlying seawater to create steep redox gradients in the subsurface biosphere. The products of these redox reactions provide a suite of electron donors and acceptors that stimulate microbial metabolism and support chemosynthetic consortia of subseafloor micro-organisms. We are yet to fully understand the impact of macro-faunal and microbial communities on the geochemical flux of C, S, Fe, Mn and other elements across redox boundaries near the sediment-water interface. Here we present the pore-fluid and solid phase geochemistry of sediments from Hook Ridge – an extensive, high-temperature, hydrothermal system in the central Bransfield Strait, Antarctica [1].

Hook Ridge hydrothermalism is characterised by areas of shimmering water and water column E_h anomalies at a depth of 1100m. Ship-board and shore-based, analyses of extracted pore-fluids demonstrate the advection of low-chlorinity (<490 mM), high-sulfide (>120 μM), high-methane (>15 μM) and Fe-rich (>545 μM) fluids through the sediments, at rates of 20-50 $cmyr^{-1}$. Downcore sulfate-methane distributions suggest the presence of anaerobic oxidation of methane (AOM) at this site. These sediments are dominated by patches of the siboglinid chemosynthetic polychaete *Sclerolinum sp*. that likely contain sulfophilic chemosynthetic symbionts [2]. Faunal, mineralogical and geochemical analyses of Hook Ridge sediments are used to constrain the distribution and impact of the biogeochemical processes occurring in this sediment-hosted hydrothermal system.

Pilot-scale barrier system for removal of nitrate in mine drainage

ROGER HERBERT[1]* AND HARRY WINBJÖRK[2]

[1]Department of Earth Sciences, Uppsala University, 752 27 Uppsala, Sweden.
(*correspondence: Roger.Herbert@geo.uu.se)
[2]LKAB, 983 34 Malmberget, Sweden

Undetonated ammonium nitrate is readily soluble in water and quickly enters into the mine water and process water at a mine site. In order to investigate the application of nitrate removal by denitrification in the cold climate of northern Sweden, a pilot-scale barrier system was constructed of sheet metal in autumn 2009 at the Malmberget iron ore mine. The barrier (9m x 2m x 1.5m) appears as an open basin with three inner dividing walls, and is filled with a reactive mixture consisting of crushed rock, sawdust, and sewage sludge. Water flows through the barrier at ca. 0.45 m^3/hour.

The chemical analyses of water flowing into and out of the barrier during 2010 indicate that the degree of nitrate removal generally lay in the range between 11 and 77% of influent nitrate concentrations. Stable isotope analyses of $\delta^{15}N$ and $\delta^{18}O$ in nitrate demonstrate an enrichment in ^{15}N and ^{18}O in nitrate as water flows through the barrier, supporting the conclusion that denitrification is responsible for nitrate removal. Ammonium concentrations in the barrier effluents are initially high, but these high levels are subsequently flushed from the barrier.

In order to increase the degree of nitrate removal by denitrification in the barrier, a reactive carbon source needs to be added to the influent waters; this will be tested during the 2011 field season.

Temporal variations in Galápagos plume-ridge interaction at the Cocos-Nazca spreading center

A. HERBRICH[1]*, K. HOERNLE[1], F. HAUFF[1], R. WERNER[1] AND D. GARBE-SCHÖNBERG[2]

[1]Leibniz Institute of Marine Sciences IFM-GEOMAR, Wischhofstrasse 1-3, 24148 Kiel, Germany
(*correspondence: aherbrich@ifm-geomar.de)
[2]Inst. Geosciences, Christian Albrechts Universität zu Kiel, Ludewig-Meyn-Strasse 10, 24118 Kiel, Germany

The major goals of cruise SO208 with the German research vessel Sonne were to investigate 1) plume-ridge interaction through time at the Cocos-Nazca spreading center (CNS) north of the Galápagos Islands by sampling across axis profiles of the seafloor and 2) off axis volcanism at the East Pacific Rise (EPR) versus far field effects of the Galápagos hotspot documented in seamounts off the coast of N Costa Rica and Nicaragua. Overall the nature of material transfer from the plume to the ridge and its large scale distribution throughout the Eastern Pacific is beeing investigated by means of major and trace element and Sr-Nd-Pb (double spike) isotope data.

The seamounts on the EPR generated part of the Cocos plate appear to originate on one hand from a depleted MORB-like source consistent with their formation near the EPR axis, while other seamounts formed through lower degrees melting of an enriched OIB source either more distant from the EPR or by intraplate volcanism. Geochemical profiles across the Western and Eastern CNS indicate the participation of two different Galápagos plume components with a change in the amount this material entering the CNS with time. While at the western profile element ratios of more to less incompatible elements show an overall decrease of a plume component, Wolf-Darwin or Northern domain [1], with increasing age, the opposite is observed at the eastern profile. The Central domain component [1] increases with increasing age of the crust in this area. These observations indicate variable flux of specific Galápagos plume components to the CNS over the past 800 000 years. Sr-Nd-Pb isotope data to verify these observations are currently being generated and will be presented at the conference.

Secondary organic aerosol (SOA) comprises a major fraction of the submicron aerosol mass [1]. It consists of thousands of different compounds, and undergoes permanent chemical evolution during the atmospheric aging process, resulting in an increasingly oxidized aerosol [2]. As a result of this, chemical features of SOA (such as unit mass spectra from aerosol mass spectrometry) become increasingly similar with increasing aging time. This is good news for modeling purposes, as the specific SOA source becomes less important for the quantification of the SOA impact e.g. on climate. However, this also means that it is difficult to perform an apportionment of the SOA to its various sources, e.g., by positive matrix factorization [3]. We have investigated SOA formation from a variety of sources, including both combustion exhaust (with either the full exhaust or only the gaseous precursors) [4, 5], as well as anthropogenic and biogenic model precursors such as trimethylbenzene and α-pinene. We characterized the formed SOA using a high resolution time-of-flight aerosol mass spectrometer. The various fragments obtained from the high-resolution spectra were tested for characteristic differences using a variety of methods. The results will be discussed along with a comparison to high-resolution aerosol mass spectra from ambient samples.

How does the slab component get across the mantle wedge?

JÖRG HERMANN[1] AND CASSIAN PIRARD[2]

[1]Research School of Earth Sciences, The Australian National University, 0200 Canberra, (joerg.hermann@anu.edu.au)

[2]Department of Petrology, Vrije Universiteit Amsterdam, 1081HV Amsterdam, (cassian.pirard@falw.vu.nl)

Arc lavas are enriched in volatiles, LILE and LREE with respect to MORB. This enrichment is attributed to mantle metasomatism by a slab-derived fluid phase (slab component). There has been great progress in the last years to constrain the nature and composition of this fluid phase. The slab fluid is in disequilibrium with the mantle wedge and the way how it reacts with peridotites is crucial for understanding subduction recycling of volatiles and trace elements. In this contribution, evidence from natural rocks and experiments are presented to constrain the nature and extent of mantle wedge metasomatism by slab-derived fluids.

Contacts between felsic and ultramafic rocks in high- and ultrahigh-pressure terrains can be used as proxies for processes acting at fore-arc (50-80 km) and sub-arc depth (80-120 km), respectively. Interaction of aqueous fluids released from felsic rocks at for-arc conditions (P=10-20 kbar, T ~600°C) with peridotites leads to metasomatic rinds that are rich in talc, amphibole and phlogopite. Phlogopite sequestres most of the LILE and thus residual fluids are very dilute. At higher pressures and temperatures, interaction of hydrous melts with peridotites produces garnet and orthopyroxene and minor phlogopite and residual fluids show some enrichment of LILE and LREE.

Experiments were designed to constrain interaction of a slab-derived hydrous melt with harzburgites during porous and channel flow. The porous flow experiments produced a highly metasomatized peridotite consisting of amphibole, phlogopite, olivine, orthopyroxene and an aqueous fluid at subsolidus condition. Amphibole and phlogopite host significant amounts of LREE and LILE, respectively. The wet solidus in this metasomatised mantle wedge peridotite is at 900°C at 25 kbar and at 950°C at 35 kbar. The extent of mantle metasomatism in layered experiments, mimicking channel flow, is minimal. At the interface between the slab melt and olivine a small ~200μm wide layer of garnet-orthopyroxenite forms that shields the melt from further interaction with the olivine grains. Most importantly, no phlogopite and amphibole have been observed in all such experiments. Therefore, data from natural rocks and experiments indicate that channel flow appears to be the most efficient way to transfer trace elements from the top of the slab to the locus of partial melting in the mantle wedge.

Reactive fluid flow and time-integrated fluxes in an upper crustal magmatic-hydrothermal system, Krušné hory Mts., Central Europe

MATYLDA HEŘMANSKÁ* AND DAVID DOLEJŠ

Institute of Petrology and Structural Geology, Charles University, 128 43 Praha 2, Czech Republic (*correspondence: matylda.h@seznam.cz)

Advances in thermodynamic modeling of fluid-mineral interactions at elevated temperatures and pressures permit calculation of time-integrated fluid fluxes in metamorphic complexes and shear zones using inversion of mineral reaction progress and application of local equilibrium. Such estimates may, however, only provide an upper bracket on the integrated fluid flux when the incoming fluid is out of equilibrium with the host lithology. We extended the transport theory to account for effects of thermal and pressure gradients and chemical disequilibrium simultaneously, and apply it to greisen alteration in the Western Krušné hory granite pluton (central Europe). Veins and swarms of fracture-controlled greisens up to 400 m long and 800 m deep show the following spatial alteration zoning (from margin to interior): greisenized granite, muscovite-quartz greisen, topaz-quartz greisen, pure quartz greisen, and hydrothermal quartz vein. Greisen textures and distribution of relics of magmatic quartz phenocrysts suggest that greisenization was a constant-volume replacement process. We modeled set of infiltrating fluids, from 650 °C and 1 kbar (magmatic fluid phase exsolving at the solidus) to 400 °C and 500 bar (greisen formation). The corresponding time-integrated fluid fluxes vary from 10^2 to 10^6 m^3 fluid m^{-2} rock, dictated by chemical disequilibrium whereas pressure and temperature gradients have subordinate effects. Successive replacement of feldspar by muscovite and topaz under conserved volume constrains the time-integrated fluid flux to $0.2\text{-}1.0\cdot10^3$ m^3 fluid per m^2 rock. The formation of a single greisen vein with a typical volume of $0.1\text{-}5\cdot10^4$ m^3 would require $0.01\text{-}3.10^7$ m^3 aqueous fluid. For a characteristic vein length (transport distance) of 400-800 m, the plausible fluid flow rate is 10^{-10} to 10^{-9} $m.s^{-1}$. By using mass balance and an assumed 5 wt. % H_2O dissolved in a granitic magma, such amount of fluid phase would have exsolved from 5.10^5 to 3.10^8 m^3 magma or an intrusion measuring $0.8\text{-}7\cdot10^2$ m in each dimension, which is comparable with dimensions of the host granitic pluton. Our results indicate that strong alterations may be produced by integrated fluid fluxes that are by 2-3 orders of magnitude lower than those in metamorphic shear zones.

Fluid and trace element migration in subducted oceanic rocks from Ecuador

P. HERMS[1]*, T. JOHN[1,2], R. J. BAKKER[3] AND V. SCHENK[1]

[1]Institut für Geowissenschaften and SFB 574, Universität Kiel, 24098 Kiel, Germany (*correspondence:ph@min.uni-kiel.de, vs@min.uni-kiel.de)

[2]Institut für Mineralogie, Universität Münster, 48149 Münster, Germany (timm.john@uni-muenster.de)

[3]Department Applied Geosciences & Geophysics, Mineralogy & Petrology, University of Leoben, 8700 Leoben, Austria (Ronald.Bakker@mu-leoben.at)

The ophiolite association of the Raspas complex in Ecuador, representing subducted oceanic lithosphere, stands out by high-pressure zoisite veins and associated metasomatized zoisite eclogites, indicating fluid flow and element mobility at depth of about 60 km. Fluid inclusion investigations in vein zoisite and metasomatized zoisite eclogites reveal a homogeneous low-salinity fluid composition in the system H_2O-NaCl-CH_4-CO_2 which is conform with an open-system fluid infiltration derived from an external source. Deserpentinized, pseudo-spinifex textured chlorite harzburgites found within the ultramafitites of the Raspas Complex are a potential source for the external CH_4-bearing low-salinity aqueous fluid. However, the enrichment in LREE, MREE, Pb, Sr, Th, U, found in the metasomatically overprinted seafloor-altered MORB-type eclogites and in zoisite veins can be explained best by leaching of these elements from metabasites and metapelites in zones of intense fluid-rock interaction. A garnet-amphibole rock, deficient in LREE and Sr, could represent such a leached metabasite. Other LIL elements, as well as B, Th and U could be derived from metapelites. All the elements enriched in the metasomatized eclogites and zoisite veins must have been fluid mobile at eclogite-facies conditions and transported by channelized fluid flow and high fluid flux.

Biogeochemical characterization of contaminant Mn sequestration

ELIZABETH M. HERNDON[1]*, DAVID EISSENSTAT[2], CARMEN ENID MARTINEZ[3] AND SUSAN L. BRANTLEY[1,4]

[1]Dept. of Geosciences, Penn State University, University Park, PA, USA 16802 (*eherndon@psu.edu)
[2]Dept. of Horticulture, Penn State University
[3]Dept. of Crop and Soil Sciences, Penn State University
[4]Earth & Environ. Systems Institute, Penn State University

Manganese contamination in soils is prevalent in industrialized regions. Over the past few centuries, large quantities of Mn have been extracted from the lithosphere, emitted to the air via anthropogenic activities, and redeposited to the Earth's surface. In order to evaluate environmental impacts of Mn deposition, we must better understand the biogeochemical behaviours of Mn in soils. Vegetation can act as an element "capacitor", storing large quantities of Mn and releasing it slowly into the environment over time. Here, we quantify mass fluxes of Mn amongst soil, vegetation, and pore fluid reservoirs in field and greenhouse experiments. We find that much greater quantities of Mn are taken up by vegetation than leached into pore fluids each year, preventing Mn loss from the soil system.

Characterization of Mn-compounds in the environment is often limited by their high reactivity and poor crystallinity; however, synchrotron source radiation can be used to map the microscale distribution of Mn (X-Ray Fluorescence) and identify its chemical state (X-ray Absorption Spectroscopy) in environmental samples. We use XRF and XAS to characterize the spatial abundance and chemical forms of Mn in mineral soil, organic soil, and tree leaf samples from both the field and a controlled greenhouse experiment. XRF analysis of leaves from trees exposed to high Mn reveals that the Mn is concentrated in visible dark spots, the key indicator of Mn toxicity in vegetation. XAS results indicate that Mn is present as an organically-complexed Mn^{+3} compound in vegetation and as mixed-valence oxides ($Mn^{+3/+4}$) in organic and mineral soils. Vegetation has previously been thought to contain primarily Mn^{+2} due to the instability of the trivalent ion. The dominance of Mn^{+3} in foliage would change current perceptions of biogeochemical Mn cycling and has implications for litter decomposition, a process that often uses Mn^{+3} as a catalyst. The presence of Mn-oxides in soil organic matter is consistent with the rapid oxidation of Mn released from foliage during decomposition. High rates of Mn uptake into vegetation, combined with accumulation of solid-phase Mn in the soil, effectively increases the residence time of Mn in contaminated systems.

Simulations of glacial/interglacial cycles with simple box-models: Key triggers for deglaciations

C. HERRERO*, A. GARCÍA-OLIVARES AND J. L. PELEGRÍ

Institut de Ciències del Mar (ICM-CSIC). Pg. Marítim de la Barceloneta, 37-49, 08003 Barcelona, Spain (*correspondence: herrero@icm.csic.es)

García-Olivares *et al*. [1] have calibrated Paillard's model [2] to obtain a best fit with experimental time-series of $\delta^{18}O$ and CO_2 available for the last 800 kyr.

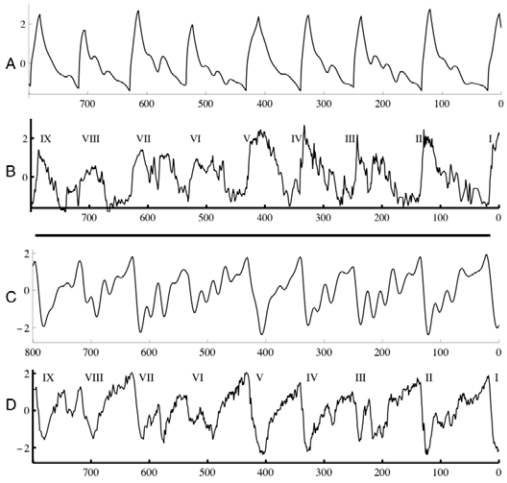

Figure 1. CO_2 predicted by the model (A) and experimental time-series [3] (B). Ice Volume V predicted by the model (C) and $\delta^{18}O$ experimental time-series [4] (D).

We discuss how the physical pump and, to some extent, the density of Antarctic deep water, may be important factors controlling the oceanic pulse that triggers deglaciations. Specifically, an increase of sea ice coverage during a glaciation may modulate the annual net heat gain of the Southern Ocean surface, and a reduction of the deep mixing rate would limit the upwelling of CO_2 enriched deep water, thus being key factors for triggering deglaciations.

Thermodynamic principles of soil organic matter decomposition in a changing world

A.M. HERRMANN[1]*, S.M. GRICE[1,2], K. RITZ[2] AND J.A. HARRIS[2]

[1]Uppsala BioCentre, Swed. Univ. Agric. Sci., 75007 Uppsala, Sweden (*correspondence: Anke.Herrmann@slu.se)
[2]School of Applied Sciences, Cranfield University, U.K.

The role of soils in governing the terrestrial carbon balance is acknowledged as being important but remains poorly understood within the context of climate change. Soils exchange energy with their surroundings and are therefore open systems thermodynamically, but little is known how energy transformations of decomposition processes are affected by temperature. Soil organic matter and the soil biomass can be conceptualised as analogous to the 'fuel' and 'biological engine' of the earth, respectively, and are pivotal in driving the belowground carbon cycle.

Thermodynamic principles of soil organic matter decomposition were evaluated by means of isothermal microcalorimetry (TAM Air, TA Instruments, Sollentuna Sweden: (i) Mineral forest soils from the Flakaliden long-term nitrogen fertilisation experiment (Sweden) were amended with a range of different substrates representing structurally simple to complex, ecologically pertinent organic matter and heat signatures were determined at temperatures between 5 and 25°C. (ii) Thermodynamic and resource-use efficiencies of the biomass were determined in arable soils which received contrasting long-term management regimes with respect to organic matter and nitrogen since 1956.

The work showed that (i) structurally labile components have higher activation energy and temperature dependence than structurally more complex organic components. This is, however, in contrast to the thermodynamic argument which suggests the opposite that reactions metabolising structurally complex, aromatic components have higher temperature dependence than reactions metabolising structurally more labile components. (ii) Microbial communities exposed to long-term stress by heavy metal and low pH were less thermodynamic efficient and showed a decrease in resource-use efficiency in comparison with conventional input regimes. Differences in efficiencies were mirrored in both the phenotypic and functional profiles of the communities.

We will present our findings illustrating the capacity of isothermal microcalorimetry to evaluate temperature dependencies of soil organic matter decomposition, associated energy transformations and thermodynamic principles in soil ecosystems.

Compositional and structural dynamics of dissolved organic matter in Taihu lake, China

NORBERT HERTKORN*[1], FENFEN ZHANG[2], PHILIPPE SCHMITT-KOPPLIN[1], AGNES FEKETE[1], ANDRAS GASPAR[1], YING WU[2] AND JING ZHANG[2]

[1]Institute of Ecological Chemistry, Helmholtz Zentrum München, German Research Center for Environmental Health, Ingolstaedter Landstrasse 1, D-85764 Neuherberg, Germany (hertkorn@helmholtz-muenchen.de)
[2]State Key Laboratory of Estuarine and Coastal Research, East China Normal University, 3663 North Zhongshan Road, 200062 Shanghai, P.R. China

Lake Tai (Taihu) near Shanghai / China experiences with a surface area of 2250 square kilometers and a remarkable average depth of only 1.9 m pronounced seasonal variance in climate conditions, biodiversity and composition of dissolved organic carbon (DOC). High resolution organic structural spectroscopy (high field NMR and FTICR mass spectrometry) revealed a remarkable seasonal variation of DOC composition and structure throughout all structural regimes which nevertheless followed the seasonal cycles. Taihu DOC showed variable contents of abiotic molecules and biosignatures; however, the time-dependent individual molecular signature of Lake Taihu DOM was likely dominated by microbial metabolism rather than abiotic chemistry. Non-target high-resolution organic structural spectroscopy offers opportunities to considerably improve the significance of future functional biodiversity studies which might lead to a novel unified perception of biodiversity and biogeochemistry.

Quantifying the $[Ba^{2+}]$: $\delta^{18}O_{SEAWATER}$: surface salinity relationship in the Eastern Equatorial Pacific

J.E. HERTZBERG* AND M.W. SCHMIDT

Department of Oceanography, Texas A&M University, College Station, TX 77843, USA (*correspondence: jhertzberg@ocean.tamu.edu)

Fluvial inputs to the world's oceans serve as the main source for dissolved barium in seawater. Barium desorbs from suspended clays in freshwater, making riverine water enriched in $[Ba^{2+}]$ [1, 2]. The suspended clays flocculate when riverine water mixes with seawater in estuaries, resulting in a conservative linear mixing between high $[Ba^{2+}]$, low sea surface salinity (SSS) in estuaries and low $[Ba^{2+}]$, high SSS in open ocean waters. Therefore, SSS can be estimated from dissolved barium concentrations in regions influenced by high riverine input. Furthermore, planktonic foraminifera incorporate barium into their calcium carbonate tests in proportion to seawater Ba/Ca ratios [3, 4]. Thus, foraminiferal Ba/Ca ratios from ocean sediment cores can be employed as a proxy for paleosalinity reconstructions. However, integral to the use of this proxy is the quantification of the regional seawater Ba/Ca:SSS relationship. Here, we quantify this relationship for the eastern equatorial Pacific Ocean, a location where intense seasonal rainfall and high riverine input from Central and northern South America creates the sharpest SSS gradient in the modern tropics. In October and November of 2010, surface seawater samples were collected along 85°W in a latitudinal transect from 10°N to 8°S during the RV *Melville* cruise MV1014, and analyzed for SSS, Ba/Ca ratios, and $\delta^{18}O$. For salinities < 31.4, we find a large change in Ba/Ca of 8.02 µmol/mol per salinity unit, while for salinities > 31.4 the relationship levels off at a Ba/Ca ratio of 4.5 µmol/mol. Based on the $\delta^{18}O$:SSS relationship in our samples, we also find two distinct end members of freshwater input to the region, one with a Costa Rican riverine $\delta^{18}O$ end member of -10.0‰ for salinities up to 31.4 and one with a freshwater end member of -7.2‰ dominated by freshwater precipitation for salinities > 31.4. This indicates that the Ba/Ca:SSS relationship for salinities < 31.4 is indeed driven by regional fluvial inputs. We will also present new reconstructions of regional SST and SSS based on a new set of multicores collected from the Cocos and Carnegie Ridges.

REE in fossil biogenic apatite

D. HERWARTZ[1]*, T. TÜTKEN[1], KP. JOCHUM[2] AND P.M. SANDER[1]

[1]Steinmann Institut, Universität Bonn, Poppelsdorfer Schloss, 53113 Bonn, Germany

[2]Max-Planck Institut für Chemie, Becherweg 27, 55128 Mainz, Germany

Rare earth elements (REE) in fossil biogenic apatites are frequently used as palaeonevironmental proxies, because the in-vivo REE concentrations (lower ppb range) are efficiently overprinted by diagenetic post-mortem REE uptake (in the ppm range) especially in fossil bone and dentin. The post-mortem REE uptake was long assumed to be limited to the fossilisation process, were carbonate hydroxyl-apatite is transformed into a more stable fluor-apatite, organic components are degraded and the porosity is filled by secondary minerals. However, recent studies reveal that REE uptake takes place over prolonged timescales in the order of millions of years, rather than thousands of years [1,2]. Furthermore, substantial intra-bone fractionation of the REE is observed, even exceeding two orders of magnitude in $(La/Sm)_N$ and $(La/Yb)_N$ within single bone specimens [2]. These observations necessiate a deeper understanding of REE with respect to fossil bones, if this group of elements is to be used as a palaeoenvironmental proxy in the future.

We will present REE profiles measured by LA-ICPMS over individual fossil bone samples from a wide range of diagenetic settings, ranging from Lower Triassic to Holocene age. Key observations are (1) MREE are efficiently scavenged at the outer bone rim and are increasingly depleted towards the central bone; (2) negative Ce-anomalies develop with increasing distance from the outer bone rim, which have no environmental significance; and (3) positive La and superchondritic Y/Ho anomalies evolve with increasing distance from the bone rim and decrease again towards the marrow cavity. A comparison with literature data indicates that (1) fossil bones derive their REE budget from the ambient pore fluid, rather than surface waters; and (2) that individual fossil bones may have intra-bone $(La/Sm)_N$ and $(La/Yb)_N$ variability covering more than half of the range previously found in literature compilations [n = 1691; 3]. Our data implies, that HREE are generally more mobile in diagentic fluids, which is likely due to stronger complexation of HREE with carbonate ions, when compared to the LREE.

Heavy isotope fractionation in magmatic systems: The example Tl

K. HETTMANN[1]*, K. KREISSIG[2], E. SCHAUBLE[3], M. REHKÄMPER[2], M. MARKS[1] AND G. MARKL[1]

[1]Eberhard Karls Universität Tübingen, Wilhelmstrasse 56, 72072 Tübingen, Germany (*correspondence: kai.hettmann@uni-tuebingen.de)
[2]Dept. of Earth Science & Engineering, Imperial College London, SW7 2AZ London, United Kingdom
[3]University of California, Los Angeles, 595 Charles Young Drive East, Los Angeles, CA 90095-1567, USA

Variations in the isotopic composition of heavy isotopes are not expected to occur by mass-dependent fractionation in high-temperature systems, since relative mass differences are very small (e.g. < 1% for Tl) and the fractionation scales with $1/T^2$ [1]. In contrast, the mass-independent fractionation due to differences in the nuclear volume between isotopes generally increases with atomic number and scales with 1/T [2].

In this study we show that isotopic fractionation of Tl occurs in the peralklaline Ilimaussaq intrusion, southwest Greenland. We studied magmatic and hydrothermal amphiboles and astrophyllite, which is a rare amphibole-related mineral. The isotopic compostion of Tl varies systematically with increasing magmatic differentiation. The most differentiated rocks show the largest variations, which are most probably related to fluid unmixing from the late-stage magma, as shown in previous studies [3]. Late-stage magmatic and hydrothermal minerals exhibit contrasting isotopic compositions, with isotopically light Tl in the magmatic samples and heavier Tl in the hydrothermal rocks. Post-magmatic hydrothermal alteration affected a single sample and produced the heaviest observed Tl isotope composition. Overall, the rocks of the Ilimaussaq intrusion thus display a variability of 1‰ in the $^{203}Tl/^{205}Tl$ isotope ratio as a results of fractionation that occurred at temperatures of between 250 and >1000°C [4].

In addition to this study of natural samples, we will carry out ab-initio modelling of the isotopic fractionation of Tl due to mass-dependent and –independent effects to enhance the existing knowledge [5] of the importance of non-classical fractionation processes in high-temperature systems.

Tracing water masses with radiogenic isotopes: Water column and Fe-Mn crust records from the eastern equatorial Pacific Ocean

L. HEUER[1]*, M. FRANK[1], A. EISENHAUER[1] AND M. CHRISTL[2]

[1]IFM-GEOMAR, Wischhofstr. 1-3, 24148 Kiel, Germany (*correspondence: lheuer@ifm-geomar.de)
[2]Laboratory of Ion Beam Physics, ETH Zurich, Switzerland

The radiogenic isotope compositions of neodymium (Nd) and lead (Pb) have been shown to be effective tracers for continental weathering inputs and in the case of Nd, due to its quasi-conservative behavior, also for present and past ocean circulation.

We present the first full water depth profiles of dissolved Nd isotopes and concentrations from the eastern equatorial Pacific. Time series of past deep water Nd and Pb isotope compositions were obtained from a Mn nodule, as well as from two Fe-Mn crusts that grew on the flank of a seamount at different water depths (4000-3500 m; 3500-3000 m). We also present a comparison of vertical and horizontal time series obtained from a discoidal Mn nodule. The ages of the crusts and the nodule were derived from $^{10}Be/^{9}Be$ chronology. Growth rates are on the order of 3-6 mm/Myr for the crusts and much higher at 24-46 mm/Myr for most of the nodule.

Nd concentrations of the unfiltered water samples range from 8 to 58 pmol/kg and show a systematic increase with water depth caused by scavenging processes. Compared with previous data the deep water concentrations at around 4000 m yield exceptionally high values greater than 50 pmol/kg.

The seawater Nd isotope compositions (εNd) vary between -5 at depth and +1 near the surface. While surface waters are primarily influenced by the weathering inputs from young volcanic rocks (radiogenic εNd signatures) the deep water signatures are influenced by admixture of Circumpolar Deep Water (unradiogenic εNd signatures), which spreads northwards into the Pacific Ocean. The deep water Nd isotope signatures at 4000 m water depth (εNd = -3.5) corresponds well to the signatures measured for surface layers on a Fe-Mn crust and a nodule from the study area. This demonstrates that the present day bottom water at this site has been dominated by modified North Pacific Deep Water rather than of less radiogenic Antarctic Bottom Water (εNd=-8).

Calcium isotopes in human urine under simulated microgravity conditions

A. HEUSER[1]*, P. FRINGS-MEIUTHEN[2], J. RITTWEGER[2], AND S.J.G. GALER[3]

[1]Steinmann-Institut, Universität Bonn, Bonn, Germany (*correspondence: aheuser@uni-bonn.de)
[2]Institute of Aerospace Medicine, German Aerospace Center (DLR), Köln, Germany
[3]Max-Planck-Institut für Chemie, Abteilung Biogeochemie, Postfach 3060, 55020 Mainz, Germany

Living under microgravity in space leads to a migration of bodily fluids into the upper parts of the body and mechanical unloading of the weight-bearing muscles and bones. The latter results in bone loss, which remains a key physiological issue for astronauts during long-duration space flights. Many of the physiological effects of microgravity can be simulated on Earth by a head-down-tilt bed rest (HDTBR) study, in which the head is tilted down at 6° during prolonged bed rest.

In order to evaluate the response of Ca metabolism during HDTBR, we analyzed the Ca isotopic composition of urine taken at different phases of such a study. This involved 7 test subjects, and consisted of two sessions, of 35 days each, comprising four phases: adaptation, bed rest, inpatient and outpatient regeneration.

The Ca isotopic composition of urine reflects a balance between bone loss and bone gain and/or kidney function [1]. During bone gain, blood gets enriched in heavy Ca, while during bone loss, light Ca is released from bones into the blood without further fractionation, and passes into the urine from the blood via the kidneys.

Preliminary data show that large differences of about 0.8‰ exist in the Ca isotopic composition ($\delta^{44/42}$Ca) of urine between subjects, which reflect individual Ca metabolism. The time-evolution of $\delta^{44/42}$Ca during the course of the study is similar for all subjects, however. During the adaptation phase, $\delta^{44/42}$Ca increases and reaches a peak at the beginning of the bed-rest phase. This can be explained in terms of a changed diet. During the bed rest period, $\delta^{44/42}$Ca decreases and returns to values seen at the start of this phase. This decrease indicates that loss of bone mass takes place during the bed-rest period, and persists during the early regeneration phase. Towards the end of outpatient regeneration, $\delta^{44/42}$Ca increases, returning to values at the study onset, closing the overall cycle.

This study confirms that Ca isotopes in urine are a valuable noninvasive tool for investigating Ca metabolism in humans, and presumably other vertebrates as well, whether or not the body is functioning normally or adapting to new, imposed conditions.

The origin of an oceanic plateau: Isotope geochemistry (Sr, Nd, Pb and Hf) of volcanic rocks from IODP Site U1347 on the Shatsky Rise (Northwest Pacific)

K. HEYDOLPH[1]*, J. GELDMACHER[2] AND K. HOERNLE[1]

[1]IFM-GEOMAR, Wischhofstr. 1-3. D-24148 Kiel, Germany, (*correspondence: kheydolph@ifm-geomar.de)
[2]Integrated Ocean Drilling Program, Texas A&M University, 1000 Discovery Drive, College Station, Texas 77845-9547 (geldmacher@iodp.tamu.edu)

The submarine Shatsky Rise plateau is a unique large igneous province (LIP) in the northwest Pacific Ocean ca. 1500 km east of Japan. It is the only large intraoceanic plateau, which formed during the Late Jurassic to Early Cretaceous at a time period with numerous reversals of the Earth's magnetic field. The magnetic reversals combined with bathymetric data allow a detailed reconstruction of the tectonic history. Accordingly the three main volcanic edifices Tamu, Ori and Shirshov massifs formed by massive volcanism during a short time span along a southwest - northeast trending, rapidly spreading triple junction. Therefore, the magnetic and bathymetric data suggest that the Shatsky Rise formed through the interaction of a mantle plume head with a ridge [1, 2].

We present new Sr-Nd-Pb and for the first time Hf isotope data from volcanic rocks of relatively fresh basaltic lava flows from the southernmost drill site U1347 on Tamu massif. Initial ^{176}Hf/^{177}Hf and ^{143}Nd/^{144}Nd isotopic compositions are fairly uniform throughout the entire hole ranging between 0.283076 to 0.283100 and 0.512909 to 0.512981 respectively, showing neither distinct MORB nor intraplate (plume) affinity. Relatively unradiogenic ^{87}Sr/^{86}Sr data ranging from 0.70276 to 0.70296 mostly overlaps with Pacific MORB like values. Combined Nd and Hf isotopic compositions form a tight cluster at the edge of the Pacific MORB field below the present-day Hf-Nd mantle array. Although initial Pb double spike $^{206/204}$Pb and $^{208/204}$Pb isotopic compositions range from 18.13 to 18.46 and 37.71 to 37.96 respectively and overlap with MORB-like compositions, they trend towards more intraplate-like values. Whereas combined initial Pb double spike $^{207/204}$Pb and $^{206/204}$Pb and Hf values form clusters within the Pacific MORB field.

Iron isotopes and komatiites: Implications for mantle oxygen fugacity

KATE HIBBERT[1]*, HELEN M. WILLIAMS[1,2], ANDREW KERR[3] AND IGOR PUCHTEL[4]

[1]Department of Earth Sciences, University of Oxford, South Parks Road, Oxford, UK (*correspondence: kate.hibbert@bristol.ac.uk)

[2]Department of Earth Sciences, Durham University, Durham, UK

[3]School of Earth and Ocean Sciences, Cardiff University, Park Place, Cardiff, Wales

[4]Department of Geology, University of Maryland, College Park, MD 20742, USA

Due to the high degrees of partial melting involved in komatiite genesis, komatiites provide a unique insight into the mantle. We report iron isotope data for 3 exceptionally preserved komatiite localities ranging from 2.7Ga to 90Ma, which enable a study of mantle fO_2 and melting processes over this time period. Data is presented both for whole-rocks and mineral separates. Whole-rock δ^{57}Fe values range from -0.23 to 0.34‰. Olivine samples are consistently lighter than corresponding whole-rocks (δ^{57}Fe = -0.47 to -0.11‰). Pyroxene samples range from δ^{57}Fe = -0.16 to 0.41‰.

Consistent with previous findings [1] iron isotope data for all localities correlate with proxies of partial melting. The highest degree partial melts show the lightest iron isotope compositions ($\delta^{57/54}$Fe = -0.23‰). This trend is also observed for olivine separates from the same samples. Consequently no simple relationship exists between the iron isotope composition of komatiites and the bulk silicate earth (BSE) value.

Furthermore we show that whole-rock iron isotope data correlate with V/Sc and propose that this effect is not due to crystal fractionation, but rather due to oxygen fugacity. The relatively incompatible behaviour of vanadium compared to scandium demonstrates that the komatiite source is relatively oxidising. As a result we are able to show that the variations in iron isotopes measured were created by partial melting in relatively oxidising conditions. It is further shown that there is no marked difference between 90Ma and 2.7-2.4Ga komatiites suggesting little or no change in mantle fO_2 from the late Archean to the present day.

A depth transect of four 25 kyr ^{231}Pa/^{230}Th records from the Argentine Basin: Assessing southern component flow rates

B.J. HICKEY[1]*, G.M. HENDERSON[1], A.L. THOMAS[1], J.W.B RAE[1], C. CHIESSI[2] AND S. MULITZA[2]

[1]Department of Earth Sciences, University of Oxford, UK (*correspondence: benh@earth.ox.ac.uk)

[2]Department of Geosciences, University Of Bremen, Germany

We present ^{231}Pa/^{230}Th data from a suite of cores along a depth transect in the Argentine Basin, to reconstruct water mass distribution and circulation histories of southern component water masses for the last 25 kyr .

Opal and particle flux data from these cores show little correlation with ^{231}Pa/^{230}Th values meaning that changes in ^{231}Pa/^{230}Th cannot be explained by a local composition or particle flux effect and are instead likely to be reflecting changes in circulation.

A core bathed by AAIW throughout the last 25 kyrs (GeoB 2107, 1048 m), has relatively high ^{231}Pa/^{230}Th values (0.075) during the Holocene and distincly lower values (0.055) at the LGM suggesting faster AAIW transport during the last glacial. At greater depths, ^{231}Pa/^{230}Th and δ^{13}C data in core GeoB 2109 (2504 m) indicate a change in both circulation and water mass distribution on glacial-interglacial timescales, with moderate flow of AABW at the LGM being replaced by more vigorous flow of NADW during the Holocene.

On millenial timescals, ^{231}Pa/^{230}Th values in deep cores GeoB 2109 and GeoB 2112 (4010 m) indicate enhanced production of AABW during northern hemisphere stadials, when ^{231}Pa/^{230}Th records are of opposite signal between hemispheres, supporting a possible bipolar seesaw relationship in deep water formation between hemispheres. These data indicate that the ^{231}Pa/^{230}Th proxy can be used to reconstruct past flow rates of multiple water masses in the Argentine Basin and provide evidence that southern source water masses play a dynamic counterpart to NADW formation on abrupt as well as glacial-interglacial timescales.

Evaluating $^{238}U/^{235}U$ in U-bearing accessory minerals: Implications for U-Pb geochronology

J. HIESS*[1], D.J. CONDON[1], S.R. NOBLE[1], M.S.A. HORSTWOOD[1], N. MCLEAN[2] AND J.M. MATTINSON[3]

[1]NERC Isotope Geoscience Laboratory, BGS, Keyworth, UK (*correspondence: jies@bgs.ac.uk)
[2]EAPS, Massachusetts Institute of Technology, MA, USA
[3]DES, University of California, Santa Barbara, CA, USA

U-daughter (U-Pb, Pb-Pb, and U-series) geochronology and cosmochronology utilise the value of the present day $^{238}U/^{235}U$ ratio to calculate U/Pb and Pb/Pb isotopic dates. For decades, this value has been assumed to be invariant and equal to 137.88, but recent experiments indicate that there is potential for per mil level variation in $^{238}U/^{235}U$ in natural materials, hypothesized to be the result of redox reactions. These studies have largely focused on materials formed in low-temperature environments (e.g. speleothems, corals) and U ore deposits. At present there is no published high-precision $^{238}U/^{235}U$ data for U-bearing accessory minerals commonly used for U-Pb geochronology.

We present $^{238}U/^{235}U$ determinations (total uncertainties of ~200 ppm) for a suite of common U-bearing accessory minerals (zircon, monazite etc.), from a variety of geological environments and ages. Measurements have been made by multi-collector thermal ionization mass spectrometry (MC-TIMS) and multi-collector inductively coupled plasma mass spectrometry (MC-ICPMS), accurately correcting for mass fractionation using the IRMM 3636 ^{233}U-^{236}U double spike. These results indicate that accessory mineral $^{238}U/^{235}U$ ratios are in general lower than the 'consensus' value of 137.88 and record limited but resolvable variation.

Systematic discordance has been observed between ^{238}U-^{206}Pb and ^{235}U-^{207}Pb dates for closed-system minerals, and has been used to reassess the relative decay constants of ^{238}U and ^{235}U [1,2,3]. Our new determination of coupled $^{238}U/^{206}Pb$, $^{235}U/^{207}Pb$ and $^{238}U/^{235}U$ measurements on closed system zircons permits further refinement of $\lambda^{238}U/\lambda^{235}U$ estimates using parameters whose values and uncertainties are all traceable to SI units.

[2]Centre for Atmospheric Science, University of Manchester, Manchester, UK
[3]Now at Colorado State University, USA
[4]Formerly at Department of Meteorology, University of Reading, UK.

Overview

Aerosols have played a major role in past climate change, and it is likely that they will continue to do so in the future. Although our understanding of the underlying physical processes has improved over recent years, the mechanisms by which they affect climate are still more uncertain than those relating to well mixed greenhouse gases. This overview talk will discuss the various ways in which atmospheric aerosols can interact with radiation thereby producing a climate forcing and initiating a climate response.

Examples used

1) The optical properties and direct effect of Saharan dust from aircraft measurements and models
2) Optical closure studies for aerosol in anthropogenically perturbed air masses and the influence of uncertainty in aerosol refractive index
3) The impact of sulphate and black carbon aerosol on the East Asian summer monsoon.
4) Mechanisms involved in the semi-direct effect of absorbing aerosols.

Radiolabelling of engineered nanomaterials as a tool for sensitive particle tracking

H. HILDEBRAND AND K. FRANKE

Helmholtz Centre Dresden – Rossendorf, Institute of Radiochemistry, Reactive Transport Division, Permoserstrasse 15, D-04318 Leipzig, Germany (h.hildebrand@hzdr.de, k.franke@hzdr.de)

Engineered nanoparticles (NPs) are present in a wide variety of consumer products, occasionally in significant quantities. During aging, abrasion or disposal of such products, NPs-release is likely - accompanied with effects for the environment that have to be investigated in more detail. The aim of this study is to quantify the amount of NPs (TiO_2 and Ag^0) released from composite coatings due to weathering, aging or mechanical stress and to follow the NPs along their further fate in the environment.

Generally, particle tracking may provide information on the transport behavoir of the particles in aqueous media or on their interactions with biota. Since NPs are possibly released in tiny amounts and into very complex natural systems, we suggest the radiolabelling of NPs as a tool for their very sensitive detection throughout their life cycle including complex media such as aquifer sands, soil or cells.

Within this study, a novel radiolabelling technique for TiO_2 (P 25, Evonik Degussa) and Ag^0 (Sigma-Aldrich) NPs is under development. During this labelling process, significant changes of the chemical composition and properties of the particles are avoided to the greatest possible extend.

Stability of the NPs in different media has been studied and results contribute to first estimates concerning their transport behaviour in the aquatic environment. Batch tests including sediment materials were conducted to describe interactions of Ag^0 and TiO_2 NPs with natural matrices.

Interactions of engineered NPs and natural colloids have been studied as well. Results show that natural colloids have a strong influence on stability and transport of engineered NPs under environmental conditions.

Based on these data, radiolabelling of engineered NPs may open up the chance for sensitive tracking of particles not only in environmental media but also in other complex systems.

How precisely can we date climate/ocean instabilities of the Last Interglacial?

CLAUDE HILLAIRE-MARCEL

GEOTOP-UQAM, Montreal (Qc) H3C 3P8, Canada, (hillaire-marcel.claude @uqam.ca)

We examine here how precisely climate and environmental events of the Last Interglacial (LI) can be correlated and/or dated. For example, the SPECMAP chronology, often used for correlations (e.g., through stable isotope stratigraphies) cannot be linked to any given time series without taking into consideration: i) the specific lag times of Earth system components to insolation at a given latitude, ii) feedback processes between these components. As a matter of fact, the SPECMAP chronology and the timing of changes in the paleocean mass, salinity and isotopic composition, should unavoidably be in offset up to a few thousand years. In addition, neither geochemical signatures, nor the ocean volume, respond linearly to mass transfers into the hydrosphere (ocean/glaciers). A fortiori, adding tectonics, geoidal anomalies, site specific morphological responses to relative sea-level (RSL) changes and littoral activity, one may conclude that any direct attempt at correlating "RSL records" is risky. Finally, one cannot assume an equilibrium state of the Earth and its oceans, neither any probability of a "return" to a given state (i.e., the Earth is always in a no-analogue situation). Fortunately, the LI falls within U-series time control. Most other geochronometers lack precision (OSL, fission track) or are not necessarily applicable to relevant time series ($^{40}Ar/^{39}Ar$). If analytical techniques now permit to calculate ^{230}Th-ages with a fairly high precision, a large array of intrinsic limitations still prevail. For example, closed chemical systems are rarely secured in geological samples and there is no way to assess this closure with the degree of precision required to estimate age differences of the order of $\sim 10^3$ yr. Furthermore, uncertainties in our present knowledge of the U-series decay constants already result in an age uncertainty of about ±1250 years (2σ) within MIS age ranges. Thus, one must conclude that unequivocal correlation of proxies documenting millennial frequency, climate/ocean instabilities of the last interglacial remains out of reach, but in exceptional cases and short intervals (Blake paleomagnetic event, tephra events). In a similar fashion, most processes which are critical for the understanding and modeling of the immediate future of the Earth climate/ocean system are within the error bars/stochastic noise of the paleo-records.

Superplume control of East Africa Rift volcanism: Helium isotope evidence from alkaline magmatism of Tanzania

D.R. HILTON[1], S.A. HALLDÓRSSON[1], P.H. BARRY[1], T.P. FISCHER[2], J.M. DE MOOR[2], C.J. RAMIREZ[3], F. MANGASINI[4] AND P. SCARSI[5]

[1]Scripps Inst. Oceanography, UCSD, La Jolla, CA, USA. (drhilton@ucsd.edu, shalldor@ucsd.edu, pbarry@ucsd.edu)
[2]Dept Earth Planet. Sci. UNM, Albuquerque, NM, USA. (fischer@unm.edu, mdemoor@unm.edu).
[3]U. Costa Rica, San Jose, Costa Rica. (carlosjru@yahoo.com)
[4]U. Dar es Salaam, DeS, Tanzania. (mangasini@udsm.ac.tz)
[5]NRC Italy, Pisa, Italy. (paolo.scarsi@gmail.com)

We present new helium isotope data on mafic crystals of lava/tephra samples from both Older and Younger Extrusives of Rungwe Volcanic Province (RVP) in southern Tanzania – the southernmost expression of Cenozoic volcanism along the East Africa Rift System (EARS). All samples are alkalic in composition and include alkali basalts, basanites, nephelinites and a picrite and trachy-basalt. We compare these samples with peridotite xenoliths from 5 localities on or close to the Archean craton in northern Tanzania.

Regarding the He results: (1) The highest measured $^3He/^4He$ ratios (~ 15 R_A) far exceed the canonical range of 8 ± 1 R_A, diagnostic of MORB-source mantle. Indeed, a total of 17 (out of 31) RVP samples have OL/CPX $^3He/^4He$ > MORB. High $^3He/^4He$ ratios are found in volcanoes of the Younger Extrusives (Ngozi, Rungwe and Kiejo) and in the Kiwira Series (Older Extrusives), and thus are widespread in time and space. (2) Remaining RVP samples fall within the range normally associated with MORB: this He component is sampled in all 6 Rungwe volcanic series. (3) All of the northern Tanzania peridotite xenoliths fall within or overlap the SCLM range (6.1 ± 0.9 R_A).

The range of $^3He/^4He$ ratios at RVP reveal a heterogeneous mantle source including a deep (plume) component. In contrast, the peridotite xenoliths sample shallow lithospheric mantle. We view the African Superplume – a huge low velocity anomaly originating near the core-mantle boundary – as the ultimate source of high $^3He/^4He$. Alkaline volcanism at RVP samples this component implying the superplume is a continental-scale feature. It provides dynamic support for topographic swells throughout the EARS and heat/mass to drive continuing magmatism.

Erosion in the Arctic: Enhanced carbon sequestration associated with high latitude warmth?

R.G. HILTON[1]*, V. GALY[2], J. GAILLARDET[3], D. CALMELS[3], D.R. GRÖCKE[4] AND C. BRYANT[5]

[5]NERC Radiocarbon Facility, East Kilbride, Scotland, G75 OQF, UK (c.bryant@nercrcl.gla.ac.uk)

Soils at high latitudes contain ~40% of the total carbon stock in organic matter on land (~500x10^{15} gC). This region experienced large climatic fluctuations over glacial-interglacial cycles and throughout the Cenozoic, while is extremely sensitive to changes in climate predicted over the coming century. If these changes force transfer of this C back to the atmosphere, or transfer to lithospheric storage, they may induce feedbacks in the Earth System. Here we question whether erosion of this soil organic matter results in a significant transfer of particulate organic carbon (POC) by Arctic Rivers to the ocean. We have sampled the Mackenzie River, Canada, and its major tributaries shortly after freshet (ice break up floods) in June 2009, using a depth-sample approach to collect the full range of erosion products in river suspended and bed sediment. The ^{14}C-content (fraction modern, F_{mod}) and the stable carbon isotopes ($\delta^{13}C_{org}$, ‰) provide the first systematic assessment of POC source in this river. They demonstrate mixing of ^{14}C-enriched (F_{mod}>0.84) and depleted (F_{mod}<0.10) POC, consistent with input of fossil POC from bedrock and modern POC from vegetation and soils. However, $\delta^{13}C_{org}$ requires a third component with a ^{14}C-age of ~12ka (F_{mod}~0.22). This is consistent with soils formed following the retreat of ice after the Last Glacial Maximum. We estimate that the Mackenzie River is likely to have exported ~15-20x10^{15} gC of post-LGM soils to the Arctic Ocean as POC during the Holocene. This is a result of the prevailing climate, promoting high soil carbon stocks and very high erosion rates during the freshet. We propose that the erosion and transfer of soil-derived POC to the ocean by Arctic Rivers may sequester CO_2 while high-latitudes are ice-free, providing a negative feedback to climate over glacial-interglacial cycles.

[4]Water Resources Agency, Ministry of Economic Affairs, Taipei 10651, Taiwan (mjhorng@gmail.com)
[5]Department of Geoscience, National Taiwan University, Taipei 10617, Taiwan (hchen@ntu.edu.tw)

Erosion of particulate organic carbon (POC) from the continents and its delivery to the ocean by rivers is an important global carbon transfer. POC yields are highest in mountain river catchments which contribute a significant part of this flux. To understand how surface processes drive CO_2 sequestration, it is key to better constrain how POC is eroded from the terrestrial biosphere (POC_{mod}) in mountain landscapes. This necessitates river sampling over a large range of hydrological conditions and recognition that fossil POC from sedimentary rock is important in these settings[1]. Here we focus on 11 major catchments of the Central Range, Taiwan, where physical erosion is high and frequent tropical cyclones provide a large range of flow conditions. We sampled river suspended load at hydrometric gauging stations one to three times a month over two years. The fraction of non-fossil POC of the suspended load was quantified using a mixing model constrained by the stable carbon isotopes and nitrogen to organic carbon ratio (whose precision and accuracy was independently assessed using ^{14}C[1]). A general positive relationship was observed between suspended sediment and POC_{mod} yields across the mountain belt. However, four catchments with similar sediment yields over the gauged period ($20\pm2\times10^3$ t km^{-2} yr^{-1}, mean ± σ) had POC_{mod} yields which varied by a factor of ~4 (15 ± 8 tC km^{-2} yr^{-1}, mean ± σ). We can explain the general trend and variability by modelling erosion processes in mountain landscapes: bedrock landslides supply the bulk of clastic sediment and some POC_{mod}; further POC_{mod} is supplied by shallow landsliding and overland flow. Erosion of POC_{mod} is strongly controlled by climate in these catchments.

Experimental constraints on molybdenum isotope fractionation between metal and silicate liquids

REMCO C. HIN[1]*, CHRISTOPH BURKHARDT[1], MAX W. SCHMIDT[1], BERNARD BOURDON[1,2] AND THORSTEN KLEINE[3]

[1]Institute of Geochemistry and Petrology, ETH Zurich, Switzerland (*correspondence: remco.hin@erdw.ethz.ch)
[2]Ecole Normale Supérieure de Lyon and CNRS, France
[3]Institut für Planetologie, Westfälische Wilhems-Universität Münster, Germany

So far planetary core formation conditions have been mainly constrained by element partitioning, particularly by experimental determination of distribution coefficients between metal and silicate liquids. However, driven by analytical developments fractionation of non-traditional stable isotopes has become a new tool for studies of core formation. Experimental determinations of metal-silicate liquid equilibrium Si and Fe isotope fractionation factors reveal significant effects for Si, but not for Fe [1,2].

As a siderophile and refractory element, Mo can provide additional information about conditions of core-mantle differentiation. As oxidised Mo should occur in a 4+ valence state in equilibrium with metal [3], its bond stiffness may be more similar to that of Si than to that of Fe.

To evaluate the possibility of equilibrium mass-dependent Mo isotope fractionation during metal-silicate segregation, we have designed piston cylinder experiments with a basaltic silicate composition and an iron based metal with ~8 wt% Mo. Metal and silicate phases are completely segregated by use of a centrifuging piston cylinder at ETH Zurich, such preventing analyses of mixed metal and silicate signatures. Molybdenum isotope compositions were measured using a Nu1700 MC-ICP-MS at ETH Zurich. To ensure an accurate correction of analytical mass fractionation a ^{100}Mo-^{97}Mo double spike was admixed before chemical Mo purification.

Preliminary results suggest that the equilibrium $^{98}Mo/^{95}Mo$ isotope fractionation factor between metal and silicate liquids may be -0.17±0.15‰ (2σ uncertainty) at 1350°C and 1 GPa. More analyses on reproduced experiments will have to show if this small fractionation can be confirmed, making Mo isotopes a potential tool for constraining the conditions of core formation in asteroids and terrestrial planets.

Release of trace metals in soil suspensions as affected by redox potential and temperature

I. HINDERSMANN AND T. MANSFELDT

Department of Geosciences, Soil Geography/Soil Science, University of Köln, Albertus-Magnus-Platz, 50923 Köln, Germany (iris.hindersmann@uni-koeln.de)

The redox potential is a master variable for the behavior of trace (semi)metals in the soils and sediments environment. In this study we investigated the influence of redox potential and temperature on the solubility of trace metals. A humic topsoil of a floodplain soil at the river Wupper in Northrhine Westphalia, Germany, was chosen. The total amounts (aqua regia) were for Zn 903, Cu 551, Pb 354, Ni 93.5, As 35.7, Co 22.4, Sb 20.5, Cd 8.3, and Mo 6.5 mg kg^{-1}. Microcosm experiments were performed under controlled redox und temperature conditions at 500, 300 and 100 mV and at 7, 15 and 25 °C, respectively. Soil suspensions were obtained at different intervals und analyzed by ICP-MS for trace metals.

Most of the metals demonstrate an increase of concentration with lowering the redox potential. Especially Co and Mo showed a strong increase that is expressed by a high correlation between metal activity and pe+pH. Increasing the temperature resulted in a quicker decrease of the redox potential that can be explained by a higher activity of microorganisms. Only Sb revealed after a first increase a continuous decrease in its concentration. Responsible for this feature are presumably gaseous losses due to biological methylation.

Metal behavior depends among other things on the amounts of adsorbents. The most important adsorbents for Mo and Co are iron and manganese oxides. Under reducing conditions these oxides are dissolved and metals are liberated. However, for Pb, Cd, Cu, Zn, Ni and Cr other processes like complexation or pH-depending sorption are also important.

Calcium isotope fractionation in alpine plants

R.S. HINDSHAW[1,2]*, B.C. REYNOLDS[1], J.G. WIEDERHOLD[2,1], M. KICZKA[2,1], R. KRETZSCHMAR[2] AND B. BOURDON[1,3]

[1]Institute of Geochemistry and Petrology, ETH Zurich, Switzerland (*correspondence: hindshaw@erdw.ethz.ch)
[2]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland
[3]ENS Lyon and CNRS, France

The presence of vegetation has a major impact on the biogeochemical cycles of many elements, through uptake, recycling and the acceleration of weathering rates. As one of the essential plant macronutrients, the biogeochemical cycle of calcium is particularly affected. Calcium uptake by plants is one of the few processes known to fractionate stable calcium isotopes, but the mechanisms of this process and the impact of vegetation on the Ca isotope ratios in runoff are poorly understood. This study aims to increase understanding of the fractionation processes during uptake and translocation within plants by analysing the calcium isotopic composition of alpine plants taken directly from a granitic, glacier forefield (BigLink CZO, Damma glacier, Switzerland).

Stable calcium isotope fractionation was measured (double-spike TIMS) in various species of alpine plants, including woody species, grasses and herbs. Analysis of plant parts (root, stem, leaf and flower samples) provided information on Ca isotope fractionation within plants. Additional seasonal sampling of leaves revealed temporal variation in leaf Ca isotopic composition.

There was significant Ca isotope fractionation between bulk soil and both root tissue ($\Delta^{44/42}Ca_{root\text{-}soil} \approx -0.40‰$) and whole plant Ca isotopic compositions. Ca isotope fractionation between roots and leaves was species dependent, with negligible fractionation between leaves and roots in some species and isotopically heavier leaves compared to roots in others. Ca isotope ratios increased with leaf age in woody species but remained constant in herbs and grasses. The large Ca isotopic difference between root tissue and bulk soil is considered to be caused by the preferential binding of isotopically-light Ca to root adsorption sites. Several factors such as presence of a woody stem, root cation exchange capacity, presence of Ca oxalate and levels of mycorrhizal infection are likely to contribute to the observed differences in whole plant Ca isotopic compositions both between and within species.

Development of an aqueous activity model for geothermal conditions

F.F. HINGERL[1,2]*, T. WAGNER[2], D.A. KULIK[1], G. KOSAKOWSKI[1] AND T. DRIESNER[2]

[1]Paul Scherrer Institut, Nuclear Energy and Safety Research Department, 5232 Villigen PSI, Switzerland (*correspondence: ferdinand.hingerl@psi.ch)
[2]ETH Zurich, Geochemistry and Petrology, Clausiusstrasse 25 8092 Zurich, Switzerland

Geochemical and reactive transport modeling of fluid-rock interaction in enhanced geothermal systems is a challenging task because of the high temperatures, pressures, and sometimes extreme fluid salinities. For such systems, extended thermodynamic databases and activity models are needed to accurately predict fluid-mineral equilibrium reactions. Typically, the Pitzer activity model is used for high salinity fluids. We tested the EUNIQUAC local composition model [2] as an alternative, because it needs substantially fewer fitting parameters to describe species interactions and temperature dependence. However, tailoring the model parameters of EUNIQUAC to geothermal applications requires re-fitting and extending the existing parameter space.

We developed a new tool named GEMSFIT that allows generic fitting of activity models (for aqueous electrolyte and non-electrolyte solutions) and equations of state implemented in our geochemical equilibrium solver GEM-Selektor (http://gems.web.psi.ch). GEMSFIT combines a PostgreSQL database for storing and managing the datasets with experimental measurements and interaction parameters, the parallelized genetic algorithm toolbox of MATLAB® for the parameter fitting, and an interface to the GEMS3K code (kernel of GEM-Selektor) to access activity models and perform chemical equilibrium calculations.

Our comparison revealed that the original EUNIQUAC model is less accurate than the Pitzer model. Hence, we modified the EUNIQUAC model in order to enhance its accuracy and retain its advantages. The new model called ELVIS combines an electrostatic framework developed by Helgeson and coworkers [1] with non- electrostatic concepts derived from the EUNIQUAC model [2].

ELVIS has significantly less fitting parameters than the Pitzer approach, but is comparable in terms of quality of the fit to experimental data. We believe that with the ELVIS approach, it will be possible to derive correlations and predictions for the model parameters, which is very difficult in the Pitzer framework.

Rare earth elements of Precambrian-Cambrian phosphorites from the Yangtze Platform (S. China)

DOROTHEE HIPPLER AND GERHARD FRANZ

Technical University Berlin, Department of Mineralogy, Ackerstrasse 76, 13355 Berlin, Germany (dorothee.hippler@tu-berlin.de; gerhard.franz@tu-berlin.de)

The Precambrian to early Cambrian transition comprises an episode of major environmental changes which are believed to be relevant for the most prominent bioradiation in Earth's history: from an ocean in which algae and microbes were the dominant form of life to one in which significant skeleton-forming higher life spread. Concomitant with these global changes is the onset of biomineralization and widespread calcium phosphate deposition. However, so far, neither the source of phosphate for massive phosphorite, nor the formational mechanisms are known with certainty.

The investigation of the rare earth element (REE) content in phosphorites constitutes a powerful tool to obtain important information on depositional conditions, detrital influence and post-depositional alteration. The authigenic nature of most sedimentary apatites moreover helps in understanding the palaeochemistry of the primary marine environment.

Here, we present rare-earth elements of Precambrian Cambrian phosphorites form different sediment successions on the Yangtze Platform, representing the known facies belts from shelf to basinal environments. The total REE contents of all phosphorites investigated cover a wide range (37 - 1154 ppm), with two samples recording > 700 ppm, which is lower than the averages reported for geologically old phosphorites. PAAS (= Post-Archaean Average Shale) normalized REE patterns are characterized by LREE depletion and MREE enrichment. Low detrital input is indicated by low concentrations of Zr, the lacking correlation of HREE vs. Zr, and low Sc/La ratios. All phosphorites investigated yield negative Ce-anomalies, which is typical of seawater, indicating the palaeoceanic redox conditions of the primary water body. Unlike Ce, Eu does not show any marked anomaly. A positive Eu anomaly can only be reported for one phosphorite concretion, which is likely linked to the high barium content in this phosphorite. This suggests strongly reducing conditions at the time of phosphorite formation, increasing the mobility of Eu as Eu^{2+}. The high Ba content can furthermore be indicative for an increased palaeo-productivity.

[3]Geological Survey of Japan, Tsukuba, Ibaraki 305, Japan

It is widely recognized that the combination of the ICP-Mass spectrometry (ICP-MS) and laser ablation sample introduction technique was one of the most sensitive and versatile analytical technique for the elemental analyses of solid samples [1]. We have developed a new calibration technique for multi-element and isotopic analyses of solid samples using laser ablation-ICP-mass spectrometry coupled with a galvanometric optics. With the galvanometric optics equipped with the femtosecons laser system, two or more sample points could be ablated within very short time interval (~10 msec), and the resulting sample aerosols released from different ablation pits or different solid samples was mixed and homogenized within the sample cell or during the sample transport stages. This suggests that the addition of analytes or second internal elements can be made directly onto the solid samples. In this study, we have measured the REE abundances for two zircon samples (Nancy 91500 and Prešovice) using the standard addition calibration technique using the NIST SRM912. The resulting REE abundance data show excellent agreement with the previously reported values within the analytical uncertainties achieved in this study. Another advantage to use the galvanometric optics is the "integration" of the sample aerosol released from multiple spot. Using the integration technique, the U-Pb age of the zircon sample can be determined from separate 10 ablation pits of small ablation pit sizes (~8 μm). Finally, we would like to show the analytical capability of the newly developed laser ablation in liquid (LA) technique for elemental and isotopic analysis from small areas [2]. The combination of the ICP-mass spectrometry and the laser ablation technique including the LAL has the potential to become a significant tool for *in-situ* elemental and isotopic analysis of solid samples.

The high conductivity of iron and thermal evolution of the Earth's core

K. HIROSE[1]*, H. GOMI[1], K. OHTA[1], S. LABROSSE[2] AND J. HERNLUND[3]

[1]Tokyo Institute of Technology, Tokyo 152-8551, Japan (*correspondence: kei@geo.titech.ac.jp)

[3]University of California, Berkeley, CA 94720, USA

The large amount of heat conducted down the isentropic gradient of Earth's outer core contributes nothing to driving convection or re-generation of Earth's magnetic field by dynamo action. The energy for maintaining a geodynamo for at least the past 3.5 gigayears (Gyr) must be supplied in excess of this waste heat, placing tight constraints upon the thermal evolution of the core. Here we measured the electrical resistivity of iron was measured up to 100 GPa at room temperature in a diamond-anvil cell (DAC). The resistivity of hcp-Fe strongly reduced with increasing pressure. A heating experiment was also conducted at 65 GPa in the externally-heated DAC. The observed change in the sample resistance was in good agreement with the prediction by the Bloch-Grüneisen formula, which supports the validity of this formula for hcp-Fe at high pressure. The thermal conductivity of iron is estimated from its resistivity at high pressure and temperature on the basis of the Wiedemann-Franz law. Considering the effect of light alloying element, the conductivity of the uppermost core is in the range of 90-130 W/m/K, significantly higher than previous estimates. Such high thermal conductivity implies a relatively young inner core and a large degree of secular core cooling (~1000 K). The high initial CMB temperature further suggests that a significant portion of the lower mantle would be molten in early history of the Earth [1, 2].

Deep Earth volatile cycles: From ancient to modern

MARC M. HIRSCHMANN

Dept. of Earth Sciences, University of Minnesota, Minneapolis, MN 55455 USA (mmh@umn.edu)

Earth's mantle is significant reservoir for key volatile species and exchange between the mantle and near-surface reservoirs (="exosphere") influences planetary climate and habitability as well as dynamical evolution of the interior. Volatile cycling is governed in large part through plate tectonic processes but also has significant influence on regulating the vigour of plate tectonics. Yet, it is not clear how this coupling between geodynamical and geochemical evolution arose or whether one was a prerequisite for the establishment of the other. Originally, much of Earth's volatile inventory was presumably present as a thick atmosphere, in part because volatiles were probably delivered late in the accretion history and because of the efficiency of impact degassing. The early inventory of mantle H_2O may descend from the magma ocean, in which portions of a steam atmosphere are dissolved in the magma and then precipitated with nominally anhydrous minerals. In contrast, low magmatic solubility of C-bearing species may suggest that the earliest mantle was depleted in C. Thus, the earliest Earth could have been characterized by an exosphere with low H/C and a mantle with high H/C – the reverse of the modern case in which the mantle has low H/C (as demonstrated by H/C ratios of minimally degassed oceanic basalts) and the exosphere high H/C. Thus, either some process retained carbon in the early mantle or subsequent evolution has preferentially sequestered carbon in the interior.

In this plenary review, I will consider the current state of the principal reservoirs of H and C and explore the possible key influence of magma ocean processes on the subsequent evolution of Earth's volatile cycling.

Re-Os dating and trace element characteristics of pyrite from the Lisheen Pb-Zn deposit, Ireland

DANNY HNATYSHIN[1], ROBERT A. CREASER[1] AND JAMIE J. WILKINSON [2]

[1]Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, AB T6G 2R3, Canada

[2]Department of Earth Science and Engineering, Imperial College London, South Kensington Campus, Exhibition Road, London SW7 2AZ, United Kindom

The Lisheen Mine in the Irish Midlands exploits a typical example of a carbonate-hosted base metal deposit from the district. Like the majority of the Irish Pb-Zn deposits, Lisheen is hosted by Lower Carboniferous strata, but the timing of sulfide mineralization is only poorly constrained by geochronologic methods. As such, the genetic models for this important type of sedimentary-hosted ore remain controversial, with timing constraints provided primarily by geologic relationships and, more recently, by paleomagnetic data. The widely proposed syngenetic and syndiagenetic models require that mineralization occurred around the stratigraphic age of ca. 345 Ma, but none of the available geochronological constraints gives this age. Recent paleomagnetic data from Lisheen has been interpreted to indicate post-Variscan epigenetic mineralization at ~277 Ma, much younger than previously proposed and in apparent contradiction to Variscan (~300 Ma) thrust deformation of the ores. In order to address this problem we have applied Re-Os dating to main ore-stage pyrite from different parts of the deposit. Pyrite samples from the Main Zone, Derryville Zone, and Bog Zone were found to be very variable in Re/Os ratios (300 – 10000), as well as in the trace element abundances in general. Thirty-three Re-Os analyses of pyrite from the Main Zone, Bog Zone, and the nearby Galmoy deposit yielded an age of 342 ± 5 Ma, within uncertainty of the stratigraphic age. However, data from the Derryville zone give an age of 306 ± 10 Ma with a very high initial $^{187}Os/^{188}Os$ value of 3.6, suggesting resetting. The variation within and between these isochrons were investigated using electron mircoprobe and ICPMS analysis to help understand the relationship between rhenium, various trace elements, pyrite morphology and its subsequent alteration. Based on our results it is evident that pyrite throughout Lisheen has been heavily disturbed providing a possible explanation for the scatter seen in the isochrons and a reason why the paleomagnetic age of 277 Ma does not appear to record the timing of primary sulfide mineralization.

Influences of pH and oxidation on the leaching potential of As, Cu, Pb and Zn from sediments through a pH_{stat}-leaching test in combination of a BCR 3-step extraction

HUU HIEU HO[1,2]*, RUDY SWENNEN[2] AND VALÉRIE CAPPUYNS[2]

[1]Vietnam Institute of Geosciences and Mineral Resources (VIGMR), Hanoi, Vietnam (*correspondence: hohuuhieu@yahoo.com)

[2]Department of Earth and Environmental Sciences, K.U. Leuven, Belgium (rudy.swennen@ees.kuleuven.be)

Since contaminated river-bed sediments in Haiphong Harbor (Vietnam) are regularly dredged and disposed on land, an understanding about the influences of key parameters such as pH and oxidation on the leachability of As, Cu, Pb and Zn is necessary for management and treatment of these dredged wastes. A 96h pH_{stat}-leaching test examining the leaching behaviors of elements at pre-set pH values (2, 4, 6, 8 (natural), 9 and 11), is performed on a freshly-collected wet sediment and a 2 month-ripened dry sediment. Additionally, a BCR 3-step extraction is also used to clarify the differences in leachability between 2 types of sediment. The results indicate that the pH-dependent leaching behavior reflects a concave curve with the lowest value at pHs 6 or 8 and the highest value at pH 2 in case of Cu, Pb and Zn, or at pH 11 in case of As. Generally, due to oxidation, the leachability of As and Zn has decreased considerably at highly-acid and highly-alkaline pHs (2–4 and 9–11) while , for Cu and Pb, it has increased at acid pHs (2–6), but decreased at highly-alkaline pHs (9–11). As shown by results of BCR 3-step extraction, for As and Zn, there is a transfer from easily-soluble exchangeable & carbonate fraction to hardly-soluble reducible fraction through oxidation. As a consequence, the smaller exchangeable & carbonate fraction in the oxidized sediment is the cause for the lower leachability of As and Zn at almost all pH values. In contrast, for Cu and Pb, there is a transfer from the oxidizable fraction to the reducible fraction. Therefore, the more important reducible fraction in the oxidized sediment contributes to the higher leachability of Cu and Pb at acid pHs (2–4) while the smaller oxidizable fraction contributes to their lower leachability at alkaline pHs (9–11) if compared with the fresh sediment.

Is TEX_{86} paleothermometry applicable in the polar regions?

S.L. HO[1]*, S. FIETZ[2], G. RUEDA[2], A. MARTINEZ-GARCIA[3], G. MOLLENHAUER[1], A. ROSELL-MELE[2], F. LAMY[1], N. RUGGIERI[1] AND R. TIEDEMANN[1]

[1]Alfred Wegener Institute, 27515 Bremerhaven, Germany; (*correspondence: Sze.Ling.Ho@awi.de)

[3]Swiss Federal Institute of Technology Zürich, 8092 Zürich, Switzerland.

TEX_{86} paleothermometry [1] is an organic sea surface temperature (SST) proxy based on the archaeal glycerol dialkyl glycerol tetraethers (GDGT) lipids, which are ubiquitous in the global ocean. This relatively recent proxy potentially offers an advantage over its more established counterpart, i.e. the alkenone unsaturation index, that has limited success in the polar regions due to its absence or extremely low abundance in this realm. Furthermore, the polar regions, especially the Southern Ocean, are severely under-represented in the global TEX_{86}-SST calibration data set. Therefore, this study aims to investigate the distribution pattern of GDGTs and to evaluate the applicability of TEX_{86} paleothermometry in the polar regions. A principal component analysis (PCA) on the GDGTs data shows that the variance in the relative distribution of the GDGTs in our study region is similar to that of the global data set, suggesting that the lipids are probably contributed by a common group of source organism. However, the TEX_{86}-SST relationship in the Arctic differs substantially from that of the Southern Ocean, resulting in poor overall correlation ($r^2 = 0.06$). Meanwhile, the TEX^L_{86} [2] fares much better than TEX_{86} ($r^2 = 0.50$). Seasonality does not lead to a different TEX_{86}- and TEX^L_{86}-SST relationship, relative to that of the annual mean. Interestingly, the TEX_{86} and TEX^L_{86} are found to correlate well, if not better, with the temperature at the base of thermocline and the oxygen minimum zone. At this stage, the explanation for this finding is still elusive. Nevertheless, its implication for paleo reconstruction work could be significant. Therefore, future work shall be focused on the elucidation of the relationship of TEX_{86} with the temperature at different water depths, and the reason for the large scatter in the TEX_{86} data in the polar regions.

Cd isotope fractionation in some phytoplankton: A novel proxy for Fe limiting status in the oceans

TUNG-YUAN HO[1]*, SHUN-CHUNG YANG[1,2,3] AND DER-CHUEN LEE[2]

[1] Research Center for Environmental Changes, Academia Sinica, Taipei, Taiwan (*tyho@gate.sinica.edu.tw)
[2]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan
[3]Department of Geosciences, National Taiwan University, Taipei, Taiwan

The concentrations of carbon dioxide and dusts in Antarctica ice cores exhibit close correlation, indicating that Fe input in the oceans may regulate carbon cycling and climate change globally. The information of bioavailable Fe status in the surface waters of the oceans may help us appreciate how carbon dioxide has been cycled on Earth. Because Fe status in seawater influences intracellular Cd composition and transport in phytoplankton, Cd isotopic fractionation in phytoplankton may serve as a useful proxy for Fe availability in oceanic surface waters. Here, we show that marine diatom take up light Cd isotopes under Fe limited condition, attributed to dominant high affinity transporter for Cd under Fe deplete condition and to dominant low affinity non-specific Fe transporter for Cd under Fe deplete condition. Our findings elucidate why Cd isotopic composition are relatively light in seawater and Fe-Mn crusts collected in the Southern Ocean, where the surface water is Fe-limited and diatom is dominant. We anticipate our study provide the basis for applying Cd isotopic composition in environmental recorders (e.g., biogenic hard parts, coral reef, Fe-Mn crusts) to re-establish Fe limiting and non-limiting status in the contemporary and ancient oceans.

Characterization of airborne dust particles in the coal mining area of Cam Pha, northern Viet Nam

T.B. HOÀNG-HÒA[1 1]*, R. GIERÉ[1], V. DIETZE[2], U. KAMINSKI[2] AND P. STILLE[3]

[1]Albert-Ludwigs-Universität, D-79104 Freiburg, Germany (*correspondence: hoahtb@gmail.com)
[2]German Meteorological Service, Research Center Human Biometeorology, Stefan-Meier-Str. 4, D-79104, Freiburg, Germany
[3]École et Observatoire des Sciences de la Terre, Université de Strasbourg, F-67084 Strasbourg, France

Cam Pha, located in Quang Ninh province, is one of the largest coal mining areas in Viet Nam (reserves ~10 Gt). This study focuses on the mineralogical and chemical characterization of airborne dust. Exposure to dust is a major challenge for the population living near the mines, especially the open-pit mines. Additional major dust sources comprise mine dumps containing the overburden, a coal-processing facility, a coal-shipping harbour, mining traffic, and various industries, including coal-fired power stations.

Coarse particles (d_p >2.5 μm) have been collected with the passive sampler device Sigma-2 on transparent adhesive collection plates for subsequent single-particle analysis by automated optical microscopy according to VDI guideline 2119 [1]. Select specimens, sampled during different meteorological conditions, were investigated further by SEM-EDX single-particle analysis and by determining their bulk chemical and isotopic composition (ICP-MS and MC-ICP-MS, respectively).

Wind directions indicate that the particles are mainly derived from the open-pit mines, consistent with bulk chemical and isotopic data ($^{87}Sr/^{86}Sr$ = 0.7278 – 0.7427; ε_{Nd} = -14.6 – -14.9; $^{206}Pb/^{207}Pb$ = 1.1789 – 1.1884), which suggest that the dust contains mostly natural materials (coal, silicate minerals from sedimentary rocks). Relative to the coal, the bulk airborne dust is enriched in Na, Mg, K, and Ca, but depleted in most other components. Element-ratio plots reveal some systematic differences between the dust samples and specimens of coal and overburden, pointing to an additional, yet unknown particle source. To verify the hypothesis of an additional dust source and to provide quantitative data on the mineralogical composition of the dust samples, we are currently optimizing the automated SEM-EDX single-particle analysis technique.

Naturally occurring inorganic nanoparticles: General assessment and a global budget for one of Earth's last unexplored major geochemical components

M.F. HOCHELLA, JR.[1]*, D. ARUGUETE[1,2], B. KIM[1] AND A.S. MADDEN[3]

[1]Department of Geosciences, Virginia Tech, Blacksburg, VA 24061, USA (*correspondence: hochella@vt.edu)
[2]Present address: Geobiology and Low Temperature Geochemistry, Division of Earth Sciences, National Science Foundation, 4201 Wilson Blvd., Rm. 785, Arlington, VA 22230, USA
[3]School of Geology and Geophysics, Univeristy of Oklahoma, Norman, OK 73019, USA

Naturally occurring inorganic nanoparticles have been one of the principal catalytic components of Earth throughout its history. Yet these ubiquitous materials have largely escaped our close scrutiny until very recently. They are illusive and difficult to study. They have properties that change significantly with their exact size, shape, aggregation state, and surrounding environment. It has not even been clear how they accumulate, disperse, and move around the planet, nor even for sure what their major sources and sinks are. In this project, we derive a global budget for naturally occurring inorganic nanoparticles, assessing the sources and sinks for there materials, as well as the fluxes between these compartments (atmosphere, continents, continental shelves, and open oceans). Although this worldwide natural nanomaterial budget has a great amount of uncertainty because of limited available observations and data, it still should be a valuable guide as geoscientists attempt to better understand this poorly understood, yet fundamentally important driver of many significant Earth processes and functions. In addition, these kinds of budgets provide a basis for fundamental understanding such as residence and transfer times between compartments.

Specific findings include the following: 1) The primary producer of Earth's inorganic nanoparticles is soil through terrestrial weathering processes; 2) rivers, and to a lesser extent glaciers, bring 0.1% to 0.01% of the Earth's continental nanomaterial reservoir to the continental edge/ocean margins each year; 3) only about 1.5% of this material makes it to the deep oceans due to aggregation and settling in saline ocean margins; and 4) the airborne and waterborne inputs of nanominerals and mineral nanoparticles to the open oceans are very similar.

Palaeotemperature estimation by tandem $\delta^{18}O$ measurement of calcium carbonate and gypsum hydration water

D.A. HODELL*, A.V. TURCHYN AND C.J. WISEMAN

Department of Earth Sciences, University of Cambridge, Cambridge, UK (*correspondence: dah73@cam.ac.uk)

A fundamental problem in oxygen isotope palaeothermometry is the carbonate mineral-water temperature equation is often under constrained. Both the oxygen isotope composition of the carbonate mineral and water from which it precipitated must be known to calculate temperature. Gypsum ($CaSO_4 \cdot 2H_2O$) is a hydrated mineral containing 20.9% water by weight that records the oxygen and hydrogen isotopic of the water from which it formed. If (i) isotopic equilibrium is achieved between the mother water and hydration water; (ii) the fractionation factors are known and temperature independent, and (iii) no exchange has occurred between environmental water and hydration water after deposition, then palaeotemperature can be calculated by measuring oxygen isotopes of co-occurring gypsum hydration water and biogenic carbonate. We developed a precise and accurate method for the simultaneous measurement of $\delta^{18}O$ and δD of gypsum hydration water by cavity ringdown spectroscopy using a Picarro water isotope analyzer. The fractionation factors between gypsum hydration water and mother water were re-determined to be α_{18O}= 1.004 and α_D = 0.981 and found to be temperature independent between 12 and 40ºC, in excellent agreement with previous studies. Three paired measurements of 1200-yr old gypsum and carbonate from Lake Chichancanab, Mexico, yielded a temperature of 25ºC (range 23 to 27 ºC), which is equal to mean annual temperature (MAT) today. Twenty paired measurements of ostracods and gypsum hydration water samples from Late Peten-Itza, Guatemala, yielded a mean temperature of ~19°C (range 16 to 22 ºC) for the Late Glacial period (18 to 10 ka), which is 6 to 7°C cooler than MAT today (~25 to 26ºC). When isotope values of gypsum hydration waters from both lakes are corrected for fractionation, the $\delta^{18}O$ and δD of the palaeo-lake water fall on a projection of the modern evaporative line for the region with slope of ~5, suggesting the crystal water preserves the isotopic signal of the lake water, and has not undergone isotopic exchange with sediment pore water. The method is promising for deconvolving $\delta^{18}O$ of calcite into its temperature and $\delta^{18}O_{water}$ components.

The Christmas Island Seamount Province, Indian Ocean: Origin of intraplate volcanism by shallow recycling of continental lithosphere?

K. HOERNLE[1]*, F. HAUFF[1], R. WERNER[1], P. VAN DEN BOGAARD[1], S. CONRAD[1], A. GIBBONS[2] AND D. MÜLLER[2]

[1]IFM-GEOMAR, Kiel, Germany
(*correspondence: khoernle@ifm-geomar.de)
[2]School of Geosciences, University of Sydney, Australia

The east-west-trending Christmas Island Seamount Province (CHRISP, 1800x600 km) in the northeastern Indian Ocean is elongated orthogonal to present-day plate motion, posing the question if a mantle plume formed this volcanic belt. Here we report the first age (Ar/Ar) and geochemical (Sr-Nd-Hf-Pb DS isotopic data) from the CHRISP seamount chain. A crude E-W age decrease from the Argo Basin (136 Ma), to the Eastern Wharton Basin (115-94 Ma) to the Vening-Meinesz seamounts (96-64 Ma) to the Cocos-Keeling seamounts (56-47 Ma) suggests spatial migration of melting. Christmas Island, however, yields much younger ages (44-4 Ma), inconsistent with an age progression. The isotopic compositions (e.g. $^{206}Pb/^{204}Pb$ = 17.3-19.3; $^{207}Pb/^{204}Pb$ = 15.49-15.67; $^{143}Nd/^{144}Nd$ = 0.51220-0.51295; $^{176}Hf/^{177}Hf$ = 0.28246-0.28319) range from enriched MORB (or "C") to very enriched mantle (EM1) type compositions more typical of continental than oceanic volcanism. Lamproitic and kimberlitic rocks from western Australia, India and other continental areas, derived from metasomatized subcontinental lithospheric mantle, could serve as the EM1 type endmembers. The morphology, ages and chemical composition of the CHRISP, combined with plate tectonic reconstructions, cannot be easily explained within the framework of the mantle plume hypotheses. We therefore propose that the seamounts are derived through the recycling of continental lithosphere (mantle ± lower crust) delaminated during the breakup of Gondwana and brought to the surface at the former spreading centers separating Argoland (western Burma), Greater India and Australia.

Mercury colloid formation in a floodplain soil

A.F. HOFACKER[1]*, A. VOEGELIN[2] AND R. KRETZSCHMAR[1]

[1]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland
(*correspondence: anke.hofacker@env.ethz.ch)
[2]Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland

Understanding the biogeochemistry of mercury (Hg) in contaminated floodplain soils is essential for predicting potential Hg release induced by soil redox fluctuations. We studied Hg in the porewater of a surface soil collected in the contaminated floodplains of the river Mulde (Germany) during 26 days of flooding in laboratory microcosms. Porewater was sampled anoxically and analyzed for dissolved and colloidal Hg and other elements. Colloids collected on filter membranes (0.025 μm) were analyzed by X-ray absorption spectroscopy (XAS) at the Hg L3-edge at 30 K.

The concentrations of colloidal Hg increased rapidly upon soil flooding, peaked at 12 μg/L at day 3, and decreased during subsequent sulfate reduction. Total Hg in the porewater was dominated by colloidal Hg over the duration of the experiment. We previously reported a similar behavior for Cu in soil from the same site [1]. The peak in colloidal Cu was shown to result from the formation of metallic Cu(0) nanoparticles associated with bacterial cells, followed by their transformation into Cu_xS colloids and the precipitation of dispersed Cu_xS nanoparticles upon sulfate reduction [1]. Hg EXAFS (extended X-ray absorption fine structure) spectra of colloids collected during the first 5 days of flooding exhibited oscillations, which indicated that Hg was incorporated in a highly crystalline structure. The spectra did not match any crystalline HgS reference, but were well described by a shell-fit based on a structural model for Hg-substituted Cu metal. This showed that colloidal Hg has formed by Hg(II) reduction and substitution of Hg(0) for Cu(0) in metallic Cu nanoparticles (molar Hg/Cu ratio ~0.002). Since metallic Cu increased to ~14% of total soil Cu within the first days of flooding [2], Hg-substituted Cu-metal likely also formed in the soil matrix. Like for Cu, subsequent sulfate reduction may have caused a transformation of Hg(0) into HgS, but colloidal concentrations were too low for Hg L3-edge XAS.

The formation of Hg-substituted Cu metal nanoparticles in soil is a novel finding with important implications for colloidal transport and volatilization of Hg in contaminated floodplains. Hg-substituted Cu metal nanoparticles may act as effective colloidal carriers for Hg release. On the other hand, incorporation of Hg(0) in Cu metal may impede the formation of volatile elemental Hg(0), which plays an important role for gaseous Hg release from contaminated floodplain soils.

Eoarchean TTG formation by melting of thickened mafic arc crust

J.E. HOFFMANN[1,2,*], T.J. NAGEL[1] AND C. MÜNKER[2]

[1]Steinmann Institut, Universität Bonn, Germany (*correspondence: hoffjoel@uni-bonn.de)
[2]Institut für Geologie und Mineralogie, Universität zu Köln, Germany

The processes leading to the formation of the earliest preserved continental crust are strongly debated. Here we present trace element and radiogenic isotope data combined with petrological and geochemical modelling that provides evidence for the formation of massive Eoarchean TTGs from southern West Greenland from mafic precursors emplaced in an arc related setting. New trace element and Hf-Nd isotope data of well preserved tholeiites from the Isua Supracrustal Belt (ISB) confirm an island-arc origin and yield decoupled Hf-Nd isotope values with near chondritic initial εHf (-0.7 to +2.5) and depleted εNd (ca. -0.1 – +4.4) [1]. The TTGs from the Itsaq Gneiss Complex (IGC; εHf = -1.1 – +1.3; εNd = -2.2– +4.1) overlap the ISB tholeiites in their Hf-Nd isotope composition and also share positive ^{142}Nd anomalies [e.g., 2] both arguing for a genetic relationship. Thermodynamic calculation of mineral assemblages in a partially molten typical ISB tholeiite using the Theriak/Domino software predicts 10-20 % of tonalite melt between 800-950 ˚C at pressures of 10-14 kbars. Calculated co-existing residues are garnet-amphibolite and amphibole/rutile-bearing eclogite. Trace element modelling of melt compositions in equilibrium with the calculated assemblages yields compositions that are very similar to those of representative juvenile Eoarchean TTGs from the IGC [3]. In contrast, melting of N-MORB at equal pressures does not produce similar trace element patterns in the TTGs, because the stability field of plagioclase is enlarged if compared to IAT residues.

New high-precision HFSE data for the best preserved Eoarchean juvenile TTGs from Greenland, in particular Nb/Ta compositions, confirm the source compositions indicated by the modeling approach, suggesting residual amphibole, ilmenite and rutile to control the HFSE budget.

Altogether, our results suggest formation of the earliest TTG components of the IGC by partial melting of thickened mafic crust with island arc affinity rather than through direct melting of the subducting slab.

Hydrogen sulfide reaction with natural organic matter: Implications for arsenic binding

M. HOFFMANN, C. MIKUTTA* AND R. KRETZSCHMAR

Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland (*correspondence: christian.mikutta@env.ethz.ch)

Natural organic matter (NOM) represents a major source and sink of sulfur (S). As part of the S-cycle, the incorporation of S into NOM has been shown to proceed via different pathways involving hydrogen sulfide (HS^-) ions [1]. Nucleophilic introduction of S into NOM can generate highly reactive S species such as thiol groups, which in turn strongly interact with soft metal cations or metalloids. In our study we tested the reactivity of NOM towards arsenite (As(III)) and arsenate (As(V)) after its equilibration with HS^- at pH 7 under anoxic conditions (pO_2 <1ppm). We hypothesized that this reaction increases the content of reduced S species in NOM and thus its ability to retain arsenic.

Natural organic matter (40-250 μm) was extracted from an oxic ombrotrophic peat bog and reacted with HS^- solutions (1-29 mmol S/mol C) at pH 7. Afterwards the sorption of arsenic to pure and HS^--reacted NOM was studied in batch experiments. The speciation of S in untreated and HS^--treated NOM was characterized by S K-edge X-ray absorption near edge structure (XANES) spectroscopy. The coordination of arsenic reacted with NOM was investigated by both As K-edge XANES and extended X-ray absorption fine structure (EXAFS) spectroscopy.

Reaction of NOM with HS^- solutions increased its S content from 1210 up to 28000 mg/kg. Sulfur K-edge XANES spectra of pure NOM revealed that S in reduced (-I to I) and intermediate (II to IV) oxidation states prevailed. Sulfur incorporation did not result in a preferential formation of reduced S species, suggesting the partial oxidation of thiol groups.

Arsenate was not retained by pure and HS^--reacted NOM. While As(III) did not sorb to pure NOM, its sorption increased linearly with S content of HS^--reacted NOM. Arsenic K-edge EXAFS spectra showed that the first coordination shell of As(III) was progressively dominated by S atoms with increasing S content of NOM.

Our results document that NOM can rapidly incorporate S under sulfate-reducing conditions. The organic S species formed are highly reactive towards potentially toxic metals and metalloids such as As(III). Our findings provide a possible explanation for recently observed As accumulations in peatlands [2].

Anions dramatically enhance proton transfer across the air-water interface

MICHAEL R. HOFFMANN, HIMANSHU MISHRA, SHINICHI ENAMI, ROBERT J. NIELSEN, WILLIAM A. GODDARD III AND AGUSTÍN J. COLUSSI

California Institute of Technology, Pasadena 91125 USA

Fundamental processes in chemistry and biology are driven by proton transfer (PT) across water interfaces with hydrophobic media. However, what distinguishes PT 'on water' from conventional PT 'in water' remains unclear. Here we show that PT from gaseous nitric acid to liquid water is dramatically accelerated by non-specific anions. We found that $HNO_{3(g)}$ fails to dissociate on pure water surfaces but is fully deprotonated on 1 mM electrolytes. Quantum mechanical (QM) calculations confirm that $HNO_{3(g)}$ dissociation on pure water is unfavorable and show that anions pre-organize interfacial water, thereby setting the stage for adiabatic PT. Our findings provide direct evidence of the critical role electrostatic pre-organization plays in catalyzing proton transfers across water-hydrophobe interfaces, such as those involved in cloud acidification and enzymatic events.

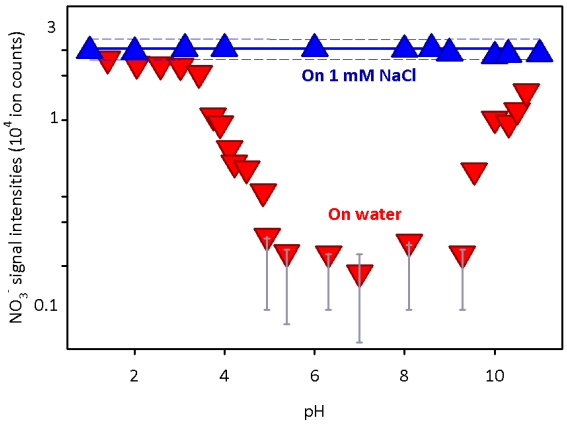

Figure 1: Electrospray ionization mass spectral nitrate (m/z = 62) signals detected on water or 1 mM NaCl microjets exposed to 0.4 ppbv gaseous nitric acid for ~ 10 μs as functions of water pH. Solid, dashed lines are a linear regression and its 95% confidence limits, respectively, to the data obtained on 1 mM NaCl. Error bars estimated from reproducibility tests. All experiments in 1 atm of $N_{2(g)}$ at 300 K.

George Tilton: Pioneer of lead isotope geochemistry

A.W. HOFMANN[1,2]

[1]Lamont-Doherty Earth Observatory, Columbia University, P.O. Box 1000, Palisades NY 10964, USA
[2]Max Planck Institute for Chemistry, Postfach 3060, 55020 Mainz, Germany (albrecht.hofmann@mpic.de)

George Tilton, who died on October 12, 2010, was one of the giants of isotope geochemistry and cosmochemistry. He is best known as the father of U-Pb dating of zircons and other minerals, a method for measuring ages of minerals and rocks that now yields uncertainties of one million years or less, for rocks and meteorites as old as 4.5 Ga. Thousands of papers have been published based on this method.

George Tilton also contributed pioneering work applying lead isotopes to measure the age of the solar system and to determine the evolution of the Earth. Later in his career, he turned his attention to the isotope geochemistry of carbonatites.

I will highlight some of George's landmark contributions and discuss the current state of some of the enduring puzzles, often called "paradox", posed by the lead isotope systematics of modern and ancient rocks. I will also discuss two basic questions that continue to engage isotope geochemists: (1) Did the U/Pb ratio of the accessible silicate Earth increase subsequent to accretion and core formation, and if so, why? (2) Why did the Th/U ratio of the accessible Earth begin with an apparently superchondritic value in Hadean time and decrease to subchondritic values subsequently? Answers to these seemingly arcane questions are fundamental to understanding the origin and global evolution of our planet.

Displaced helium in tilted mantle plumes

A.W. HOFMANN[1,2], C.G. FARNETANI[3], M. SPIEGELMAN[1] AND C. CLASS[1]

[1]Lamont-Doherty Earth Observatory, Columbia University, P.O. Box 1000, Palisades NY 10964, USA
[2]Max Planck Institute for Chemistry, Postfach 3060, Mainz 55020, Germany (albrecht.hofmann@mpic.de)
[3]Institut de Physique du Globe de Paris, Université Paris Diderot, Paris, France

Primordial 3He is widely thought to be a diagnostic tracer distinguishing mantle plume-related magmas from MORB-type magmas, under the assumption that the deep mantle serves as storage reservoir of primordial ^{3}He and also as source of mantle plumes. Yet on several high-^{3}He/^{4}He-hotspots, e.g. Hawaii, Galapagos, and Iceland, the maximum ^{3}He/^{4}He ratio appears to be displaced from the plume center in the direction opposite to that of inferred asthenospheric flow and/or plate motion. We model this process using the assumption that helium initially located in the center of a plume conduit is sequestered into a carbonatite melt forming in the rising plume at a depth of 400 to 600 km. The model predicts that such a carbonatite liquid will ascend rapidly and subvertically through the plume with separation velocities up to a meter per year or more. As the plume is tilted by upper-mantle flow, the carbonatite carrier of the plume helium is displaced in the upwind direction. This can explain the helium maximum at Loihi Volcano for Hawaii, at Fernandina (Galapagos), and possibly the high ^{3}He/^{4}He values on the Reykjanes Ridge. The model also predicts the declining ^{3}He/^{4}He ratios on Mauna Loa, Mauna Kea, and Haleakala, as these volcanoes age, as well as the uniformly MORB-like helium in all post-shield and rejuvenated Hawaiian lavas.

Our model is consistent with the model of Tolstikhin and Hofmann (2005), in which the storage reservoir for primordial solar helium is located in the D'' layer at the base of the mantle, from where it diffuses into the overlying actual source of the mantle plume. The base of this source layer, which subsequently forms the center of the conduit, therefore contains the highest ^{3}He/^{4}He ratio. This plume source consists of a mixture of recycled (oceanic) crustal-lithospheric material and normal depleted mantle peridotite; the radiogenic 4He derived from its local Th-U content strongly affects the ultimate ^{3}He/^{4}He ratio of a given plume.

Ion desolvation as a mechanism for kinetic isotope fractionation

A.E. HOFMANN[1]*, I.C. BOURG[1] AND D.J. DEPAOLO[1,2]

[1]Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, USA 94720 (*correspondence: aehofmann@lbl.gov)
[2]Department of Earth & Planetary Sciences, U.C. Berkeley, Berkeley, CA, USA 94720

Kinetic processes, including mass-dependent diffusivity differences and boundary-layer reactions, have been invoked to explain non-equilibrium Ca isotopic fractionations observed in calcite precipitation from aqueous solutions [1,2]. Current available data suggest that a 1.6 ‰ kinetic fractionation between ^{44}Ca and ^{40}Ca occurs during non-biogenic calcite precipitation [2]. This fractionation cannot be attributed to isotopic diffusion in bulk liquid water, which causes a much smaller fractionation of 0.6‰ [3]. Ion desolvation—both of the crystal surface and of the cations in solution—has been implicated as a rate-limiting step in crystal growth [4,5,6,7], but, to the best of our knowledge, it has not previously been proposed as a mechanism for isotopic fractionation. Here, we carry out the first study of the isotopic mass dependence of metal cation desolvation rates.

To investigate the effect of isotopic mass on desolvation rate, we performed a series of classical molecular dynamics simulations involving one cation (Li^+, K^+, Rb^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, or Ba^{2+}) and 550 water molecules in a periodically replicated cell. Simulations were performed with two prominent water models (SPC/E and TIP4P) at 278, 298, and 323K for a range of real and hypothetical masses (2-200 Da).

Our results indicate that the desolvation rates k_w of the alkali metals and at least some of the alkali earths follow an inverse power-law dependence on isotopic mass m ($k_w \propto m^{-\gamma}$). In other words, lighter isotopes exchange water molecules between their first hydration shell and the bulk liquid more quickly than heavier isotopes of the same species. Preliminary results show that the power-law exponent $\gamma \sim 0.05 \pm 0.02$ for Ca^{2+}, Ba^{2+}, Li^+, K^+, and Rb^+ at 298 K, with no clear dependence on temperature, water model, or the identity of the cation. Thus, if ion desolvation is the rate-limiting step for calcite precipitation, our preliminary results are consistent with a fractionation between ^{44}Ca and ^{40}Ca of ca. 5 ± 3 ‰.

Geochemical evolution of lavas of the Rabaul caldera – Fractionation of Fe isotopes and HFSE ratios during fractional crystallisation

S.V. HOHL[1], S. KÖNIG[2], C. MÜNKER[2], S. SCHUTH[3] AND J. KUDUON[4]

[1]Steinmann Institut, University of Bonn, Germany
[2]Institut für Geologie und Mineralogie, University of Cologne, Germany
[3]Institut für Geographie, University of Colgne, Germany
[4]Rabaul Volcanological Observatory, Papua New Guinea

The Rabaul area, Papua New Guinea, is among the few examples worldwide, where the magmatic evolution of a single, still active system can be examined *in situ*. Our work focusses on the geochemical evolution of the Rabaul caldera system, and on differences between the two major volcanic cycles found at Rabaul.

Crystal fractionation of olivine, pyroxene and plagioclase is the most important process controlling the long-term magmatic evolution. The abscence of systematic variations in Sr-Nd-Hf isotope compositions with MgO or SiO_2 suggests that the volcanic system has been in steady state or even behaved as closed system, indicating that isotopically different materials such as crustal rocks or older basement have not been assimilated to a significant extent. Within the analytical error of ±0.4 б-units, most Fe isotope compositions of inner caldera lavas (б ^{56}Fe from 0.01 to 0.14 ‰) overlap with the mafic outer caldera samples and compositions of terrestrial basalts. Only some felsic samples show slightly lower values indicating possible fractionation of magnetite [2]. Trace element compositions of Rabaul lavas indicate that slab derived fluids control the subarc enrichment of the mantle wedge. Coupled Hf-Nd isotope compositions (εHf from +13.9 to +15.4 and εNd from +6.4 to +8.1) reveal the presence of the Indian-Australian mantle domain beneath Rabaul. High-precision HFSE data obtained by isotope dilution reveal subchondritic Nb/Ta ratios (15.5 to 18) and near chondritic Zr/Hf (40-44). Ratios of Nb/Ta tend to decrease with increasing degree of differentiation, consistent with amphibole fractionation. Likewise, a distinct increase of Zr/Hf ratios from the basaltic lavas (40) to the dacitic lavas (43-44) can be explained by fractionation of clinopyroxene or amphibole. Increasing W/Th (0.27-0.42) and decreasing Ta/W (0.73-0.49) ratios with increasing degree of differentiation indicate a higher incompatibility of W relative to Th and Ta. The overall low Ta/w and high W/Th in Rabaul lavas support previous models [3] arguing for a high mobility of W in fluid-dominated subduction systems.

Measurement of isotopes and chemistry in tunnel inflow for study of water flow in fractured rock

MILAN HOKR[1]* AND ALEŠ BALVÍN[2]

[1]Technical University of Liberec, Studentska 2, Liberec, 46117, Czech Rep (*correnpondence: milan.hokr@tul.cz)
[2]Technical University of Liberec, Studentska 2, Liberec, 46117, Czech Rep (ales.balvin@tul.cz)

We present the introductive study of the starting project of water composition monitoring in the underground springs in the tunnel through a granite massif in up to 150m depth, in Bedrichov site, northern Bohemia, Czech Republic. The work continues the recent geological and multidisciplinary research at Czech Geological Survey [1][3]. The site is specific with combination of two different excavation method in the single tunnel and quite small total inflow concentrated to main faults and few fractures.

The inflow data are available with 5 years history. Within the 8 selected inflows of different depth and different flowrate, pH and conductivity is periodically measured and samples of 2H and 18O isotopes collected in 14 days intervals from beginning of 2010, together with single sampling of tritium and standard full chemical analyses. The isotope analyses are measured in connection with GNIP and GNIR data from Uhlirska exparimental basin nearby [2].

The evaluation from first year of sampling shows small but visible tranfer of year cycle of stable isotopes to the underground. We present several hypotheses based on lumped parameters model, which are still preliminary, but we expect the potential of combining more method together with sampled depth-dependence of water geochemical parameters.

Geochemical impact of seepage from a Canadian oil sands tailings pond: A radial diffusion cell study

A. HOLDEN[1], K. U. MAYER[2] AND A. ULRICH[1]*

[1]Civil and Environmental Engineering, University of Alberta, AB, Canada (*correspondence:aulrich@ualberta.ca)
[2]Earth and Ocean Sciences, University of British Columbia, BC, Canada (umayer@eos.ubc.ca)

In Northern Alberta, Canada, the first of several oil sands tailings facilities has been constructed atop glaciofluvial outwash channels that are buried by surficial clays and till. Process-affected (PA) water from such ponds is expected to infiltrate through the low permeability sediments and affect the underlying sand channel aquifer(s). These channels are highly permeable and have the capacity to act as migration pathways, facilitating the release of tailings pond seepage into nearby surface water bodies. However, the nature and significance of this impact are not known.

In this study, radial diffusion cell experiments [1] were conducted to characterize the biogeochemical processes that control the composition of the ingressing PA seepage as it interacts with the glacial till sediments. The focus was on major ions contributing to salinization and the evolution of redox chemistry.

Following the addition of PA water into the aquitard sediment core, ion exchange led to a decrease of Na contained in the PA water and the release of pre-bound Ca, Mg and K. Elevated NO_2, NO_3 and high SO_4 concentrations were mitigated by reduction reactions – the latter in contrast with earlier findings from similar sediments [2]. Cl unexpectedly showed evidence of release from the sediments into the core reservoir, which is attributed to electrochemical migration to maintain charge neutrality.

Measurement of four-isotope sulfur ratios on SHRIMP-SI

PETER HOLDEN*, RICHARD ARMSTRONG, JOHN FOSTER, PETER LANC, NORM SCHRAM AND TREVOR IRELAND

Research School of Earth Sciences, The Australian National University (*correspondance: peter.holden@anu.edu.au)

The recent postulation that metabolic pathways may leave a detectable signal in the fractionation of the four sulfur isotopes (^{32}S, ^{33}S, ^{34}S & ^{36}S), potentially gives the geochemist another tool in the search for the earliest life on Earth and beyond.

However, accurate and precise measurement of the minor isotope ^{36}S presents significant analytical challenges, even for conventional gas-phase analysis. We have developed a multi-collector ion-microprobe analysis protocol that collects in-situ 4-isotope S data from both sulphates and sulphides. Valuable spatial information is maintained.

Data are acquired using a 3nA Cs^+ primary beam focussed to a 25µm spot on the target. S isotopes are detected in faraday cups, which contain slit sizes appropriate to resolve any unwanted hydride interferences. Secondary S^- beam signals are determined using our new in-house Iflex temperature and humidity controlled electrometers. Each Iflex has 3 selectable resistors ($10^{10}\Omega$, $10^{11}\Omega$, $10^{12}\Omega$) and a 27pF capacitor so that the detection system can be tuned to the appropriate beam intensity. Under such conditions pyrite targets yield approximately 2GHz ^{32}S, 16MHz ^{33}S, 88MHz ^{34}S, and 0.3MHz ^{36}S.

The low abundance ^{36}S isotope can be collected in either current or charge mode. Charge-mode detection eliminates the dead-time correction, drift in detector response and linearity issues associated with electron multipliers. In addition, response times are much faster than high ($>10^{11}\Omega$) Ohmic resistors. Experimentation suggests that charge-mode delivers superior data quality over electron multipliers down to 50kHz, and $10^{12}\Omega$ resistors up to 1 Mhz and thus neatly bridges the "gap" between conventional electrometers and ion-counting.

Provisional data yields external 2 s.d. uncertainties for $\Delta^{33}S$ and $\Delta^{36}S$ that are better than 0.3‰ and 0.5‰ respectively, which are comparable to conventional analyses, but using several orders of magnitude less material. At this level of precision, documented anomalies of 2‰ can be easily resolved making SHRIMP a viable alternative to the protracted extraction procedures necessary for gas-phase analysis.

Noble gases from the Precambrian Shield of Canada

G. HOLLAND[1]*, B. SHERWOOD LOLLAR[2], L. LI[2], G. LACRAMPE-COULOUME[2], G.F. SLATER[3] AND C.J. BALLENTINE[4]

[1]LEC, Lancaster University, Lancaster. LA1 4YQ. U.K. (*correspondence: g.holland@lancaster.ac.uk)
[2]Dept. of Geology, Univ. of Toronto, ON, Canada M5S 3B1
[3]SGG, McMaster Universty, Hamilton ON Canada L8S 4K1
[4]SEAES, Manchester Univ, Manchester M134 9PL. U.K.

An increased recognition of the role of subsurface microbes in the production and alteration of oil and gas deposits has sparked heated debate about the volume and extent of life in the deep subsurface. The deep terrestrial biosphere in the tectonically quiescent Precambrian Shields of Canada, Scandinavia and South Africa are dominated by radiogenic noble gases and crustal-derived carbon sources. These radiogenic gases have been used previously to calculate long residence times on the order of 10–25 million years for the deepest high-salinity fracture waters [1]. Correlations of increasing salinity with highly altered hydrogen and oxygen isotope signatures for the waters, together with increasing concentrations of radiogenic noble gases, suggest that ground waters were subject to extensive water–rock reactions over geological time in hydrogeologically isolated fracture networks [2].

We have performed noble gas analyses on 6 samples from a mine site in Ontario (ON). Results show highly radiogenic noble gas ratios for He, Ne and Ar, analogous to the anomalously high Ne signatures recently described for fracture waters in South African gold mines [3]. $^{3}He/^{4}He$ in these samples are <0.02Ra. We have found very high $^{40}Ar/^{36}Ar$ ratios (up to 44,000) the highest observed in crustal fluids and the first documented ^{129}Xe excess (~1%) that cannot be attributed to a mantle component. Elemental ratios suggest solubility controlled gas/groundwater phase partition processes have operated but Kr and Xe enrichment suggest input from sediment and / or sediment derived porewater. This sediment contribution is also required to explain the ^{129}Xe excesses. ^{129}Xe is the decay product of ^{129}I with $t_{1/2}$ = 15.7Ma implying significant closed system fluid evolution, consistent with the hydrogeologically isolated nature of the fractures.

Hydrothermal alteration of diatomite for the fixation of heavy metal ions

D. HÖLLEN*[1], P. GRUNERT[2], D. KLAMMER[1] AND M. DIETZEL[1]

[1]Graz University of Technology, Institute of Applied Geosciences, Rechbauerstr. 12, A-8010 Graz (*correspondence: daniel.hoellen@tugraz.at)
[2]University of Graz, Institute of Earth Sciences, Heinrichstr. 26, A-8010 Graz

The application of alterated diatomite as a hierarchically structured material for ion fixation from aqeuous solutions is based on macropores (~100 nm) from the intricate silica structure of diatomite, micropores (~0.3-0.4 nm) from neoformed zeolites and highly active surface sites from amorphous precursor phases. Such kind of materials can be obtained by hydrothermal synthesis.

A stock solution was prepared by dissolving 1 g of gibbsite (γ–$Al(OH)_3$) in 0.5 L of 1 M KOH and subsequent filtration (0.45 μm). 0.025 L of the stock solution reacted with 0.5 g diatomite (”Thiele”) in a Teflon coated autoclave at 50 to 150°C. After distinct reaction times from 6 up to 1500 h reaction products were separated from the solutions by filtration. Solutions were analysed for composition and solids for composition and structure. Ion fixation capacities of the reaction products were studied in aqueous solutions containing 0.5 mM of Cu^{2+}, Pb^{2+} and Zn^{2+} at pH 5.1 and 25°C for 72 h.

Initially, the diatoms are converted partly into spherical amorphous nanoparticles (20-200 nm). After 24 to 192 h mainly merlinoite and minor amounts of chabazite were formed. Proportions depend on temperature and reaction time. At a reaction time between 96 and 192 h a quasi steady state was reached with ≈ 30 wt.% amorphous phase, ≈ 60 wt.% merlinoite and 10 wt.% accessory phases (relictic quartz, mica as well as newly formed chabazite). The heavy metal ion fixation capacity of the pristine diatomite is low. Interestingly, the reaction product containing the amorphous precursor phase non-selectively reduced ≥ 99 % of the primarily dissolved heavy metals (specific surface area = 38 m^2/g). The final reaction products (15 m^2/g) reduced heavy metal concentrations less efficiently (~ 90 %), but selectively. Challenging tasks for the ongoing study are to tailor the reaction products with regard to metal fixation and hierarchical pore structures for waste and drinking water purification.

Using TRLFS to explain increased uptake of Eu^{3+} and Cm^{3+} into biologically produced apatite

KIEL HOLLIDAY*[1], STEPHANIE HANDLEY-SIDHU[2], JOANNA RENSHAW[2], LYNNE MACASKIE[2] AND THORSTEN STUMPF[3]

[1]Institut für Nukleare Entsorgung, Hermann-v.-Helmholtz-Platz 1, 76344 Eggenstein-Leopoldshafen, Germany (kiel.holliday@kit.edu)
[2]University of Birmingham, Edgbaston-Birmingham, B15 2TT, (s.handley-sidhu@bham.ac.uk)
[3]Institut für Nukleare Entsorgung, Hermann-v.-Helmholtz-Platz 1, 76344 Eggenstein-Leopoldshafen, Germany (thorsten.stumpf@kit.edu)

The long term geochemical modeling of nuclear waste in the environment requires a molecular understanding of the interaction between radioactive materials and mineral phases. Of particular importance is the adsorbtion and incorporation of trivalent actinides such as plutonium, americium and curium. In this study time-resolved laser fluorescence spectroscopy was used to probe europium and curium which have been incorporated into biologically produced apatite. Apatite produced by *Serratia* bacteria has been shown to have an increased uptake of various cations. Time resolved laser fluorescence spectroscopy was used to identify and characterize the nature of Eu^{3+}/Cm^{3+} sorption and incorporation within the mineral phase. Using site-selective excitation different interactions can be isolated. The lifetime and emission spectra were analyzed at each site that was identified. The number of hydrating waters was determined by the lifetime measurement and used to distinguish species that are sorbed to the surface from those incorporated into the bulk. Emission spectra were measured to determine the symmetry of the site being occupied by the sorbed or incorporated trivalent cation and determine the substitution for non-equivalent calcium positions. By these measurements it was determined that Eu^{3+} and Cm^{3+} are incorporating into the amorphous grain boundaries of the apatite polycrystalline material. Biologically produced apatite has smaller crystalline grains resulting in a greater amount of amorphous grain boundary within a particle as compared to synthetic or natural apatite. This greater amount of amorphous grain boundary results in an increased uptake of Eu^{3+} and Cm^{3+} and is therefore a more effective barrier to radionuclide migration.

Nitrogen isotopes and geochronology of the Musselwhite Au mine, Canada

P. HOLLINGS[1]*, C. ISAAC[1,2], J. BICZOK[3], R. MAAS[4] AND R. FRIEDMAN[5]

[1]Lakehead University, Thunder Bay, ON, Canada (*correspondence: peter.hollings@lakeheadu.ca)
[2]Centre for Exploration Targeting, University of Western Australia, Western Australia 6009
[3]Goldcorp Inc. Musselwhite Mine, P.O. Box 7500, Thunder Bay, Ontario, Canada P7B 6S8
[4]University of Melbourne, VIC 3010, Australia
[5]University of British Columbia, 6339 Stores Road, Vancouver, BC, V6T 1Z4, Canada

The Musselwhite Au mine, a large orogenic lode gold deposit hosted in amphibolite grade metamorphic rocks, is located in the ~2.98 Ga North Caribou Lake greenstone belt of the North Caribou Terrane, Superior Province, Canada. The mine has produced ~3.1 million ounces of gold and has a total reserve and measured plus indicated resource base of 2.31 million ounces as of December 31, 2010. Gold mineralization within the host iron formation is largely confined to subvertical shear zones along the steeply dipping limbs of isoclinal folds and tends to swell where these limbs transition into the crests or keels of antiformal and synformal structures.

Nitrogen isotopes in biotite from Musselwhite Mine are characterized by a $\delta^{15}N$ range from -1.3 to 11.1 per mil whereas oxygen and hydrogen isotopes of biotites from the mine range from +7.1 to +10.1 per mil for $\delta^{18}O$ and -55 to -100 per mil for δD. Biotite samples from granites and metasedimentary rocks adjacent to the deposit have a $\delta^{15}N$ range of -6.9 to +6.1 per mil.

Uranium-lead ages on zircons and monazites from intrusive rocks surrounding the mine range in age from 2875 Ma to 2670 Ma, whereas Ar-Ar ages range from 2658 to 2440 Ma. An Sm-Nd age of 2690±9 Ma for garnets that host gold mineralization is bracketed by peraluminous S-type granites with ages of 2668.3±1.6 Ma and 2715.8±1.6 Ma.

The $\delta^{15}N$, $\delta^{18}O$ and δD stable isotopic data for biotite from the mine suggests that both metamorphic and magmatic fluids played a role in the formation of the deposit. Sm-Nd ages of garnets that are coeval with mineralization suggest that the orogenic gold mineralization at the Musselwhite mine was broadly synchronous with the ~2700 Ma orogeny caused by the collision of the Oxford-Stull domain with the North Caribou Terrane ~75 km northeast of the mine. The presence of coeval S-type granites suggest that these may have played a greater role in the formation of orogenic gold deposits than has been previously recognised.

$\delta^{44/40}$Ca variability in modern shallow water carbonates

C. HOLMDEN[1]*, D.A. PAPANASTASSIOU[2], P. BLANCHON[3] AND S. EVANS[4]

[1]Saskatchewan Isotope Laboratory, University of Saskatchewan, Saskatoon, Canada S7N-5E2 (*correspondence: ceh933@mail.usask.ca)
[2]Science Division, Jet Propulsion Laboratory, M/S 183-335; California Institute of Technology[3], Pasadena, CA 91109
[3]Instituto de Ciencias del Mar y Limnologìa, Apartado Postal 1152, Cancún, D.F. Mexico.
[4]Department of Geosciences[5], Boise State University, 1910 University Drive, Boise, Idaho 83725-1535

Shallow water carbonates from Florida Bay, the Florida Reef Tract and the Mexican Caribbean fringing reef at Punta Maroma were studied to determine the range of Ca isotope variation among the cohort of modern carbonate producers, and to look for local scale Ca cycling effects. The total range of Ca isotope fractionation is 0.4‰ in carbonates from Punta Maroma, yielding a production weighted average $\delta^{44/40}$Ca value –1.12‰. This value compares well with bulk carbonate sediments from the Florida Reef Tract (–1.11‰) and Florida Bay, near a tidal inlet in the Florida Keys (–1.09‰). No evidence was found for the ~0.6‰ fractionation between calcite and aragonite observed in laboratory precipitation experiments.

Isotope fractionation effects are subordinate to local scale Ca cycling effects as a potential source of isotopic variability in shallow water carbonates. This is observed in the innermost restricted region of northeastern Florida Bay, where a 0.7‰ gradient of decreasing $\delta^{44/40}$Ca values in sediments and waters occurs between the coastal zone of Florida Bay and the southern mangrove fringe of the Florida Everglades. The reduction in $\delta^{44/40}$Ca values towards the Everglades in this setting is predominantly due to submarine groundwater discharge (SGD), which is characterized by low $\delta^{44/40}$Ca values, similar to marine limestone, and Ca concentrations that are higher than seawater. Mixing model calculations show that between 9 and 71% of the Ca in coastal waters with salinities ranging between 30 and 14 ppt, respectively, is from SGD and surface water runoff.

By analogy with Florida Bay, restricted circulation with contemporaneous oceans may have led to overprinting of ocean $\delta^{44/40}$Ca signatures in carbonate deposits located in near shore settings of ancient epeiric seas. If this is correct, some of the scatter in the Paleozoic portion of the Ca isotope evolution curve of Phanerozoic of oceans, which is, itself, reconstructed from analyses of brachiopods collected from the deposits of epeiric seas, may be due to local Ca cycling effects.

Diffusive fractionation of transition metals in grain boundaries

V. HOMOLOVA, E.B. WATSON AND J.B. THOMAS

Rensselaer Polytechnic Institute, 110 8th Street, Troy, NY USA (*correspondence: homolv@rpi.edu)

Grain boundaries (GBs) provide one of the most important transport pathways in metamorphic rocks. The equilibration length scale of a particular element may be dependent upon its GB diffusivity, and inter-element differences in these quantities may lead to a diffusive fractionation of elements during metamorphism. The detector particle method is one way to study GB diffusivities and consists of juxtaposing a diffusant source with a pre-synthesized matrix "rock" containing dispersed sink phases. The diffusion profile obtained by measuring diffusant concentrations in the detector (sink) particles will reflect the GB concentration of the diffusant to an extent determined by the volume percent of sink phases ($vol\%_{sink}$) and the partitioning behaviour of the diffusant between the grain boundary and the sink phase ($K_d^{prt/gb}$). To better constrain GB diffusivities, experiments and finite difference modelling were undertaken to elucidate the relationships between $vol\%_{sink}$, $K_d^{prt/gb}$, and the characteristic distance (x). Experiments involved juxtaposing a pre-synthesized quartzite matrix containing 1-3.5wt% dispersed enstatite with a source of either chromium-nickel-iron alloy, chromium oxide, or nickel metal containing 2200ppm manganese. Experiments were run in a piston cylinder apparatus at 1250°C and 1GPa for durations of 9.25-92 hours. Post-experiment analyses of the enstatite sink particles for the GB diffusants (Cr, Mn, Ni) were performed with a Cameca SX100 microprobe. In 24 hours, Cr GB diffusion length scales decrease from 0.069 to 0.019cm in experiments containing 1 to 3.5wt% sink particle, respectively, while Mn GB diffusion length scales decrease from 0.108 to 0.027cm. Due to the incompatibility of Ni in the sink particles (relative to Mn), Ni effectively experiences 0 $vol\%_{sink}$ at short diffusion distances where Mn concentrations are high. Nonetheless, Ni GB diffusion length scales decrease by ~70% (from 0.94 to 0.26cm) in experiments containing 1 and 3.5wt% sink particles, respectively. GB diffusion length scales of Cr, Mn and Ni all appear to decrease by a factor of ~4 over the range of $vol\%_{sink}$ studied here. These results are in line with finite difference modelling which also predicts a decrease in x with a decrease in spacing of the sink particles (which is equivalent to an increase in $vol\%_{sink}$). The models also predict a non-linear, inverse correlation between $K_d^{prt/gb}$ and x.

New data on unexpectedly high arsenic concentrations within a landfill plume in Central Massachusetts, USA

R. HON[1]*, Y. XIE[1], C. SOELLER[1], W.C. BRANDON[2] AND R.J. SIMEONE[3]

[1]Earth and Environmental Sciences, Boston College, 140 Commonwealth Ave, Chestnut Hill, MA 02467, USA (*correspondence: hon@bc.edu)

[2]U.S. EPA, Region 1, 5 Post Office Square, Suite 100, Boston, MA 02109, USA

[3]Department of the Army, Base Realignment and Closure Division, U.S. Army Garrison Fort Devens, 30 Quebec Street, Unit 100, Devens, MA 01434-4479, USA

A contaminant leachate plume, associated with a closed and capped landfill in North Central Massachusetts, USA, contains surprisingly high levels of arsenic which at several locations within the plume can reach and exceed 15,000 ppb of As in groundwater. The landfill waste material was dumped over a layer of peat of variable thickness (up to 4 m thick), originally a marshland that developed over a thick sequence of glacial lake deposits (50 to 100 ft). During the summer of 2010 a comprehensive study of the landfill area included direct-push drilling at 18 separate locations, with sampling at regular 10 ft vertical intervals. The results indicate the regions of elevated arsenic concentrations and more importantly provide a unique opportunity to delineate arsenic pathways in 3D space. The study identified an existence of unexpectedly high arsenic zone in groundwater with strong concentration gradients on each side of the zone. The zone is less than 3.5 m thick, contains As above 10,000 ppb (up to 16,000 ppb), and is positioned beneath the peat layer and above a basal till unit. Although the landfill waste can not be ruled out as potential source, one possibility for the source of As is the peat layer itself which, when covered by the waste material, may have promoted bacterial activity driven by organic carbon transported downward from landfill waste prior to capping, creating a reducing environment and remobilization of arsenic. However, the post-glacial geohydrologic evolution of the area is poorly constrained. Historically, the landfill operated as an open dump for a period of 100 years or more. Hydraulic conditions necessary to move shallow groundwater through waste to depth were eliminated by cap construction in the mid-1990's, and the hydraulic regime following capping continues to evolve.

Geological characteristics and fluid inclusions of Chagangnuoer iron ore deposit in the western Tian Shan Mountain, NW China

WEI HONG AND ZUOHENG ZHANG

MLR Key Laboratory Metallogeny and Mineral Assessment, Institute of Mineral Resources, CAGS, Beijing 100037, China (correspondence: zuoheng@hotmail.com)

Located along the southwestern margin of the Central Asia Orogenic belt, the Chinese western Tian Shan Mountain is famous for abundance of mineral resources. In recent decade, remarkable advances have been made in the iron ore exploration in the Awulela metallogenic district. Take Chagangnuoer iron ore deposit for example, which is found in the late 1960s with only 6 millions ton reserves. With careful magnetic survey in 1980s and drilling prospecting since 2004, this iron ore has become a large scale one whose reserves are more than 210 million tons. Hosted in the andesite and andesitic volcaniclastic rock of the Lower Carboniferous Dahalajunshan Formation, orebodies are controlled by NW, NWW, NEE strike faults and circular faults. This iron ore is composed of two major orebodies as FeI and FeII. FeI orebody is NE-SW strike, about 2900 meters in length, 63 meters in average thickness, and about 190 million tons reserves with thin copper layer. Wall rock alterations mainly exhibit garnetization, actinolitization, chloritization, epidotization, calcitization and so on. And marble distributes in the bottom of orebody. Ore minerals are consisted of magnetite, pyrite and chalcopyrite while gangue minerals are composed of garnet, actinolite, chlorite, epidote, tremolite, calcite *et al*.

Three kinds of fluid inclusions have been discovered in calcite, liquid-rich inclusion (75%), pure liquid inclusion (20%), and daughter (halite) inclusion (3~5%). Homogenization temperature is 290~410℃in the calcite paragenesis with garnet, whereas homogenization temperature is 120~230 ℃ in the calcite paragenesis with chlorite and epidote. According to a table describing the relationship between salinity and freezing-point depression [1], NaCl-eq salinity is 10.49~17.87%.

Impact of biological and mineral dust aerosols on mixed-phase clouds

C. HOOSE[1]*, C. ANQUETIL-DECK[1], S.M. BURROWS[2], M. HUMMEL[1], J.E. KRISTJANSSON[3] AND O. MÖHLER[1]

[1]Karlsruhe Institute of Technology, Institute for Meteorology and Climate Research, Karlsruhe, Germany (*correspondence: corinna.hoose@kit.edu)

[3]University of Oslo, Department of Geosciences, Oslo, Norway

Freezing of supercooled water droplets, at temperatures between 0 and -37°C, is facilitated by insoluble aerosols acting as ice nuclei. Numerous laboratory experiments have investigated the efficiency of aerosol particles to induce freezing. Different particle types (e.g., mineral dusts or ice nucleation active bacteria) are usually studied in isolation. Here we summarize experimental results by using the metrics of "surface site densities" [1], which allows a more quantitative comparison than if only the nucleation onset temperatures are studied. This approach accounts for the size dependency of the nucleation process, but does not consider any time dependency.

In the atmosphere, in addition to the ice nucleation efficiencies, the available surface and number concentrations at cloud altitudes of the various ice-nucleating particle types are main determinants of their contribution to cloud ice formation. The concentrations of bacteria, fungal spores, pollen and mineral dust are simulated in the global climate model CAM-Oslo [2,3], and (so far for pollen and mineral dust only) the mesoscale model COSMO-ART [4]. In the global model, ice nucleation is dominated by mineral dust due to its higher average concentrations. The mesoscale model is capable of capturing small-scale fluctuations. The implications of this variability will be investigated.

Bacterial oxidation of pyrrhotite and troilite under acidic conditions

J. HOPF[1]; K. POLLOK[1], M.F. HOCHELLA[2] JR. AND FALKO LANGENHORST[3]

[1]Bayerisches Geoinstitut, University of Bayreuth, D-95440 Bayreuth, Germany
[2]Center for NanoBioEarth, Department of Geosciences, Virginia Tech, Blacksburg, Virginia 24061, USA
[3]Institute of Geosciences, FSU Jena, D-07749 Jena, Germany

To study the influence of microorganisms on sulfide oxidation, experiments on pyrrhotite in the presence of the two acidophilic species *Acidithiobacillus ferrooxidans* (*A.f.*) and *Acidithiobacillus thiooxidans* (*A.t.*) were performed. Pyrrhotite cubes with approximate dimensions of ca. 3×3×3 mm were polished on four faces to a smooth mirror finish. The host pyrrhotite was of the NC-type and contained 1-3 μm wide, fine exsolution lamellae of troilite [1].

First, oxidation experiments with *A.f.* cells were carried out in a simple acidic medium supplemented with pyrrhotite cubes for different time intervals (1 to 40 days). A consistent abiotic experiment was performed, serving as a control. *A.f.* developed a whitish biofilm on the cubes within 40 days. The surface underneath had deep trenches, inferring a preferential dissolution of the embedded troilite lamellae. Surfaces between these trenches displayed a layered and frayed structure, indicating enhanced pyrrhotite surface dissolution. XPS results indicated that *A.f.* drastically enhanced the oxidation of Fe(II) to Fe(III) on the pyrrhotite surface, whereas the pure abiotic experiment did not show any alteration, under the given conditions.

Further oxidation experiments with both acidophilic species (*A.f.* and *A.t*) were performed similarly. *A.f.* and *A.t.* distinctly augmented the pyrrhotite oxidation and particularly enhanced troilite lamellae dissolution. Experiments with bacteria in a dialysis capsule revealed a slower increase in surface roughness compared to free cells, indicating an active involvement of bacteria in the dissolution. Troilite lamellae dissolved similarly in both biotic experiments, but not in the control. The total rate constant for pyrrhotite dissolution was lowest for the control (1.9×10^{-9} mol/(m²×s)) and highest for the *A.f.* experiment with free cells (1.4×10^{-8} mol/(m²×s)). Both bacterial strains oxidized pyrrhotite and especially the troilite phase. The bacterial cell contact to the mineral surface seemed to be irrelevant for the process, therefore a contact-independent mechanism is most likely for biotic pyrrhotite/troilite oxidation.

Early thermal events of the HED parent body (4 Vesta) from eucrite zircon U-Th-Pb-Ti depth profiles

M.D. HOPKINS[1,3]*, S.J. MOJZSIS[1,3] AND W.F. BOTTKE[2,3]

[1]University of Colorado, Department of Geological Sciences, 2200 Colorado Avenue, Boulder, CO, 80309 USA (*correspondence: michelle.hopkins@colorado.edu)
[2]Southwest Research Institute, Department of Space Studies, 1050 Walnut Street, Ste. 300, Boulder, CO, 80302 USA
[3]Center for Lunar Origin & Evolution, NASA Lunar Science Institute

Meteoritic zircons provide a means to probe the thermal evolution of asteroids, but this technique has been limited due to generally low yields of small (~10μm ∅) grains in thin sections cut at random orientations and analyzed in 2-D "spot mode". Conversely, the 3-D zircon depth-profile method chemically and isotopically maps minute (sub-μm) domains within individual grains that conventional 2-D spot analyses cannot capture. We report data from coupled Ti-thermometry and U-Th-Pb profiles used to evaluate apparent crystallization temperature and composition as a function of age in zircons from the Millbillille brecciated eucrite. Crushed and sieved ~3g aliquots were separated using reagent grade methylene iodide to extract the largest zircons. Two large grains (mb1_gr1 ~40μm; mb7_gr1 ~20μm) were imaged by back-scattered electrons, and the internal distributions of U-Th-Pb-^{49}Ti (and -^{57}Fe-^{177}Hf^{++}-^{89}Y) in each zircon measured on the UCLA Cameca ims1270 ion microprobe in depth-profile mode. Results show that mb1_gr1 preserves a concordant core age of 4561±13 Ma (2σ; mswd=0.72; n=7) and a 4.5μm overgrowth at 4524±9 Ma (2σ; mswd=2.52; n=19). Sample mb7_gr1 shows one domain age of 4537±10 Ma (2σ; mswd=3.0; n=19) statistically indistinguishable from the younger mantle in zircon mb1_gr1. Core ages from mb1_gr1 correlate well with other reported crystallization ages for eucrites [1] and ^{40}Ar-^{39}Ar ages of unbrecciated eucrites [2]. Because the decay of ^{26}Al was effectively complete 5 Myr after t_0, we propose that later ~4530 Ma events that overprint ca. 4560 Ma ages were caused by shock-heating from a large impact, or burial of hot material excavated by impact. The manifestation of such a large and early impact event on a small (900km) body such as 4 Vesta should be as a subdued impact basin from the mechanical relaxation of the asteroid's crust. NASA's DAWN mission will encounter Vesta (July, 2011) and should be capable of resolving whether such an old basin is present.

Rejuvenation of an old magmatic system at Parinacota Volcano, Chile

J.M. HORA[1]*, G. WÖRNER[1], A. KRONZ[1], M. BANASZAK[1], B.S. SINGER[2] AND C.M. JOHNSON[2]

[1]GZG Abt. Geochemie, Georg-August Universität Göttingen. Goldschmidtstraße 1, 37077 Göttingen, Germany (*correspondence: jhora@gwdg.de)
[2]Department of Geoscience, University of Wisconsin-Madison. 1215 W. Dayton St. Madison WI 53706, USA

The history of Parinacota Volcano in the Andean CVZ represents a transition between two fundamentally different modes in which magmatic reservoirs can operate: long-term crystal accumulation and storage vs. rapid throughput with minimal crustal transit times. Changes in volcanic output rate and compositional range parallel reorganization of the magma system preceding a sector collapse, after which the volcano was rapidly rebuilt [1]. ^{238}U-^{230}Th disequilibria indicate crystal ages of >120 k.y. in the pre-collapse time interval. In contrast, some post-collapse magmas have $(^{230}Th/^{238}U)_0$ eruption-age-corrected activity ratios as high as 1.33, implying that transit times from a region of garnet-residual partial melting in the lower crust to the surface were < 20 ky.

Minerals from pre-collapse highly porphyritic rhyodacite domes (eruption age 47-40 ka) do not form a linear array on an U-Th equiline diagram, but rather define a pair of wedges delineated by reference isochrons that have ages of 47.7 and 168 ka [2]. Because these are bulk crystal ages, two possible explanations are: (1) a protracted crystallization interval, during which crystals were nucleating continuously, or (2) crystal cores from a nascent pluton or crystal-rich mush zone that are older than 168 ka were subsequently overgrown with younger rims of variable thickness, resulting in average ages that in some cases approach that of eruption.

The phase assemblage present in these domes allows several geothermometers to be applied, recording different points along a pre-eruption Temperature-time path. Fe-Ti oxide equilibria yield temperatures of 792±30°C, whereas Zr-in-titanite gives temperatures that are ~85°C cooler. Because Zr diffusion in titanite is slow [3] compared to Fe-Ti oxide reequilibration, it is likely that the lower temperatures in titanite record an earlier point in T-t history. This would contradict the hypothesis of protracted monotonic cooling prior to eruption. Instead, it may indicate a re-heating event associated with recharge that remobilizes older (colder) crystals and facilitates their eruption after a long period of storage.

Palladium-silver systematics in the oldest differentiated planetesimal

M.F. HORAN[1]*, R.W. CARLSON[1] AND J. BLICHERT-TOFT[2]

[1]Carnegie Institution of Washington, Dept. of Terrestrial Magnetism, Washington DC 20015, USA (*correspondence: horan@dtm.ciw.edu)
[2]Ecole Normale Supérieure de Lyon,69007, France

Combined Hf-W and Pb–Pb isotopic data and calculated cooling rates from Muonionalusta, a Group IVA iron meteorite, indicate that it accreted, differentated and cooled within 2-3 Ma after the formation of CAIs [1]. This chronology suggests that its Pd-Ag isotopic systematics hold the potential of better constraining the Solar System initial abundance of ^{107}Pd ($t_{1/2}$ = 6.5 Ma). High-Pd/Ag metal from Gibeon (also group IVA) has given ^{107}Pd/^{108}Pd = (2.40±0.05) x 10^{-5}, but interpreting this ratio as the Solar System initial has been complicated by unsupported radiogenic ^{107}Ag in associated low-Pd/Ag troilite [2,3]. By contrast, a much higher Solar System initial ^{107}Pd/^{108}Pd of (5.9±2.2) x 10^{-5} was inferred from carbonaceous chondrites [4].

Metal and troilite samples were taken from two slabs of Muonionalusta [1]. Pd and Ag concentrations, determined by isotope dilution, and Ag isotopic compositions, measured on unspiked aliquots, were analyzed using a Nu Plasma MC-ICP-MS [5]. Troilite results confirm that Muonionalusta escaped isotopic resetting by shock [1], and indicate that the Pd/Ag ratio of Muonionalusta parental materials was ≥100 times chondritic. Metal compositions represent 1-10% troilite mixed with radiogenic ^{107}Ag, implying that metal and troilite were once isotopically homogenized in a molten core with 6-12% S. Pd-Ag isotopic data from three metal pieces, however, do not lie on a single isochron, but two samples have slopes corresponding to ^{107}Pd/^{108}Pd = (2.33 ± 0.27) x 10^{-5}, within the uncertainty of Gibeon [2,3]; one metal has a slope of 1.58 x 10^{-5}, implying an age 4 Ma younger than Gibeon.

If the Solar System initial ^{107}Pd/^{108}Pd was as high as inferred for carbonaceous chondrites [4], then Muonionalusta Pd-Ag records an age of ≥ 8 Ma, inconsistent with the quick formation and cooling required by W and Pb-Pb ages. If the Pd-Ag and Pb-Pb systems closed at the same time and record the same event in Muonionalusta, then these data imply an initial Solar System ratio between 2.6 x 10^{-5} and 3.0 x 10^{-5}.

Distribution and time variation of helium isotope ratios around the source region of the Iwate-Miyagi Nairiku Earthquake in 2008

KEIKA HORIGUCHI[1]*, TAKASHI NAKAYAMA[2] AND JUN-ICHI MATSUDA[1]

[1]Department of Earth and Space Science, Graduate School of Science, Osaka University, Toyonaka, Osaka 560-0043, Japan. (*correspondence: keika@ess.sci.osaka-u.ac.jp)
[2]Research Center for Prediction of Earhthquakes and Volcaic Eruptions, Graduate School of Science, Tohoku University, Sendai, Japan.

The Iwate–Miyagi Nairiku Earthquake in 2008 (M_{JMA}7.2) occurred on June 14th 2008. We monitored the time change for helium isotopic ratios before and after the earthquake, to define the behavior of the upcoming fluid around the source region. The spring water and gas samples were collected in eight localities, only a week after the earthquake [1]. We repeated the sampling over the next two years (after half a year, one year, one and a half years, two years). Compared to the data before the earthquake [2], we found 10-85% increase of ^{3}He/^{4}He ratio of hot spring gas in five hot springs after the earthquake, suggesting that the upwelling of aqueous fluid containing mantle fluid [1]. The ^{3}He/^{4}He ratios show a very large change that becomes steady after half a year and increases slowly as a whole in this region following the earthquake. In addition, in order to investigate the diurnal variation of helium isotopic ratios, hot spring water was collected every hour or every three hours for 24 hours in Yabitsu hot spring. The diurnal variation of the ^{3}He/^{4}He ratio is only about 3%. The ^{3}He/^{4}He ratios in this region show a significant change after a week, become steady after half a year, and increase slowly as a whole thereafter. This variation is much larger than the diurnal variation, indicating that a gradual upwelling of magmatic fluid still continues in this region.

Extensive denitrification in the subsurface of the Oak Ridge Site, Tennessee

J. HORITA[1]*, M.E. CONRAD[2], N. YOSHIDA[3], M. BILL[2], J. KOSTKA[4], D.B. WATSON[5], S. BROOKS[5] AND P. JARDINE[6]

[1]Texas Tech University, Department of Geosciences, Lubbock, TX 79409-1053 (*correspondence: juske.horita@ttu.edu)
[2]Lawrence Berkeley National Laboratory, Berkeley, CA
[3]Tokyo Institute of Technology, Tokyo, Japan
[4]Georgia Institute of Technology, Atlanta, GA
[5]Oak Ridge National Laboratory, Oak Ridge, TN
[6]University of Tennessee, Knoxville, TN

The operation of a waste disposal facility on the Oak Ridge Reservation in East Tennessee has resulted in extensive subsurface contamination. Groundwater is highly contaminated near the source with U (>60 ppm), Tc (>40,000 pCi/L), nitrate (up to 40,000 ppm), and acidity (pH range of 3 to 7). Due to high groundwater nitrate concentrations at this site, nitrate is often the most abundant electron acceptor available for microbial growth in the subsurface, and denitrifying bacteria have been shown to predominate over the microbial communities. Significant quantities of gases (CO_2, CO, H_2 and CH_4) indicative of microbial activity were also detected in groundwater, including high concentrations of N_2O (up to 4% of gases) and excess N_2.

The dissolved nitrates are intimately linked to the fate of uranimum contamination via redox cycles. To quantify the relative roles of dilution, assimilatory uptake, and denitrification as mechanisms of nitrate attenuationan, an integrated hydrobiogeochemical study was conducted. The fate of nitrate and denitrification products (N_2O and N_2) were investigated by means of mass-balance and stable isotope techniques. The degree of denitrification is up to 13% or greater, and systematic variations in $\delta^{15}N$ were observed (NO_3>N_2O>excess N_2) with decreasing concentrations of dissolved nitrates. Large negative isotope fractionations were calculated during denitrification: -30's and -40's of ‰ for $\delta^{15}N$ and $\delta^{18}O$, respectively. Large isotopic variations of the intermediate N_2O, including site-specific $\delta^{15}N$ fractionation, also provide insights into extensive denitrification processes of dissolved nitrate in groundwater at the site.

Isotopic fractionation of cadmium into calcite

T.J. HORNER*, R.E.M. RICKABY AND G.M. HENDERSON

Dept. Earth Sciences, University of Oxford, OX1 3AN, UK (*correspondence: Tristan.Horner@earth.ox.ac.uk)

Isotopic analyses of dissolved Cd (cadmium) in surface seawater have recently shown great potential as a new proxy for disentangling phytoplankton Cd (and by inference 'nutrient') utilization from abiotic processes, such as ocean mixing. Extending this information into the past requires the signal to be captured and faithfully preserved in a suitable sedimentary archive. However, the importance of environmental factors and the controls they may have on Cd isotopic fractionation into such archives, particularly calcite, remain poorly understood.

To this end, we performed controlled inorganic $CaCO_3$ precipitation experiments in artificial seawater solutions to understand such environmental controls. We precipitated calcite under different growth rates, temperatures, salinities, and ambient [Mg^{2+}], measuring isotopic compositions using double spike MC-ICPMS.

We find that the isotopic fractionation factor for Cd into calcite, $\alpha_{Cc\text{-}Cd}$, in artificial seawater solutions is always less than unity (i.e. light isotopes of Cd preferred in the reaction product) and appears to be insensitive to the majority of environmental factors studied. The magnitude of the fractionation factor shows no response to temperature or Mg concentration; or growth rate across the ranges studied.

However, no isotopic offset was recorded between the growth solution and carbonate when precipitated from de-ionized water, in contrast to those precipitated from artificial seawater solutions. This and other observations lead us to conclude that the cause of isotopic fractionation is related to kinetic isotope effects during the largely unidirectional incorporation of Cd at the mineral surface. This process is modulated by increased ion blocking of surface sites as salinity – and therefore the concentration of impurity ions – increases.

With the isotopic constraints from our experiments, we evaluate the role of $CaCO_3$ productivity in surface waters in the modern oceanic Cd budget, comparing with phytoplankton physiological Cd utilization. We conclude that carbonates are unlikely to play a significant role in setting the Cd isotope composition of seawater, although they are likely to be a minor sedimentary sink (and thus temporal archive) because of the low solubility of $CaCO_3$-bound Cd.

REE abundances in CAIs from Rumuruti chondrites

M. HORSTMANN[1]*, A. BISCHOFF[1] AND J. BERNDT[2]

[1]Institut für Planetologie, WWU Münster, Germany (*correspondence: marianhorstmann@uni-muenster.de)
[2]Institut für Mineralogie, WWU Münster, Germany

Introduction

Ca,Al-rich inclusions (CAIs) are the oldest objects known in our solar system (~4.56 Ga; [1]). Recently, CAIs from Rumuruti (R) chondrites were studied in great detail [2-4] but only limited trace element data [5] exist. The latter are important to reveal information on the formation processes of individual CAIs. So far, the rare earth element (REE) abundances of 16 inclusions have been determined by LA-ICP-MS.

Samples and Analytical Techniques

Sixteen randomly selected CAIs from the R chondrites NWA 753 and 1476 as well as Dar al Gani 013 described by [2-4] were measured with a ThermoFisher Element 2 single collector ICP-MS coupled to a laser ablation (New Wave 193 nm excimer system) unit. NIST SRM-612 was used as an external standard and BCR2-G for additional verification of precision and accuracy of the analyses. Data was processed with Glitter using Ca or Mg as internal standard (EPMA data by [4]).

Results

The CAIs show REE enrichments typically between ~5 and ~30 × CI for most elements. Four inclusions were found that exhibit fractionated patterns similar to Group II [e.g., 6]. The other twelve patterns are generally flat (Groups I (2 inclusions), III (1), V (4); [e.g., 6]) with variable abundances of the most volatile REEs (Eu, Yb) or display flat patterns with negative Eu anomalies (5 inclusions). The two CAIs of Group I have almost chondritic REE abundances.

Discussion

The REE patterns can be explained by different processes, including fractional condensation and (in)complete equilibrium condensation from a gas of solar nebula composition. However, distillation might also be a mechanism to account for the depletions of the volatile elements observed.

Employment of the nanoscaled-SIMS in soil science

C. HÖSCHEN*, K. HEISTER , C. W. MÜLLER AND I. KÖGEL-KNABNER

Lehrstuhl für Bodenkunde, Technische Universität München, 85350 Freising-Weihenstephan, Germany (*correspondence: hoeschen@wzw.tum.de)

The NanoSIMS technique is needful for investigating soils systems which are inevitable structurally heterogeneous down to submicron scale. Clay minerals, iron oxides, aluminium (hydr)oxides and charcoal are considered as major components controlling the formation of soil interfaces and aggregates which are relevant for the sorption of organic matter.

The high lateral resolution achieved with the NanoSIMS 50L instrument makes possible elemental localisation at such small spatial ranges and offers inside views into the complex elemental structural architecture of soil samples.

Allowing the simultaneous detection of up to 7 ion species by NanoSIMS it is possible to obtain information about elements characteristic for the coexistent soil constituent phases: organic matter (carbon, nitrogen, sulphur) and minerals (oxygen, silicium, aluminium, iron). Accurately measuring these organic matter-minerals associations has the need of solving isobaric mass interferences.

The good transmission at high mass resolution power of the nano-scaled SIMS technique is necessary to image processes playing an important role in soil science and taking place at small spatial scales and low concentrations in soils.

We discuss the employment of the NanoSIMS 50L instrument at TU München in soil science. We have explored the potentials of this new technique for the study of model compounds (clay minerals, iron, aluminium (hydr)oxides and charcoal) of incubated mixtures of known composition, i.e. artificial soils.

We present examples of mass interferences occuring in soil investigations solved by the NanoSIMS technique. At mass number 43 high mass interferences are occuring which are given from elements associations like $^{12}C^{31}P$, $^{27}Al^{16}O$, $^{12}C^{16}O^{15}N$, $^{30}Si^{12}C^{1}H$. Their differenciation needs an MRP of about 16000. By choosing the right beam deflection in front of the detector it is possible to measure these masses independently.

[3] Lab. Mat. Mineraux, UMR CNRS 7016, Univ. Haute Alsace, 68093 Mulhouse, France
[4] Institute of Geological Sciences, Hydrogeology Group, Freie Universität Berlin, 12249 Berlin, Germany

Compacted bentonite will be used in the context of a deep geological high level nuclear waste disposal as geo-engineered barrier and might be eroded in contact with water conducting features having low salinity (glacial melt water intrusion scenario) forming colloidal/nanoparticular phases. The potential role of these generated colloids enhancing radionuclide (RN) mobility is *inter alia* depending on the RN sorption reversibility and the colloid attachment probability.

Former laboratory batch studies on the sorption/ desorption of RN in the ternary system RN–fracture filling material (FFM)–FEBEX bentonite revealed relative high uncertainties in the measured bentonite colloid concentrations based on the ICP-MS Al signal indicative for structural Al [1,2] and the Al concentrations found in the natural Grimsel Groundwater (GGW; pH 9.6; ionic strength 1.2 mM) used as background electrolyte. The use of Zn-labeled montmorillonite, where Zn occupies the Mg positions within the octahedral layers of the clay mineral [3] is considered as a good way to circumvent these analytical drawbacks. Detailed studies on the characteristics (size, morphology and stability) of Zn-montmorillonite colloids released into GGW using ICP-MS, PCS, AFM, AsFlFFF and LIBD showed a very good agreement of their properties compared to those of the FEBEX bentonite derived montmorillonite colloids. Therefore, Zn-montmorillonite was chosen to carry out compara-tive batch type studies. We will present results of the ongoing sorption/desorption laboratory experiments in the ternary system RN (^{243}Am(III), ^{232}Th(IV), ^{242}Pu(IV), ^{237}Np(V), ^{233}U(VI) and ^{99}Tc(VII))–FFM (1-2 mm size fraction from the Grimsel Test Site (GTS, Switzerland)–Zn-montmorillonite.

Lithium isotope fractionation during extreme weathering of basalt in Hainan island, South China

KEJUN HOU[12], YANHE LI[1] AND DEFANG WAN[1]

[1]MRL Key Laboratory of Metallogeny and Mineral Assessment, Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing 100037, China; (Kejunhou@126.com)
[2]China University of Geological Sciences (Beijing), Beijing 100041 China

Many isotope systems are sensitive to weathering processes, including radiogenic isotopes like those of Sr and Nd and stable isotopes, such as those of Li and Mg. Lithium is a fluid-mobile, moderately incompatible trace element having two isotopes with ~16% relative mass difference. Like other alkali metals, lithium is present on the Earth only in the +1 valence state, so its isotopic composition is not influenced by redox reactions. Moreover, lithium is not a nutrient and does not participate in biologically mediated reactions. These characteristics make lithium isotopes potentially excellent tracers of near-surface fluid–rock reactions (Rudnick *et al*., 2004).

Lithium and Lithium isotopes of the samples from from a laterite profile developed from Neogene basalts in the northern region of Hainan Island, South China were detail measured. The results show a trend of decreasing δ^7Li with increasing weathering intensity. These observations are consistent with leaching of Lithium via Rayleigh distillation during progressive weathering. The δ^7Li was extremely low in the middle (2-3m) profile, this may indicate there has an paleo-water profile.

[6]Tandem Laboratory, Uppsala University, SE-751 21 Uppsala, Sweden

Anthropogenic ^{129}I discharged from European reprocessing plants has widely dispersed in the Nordic waters including the Arctic. Due to the high solubility and long residence time of iodine in seawater, anthropogenic ^{129}I has become an ideal oceanographic tracer for investigating transport pathways and the exchange of water masses. Iodine is a redox sensitive element, existing mainly as iodide and iodate, with minor amounts of organic iodine in marine water. The chemical speciation analysis of ^{129}I in seawater can be used not only to investigate the marine geochemical cycle of iodine, but any variation in the chemistry of a particular marine system.

Depth profiles of seawater were collected from 60 locations in the Arctic in four Arctic expeditions during 2005-2008. Collected seawater samples were stored in plastic bottles without any treatment until analysis. A volume of 1 l of each sample was used for the chemical separation of iodine species. Iodide and iodate were separated using anion exchange chromatography. The separated iodine species, as well as total iodine were separated from the water matrix component and all interfering elements by solvent extraction and were then precipitated as AgI for measurement of ^{129}I by accelerator mass spectrometry. The ^{127}I of different species separated from each water sample was measured using inductively coupled plasma mass spectrometry. The analytical results on the concentrations of chemical species of ^{129}I and ^{127}I as well as ^{129}I/^{127}I ratios of different species of iodine for these water samples will be presented. The spatial variations of ^{129}I, ^{127}I and their speciation in seawater in the Arctic will be derived. Sources and transport pathways of ^{129}I in the Arctic, the transformation process of chemical species of iodine and their mechanism will be discussed.

Colloidal processes in gold transport and deposition

R M HOUGH

CSIRO Earth Science and Resource Engineering, Perth, Australia, (robert.hough@csiro.au)

New studies of gold are revealing how metallography is a key component of our understanding of the deposition of precious alloys in primary ore systems. Alluvial gold nuggets once thought to be secondary in origin have now been shown to be the erosional residue of hypogene systems, i.e. primary. A new frontier in both hypogene and supergene systems is the nano domain. In hypogene settings gold at all scales can be metallic and particulate as has been directly observed in refractory ores, or the so called "invisible gold" in pyrite and arsenopyrite. Such nanoparticulate and colloidal transport of gold is a viable mechanism of dispersing the gold during weathering of ore deposits. Deposition of supergene (secondary) gold in the regolith is a product of the dissolution of hypogene gold from the a primary deposit (hosted by sulphides or quartz), transportation in solution and then re-precipitation elsewhere in the weathering profile. The natural nanoparticulate fraction of Au in these environments probably occurred as a colloidal suspension before final deposition as metallic particles and raises the question of how common a process is this in all gold depositional settings? These gold nanoparticles, long known about in materials sciences and manufacturing have now been seen in these natural environments as pure Au nanotriangles, hexagons and spheres. The destabilisation of the colloid will produce rapid deposition of the Au, potentially through evaporation in a single drying even meaning Au deposition can be a rapid event in the critical zone. The regularly heterogeneous distribution, trace concentration and nanoparticulate grain size of metallic gold in all ore systems has made it difficult for direct observation. Yet, it is critical to be able to establish a broad view of the microstructural/microchemical residence of the actual gold in a given sample. New generation element mapping (e.g. Maia on the Australian Synchrotron) tools now allow us to 'see' this invisible gold component and detect is wider distribution for the first time and to probe its chemistry and controls on deposition. These studies have the potential to provide a new approach and view of the formation, deposition and provenance history of the metal in all gold deposits.

Experimental and numerical investigation of focused flow through porous media due to mineralization

J. HOUGHTON[1] AND L. URBANO[2]

[1]Environmental Science, Rhodes College, USA (houghtonj@rhodes.edu)
[2]Lamplighter Montessori School, Memphis, TN, USA (lurbano@lamplighterschool.org)

The chemical input to the world's oceans from subsurface microbial biofilms in mid-ocean ridge hydrothermal systems has been difficult to quantify due to their inaccessibility. Results from experiments in a novel flow-through experimental apparatus using non-invasive monitoring of mixing via infrared imaging coupled to a 2D solute transport model allows the evaluation of changes in permeability, hydraulic conductivity and flow velocity during mixing of two end-member fluids within porous media. Initial Tests were conducted using instantaneous precipitation of amorphous Fe(III) oxyhydroxide upon mixing NaOH (1.2M) with $FeCl_3$ (0.4M) at the range of temperatures tested (25 to 40°C), according to the reaction:

$$3NaOH + FeCl_3 = FeOOH + 3NaCl + H_2O$$

Results indicate clear alteration of fluid flow vectors after 4.3 minutes of mixing, corresponding to the precipitation of 0.059 g FeOOH and a reduction in bulk porosity of 11.6% over only 35% of the flow cell. The NaOH solution was subsequently focused through a high permeability zone at double the starting velocity as Fe(III) precipitation increasingly blocked flow until complete blockage of all fluid outflow due to mineral precipitation occurred at 8 minutes. The corresponding bulk chemistry of the outflow changed from complete titration of the NaOH solution initially, to an excess of 9.56 mM/s in the outflow at the time of clogging as the availability of $FeCl_3$ becomes limiting. This technique successfully quantifies mm-scale changes in permeability due to amorphous FeOOH, a biofilm analogue, allowing non-invasive monitoring in real-time on spatial scales relevant to microbial biofilms.

F,Cl-rich mineral assemblages from burned spoil-heaps in the Rosice-Oslavany coalfield, Czech Republic

S. HOUZAR[1]*, P. HRŠELOVÁ[2], J. CEMPÍREK[1] AND J. SEJKORA[3]

[1]Moravian Museum, Brno, Czech Republic (*correspondence: shouzar@mzm.cz)
[2]Palacký University, Olomouc, Czech Republic
[3]National Museum, Prague, Czech Republic

Unusual Si-Al deficient and F,Cl-rich oxide-sulphosilicate-sulphate mineralization was found on burned spoil-heaps at Oslavany and Zastávka in the Rosice-Oslavany coalfield, Czech Republic. The assemblage typically forms irregular, zoned nodules ~5–15 cm in size enclosed in the common pyrometamorphic material of the piles, i.e. hematite-rich clasts, paralavas and clinkers. Their cores are usually formed by fine-grained mixture of gypsum and brucite with relics of anhydrite and periclase, respectively; locally, portlandite was found. The cores are rimmed by (or intersected by veinlets of) dark gray aggregates of medium- to fine-grained mixture of gypsum, anhydrite, Mn-rich srebrodolskite (X_{Mn}~0.4), magnesioferrite, unnamed $Ca_4(Mn,Fe)_2O_7$, and F,Cl-rich silicates that commonly replace anhydrite and gypsum. Prevailing F,Cl-rich minerals are fluorellestadite and Cl-rich hydroxylellestadite (X_{Cl}≤0.25). Rarely, inclusions of subhedral crystals of Fe,Si,Cl-rich mayenite (≤3.2 apfu Fe^{3+}, ≤2.2 apfu Si, ≤4.6 apfu F+Cl) were found in ellestadite at both localities; in Oslavany, it is associated with cuspidine. In Zastávka, assemblage with fluorite and F,Cl-rich Ca-silicates (rondorfite and kumtyubeite replaced by ellestadite and bultfontainite / cuspidine-like mineral) was rarely encountered. Surface and cavities of the nodules are sometimes covered by Mg-sulfates (epsomite-kieserite) and needles of gypsum. The observed oxide-sulfosilicate-sulfate assemblage is a high-grade pyrometamorphic product of the original dolomite-anhydrite-gypsum protolith, at T_{min} > 800°C. The most probable source of F is a thermal decomposition of fluorite and micas while chlorine was most probably released from the organic matter.

Burning spoil-heaps in the Rosice-Oslavany coalfield are characterized by high-grade pyrometamorphism followed by multi-stage mineral assemblages formed at lower temperature [1]. Similar oxide-sulfosilicate-sulphate assemblages were rarely found in nature e.g. in marble xenoliths in ignimbrites [2] or tephrites [3], and also on burning coal spoil-heaps [4].

A novel technique for F/OH apatite series synthesis and early results on thermodynamic mixing properties of fluor-hydroxylapatite solid solutions

GUY L. HOVIS

Department of Geology & Environmental Geosciences, Lafayette College, Easton, PA 18042 USA (*correspondence: hovisguy@lafayette.edu)

Synthesis and Unit-Cell Data

We have used a novel technique, to be described at the Goldschmidt Conference, to synthesize fluorapatite from a hydroxylapatite end member. In turn, these F and OH apatite end members have been utilized to synthesize multiple intermediate compositions along the F-OH apatite join. Employing NIST 640a Si as an internal standard, X-ray powder diffraction data were collected for all series members and, with the software of Holland and Redfern [1], utilized to refine unit-cell dimensions. The resulting data for these hexagonal crystalline solutions indicate that the "a" unit-cell dimension decreases linearly across the series as fluorine content increases, while the "c" dimension is nearly constant. Unit-cell volumes are linear, or nearly so, with composition, indicating volumes of mixing that are either small or non-existent.

Solution Calorimetric Results

Heats of solution have been measured at 50 °C in 20.0 wt% HCl under isoperibolic conditions for all F-OH apatite series members. Utilizing a 50-mg sample size in all experiments, calorimetric data collected prior to the abstract deadline for this conference show enthalpies of solution that behave linearly with composition for the F-rich half of the series, while data for OH-rich compositions appear to show small negative enthalpies of mixing. Overall, calorimetric results indicate that there is no enthalpy barrier to complete mixing between the hydroxylapatite and fluorapatite end members. We anticipate completion of the calorimetric study prior to the Goldschmidt Conference, but even at this time the nearly ideal thermodynamic behaviour of both volume and enthalpy is clear. Present results extend the thermodynamic data base for the apatite system [$Ca_5(PO_4)_3$(F,Cl,OH,0.5CO_3)] to compositions beyond the F-Cl apatite binary (Hovis and Harlov [2]; Schettler, Gottschalk and Harlov [3]).

Efficient cycling of Particulate Organic Carbon through orogenic systems

N. HOVIUS[1], A. GALY[1], R.G. HILTON[2], R.B. SPARKES[1], S.-J. KAO[3], AND J. LIU[4]

[1]Department of Earth Sciences, University of Cambridge, UK. (nhovius@esc.cam.ac.uk)

[2]Department of Geography, Durham University, UK. (r.g.hilton@durham.ac.uk)

[3]Research Center for Environmental Changes, Academia Sinica, Taipei, Taiwan. (s.j.kao@gate.sinica.edu.tw)

[4]Institute of Marine Geology and Chemistry, National Sun Yat-Sen University, Kaohsiung, Taiwan.

High erosion rates on convergent margins drive a transfer of Particulate Organic Carbon (POC) from standing biomass and soils into sedimentary basins. These basins are prone to rapid tectonic recycling, entraining buried POC in mountain building, exhumation and renewed erosion. The role of mountain building in the global carbon cycle depends, in part, on the rate of remineralization of entrained or fossil POC during exhumation and erosion. We have determined the geological resilience of POC in Taiwan, a small and fast eroding mountain belt in the west Pacific rim.

The flux weighted average of POC in 11 Taiwanese comprises a mixture of ~70% fossil POC and ~30% recently photosynthesised POC from the terrestrial biosphere. Measured fossil POC yields from Taiwan ranged from about 10 to 250 tC $km^{-2}yr^{-1}$. Efficient transfer of this material involved supply of about 1.3 X 10^6 t yr^{-1} of fossil POC exhumed in Taiwan to the ocean, with <15% loss due to weathering in transit. Nearby marine sediments show a positive trend between $\Delta^{14}C_{org}$ and $\delta^{13}C_{org}$ which is consistent with a mixture of the known terrestrial input and recent marine organic carbon. This indicates that fossil and non-fossil terrestrial POC is efficiently buried offshore Taiwan.

Plio-Pleistocene marine sediments have been exhumed in the frontal ranges of west Taiwan. These sediments contain first cycle fossil POC and graphitized carbon harvested from bedrock of the Taiwan Central Range. Peak metamorphic conditions in the Taiwan orogen have been insufficient to form highly ordered graphite found in the frontal ranges. Instead, this may have originated in an older orogeny elsewhere in east Azia before entrainment in Taiwan. Presence of this graphite in recent hyperpycnal deposits off SW Taiwan suggests that POC can survive multiple cycles of burial, exhumation and erosion. Resilience of fossil organic carbon during orogenic cycling in coastal mountain belts may enhance long-term storage of carbon in Earth's lithosphere.

Mineralogical study of arsenic carrier in coal combustion by-products of Kyjov-Poša impoundment (Slovakia)

R. HOVORIČ[1]*, Ľ. JURKOVIČ[2] AND E. HILLER[2]

[1]Department of Mineralogy and Petrology, Comenius University, Bratislava (*correspondence: hovoric@fns.uniba.sk)
[2]Department of Geochemistry, Comenius University, Bratislava (jurkovič@fns.uniba.sk, hiller@fns.uniba.sk)

The annual production of the coal combustion by-products (hereinafter CCB's) plays widely significant role as the anthropogenic arsenic resource [1, 2].

Previous research in the Kyjov-Poša locality well identified impoundment itself as the source of numerous organic and inorganic pollutants [3, 4, 5]. Downstream aquatic system which receives CCB's storage leachate contains elevated concentration of As exceeding the maximal allowed concentration for ground water after governmental regulation 296/2005 (<0.03 mg/l, Slovak Republic).

CCB's deposit stores circa 4.25 milion tons of ash with average As content 461 mg/kg (34 samples), thus 1960 tons of As in total.

The present study clarify As pathways after brown coal burning through storage deposit into the aquatic system. Realgar and orpiment rich coal after desulfurization in high-pressure boilers create As_2O_3 (gas?) as the main As (III) carrier that precipitate on the CCB's particle surfaces in the form of arsenolite and claudetite. Moreover, it is observed that arsenic oxidation state changes from tri-valent to penta-valent form linked with arseniosiderite crystalization. Solubility of arsenolite and claudetite in water seems to be dominant controlling factor of the arsenic mobility in studied site.

Mixed-habit diamonds: Evidence of a specific mantle fluid chemistry?

D. HOWELL[1]*, W.L. GRIFFIN[1], S.Y. O'REILLY[1], C. O'NEILL[1], N. PEARSON[1], S. PIAZOLO[1], T. STACHEL[2], R. STERN[2] AND L. NASDALA[3]

[1]GEMOC, ARC National Key Centre, Macquarie University, Sydney, NSW 2109, Australia (*correspondence: daniel.howell@mq.edu.au)
[2]CCIM, Earth and Atmospheric Sciences, University of Alberta, Edmonton, AB, T6G 2E3, Canada
[3]Institute of Mineralogy and Crystallography, University of Vienna, Althanstr. 14, 1090 Wien, Austria

Mixed-habit diamonds are a relatively understudied subset of samples, considering the amount of research that has been carried out on these vessels from the mantle. They exhibit periods of growth during which they were bound by two surface forms [1]; smooth octahedral facets, along with hummocky, non-facetted "cuboid" surfaces whose mean orientation is {100} [2]. This type of diamond is commonly referred to as *star* or *centre-cross*, because the cuboid sectors have a much darker appearance due to abundant graphite inclusions (Figure 1). However, for unknown reasons, cuboid sectors do not always contain these graphite inclusions. This means that occurrence of this type of diamond is likely under-reported simply as it is not always visible.

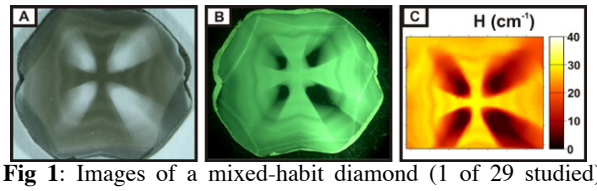

Fig 1: Images of a mixed-habit diamond (1 of 29 studied), under (A) visible light, (B) UV, & (C) IR map showing H concentration.

Mixed-habit diamonds have a number of unique characteristics (i) high nitrogen concentrations in both O and C sectors (higher in O than C), (ii) high hydrogen concentrations in the C sectors only (iii) low levels of nitrogen aggregation (iv) anomalously low platelet concentrations in the C sectors (v) vivid green CL that highlights an extremely complex growth history. We present a study that utilizes a holistic analytical approach (IR mapping, CL imaging, CL spectroscopy, SIMS C-isotope, Raman, EBSD) to identify all of these unique characteristics and understand them within the context of diamond growth. This will provide insights into the chemistry of the mantle fluids involved in this type of diamond growth.

Tin-bearing skarns with As mineralization at the south-eastern margin of the Bohemian Massif

V. HRAZDIL*, S. HOUZAR AND J. CEMPÍREK

Moravian Museum, Brno, Czech Republic
(*correspondence: vhrazdil@mzm.cz)

Rare but geochemically significant tin mineralization occurs in calc-silicate rocks (unzoned skarns) in marbles at the south-eastern margin of the Bohemian Massif (Svratka Unit); it is locally associated with arsenic and boron mineralization. The three stage origin of the skarn assemblage commenced by high-temperature reactions in a Fe-poor system, resulting in diopside, grossularite, wollastonite and clinozoisite. During the second stage, fluid infiltration introduced Fe, Sn, As, Bi and locally also B and F in the system, producing Sn-rich titanite and malayaite, Sn-bearing andradite ($Adr_{85-90}Grs_{10-13}$; 1.2-2.4 wt.% SnO_2), löllingite, As-bearing fluorapatite (≤12.24 wt.% As_2O_5), As,B-rich vesuvianite (≤1.97 wt.% As_2O_5; ~1.96 wt.% B_2O_3), bismuth and rare nordenskiöldine and fluorite. The third, retrograde stage caused alteration of the primary phases and produced e.g. secondary cassiterite, stokesite or datolite.

The infiltration of fluids modified the system evolution to the conditions with high fO_2, $a(H_2O)$ and locally elevated a(F) and a(B). Initial tin storage in the Sn-rich titanite and the malayaite as the earliest phases of skarn evolution [cf. 1] was followed by subsequent exsolution of cassiterite from malayaite and corrosion of primary phases. Distribution of As and Sn during following contemporaneous crystallization of silicates (Sn-rich andradite, As,B-rich vesuvianite), phosphates (As-rich fluorapatite) and borates (nordenskiöldine) was constrained also by structures of individual phases rather than by the P-T-X conditions (Tmin > 300°C, elevated activity of fluids) alone. Residual As in the fluid produced löllingite.

The occurrences of tin-bearing calc-silicate rocks are spatially bound to tourmaline orthogneisses with elevated contents of tin and fluorine [2,3]. The orthogneisses were earlier suggested being a source for Sn-anomalies in surrounding metapelites [3]. The tin skarns provide new evidence for metasomatic processes during the multistage metamorphic evolution of the area in a time span between late Cambrian and Carboniferous [4].

Mid-latitude continental response to falling atmospheric P_{CO2} during the Eocene-Oligocene transition

MICHAEL T. HREN, N.D. SHELDON, STEPHEN GRIMES, M. COLLINSON, J. HOOKER, M. BUGLER AND K. LOHMANN

The Eocene-Oligocene transition represents one of the most dramatic and permanent changes in global climate during the Cenozoic and was driven in part, by large-scale changes in atmospheric CO_2. Marine sediments provide a detailed record of changes in surface and deep ocean temperature and the development of the Antarctic ice-sheet during this time interval, however continental records that can be correlated to the geomagnetic polarity timescale are relatively few. As a result, there is considerable uncertainty over the magnitude and rate of continental climate response to changing CO_2 levels and the feedbacks associated with these changes. We measured the Δ_{47} of aragonite shells from freshwater gastropods in Eocene to Oligocene sediments in the Hampshire Basin, Isle of Wight, UK, to reconstruct the change in mid-latitude (~50°N) Northern Hemisphere terrestrial temperature during this critical climate transition. Isotopologue data show that growing season water temperatures decrease by more than 15°C from 34.5 to 33 Ma, corresponding to a maximum decrease in mean annual air temperature of more than 10°C. This drop in mid-latitude continental temperature occurs in tandem with a large-scale declines in atmospheric CO_2. The magnitude of this continental temperature change during a near-halving of CO_2 levels indicates a strong regional climate sensitivity for this climate transition. These data highlight the importance of understanding the relationship between the marine record and the continental realm, and spatial heterogeneity in the climate-CO_2 feedback systems.

Separating the sources of ^{228}Ra to the open ocean with ^{223,224,226,228}Ra measurements in Loch Etive and the South-East Atlantic

Y.-T. HSIEH[1], W. GEIBERT[2,3], P. VAN BEEK[4] AND G.M. HENDERSON[1]

[1]Department of Earth Sciences, University of Oxford, Oxford, UK (yuteh@earth.ox.ac.uk)

[4]LEGOS, Toulouse, France

Open ocean ^{228}Ra concentrations have been suggested as a proxy to constrain SGD fluxes – an important flux of nutrients and other dissolved species to seawater which is otherwise very difficult to constrain in magnitude [1]. Using open-ocean ^{228}Ra to assess SGD fluxes relies on being able to independently estimate the global fluxes of ^{228}Ra from other sources, particularly from shelf sediments and rivers. The magnitude of these fluxes has significant uncertainty.

We have provided new constraints on these fluxes with a suite of analysis on Loch Etive, a Scottish fjord. The loch has no known or expected groundwater input, and the fjordic overturning circulation usually restricts water exchange in the inner deep basin, with renewal events resetting the system to ocean values irregularly, about every 1 to 2 years. This allows us to assess ^{228}Ra flux from typical shelf sediments to the deep water, without groundwater inputs. At the same time, riverine input is assessed by measurement of the surface layer. We report ^{224}Ra and ^{223}Ra measurements by RaDeCC, and ^{228}Ra and ^{226}Ra measurements using a newly developed MC-ICP-MS approach [2]. Water in the deep loch shows higher ^{228}Ra concentrations than surface layer due to the sedimentary input, which is used to estimate ^{228}Ra sediment flux. Ra fluxes assessed from sediments and rivers in this setting are compared with values from the literature, which helps in the interpretation of the extant ^{228}Ra open ocean dataset.

We make use of understanding from Loch Etive in interpreting new preliminary data for the Ra quartet from the UK-GEOTRACES cruise in the SE Atlantic Ocean (GA10). Surface samples and depth profiles were collected for Ra using bottle and stand-alone-pumping and allow assessment of the fluxes of Ra, and hence information about the mixing transport of other elements to the open ocean.

Global distributions of mineral dust properties from SeaWiFS and MODIS: From sources to sinks

N. CHRISTINA HSU*, C. BETTENHAUSEN AND A. SAYER

NASA Goddard Space Flight Center, Greenbelt, MD, USA, (*correspondence: christina.hsu@nasa.gov, corey.bettenhausen-1@nasa.gov, andrew.sayer@nasa.gov)

The impact of natural and anthropogenic sources of mineral dust has gained increasing attention from scientific communities in recent years. Indeed, these airborne dust particles, once lifted over the source regions, can be transported out of the boundary layer into the free troposphere and can travel thousands of kilometers across the oceans resulting in important biogeochemical impacts on the ecosystem. Due to the relatively short lifetime (a few hours to about a week), the distributions of these mineral dust particles vary extensively in both space and time. Consequently, satellite observations are needed over both source and sink regions for continuous temporal and spatial sampling of aerosol properties.

With the launch of SeaWiFS in 1997, Terra/MODIS in 1999, and Aqua/MODIS in 2002, high quality comprehensive aerosol climatology is becoming feasible for the first time. As a result of these unprecedented satellite data records, studies of the radiative and biogeochemical effects due to dust aerosols are now possible. In this study, we will show the comparisons of satellite retrieved aerosol optical thickness using Deep Blue algorithm with data from AERONET sunphotometers over desert and semi-desert regions as well as vegetated areas. Our results indicate reasonable agreements between these two. These new satellite products will allow scientists to determine quantitatively the aerosol properties near sources using high spatial resolution measurements from SeaWiFS and MODIS-like instruments. The multiyear satellite measurements since 1997 from SeaWiFS will be compared with those retrieved from MODIS and MISR, and will be utilized to investigate the interannual variability of source, pathway, and dust loading associated with the dust outbreaks over the entire globe. Finally, the trends observed over the last decade based upon the SeaWiFS time series in the amounts of tropospheric aerosols due to natural and anthropogenic sources (such as changes in the frequency of dust storms) will be discussed.

[3]Univerisity of Colorado, Boulder, CO, USA

Metal sulfide precipitation is traditionally viewed as a process that reduces the bioavailability of contaminant metals in anaerobic settings. Our previous work has demonstrated that dissolved natural organic matter (NOM) can alter the kinetics of ZnS and HgS precipitation, resulting in the stabilization of nanoparticles in aqueous solution. The structure and composition of dissolved NOM varies widely and will control NOM interactions with metal sulfides. Furthermore, we have shown that NOM-coated nanoparticles of HgS may be bioavailable to methyating bacteria. This process depends on the "age" of those nanoparticles. The aim of this work was to investigate how the composition of NOM influences the stability of ZnS and HgS nanoparticles as they nucleate and aggregate in water with dissolved NOM. We utilized dynamic light scattering to monitor relative growth rates of metal-sulfide-NOM particles. We tested nine different NOM isolates that were derived from several different surface waters and represented a wide range of NOM composition. The NOM was observed to reduce particle growth rates, depending on solution variables such as type and concentration of NOM, monovalent electrolyte concentration, and pH. The rates of growth increased with increasing ionic strength, indicating that observed growth rates primarily represented aggregation of charged metal-S-NOM particles. Furthermore, our results indicated that stabilization of nanoparticles occurred mainly with NOM fractions of the greatest molecular weight and aromatic carbon content. Future work will utilized a combination of methodologies (photon scattering, X-ray absorption spectroscopy) to probe the mechanism of metal-sulfide-NOM polymerization during early stages of precipitation. Overall, our results highlight that nanoscale products are formed from reactions between trace metals, sulfide and NOM and that these entities may exhibit unique reactivities.

Isotope evidence for regional precipitation characteristics in the Poyang Lake Basin

HU CHUN-HUA[1,2], ZHOU WEN-BIN[1,2]*, JIANG JIAN-HUA[1,2], GUO CHUN-JING[1,2] AND ZHANG PEI[1,2]

[2]Key Laboratory of Lake Poyang Environment and Resource Utilization, Ministry of Education, Nanchang University, Nanchang, 330029, China

The study of hydrogen-oxygen isotopes tracing of atmospheric precipitation have been extensively used in global water circulation, water vapor source and lake palaeoenvironmental reconstruction etc, and provided significant theoretical evidence for global climate change or region research [1-2]. Region complicated geography and climatic conditions show a great effect on content of precipitation isotope in previous research with obviously different features [3]. In these work, we study isotope compositions and its change pattern of precipitation effects of water circulation in Poyang Lake Basin and its differences compared with large scale or high-altitude area rainfall isotope features.

The results show that: (1) The value of $\delta^{18}O$ and δD show significantly seasonal variability that dry season is greatly higher than wet season, which mainly affected by oceanic air mass and polar continental air mass alternatively; (2) In 2008 and 2009, precipitation line equation in Poyang Lake Basin have the regional or basin features made a greatly differences with global, coastal regions and high-altitude area, whereas being similar to low-altitude of China inland like Fuzhou and Wuhan district, also demonstrated these areas being controlled by the same type of monsoon and water vapor source of rainfall; (3) Precipitation effect in the Poyang Lake Basin is mainly controlled by southeast and southwest monsoon, but southeast monsoon has been a larger contributor.

Molybdenite Re-Os and zircon U-Pb dating of the Mesozoic Xingjiashan Mo-W deposit in the Jiaodong Peninsular, Eastern China

FANG-FANG HU, HONG-RUI FAN, TING-GUANG LAN AND KUI-FENG YANG

Key Laboratory of Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences, P.O. Box 9825, Beijing 100029, China (huff@mail.igcas.ac.cn)

The Xingjiashan deposit, located in the Jiaodong Peninsular in eastern China, is a typical skarn-type Mo-W deposit with an average Mo grade of 0.12 wt.% and W_2O_3 grade of 0.24 wt.%. The deposit is the only Mo-W one in the famous Jiaodong gold province, and temporally and spatially associated with intermediate to fine-grained Xingfushan adamellite porphyry. Mo-W mineralization is present mainly as veins, lenses and layers that are hosted by skarn.

LA ICP-MS U–Pb zircon age determinations of Xingfushan adamellite porphyry yielded a crystallization age of 162.1±1.4 Ma. Rhenium and osmium isotopes in molybdenite from the Xingjiashan deposit are used to determine the age of mineralization. Rhenium concentrations in molybdenite samples are between 3.2 and 7.8 μg/g. Analysis of seven molybdenite samples yields an isochron age of 162.9±2.7 Ma (MSWD=0.32). The W-Mo mineralization is therefore considered to be genetically related to adamellite porphyry emplacement in the Mesozoic. A low Re content of molybdenite in the ores indicates that the metal source was a crustal system. From these geochronological data and previously presented regional geological relationships, we propose that adamellite porphyry emplacement and Mo-W mineralization in the Xingjiashan mine resulted from an early stage of the subduction of the Paleo-Pacific plate beneath the North China craton.

Contamination by polycyclic aromatic hydrocarbons (PAHs) in Tianjin rivers, China

J. HU[1]*, D. LIU[2,3], Y.L. ZHANG[1,2] AND G.P. ZHANG[1]

[1]Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou, PR China
(*correspondence: hujian@vip.skleg.cn)
[2]Graduate University of Chinese Academy of Sciences, Beijing, PR China
[3]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, PR China

Tianjin is one of the most important industrial areas in northern China, and suffers from severe contamination of PAHs. Many rivers are located in the northeastern and south-western area of Tianjin city. Coal combustion, vehicle emission, coking industry, and biomass burning are the major contributors to PAHs pollution in the area. To understand the contamination status and behavior of PAHs in the river system, 72 water samples were collected from 12 major rivers in January 2008, and the levels of 16 priority PAHs in water and suspended particulate matter (SPM) samples were examined.

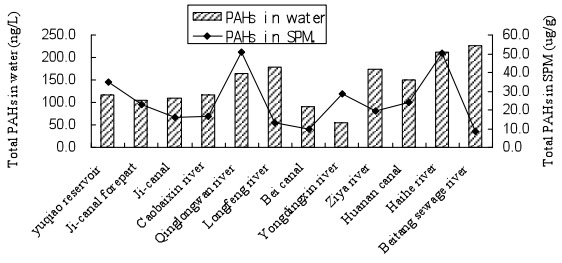

Figure 1: The contents of PAHs in water and SPM samples

The total concentrations of 16 PAHs varied from 25.1 to 131.1 ng/L in water, and from 0.13 to 213.8μg/g dry weight in SPM respectively (Fig.1). Two- to three-ring PAHs predominated in water samples of the study areas, and Nap was the most dominant. PAHs contents in SPM of the northern rivers were less polluted than those of the southern rivers. Predomination of low molecular weight PAHs suggests the relatively recent local source and coal combustion source of PAHs in the study area.

Nucleation pathways and energetic controls during templated nucleation of calcite by MHA and MUA self-assembled monolayers

QIAONA HU[1,2]*, UDO BECKER[1], MIKE NIELSEN[2] AND JIM DE YOREO[2]

[1]University of Michigan, Dept. of Geological Sciences, Ann Arbor, MI 48105 (*correspondence: qiaona@umich.edu)
[2]Molecular Foundry, Lawrence Berkeley National Lab, Berkeley, CA 94720

Organic templates in living systems are believed to control nucleation rates and crystallographic orientations of nuclei. Self-assembled monolayers (SAMs) have been frequently used as a simple model to reproduce the function of natural templates. In particular, SAMs made of alkanethiol molecules have been demonstrated to effectively induce highly-oriented nucleation of calcium carbonate [1, 2].

Although a mechanistic understanding of templating requires knowledge of the thermodynamic and kinetic barriers, no experimental work has been done to quantify these factors. Moreover, the importance of indirect nucleation pathways via amorphous precursors during templating remains unresolved. The objective of this study is to use measurements of nucleation rates to determine the interfacial energies between template-directed calcite nuclei and 16-mercaptohexadecanoic acid (MHA) and 11-mercaptoundecanoic acid (MUA), and to determine whether nucleation occurs via the amorphous phase. The results reveal that (1) MHA and MUA both significantly reduce the effective surface energy of calcite from about 97 mJ/m2 in solution to about 45.3 and 52.7 mJ/m2 on MHA and MUA respectively, providing a thermodynamic basis for the strong capacity of MHA and MUA to promote calcite nucleation; and (2) at solute activities below the solubility limit of amorphous calcium carbonate, calcite forms directly.

Late Cenozoic history of deep water circulation in the western North Pacific: Evidence from Nd isotopes of ferromangnese crusts

RONG HU, TIAN-YU CHEN AND HONG-FEI LING *

State Key Lab for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China (*correspondence: hfling@nju.edu.cn)

Despite the importance of deep ocean circulation in regulating the global climate, its past variations in the western North Pacific are still poorly understood. Nd isotopes of ferromanganese crusts have proven a good proxy for paleoceanic circulation changes. We obtained late Cenozoic Nd isotopic data of two ferromanganese crusts located near Mariana arc but at different water depths (MKD13: 1500m, MDD53: 2700m), and studied their implications for paleocirculation changes in this area. From early to late Miocene, Nd isotopic compositions of MDD53 remained stable. MDD53 was also characterized by the least radiogenic feature (Nd: -4.0 to -5.0) compared with crusts of similar water depths in the Miocene North Pacific. Afterward in the Pliocene Nd value of MDD53 increased sharply. In contrast, Nd isotopes of MKD13 became more and more radiogenic in the Miocene and were almost invariable afterwards. We interpret the continual increase in Nd of the shallower crust MKD13 as reflecting progressive closure of Indonesian Seaway in the Miocene, while the deep western boundary current originated from the Southern Pacific may have dominated Nd isotopes of the deeper crust MDD53 during the same time interval. The lack of Nd isotopic variation of MKD13 in the Pliocene indicates that there were no changes in Nd sources in the shallower water. Therefore the observed large shift to more radiogenic Nd isotopes of MDD53 in the Pliocene should not be caused by change in vertical input from shallower to deeper water. Instead, we suggest that the ventilation of deep southern component current along the studied water depth range (~2700m) may have evidently decreased in the early Pliocene.

This study was funded by the Chinese Association for Research of Oceanic Mineral Resources (DY-115-01-2-2) and the Education Ministry of China.

Noble gas isotopes of tungsten-tin polymetallic deposits in South China: Constraints on origins of ores and related granites

R.Z. HU*, X.W. BI AND G.H. JIANG

State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China
(*correspondence: huruizhong@vip.gyig.ac.cn)

South China is rich in tungsten-tin polymetallic deposits, and has the world's largest tungsten resources. These deposits have ages of ca.150-160 Ma, and are spatially, temporally and genetically related to granites which were previously believed to be S-type granitoids. Previous studies have significantly advanced our understanding of the ore formation. However, it has been poorly constrained whether or not mantle components were involved in the genesis of the deposits.

This study provides He and Ar isotope data of fluid inclusions in pyrite and arsenopyrite from the Yaogangxian, Furong, Shizhuyuan, Dajishan, Xianghualing, Yanbei, and Xihuashan tungsten-tin polymetallic deposits in South China. $^{3}He/^{4}He$ ratios range from 0.1 to 3.0 Ra (where Ra is the $^{3}He/^{4}He$ ratio of air = 1.39×10^{-6}). Moreover, there are excellent correlations between He and Ar isotopic compositions. The results suggest that the ore-forming fluids of the deposits are a mixture between a crustal fluid and a fluid containing mantle components. The existence of mantle noble gases in fluids, exsolved from the ore-bearing granitic magma, provides new insights about the origin of the deposits and associated granites. The hosting granites, previously considered as S-type, were actually formed by crustal melting induced by heat and volatile release from the mantle.

New insights on the origin of unresolved complex mixtures

S.Z. HU [1]*, S.F. LI [1], J.H. WANG[2], D.M. ZHANG[1] AND J. MA[1]

[1]Key Laboratory of Tectonics and Petroleum Resources (China University of Geosciences Wuhan), Ministry of Education, China (*correspondence: hushzh@cug.edu.cn, lishf@cug.edu.cn, zdm2007@cug.edu.cn)
[2]School of Marine Sciences, Sun Yat-sen University, Guangzhou, China (wangjh@gig.ac.cn)

Biodegradation results in the dissappearance of the dominant aliphatic and aromatic components of petroleum and in the development of an unresolved complex mixture(UCM), referred to as a big "hump" in GC. Many studies showed that UCM should result from the relative concentration of a complex mixture that is already present in crude oil, which arises from the removal of major resolved alkylated species by biodegradation[1-2]. However, the recent study on crude oil in Biyang depression, which carried out by 5A molecular sieve adduction and laboratory bacteria degraded experiment, suggested that UCM may be produced by biodegradation (Fig.1).

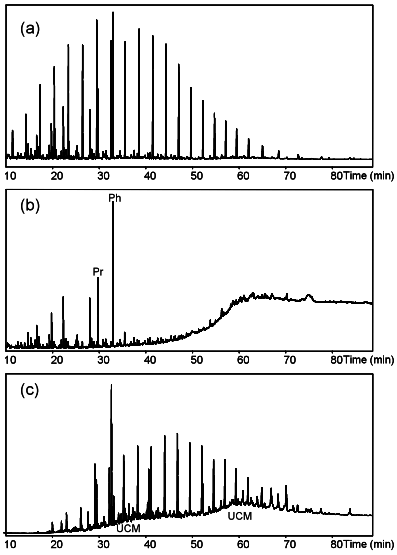

Figure 1 Gas chromatograms for : (a) SH1 crude oil; (b) non-adducted fractions for SH1 crude oil by 5A molecular sieve; (c) SH1 biodegraded oil after a 9-day laboratory experiment by a culture of aerobic bacteria isolated from a biodegraded oil in the field

Study on mineral surface reacted with water at high temperatures above 300°C

SHUMIN HU, RONGHUA ZHANG AND XUETONG ZHANG

Institute of Mineral Resources, Chinese Academy of Geological Sciences, Lab.Geochemical Kinetics. Baiwanzhuang road 26, Beijing 100037 (zrhhsm@pku.edu.cn)

Reactions at solid-water interface play an important role in a number of natural processes. Steady-state dissolution rates of pyroxene, actinolite, wollastonite, garnet and basaltic rock have been measured at temperatures (T) from 25 to 400°C and at 23-35MPa. All dissolution experiments were performed in mixed-flow reactor or packed bed reactor (with Zr metal liner). The mineral samples used in these experiments have been analyzed chemically. The compositions and structures of their surfaces are also analyzed through SEM and TEM before and after reactions. All experiments were performed at far-from-equilibrium conditions. The dissolution of silicate mineral in water, such as pyroxene, actinolite, may require the breaking of more than one metal-oxygen bond type. Different metal elements in silicate mineral behave different release rates, so that the dissolution product is often non-stoichiometric. Usually, Na, Mg, Fe, Ca dissolve faster than Si at T <300°C. In contrast, at T≥ 300°C, Si release rate is higher than other metals. For actinolite and diopside, Ca /Si release ratio at near 200°C is stoichiometric. SEM and TEM analyses of surfaces found the non-stoichiometric surface leaching-layer occurred at surface when dissolution is non-soichiometric. At T<300°C, surfaces of actinolite and pyroxene after reacted with water is a light Si-rich and little Fe (or / and Mg, Ca) deficient. In contrast, at T ≥ 300°C, the reacted surfaces are a light Fe-rich and little Si deficient. TEM study indicates that amorphous nanothin layer was found at the surface. Metal-H^+ exchange and hydration reaction at mineral surface will pass through this layer. As dissolution is non-stoichiometric, composition and structure of non-stoichiometric surface layers change with elapsed time. For instance, when basaltic rock reacted with aqueous solutions at 90°C, release rates of Ca (Mg) decrease with the elapsed time in 7 days, the rates of Si increase with the time. The surface area (m^2/g) and total pore volume (cc/g) increase with the time. Compositions of the surface vary with the time.

Raman spectroscopic study of the system $NaCl$-Na_2CO_3-Na_2SO_4-H_2O: Implications for the determination of Cl^- concentration in fluid inclusions

W. HU[1]*, X. WANG[1], I.M. CHOU[2] AND Q. SUN[3]

[1]School of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu 210093, P.R. China (*correspondence: huwx@nju.edu.cn)

[2]954 National Center, U.S. Geological Survey, Reston, VA 20192, U.S.A.

[3]School of Earth and Space Sciences, Peking University, Beijing 100037, P.R. China

Raman spectroscopy has been demonstrated to be an efficient method for the determination of salinities in aqueous solutions [1, 2]. This study demonstrates the sensitivity of the method and the effects of other common anions, SO_4^{2-} and CO_3^{2-}, on calculated salinities.

In this study, we synthesized aqueous fluid inclusions containing various salts in fused silica capillary capsules (FSCCs) [3], and collected Raman spectra of these fluids. The OH stretching vibration bands of water between 2700 and 3900 cm^{-1} wavenumbers were fitted with PeakFit v. 4.0 using two Gaussian sub-bands at ~3220 and ~3440 cm^{-1}, which are considered to result from strong (HBS) and weak hydrogen bonds (HBW), respectively [2]. Our results show that, in Cl^- solutions, the ratio (K) between the peak height (I) to width (H) ratios of the two Gaussian sub-bands ($K = (I/H)_{HBW} / (I/H)_{HBS}$) varies with salt concentration, and that the difference in the K values between salt solution and pure water ($\Delta K = K_{salt\ solution} - K_{H_2O}$) can be used to calculate Cl^- concentration.

Our results for NaCl solutions are in good agreement with those of Sun *et al*. [2], and demonstrate that a variation of 0.5 mass % of NaCl can be easily detected. We also observed that the ΔK values increase with increasing SO_4^{2-} and CO_3^{2-} concentrations at a constant NaCl concentration, and that the effect of SO_4^{2-} is much stronger than that of CO_3^{2-}. For example, the presence of 0.05 m of CO_3^{2-} and 0.05 m of SO_4^{2-} in 0.5 m of NaCl solutions will result in the increase of 0.03 and 0.12 m in the calculated Cl^- concentrations, respectively. Therefore, the relationship between ΔK and Cl^- concentration can only be applied to Cl^- dominated solutions; otherwise, the Raman spectrometer needs to be calibrated with standards such as those prepared in FSCCs.

Solubility of gold in granitic silicate melts at 850°C, 100MPa

XIAOYAN HU[1]*, XIANWU BI[1], GUOSHENG CAI[2]

[1]Institute of Geochemistry, Guiyang 550002, P.R. China (*correspondence: huxiaoyan@mails.gyig.ac.cn)
[2]Nonferrous Metal and Nuclear Industry Geological Exploration Bureau, Guiyang 550002, P.R. China

A lot of gold deposits are closely associated with intrusive igneous granites. It is curious how about the transportation of Au in the magma system, how about the gold solubility in different silicate melts and coexisting aqueous fluids. So, experiments were conducted to measure the solubility of gold in granitic silicate melts and coexisting aqueous fluids at 850°C, 100 MPa, and oxygen fugacity near NNO.

Haplogranitic gels with different compositions, distilled water, hydrochloric acid solutions with different HCl concentration were employed as starting material in the experiments. The weight ratio of the starting solid material and starting aqueous fluids are 1:1. Pure gold capsule was used as container; it also provided Au in the experiments. The temperature, pressure and run time were 850°C, 100MPa and 96 hours, respectively. Moreover, the pressure of several experiments ranged from 60 MPa to 100MPa.

The results of the experiment show that the solubility of gold in different melts is ranged from several ppm to dozens of ppm. The lowest gold solubility in silicate melt phase is 2.27ppm, in which K-rich peralkaline gels and distill water were employed as starting material. The detected gold concentration in melt phase is higher when the starting fluid is hydrochloric acid bearing. The solubility of gold in coexisting aqueous fluids is ranged from several hundred ppb to several ppm, and it increases with the content of HCl in the hydrochloric acid solutions. The contents of gold in granitic silicate melts are obviously higher than those in coexisting aqueous fluid.

The solubility of gold is also affected by the composition of the melt. Gold solubility in peralkaline silicate melts is higher than that in peraluminous silicate melts. Especially, increase of Na_2O/K_2O mole ratio in melt could increase gold solubility in melt phase. Pressure also has evident effect on gold solubility in granitic silicate melts. The solubility of gold in granitic silicate melts increases with increasing pressure.

Concluded from the experimental results, gold solubility in granitic melts is affected by the composition of the melt, the volatiles in the magma and the pressure. Gold solubility in peralkaline, especially sodium-rcih peralkaline granitic silicate melts is relative high, and this kind of granitic silicate melt could extract gold and be as an important media for gold transportation.

A discussion on ore-forming fluid sources by gas composition of inclusion and stable isotope in Qinglong Antimony deposit, Guizhou China

HU YU-ZHAO, WANG XIAO-LAN AND WANG JIN-JIN

Kunming University of Science and Technology, Kunming, 650093 (huyuzhao155@sohu.com)

Gas compositions of quartz and fluorite intergrowth with stibnite are determined as follows, H_2O-95.00 mol% (mean, n=9), CO_2 -2.36 mol%, N_2-1.429 mol%, CH_4-0.516mol%, C_2H_6 -0.444 mol%, Ar-0.146, H_2S -0.001 mol %, and O_2 not detected. In xCO_2/xCH_4-xN_2 / xCH_4chart, 4 samples fall into formation water area, and 5 into atmospheric water area. In xCH_4-xC_2H_6- xCO_2 chart, all fall into gas area.

Data determined from inclusions in authigenic quartz show that δD compositions that range from-105.8 to -128.1‰ with a mean of -114.2 (n=5). The $\delta^{18}O$ values of authigenic quartz range from 3.8 to 6.9‰ with a mean of 5.4, converted into $\delta^{18}O$ of water range from- 7.8 to -10.2‰ with a mean of -8.08. In the δD-$\delta^{18}O$ figure, the data above fall into formation water, and lie in the left inferior of formation water area in Alberta basin.

The gas compositions and their proportion of Qinglong deposit are similar to Shuangjiang CO_2 pool (approximately 100 km E) with CO_2 values of 63.81%, N_2 21.49%, CH_4 14.57%, $C_2H_6$0. 015%. In this CO_2 pool, $^3He/He$ and $^{40}Ar/^{39}Ar$ respectively with1031 and 1.28% may be explained crust-derived causes. The $\delta^{13}C$ of methane is -35.7-35.8‰ and ethane is -38.8‰ which have the characteristics of the mixture of Coal type gas and oil type gas. The δ^{13} C of CO_2 with - 4.7 ‰ may be result of pyrolysis of lots of carbonate.

The freezing point temperature of fluorite inclusions range from - 0.2 to -1.3°C, and their salinity range from 0.4 to 2.2%NaCl. So the ore-forming fluid of Qinglong antimony deposit shows certain characteristics of low salinity formation water, and light hydrocarbon comes from coal and oil field.

NIST SRM 610-614 matrix induced unique element fractionation in laser ablation ICP-MS at high spatial resolution analysis

Z.C. HU*, L. ZHOU, Y.S. LIU, L.S. ZHAO AND S. GAO

State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan, 430074, PR China (*correspondence: zchu@vip.sina.com)

The greatest strength of the LA-ICP-MS technique is its application to microsampling in which extremely small pits are obtained. The results of this study highlight some significant different laser-induced fractionations between widely used external reference materials NIST SRM 610-614 and natural silicate reference materials (e.g., USGS reference glasses (GSE-1G, GSD-1G), MPI-DING glasses, USGS basalt glasses and zircon reference material GJ-1) at high spatial resolution analysis. For the sample matrices and analytical conditions used in this study, the laser-induced elemental fractionations for 63 selected isotopes are negligible at the spot sizes of 160-44 μm. However, the laser-induced elemental fractionations of Li, Na, Si, K, V, Cr, Mn, Fe, Co, Ni, Cu, Rb, Cs and U (with respect to Ca) increase significantly with decreasing spot sizes from 44 μm to 32 μm, 24 μm and 16 μm in these natural silicate reference materials. Unlike in these sample matrices, laser-induced elemental fractionations of these elements in NIST SRM 610-614 are unique in that they are almost not affected by the change of spot sizes from 44 to 32 to 24 μm, with only slight increase at the spot sizes of 16 μm. The much less significant laser-induced elemental fractionation in NIST SRM 61X in comparison with other natural silicate materials makes them nonideal as external reference materials at high spatial resolution analysis. Alternatively, this NIST SRM 61X-specific matrix effect for Li, Na, K, V, Cr, Mn, Fe, Co, Ni, Cu, Rb, Cs and U can be minimized by using Si for internal standardization. U and Pb in zircon GJ-1 are exceptions, which are zircon-specific.

Single-grain muscovite Rb-Sr age of Xushan W deposit, central Jiangxi, China, and its geological implication

R.M. HUA[1]*, G.L. LI[1], X.L. WEI[2], X.D. WANG[1] AND X.E. HUANG[2]

[1]State Key Laboratory for Mineral Deposits Research, Nanjing University, Nanjing 210093, China (*correspondence: huarenmin@nju.edu.cn)

[2]Jiangxi Bureau of Nonferrous Metal Exploration, Nanchang 330001, China

The Xushan tungsten deposit in central Jiangxi province, China, comprises three types of ore-bodies, i.e. quartz vein type, skarn type, and altered granite type. Rb-Sr micro-isochron method [1] is first applied to determine the ore-forming age by using single grain of muscovite growing at the edge of the wolframite-quartz vein. Six pieces of muscovite are used for Rb-Sr isotope analysis. Result shows that the mineralization age is 147.1 ± 3.4Ma, with MSWD = 0.71. This ore-forming age is similar to many tungsten deposits in southern Jiangxi. The very high I_{Sr} value (0.849 ± 0.026) may suggest that the ore-related granite was a melting product of highly evolved and highly saturated crust material, and the ore-forming fluid had extracted the strontium of extremely high $^{87}Sr/^{86}Sr$ ratios from the granite through water-rock interaction. It also suggests that there was almost no contribution of mantle material during the formation of either ore-related granite or tungsten mineralization, which is also proven by some He-Ar isotope studies [2, 3].

U-series disequilibria of arc lavas revisited: Time-scales of magmatism in convergent margins

FANG HUANG[1,2]

[1]CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, USTC, Hefei 230026. (fhuang@ustc.edu.edu)
[2]Institute for Geochemistry and Petrology, ETH Zurich, 8092 Zurich, Switzerland

U-series disequilibria have provided a unique powerful tool to constrain the processes and time-scales of magmatism in convergent margins. Preferential transfer of U and Ra relative to Th via addition of slab-derived fluid to the mantle wedge has been proposed to explain the ^{238}U and ^{226}Ra excesses observed in arc lavas (e.g., [1]). However, an in-growth melting process is required to produce ($^{231}Pa/^{235}U$)>1 in most young arc lavas and ^{230}Th excess in a significant number of samples. It is thus critical to provide a self-consistent explanation for U-series disequilibria in arc lavas.

Most arc lavas are highly differentiated. Re-visiting global arc lava data shows that U-series disequilibria are correlated with magma differentiation indices (e.g., SiO_2); Sr/Th and Ba/Th generally decreases with increasing SiO_2, showing the effect of magma differentiation at crustal depths. Most importantly, although ($^{226}Ra/^{230}Th$) is correlated with Sr/Th and Ba/Th in lavas from individual arcs, such relationship is not clearly observed in less-differentiated basaltic lavas. Therefore, current observations do not support inheritance of ^{226}Ra and ^{238}U excesses from the metasomatised mantle wedge. Instead, in-growth melting may play a more important role than previously believed. Namely, partial melting of the mantle wedge produces ^{226}Ra and ^{231}Pa excesses, and ^{238}U-^{230}Th disequilibrium in arc lavas, depending on fO_2, residual phases, thermal structure, and initial conditions of the wedge [2]. U-series disequilibria are further modified by ageing effect and assimilating old materials, resulting in the positive correlation between ($^{226}Ra/^{230}Th$) and Sr/Th in arc lavas. Such a model reconciles controversial temporal implications from different parent/daughter pairs and implies that rapid magma upwelling (<8,000 years) from the mantle to the Earth's surface is not required.

Influence of microbial cells and extracellular polymeric substances on the sorption of As(V) and As(III) on Fe (hydr)oxides

J.-H. HUANG[1]*, E. J. ELZINGA[2] AND R. KRETZSCHMAR[1]

[1]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland
(*correspondence: jenhow.huang@env.ethz.ch)
[2]Department of Earth & Environmental Science, Rutgers University, Newark, New Jersey, United States

Adsorption and desorption regulate the partitioning of trace elements between aqueous and solid phases in soils and sediments. Previous studies have indicated that phosphate groups in microbial extracellular polymeric substances (EPS) form inner-sphere surface complexes on Fe(III)-oxide surfaces e.g. with phosphate groups [1], suggesting the potential influence of microbial EPS on As adsorption behavior. In this study, we investigated the adsorption behavior of As(V) and As(III) on goethite, ferrihydrite and hematite under the influence of *Shewanella putrefaciens* cells and EPS, including non P-containing EPS (xanthan, alginic acid) and P-containing EPS isolated from *S. putrefaciens* CN-32. Batch experiments for determing adsorption isotherms and As(V) desorption kinetics were performed at pH 7.0 at room temperature. Additionally, an ATR-FT-IR study was performed to reveal As(V) concurrent desorption with attachment of *S. putrefaciens* cells.

Adsorption of As(III) and As(V) at solution concentrations between 0.001 and 20 μM decreased by 10-45% in the presence of 0.3 $g.L^{-1}$ EPS from *S. putrefaciens*. Addition of 0.5 g L^{-1} xanthan and alginic acid decreased As(V) and As(III) adsorption at solution concentrations between 0.6 and 6 μM by 7-66%, which is comparable with EPS from *S. putrefaciens*. Also, inactive *S. putrefaciens* cells, which were treated with paraformaldehyde, induced desorption of As(V) from Fe (hydr)oxide surfaces. ATR-FT-IR spectra evidenced the formation of inner-sphere complexes between bacterial phosphate and carboxylate groups and hematite, which may compete for Fe (hydr)oxide surface sites with As(V). At low cell density (5×10^7 cells mL^{-1}) inner-sphere coordination of carboxylate groups became less important than at high cell density (5×10^9 cells mL^{-1}). Our results indicate that the competition between As and bacterial functional groups for Fe (hydr)oxide surface sites is an important factor leading to increased mobility of As.

Element mobility across the boundary between UHP eclogite and gneiss: Insights into supercritical fluids in continental subduction zones

JIAN HUANG[1,2]*, YILIN XIAO[1] AND GERHARD WÖRNER[2]

[1] School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, PR China (*correspondence: jhuang01@mail.ustc.edu.cn)

[2]Geowissenschaftliches Zentrum der Universität Göttingen, Abteilung Geochemie, Goldschmidtstr. 1, 37077 Göttingen, Germany

We carried out a combined study of petrology, whole-rock major and trace elements as well as Sr-Nd-O isotopes on samples from a profile across the boundary between ultrahigh pressure (UHP) eclogite and gneiss from the Dabie orogen. The contact is characterized by the presence of amphibole-rich rocks that formed by retrogression from eclogite. Directly at the contact to the gneiss, the rock has higher concentrations in K, Al, LILEs, REEs and HFSEs, but similar SiO_2, FeOt and transitional metal element contents compared to retrogressed eclogite further away from the boundary. $\delta^{18}O$ values of the gneiss show a slight decrease, while retrogressed eclogites display a progressive increase towards the boundary. This indicates fluid-assisted O isotope exchange across the contacts of different lithologies at local scales. Mass balance calculations reveal variable but significant element mobility acrross the boundary of the mafic and felsic UHP metamorphic rocks with the following order of mobility : Ba > (K, Li, Cs, Rb, Pb)> U > Th > REE > Nb (Ta) > Zr (Hf). Amphibolite-facies retrogression of eclogites are known to have no effect on their major and trace elements [1, 2]. Also, Si-rich metasomatism from partially melted gneisses should increase the silica content of the retrogressed eclogite [2]. Therefore neither process is viable here. We thus propose that the variations observed here were caused at high pressures by supercritical fluids that were probably generated by the breakdown of phengite at P-T conditions above the second critical end-point for silicate-H_2O systems.

Geochemical characteristics and geological significance of the basic intrusive rocks in Shifengshan copper deposit, Yimen, Yunnan, China

JIAN-GUO HUANG, RUN-SHENG HAN AND LEI WANG

Kunming University of Science and Technology; Southwest Institute of Geological Survey, Geological Survey Center for Non-ferrous Mineral Resources, Kunming 650093, P.R.C. (hjg1966@yahoo.com.cn)

Shifengshan copper deposit is the one of typical deposit which located at the Kunyang Rift of Proterozoic Yangtze oldland edge in Yimen Yunnan. It is found recently the basic intrusive rocks (sample as the gabbro in the 840m of the ore district) have presented intrusive contact connection with the surrounding rocks. it is seen chalcocitization in the edge of the gabbro.

Major elements are SiO_2 45.64-48.18×10^{-2}, Na_2O 4.66-5.20×10^{-2}, K_2O 1.06-2.56×10^{-2}, MnO 0.08-0.10×10^{-2}, characterized by high Na_2O but low MnO, the Rittmann index σ is 11.15-13.68. Trace elements present evident enrichment of K、Rb、Th, but the loss of Sr、Ta、Nb、Yb、Sc、Cr and so on, which are indicated the character of intra-continental rift basalts. ∑REE is 157.37-219.18×10^{-6}, Eu is Enrichment slightly (1.10-1.41), and it is rich in LREE(LREE/HREE=6.02-8.12, $(La/Yb)_N$ =7.99-12.70. REE distribution patterns show oblique to the HREE side and enrichment in LREE.

Based on reseach on geology. petrology and petro-geochemistry, we believe that the basic intrusive rock bodies formed in initial continental rift environment, which belong to the deep source of formation of basaltic magma, may be mixed with crustal material.

This paper was financially supported by the innovation team of ore-forming dynamics and prediction of concealed deposits, KMUST, Kunming, China (2008).

Research of three-dimensional engineering geology strata modeling in urban underground space

HUANG JINGLI[1,2]

[1]Geotechnical investigation and surveying institute, Changchun Institute of Technology, Changchun, China, 130000

[2]College of construction engineering, Jilin University, Changchun, China, 130000

The utility of urban underground space is a certain development trend in future. To efficient use the underground space, and to avoid of engineering accident and unnecessary resource waste, the rock and mass characteristics in strata and the distribution must be ascertained. Establishment of Three-dimensional engineering geology strata model could provide a reliable evidence for the city planning and engineering contracture.

Based on the investigation data, analysis and adjust the data according to accrual strata distribution, construct Changchun city engineering geology borehole data, then use the solids module in GMS (Groundwater Modeling System) to construct the three-dimensional engineering geology strata model of underground space in Changchun city. Analysis the cross section and vertical section of the visual three-dimensional strata, and qualitatively evaluated the engineering geology distribution characteristics of rock and mass in Changchun city.

In addition, compared to other software, GMS is convenient to draw and visualized well. The three-dimensional engineering geology strata model constructed with GMS could truly show the actual situation.

Records of sulfur isotopic composition and their significance from the Permian strata at Shangsi section of Guangyuan, Sichuan

JUNHUA HUANG, PENGWEI LI, LAISHI ZHAO, LIAN ZHOU, JUN CAO AND LIDAN LEI

State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

By analyzing the data of TOC total sulfur and sulfur isotopic composition of carbonate-associated sulfate (CAS) and pyrites from the Permian strata at the Shangsi section of Guangyuan, Sichuan province, and based on the C-S charts and associated sulfur isotopic theory, the relationship between the variation of $\delta^{34}S_{seawater}$ and the related paleoenvironments and paleoclimate was deciphered, together with discussion of the marine sulfur cycle; The organic matter burial efficiency in different periods was analyzed by dividing the $\triangle^{34}S_{CAS\text{-}Py}$ values into different grades and mineralization of the sedimentary organic carbon by BSR was also quantified. Some information about the sedimentary environments and the diagensis of the burial organic matter in this area has been obtained.

Carbon-sulfur charts show that the concentration of sulfate in the seawater was very low during the whole Permian in this area, and is just 0.6-0.8 of the modern marine in late Permian although with a little increase and the occurrence of sulfidization in bottom waters in this period. Characteristics of high S/C ratio and $\delta^{34}S_{Py}$ in the bottom of Chihsia formation indicates late intrusion of hot sulfuric fluid , therefore, the information about the sedimentary environments and early diagenesis is uncertain.

Another negative shifts in $\delta^{34}S_{seawater}$ values occurred in middle Dalong ages, however, with a lager extent of 16.5‰. There have been many hypotheses about its mechanism, among of which the reoxidization of massive H_2S from the bottom water was the direct cause. Recent research suggests that BSR is controlled by anoxic environments, supply of organic matter and SO_4^{2-} ion as well as favorable temperature. Highest activity of BSR occurs under the condition of 20-35℃. Therefore, persistent supply of heat to the bottom water released by The “short-lived” mantle plume event (lasting 10-20Ma, Siberian volcanism envent) during this period is the necessary factor of the fierce activity of BSR. In the meanwhile, the rising of the bottom water’s temperature would accelerate the upward diffusion of H_2S and mixing of the ocean, which finally caused a large amount of H_2S accumulating and reoxidized in the surface waters.

Formation of a layered Fe^{III} (hydr)oxide intercalated with dodecanoate

LI-ZHI HUANG*, KARINA B. AYALA-LUIS, CHRISTIAN BENDER KOCH AND HANS CHRISTIAN B. HANSEN

Department of Basic Sciences and Environment, University of Copenhagen, Thorvaldsensvej 40, DK-1871 Frederiksberg C, Denmark (*correspondence: lizhi@life.ku.dk)

A layered Fe^{II}-Fe^{III} hydroxide (Green rust, GR) intercalated with dodecanoate has been freeze dried under anoxic conditions and then oxidized by dioxygen to produce the corresponding layered Fe^{III} (hydr)oxide dodecanoate (isomer shift: 0.5003 mm s^{-1}, quadrupole splitting: 0.7523 mm s^{-1} at 80K). The final product ($oxGR_{C12}$) contains no Fe^{III} oxide impurities, and it has the same layer structure as the GR_{C12} (see Fig. 1).

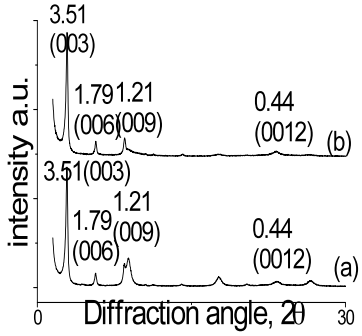

Figure 1, XRD patterns of (a) GR_{C12} (b) $oxGR_{C12}$ resulting from solid-state oxidation. (unit:nm; monochromated Co-Kα radiation (40 kV, 40 mA); randomly oriented powder sample was used.)

The average chemical composition of $oxGR_{C12}$ is $Fe^{III}_{2.8}O_{1.8}(OH)_{3.8}(C_{12})$. Mössbauer spectroscopy shows the presence of a trioctahedral Fe^{III} (hydr)oxide, and the huge variation in quadrupole splitting values of the Fe^{III} doublet reflect dramatic changes of electric field gradient due to the distortion of the octahedral sites which result from the mixture of OH^- and O^{2-} ions at the apices of Fe octahedrons. The $oxGR_{C12}$ product is stable in air and water (from pH 3 to pH 8), but it is destroyed in presence of 0.1M HCl and when dodecanoate is exchanged with carbonate. The intercalated dodecanoate stabilizes the Fe hydroxide layers and hinders transformation to Fe oxides. This is the first report describing the formation of a stable layered trioctahedral Fe^{III} (hydr)oxide.

Ab initio electronic structure of $Pu(OH)_4$: Comparison between density functional and multi-reference theories

PATRICK HUANG[1]*, MAVRIK ZAVARIN[1,2] AND ANNIE B. KERSTING[1,2]

[1]Physical & Life Sciences Directorate, Lawrence Livermore National Laboratory, Livermore CA, USA (*correspondence: huang26@llnl.gov)

[2]Glenn T. Seaborg Institute, Lawrence Livermore National Laboratory, Livermore CA, USA

Current spectroscopic techniques do not readily allow for the atomic-scale characterization of metal ions and complexes at low concentrations (i.e., < 10^{-10} M). This is problematic for highly insoluble species such as Pu(IV), where little direct information is available on its chemical behavior at environmental conditions. To this end, *ab initio* simulations are potentially useful for gaining insights into Pu complexes in aqueous environments. However, the electronic structure of actinide complexes poses difficulties. Accurate treatments of actinides often require sophisticated correlated wavefunction techniques whose cost grows rapidly with the number of electrons, and are only practical for small systems. Large-scale dynamical simulations of condensed phase phenomena typically rely on density functional theory (DFT); however, current DFT approximations for exchange-correlation (E_{xc}) can yield large errors for actinides due to the presence of localized 5*f*-electrons.

We report benchmark studies for the monomeric $Pu(OH)_4$ complex employing a range of *ab initio* techniques including single-reference approaches (unrestricted Hartree-Fock, UHF; second-order Møller-Plesset perturbation theory, MP2), multi-reference approaches (complete active space self-consistent field method, CASSCF; multi-reference perturbation theory, MRPT) and DFT. We find that single-reference methods such as MP2 provide a reasonable description of ground state geometries and energies, and an explicit inclusion of multi-reference effects involving the Pu 5*f* electrons is not essential. However, DFT with standard approximations for E_{xc} performs poorly for $Pu(OH)_4$. We explore the use of DFT+*U* as a simple way to improve on the DFT description of on-site Pu 5*f*-electron correlations. Using small hydrated cluster models, $Pu(OH)_4(H_2O)_n$, we determine an *ab initio* parameterization of DFT+*U* suitable for the aqueous phase simulation of $Pu(OH)_4$. With this DFT+*U* parameterization, we carry out periodic, *ab initio* molecular dynamics simulations of $Pu(OH)_4$ in a bulk water environment, in order to determine the aqueous solvation structure around $Pu(OH)_4$.

A critical look at the titanium-in-quartz (TitaniQ) thermobarometer

R. HUANG AND A. AUDÉTAT*

Bayerisches Geoinstitut, Universität Bayreuth, 95440 Bayreuth, Germany
(*correspondence: andreas.audetat@uni-bayreuth.de)

Synthetic quartz was grown in rutile-bearing $H_2O(\pm NaCl)$ fluids at 600-800 °C and 1-10 kbar by dissolution and reprecipitation of quartz in a small thermal gradient. Rapid attainment of rutile saturation is proved by the formation of rutile crystals at the contact between old quartz substrate and new quartz overgrowth. Titanium concentrations in new quartz correlate positively with the concentrations of Li and Al and depend strongly on quartz growth rate, increasing by up to a factor of 2.5 as the growth rate varied from ~4 μm/day to ~110 μm/day. Considering the composition of the most slowly grown quartz samples as most representative we obtain Ti concentrations that are about three times lower than those obtained during earlier calibrations of the TitaniQ thermobarometer [1, 2]. Our data can be fitted by the equation

$$\log \text{Ti (ppm)} = -0.27943 \cdot 10^4/T - 660.53 \cdot (P^{0.35}/T) + 5.6459$$

where T is given in Kelvin and P in kbar.

An independent test was made by analyzing igneous quartz from five intrusive and three volcanic magma systems that crystallized at known pressures (0.8–2.7 kbar) and temperatures (675–780 °C). The activity of TiO_2 was constrained from the composition of melt inclusions hosted in the analyzed quartz. Although the results depend on the model chosen to calculate $aTiO_2$, they agree much better with our calibration than with previous TitaniQ calibrations. Crystallization pressures calculated based on our calibration agree within 0.1-1.0 kbar with independent pressure estimates, whereas those calculated based on [1,2] are consistently higher by 3-9 kbar. Slight deviations between our calibration and the natural data are either due to uncertainties in the calculation of $aTiO_2$ of the natural melts or due to failure to synthesize structurally perfect quartz even at our slowest growth rates. Our findings imply that TitaniQ should not be applied to quartz grown from hydrothermal fluids, because growth rates in these environments can be very high. TitaniQ is more likely to work in igneous quartz, although the present models for TiO_2 solubility in quartz and silicate melts may still need to be refined.

[1] Wark & Watson (2006) *Contrib. Mineral. Petrol.* **152**, 743-754. [2] Thomas *et al.* (2010) *Contrib. Mineral. Petrol.* **160**, 743-759.

Hydrogen production from low temperature olivine alteration

SHANSHAN HUANG[1]* , HELGE HELLEVANG[2] AND INGUNN HINDENES THORSETH [1]

[1]Centre for Geobiology and Department of Earth Science, Univ. Bergen, Norway.
(*correspondence: shanshan.huang@geo.uib.no)
[2]Department of Geosciences, Univ. Oslo, Norway

Hydrous alteration of olivine, the main component in ultramafic rocks, has received much attention because the reducing power in the form of H_2 generated in this process is proposed to have fueled the emergence of life [1] and the present deep biosphere [2]. While most previous research was done at high temperatures (over 200ºC) [3], the upper temperature for living organisms is recorded as 122ºC. This study is thus focused on the H_2 production from olivine hydration at 80ºC, the core temperature for thermophiles and hyperthermophiles. Reactions with fluids representing the variety of composition of natural waters is studied.

Reactions with ground Fo90 were carried out in serum bottles which was deoxygenated with N_2. Headspace gas and solutions were analysed. A correlation between pH, olivine dissolution and H_2 production was established experimentally. Our data show that saline water and seawater promote H_2 production from olivine hydration compared with pure water. This is partly due to higher alkalinity in the seawater that buffers the pH. The H_2 production is found to correlate to the end pH in these systems. Geochemical modelling will be coupled to further understand the mechanism.

Olivine dissolution in water showed no passivation over 80 days. This means H_2 produced in this environment is proportional to the surface area of olivine in contact with H_2O. Experimental data also suggest high rock:water ratio and low pH promote H_2 generation.

We then tested the effects of seawater level of sulfate, nitrate and bicarbonate on H_2 production. Enhanced values of H_2 concentration was observed for sulfate- and bicarbonate-added reactions, in which sulfate-containing solution produced most H_2. The effect of nitrate addition is not obvious. The H_2 production in this set of expriments is not related to pH. The reaction mechanism is under further investigation.

Geochemical characteristics of natural gas reservoired in Lower Triassic Jialingjiang Formation in Naxi-Hejiang area, Southern Sichuan Basin, China

SHIPENG HUANG* AND XIAOWAN TAO

PetroChina Research Institute of Petroleum Exploration & Development, Beijing 100083, China
(*correspondence: hspsk@163.com)

Natural gases reservoired in Lower Triassic Jialingjiang Fm are mainly composed of alkanes, and the dry coefficients are more than 0.99, which indicates that the maturity of the gases is high. $\delta^{13}C_1$ values of the gas vary from -35.3‰ to -29.4‰, and $\delta^{13}C_2$ values vary from -35.1‰ to -32.1‰, $\delta^{13}C_3$ values range from -31.2‰ to -23.7‰, and the average values of $\delta^{13}C_1$, $\delta^{13}C_2$ and $\delta^{13}C_3$ are -31.3‰, -33.8‰, -29.8‰, respectively. Most of the carbon isotope series are reversed ($\delta^{13}C_1>\delta^{13}C_2<\delta^{13}C_3$). Hydrogen isotopes values of methane (δD_1) range from -140‰ to -114‰, δD_2 vary from 136‰ to -116‰, and δD_3 between -126‰ and -103‰. Gas samples with the characteristics of $\delta D_1> \delta D_2< \delta D_3$ account to 60% of the total number.

All the gas samples are of thermogenic gas based on the $C_1/C_{2+3}—\delta^{13}C_1$ correlation (correlation diagram source from [1]), and distribute between type II kerogen and type III kerogen area, indicating that gas preserved in Jialingjiang Fm was mixed, and the mixture of gases generated from two type kerogens caused the reversion of the carbon isotope series and the hydrogen isotope series. Ethane carbon isotope is often used to identify source rock's (kerogen's) type, and it is believed that carbon isotope value of ethane of the type II kerogen is less than -29‰ [2]. The gas reservoired in Jialingjiang Fm were mainly derived from type II kerogen based on the analysis of ethane carbon isotopes. Gas preserved in Low Permian Maokou Fm was studied to be generated from the carbonate strata of Lower Permian [3-4]. Gas preserved in Jialingjiang Fm is similar to the gas reservoired in the Maokou Fm in the composition of carbon isotopes, but the former is a little heavier than the latter. Gas resevoired in Jialingjiang Fm was mainly generated from type II kerogens of Lower Permian and mixed by the gas derived from type III kerogen of Upper Permian Longtan Fm.

The phase equilibrium of ternary system Cd^{2+}, $Na^+//Cl^-$-H_2O at 298 K

HUANG YI*[1], LU DANPING[2] AND ZOU FANG[1]

[1]Department of Geochemistry, Chengdu University of Technology, Sichuan, P.R.China
[2]Trade Union, Chengdu University of Technology, Sichuan, P.R.China

Solid- Liquid Equilibrium of ternary system Cd^{2+}, $Na^+//Cl^-$-H_2O at 298 K were studied by an isothermal solution saturation method. Experimental results indicate that there are three univariant curves AE, EF and FB, two invariant point s E, F, and three crystallization fields in the quaternary system. The quaternary system has one double salt $Na_2CdCl_4{\cdot}3H_2O$. The crystallization zones of equilibrium solid phases are $CdCl_2{\cdot}H_2O$ (AEC field), $Na_2CdCl_4{\cdot}3H_2O$ (EFM field) and NaCl (BDFfield), respectively. The composition of the invariant point E is $CdCl_2{\cdot}H_2O$ and $Na_2CdCl_4{\cdot}3H_2O$ of which content was 52.70% and 4.11%, respectively. The composition of the invariant point F is $Na_2CdCl_4{\cdot}3H_2O$ and NaCl of which content was 27.92% and 14.95%, respectively. The physico-chemical properties of solution in the quaternary system show regular changes along with the increased cadmium concentration. The results indicated that $CdCl_2{\cdot}H_2O$ possessed the highest solubility among those three salts, which means a strong transfer of Cd ion and a high pollution risk of soil environment. And the solubility of NaCl would be restrained as the salts existing together.

Study on distribution of technetium species and influence factors in groundwater

HUANG ZHIGANG[1] AND WANG YONGLI[2]*

[1]Department of Geochemistry, Chengdu University of Technology, Sichuan Province, (darkenerge@yahoo.cn)
[2]Department of Geochemistry, Chengdu University of Technology, Sichuan Province (*wangyl@cdut.edu.cn)

Tc is a major components in high-level radioactive wastes. The species distribution of Tc is a key factor to study the transport and deposition behavior in aqueous solution. It is easy to calculate species using geochemical computer program. We have calculated the species distribution of Tc in Beishan groundwater by PHREEQC, The result shows that TcO_4^- is the main specie. Under oxidation condition , the influence of pH to the existing form of Tc is very small, mainly in the form of TcO_4^-. however, under the reducing environmental condition that pe=-3 ~ -0.5, between the range of pH=4.6 ~ 8.8, it is mainly in the form of $TcO(OH)_2$, if it is pH> 8.8, then the mainly form will be TcO_4^-.

Crystal-poor vs. crystal-rich ignimbrites: A competition between stirring and reactivation

CHRISTIAN HUBER[1], OLIVIER BACHMANN[2] AND JOSEF DUFEK[1]

[1]School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta GA 30332, USA.
[2]Department of Earth and Space Sciences, University of Washington, Seattle WA 98195, USA.

Ignimbrites, providing unique windows into magma reservoirs prior to explosive volcanic eruptions, are of two main types: (1) crystal-rich dacites and (2) dominantly crystal-poor rhyolites. Crystal-rich dacites are typically homogeneous, while crystal-poor ignimbrites can display strong gradients in composition and crystallinity. This presents a conundrum as the more viscous, crystal-rich units should be less prone to mixing. Here we show that this dichotomy reflects the competition between two timescales that follow magma recharge prior to eruption: (1) a thermal reactivation timescale, that measures the time necessary to make a locked crystal mush rheologically eruptible (<50% crystals), and (2) a homogenization timescale associated with convective stirring. Using a thermo-mechanical model, we show that the reactivation timescale of locked mushes is much greater than the time necessary to homogenize reservoirs by convective stirring. Hence, crystal-rich units, which require a reactivation stage, are inevitably well stirred. In contrast, crystal-poor magmas are rheologically ready to be mobilized without reactivation and need not be thoroughly mixed upon eruption. This model provides an integrated picture of upper crustal reservoirs and has major implications for the link between shallow plutonic and volcanic rocks.

Optimization of thermodynamic properties and phase diagrams of P_2O_5 and CaO-P_2O_5 systems

P. HUDON* AND IN-HO JUNG

Dept. of Mining and Materials Engineering, McGill University, Montreal, QC, H3A 2B2, Canada (*correspondence: pierre.hudon@mcgill.ca)

P_2O_5 is an important oxide component in the late stage products of igneous rocks such as granites and anorthosites. More often than not, it combines with CaO and crystallizes in the form of apatite, while in volatile-free conditions, Ca-whitlockite is formed. In spite of their interest, the thermodynamic properties and phase diagrams of the P_2O_5 unary and CaO-P_2O_5 binary are not well known yet. In the case of the P_2O_5 unary, no experimental thermodynamic data are available for the liquid and the *O* and *O'* solid phases. As a result, we re-evaluated all the thermodynamic and phase diagram data of pure P_2O_5. The CaO-P_2O_5 binary was then optimized to reproduce all available thermodynamic and phase equilibrium data simultaneously in order to obtain one set of model equations for the Gibbs energies of all phases as functions of temperature and composition. Thermodynamic modeling was performed using the Modified Quasichemical Model [1-3] implemented in the FactSage software [4]. The optimized CaO-P_2O_5 binary is shown in Figure 1.

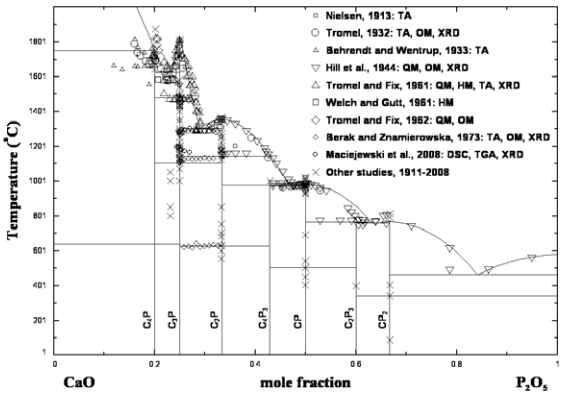

Figure 1: Optimized CaO-P_2O_5 binary.

Penetration, accumulation and degradation of Deepwater Horizon oil in Florida sandy beaches

MARKUS HUETTEL[1]*, JOEL E. KOSTKA[1], OM PRAKASH[1], WILL A. OVERHOLT[1], STEFAN GREEN[1,2], GINA FREYER[1,3], ANDY CANION[1], JONATHAN DELGARDIO[1] AND NIKITA NORTON[1]

[1]Earth, Ocean, and Atmos. Science Dept., Florida State University, Tallahassee, FL, (*correspondence: mhuettel@fsu.edu)

[2]DNA Services Facility, University of Illinois at Chicago, Chicago, IL

[3]Institute of Ecology, Friedrich Schiller University, Jena, Germany

Crude oil from the Deepwater Horizon spill was washed onto sandy shores of the Northern Gulf of Mexico, and this study investigates the fate of this oil and its impact on microbial communities in oiled beach sands. Tar balls and pancake oil were deposited on the beach surface, and due to the subsequent deposition of sand layers, congealed oil and tar were embedded as deep as 75 cm in Pensacola beach sands. Dissolved, low-viscosity and dispersed oil fractions could penetrate the sand through the pore space, staining the beach surface layers. Adsorbed oil increased the cohesiveness of the sand and reduced sand permeability. Oiled sand layers contained elevated rates of potential oxygen consumption and dissolved inorganic carbon production, indicative of ongoing degradation of the sedimentary oil deposits. Twenty-four bacterial strains from 14 genera were isolated from oiled beach sands and confirmed as oil-degrading microorganisms by phenotypic characterization and phylogenetic analysis of small subunit (SSU) ribosomal RNA (rRNA) gene sequences. SSU rRNA gene copy numbers of total bacteria were approximately 10 times higher in oiled vs. clean sand. Oil contamination from the Deepwater Horizon spill had a profound impact on the abundance and community composition of indigenous bacteria in Gulf beach sands, and our evidence points to members of the *Gammaproteobacteria* (*Alcanivorax*, *Marinobacter*) and *Alphaproteobacteria* (*Rhodobacteraceae*) as key players in beach oil degradation.

Crystal growth history of quartz in the Ordovician Millbrig K-bentonite

W.D. HUFF* AND F.O. INANLI

University of Cincinnati, Cincinnati, OH 45221
(*correspondence: warren.huff@uc.edu)

Crystal size distribution (CSD) analysis has been applied to quartz crystals of the Ordovician Millbrig K-bentonite, which represents one of the largest known fallout ash deposits in the Phanerozoic Era, to establish crystal growth histories and conditions in the magma chamber prior to eruption. Specific CSDs of the quartz crystals of the Millbrig K-bentonite were examined to establish their growth conditions prior to the eruption. On the crystal size distribution plot, all Millbrig samples exhibit concave-down shapes in agreement with previously reported CSDs on large silicic systems [1] but in contrast to more mafic systems characterized by linear CSDs. Crystal growth mechanisms responsible for the concave down CSDs are thought to be surface-controlled crystal growth followed by a episode of textural coarsening. Although all samples follow concave-down shapes, two samples exhibit rather different CSD shapes. These findings appear to fingerprint a separate magma batch with different crystal growth conditions. These ash beds appear to be a product of a series of separate eruptions that represent separate magma layers or batches, each with slightly different crystal growth conditions.

Haynes [2] interpreted the multiple ash layers as either a product of several periods of eruptive activity or the cumulative effect of an evolving magma chamber during a single massive eruptive event. Our data support the model of several periods of eruptive activity that was closely spaced in time. The two of the eight Millbrig samples must have come from an earlier phase eruption and are part of a basal section that have not been preserved in the stratigraphic record and lacks lateral continuity in distal parts of the deposits. Therefore, the multiple ash beds in the Millbrig must have been a product of series of separate eruptions that represent separate magma layers or batches that had different crystal growth conditions.

Although conclusions on crystallization processes and the origin of deposits cannot be drawn from CSD shapes alone, it is shown here that CSDs of a fallout ash deposits can be used to fingerprint separate magma batches, provide valuable information on crystal growth rates as well as nature of the crystal growth mechanisms of quartz crystals.

Photochemical transformations of carboxylates on TiO_2 and iron(III)(hydr)oxide surfaces

STEPHAN J. HUG AND PAUL BORER

Eawag, Swiss Federal Institute of Aquatic Science and Technology, CH-8600 Dübendorf, Switzerland

Colloidal iron(III)-phases play an important role in the adsorption, transport and transformation of organic and inorganic compounds. In sunlit aqueous phases, light-induced electron transfer in the bulk and on the surface of colloids can lead to photochemical oxidation, reduction and transformation of adsorbed compounds and often to dissolution of ironphases. As illumination of TiO_2 and iron(III)(hydr)oxides with UV-A light can produce oxidizing species, these solids are also of interest for water treatment and degradation of toxic compounds.

To investigate the different phototransformation pathways, we have followed photoreactions of dicarboxylates and of α-hydroxy-dicarboxylates on TiO_2 (a semiconductor known to produce OH-radicals with UV-A light) and on various iron(III)(hydr)oxides (where the photoproduced oxidizing species is not as well-defined) with in-situ ATR-FTIR measurements.

All investigated dicarboxylates adsorbed strongly to TiO_2 and to iron(III)(hydr)oxides up to circumneutral pH. Distinct changes of IR-spectra upon adsorption indicate inner-sphere coordination. On TiO_2, all dicarboxylates were quickly and completely mineralized by UV-A illumination and oxalate was formed before complete mineralization. In contrast, UV-A illumination of lepidocrocite, goethite and hematite did not lead to appreciable degradation of dicarboxylates except oxalate on the same time scale, but to transformation of α-hydroxy-dicarboxylates to oxo-carboxylates, which were further degraded only slowly.

These results suggest different photodegradation pathways. In comparison to TiO_2, OH-radicals seem not to be formed in high yield on iron(III)(hydr)oxides. Instead, photooxidation is more likely induced by direct ligand-to-metal charge transfer on the surface, or by bulk adsorption and migration of valence band holes to the surface and subsequent reaction with surface-coordinated carboxylate groups. The formed oxidants are able to readily oxidize α-hydroxy-carboxylates, but not dicarboxylates except oxalate. If generally valid, this means that iron(III)(hydr)oxides are not efficient photocatalysts for the complete mineralization of organic compounds, but that adsorbed compounds can be photo-transformed to distinct products.

Rare earth elements in pore waters of the Bering Sea sediments

YOUNGSOOK HUH* AND TSEREN-OCHIR SOYOL-ERDENE

School of Earth and Environmental Sciences, Seoul National University, Seoul 151-747, Korea
(*correspondence: yhuh@snu.ac.kr)

The rare earth elements (REEs) were measured in pore waters of the Bering Sea sediments using HR-ICP-MS after RE-spec column separation. Site U1345 was drilled during IODP Exp. 323 at the gateway to the Arctic Ocean to a depth of 140 mbsf. This is an area of high biological productivity and the drill site was at a water depth of 1008m in the center of modern oxygen minimum zone [1]. The pore water sampling depth resolution was 10m in Hole A (n=17) and 0.25m in Hole B (n=77).

The pore water REE concentrations were higher than sea water. Maximum concentrations were found below the sulfate-methane transition zone (6.5 mbsf) and centered at approximately 8–17 m: e.g. 790 pmol kg^{-1} Nd, 3000 pmol kg^{-1} Yb. The concentrations then decreased toward the bottom.

Shale-normalized REE patterns were HREE-enriched at all depths. This pattern has been linked to remineralization of POC and complexation of the HREE with DOC [3]. The HREE-enrichment was most extreme at the depth of maximum REE concentrations. There was a slight MREE bulge in the upper 3m. Ce anomalies were negligible throughout the depth profile.

Comparison to other chemical species (shipboard analyses of dissolved Fe, Mn, Ba, phosphate, etc.) will be presented.

State-dependent chemistry of model atmospheric aerosol

A. J. HUISMAN, K. U. KRIEGER* AND TH. PETER

Institute for Atmosphere and Climate, ETH Zurich, Switzerland.
(*correspondence: ulrich.krieger@env.ethz.ch)

The chemical reactivity of aerosols is often studied by techniques such as aerosol flow tubes and environmental chambers, which are well suited to study processes with timescales of minutes to many hours. However, given the multiday longevity of aerosol in the atmosphere and the potential of aerosol to access a diffusion limited, glassy state, longer timescale studies are needed to understand the physical and chemical properties of glassy (or once-glassy) aerosols in the atmosphere.

An electrodynamic balance is used to trap a single particle of 1-10 micrometer diameter for up to a week at a time. The timescale of these experiments allows us to use atmospherically relevant oxidation conditions. The particle size and composition are nondestructively monitored as a function of relative humidity and temperature (and thus, physical state) and exposure to oxidant.

We explore the properties of binary and ternary systems (of which one component is water) including the evaporation rate and hygroscopicity of the particle. The particle is oxidized and subsequently recharacterized to discern the influence of this oxidation on e.g. the hygroscopicity. The relative humidity in the balance may be reduced to decrease water content of the sample, leading to vitrification and altered hygroscopicity, volatility, and potentially reactivity.

Results will be compared with numerical solutions of the diffusion equation providing information into the role of diffusion in limiting chemical reactivity. These results provide insight into the relationship between physical state and chemical reactivity, (including the potential of chemical processing to alter physical state or properties such as hygroscopicity) and the influence, if any, of past chemical processing on future chemical reactivity.

Crystal chemistry of Fe^{3+} in $(Mg,Fe)SiO_3$ perovskite and implications for lower mantle properties

DANIEL R HUMMER* AND YINGWEI FEI

Geophysical Laboratory, Carnegie Institution of Washington Washington, DC 20015 (dhummer@ciw.edu)

Recent work on Fe-bearing silicate perovskites indicates that Fe^{3+} may be an important cation in mantle perovskites, [1,2] and the behavior of Fe^{3+}-bearing perovskite therefore has important implications for the composition and dynamics of the lower mantle. In order to understand the effect of Fe^{3+} on the perovskite structure, we carried out multi-anvil syntheses of Fe^{3+}-bearing $(Mg,Fe)SiO_3$ (with and without Al) from a starting mixture of oxides, using Fe_2O_3 as the exclusive source of iron. To maintain a $Fe^{3+}/\Sigma Fe$ ratio close to 1 in the final run product, the sample capsule was surrounded by an oxidizing layer of Fe_2O_3.

Synthesis products were characterized using electron microscopy, electron microprobe, X-ray diffraction, and Mossbauer spectroscopy. Microprobe and Mossbauer measurements indicate that the synthesized perovskites contain no Fe^{2+} within detection limits, but as much as 7.4 mol% Fe^{3+}. Although evidence of Fe^{3+} in both crystallographic sites was observed in all samples, results suggest that Fe^{3+} preferentially occupies the octahedral site. The presence of Fe^{3+} in the octahedral site of $(Mg,Fe^{3+})SiO_3$ causes a substantially larger molar volume than that of $(Mg,Fe^{2+})SiO_3$ with the same Fe content (in which Fe^{2+} substitutes exclusively into the dodecahedral site). Fe^{3+} greatly increases the b/a axial ratio, potentially enhancing the seismic anisotropy of the lower mantle. Changes in the crystal chemistry of Fe^{3+}-bearing perovskite with depth may also complicate the nature of the spin transition zone, since octahedral Fe^{3+} becomes low spin at much lower pressures than does dodecahedral Fe^{3+}. Agricultural impact on P and metal availability in stream sediments

SILJA V. HUND[1]*, ALYSSA E. SHIEL[2], SANDRA BROWN[1], LESLIE M. LAVKULICH[1] AND DOMINIQUE WEIS[2]

[1]SWC, Land and Food Systems, Univ. of British Columbia, Vancouver, Canada; (*correspondence: silja@interchange.ubc.ca)

[2]PCIGR, Earth and Ocean Sciences, Univ. of British Columbia, Vancouver, Canada

Intensive commercial agriculture is associated with significant applications of phosphorus fertilizers for crops and trace metals (e.g., Zn, Cu) for animal production. Excess amounts of these elements are often found in nearby aquatic systems. This is of particular concern as high P levels cause stream eutrophication. Therefore, analytical protocols are needed to assess the impact of agricultural pollution. Sequential extraction (SE) schemes have been developed to determine the availability of contaminants for aquatic systems in relation to their chemical bonding within the sediment. While most SE schemes consider P and metals separately, we provide an assessment of a SE scheme for both categories (modified after the method of Tiessen and Moir [1] for P).

Our study focused on the Sumas River watershed, an intensive agricultural region in British Columbia (Canada) strongly affected by nutrient and metal pollution. To quantify agricultural impacts, we collected river bed sediment samples from headwaters (no anthropogenic disturbance) to the intensively managed agricultural region downstream, over the length of 35 km. We examined trends in concentrations (e.g., P, Zn, Cu, and Pb) for different geochemical fractions of these stream sediments. Both concentrations and Pb isotopic compositions are used to trace natural (e.g. serpentinites present in headwater region) and anthropogenic sources, and to corroborate the utility of the SE scheme.

Our results show increasing contaminant concentrations towards downstream, e.g., from 33 to 5,479 ppm for P, from 24 to 167 ppm for Zn, from 9 to 60 ppm for Cu, and from 0.9 to 21 ppm for Pb. The most effective extractants were found to be 0.1 M NaOH (for labile P and Cu) and 1 M HCl for other metals. An increase of labile P with increasing agriculture intensity suggests that sediment source is important for contaminant availability, with anthropogenically-introduced contaminants often accumulating in more labile fractions. For sediments, the $^{206}Pb/^{207}Pb$ ratio decreases from headwaters (1.20373) to downstream (1.17631), consistent with increasing contributions of anthropogenic origin.

Time scales of cooling of post-plutonic picritic to dacitic dikes (Adamello-Italy)

N. HÜRLIMANN[1]*, O. MÜNTENER[1], P. ULMER[2] AND A. ULIANOV[1]

[1]Institute of Mineralogy and Geochemistry, University of Lausanne, Switzerland (*correspondence: niklaus.hurlimann@unil.ch)
[2]Institute for Mineralogy and Petrology, ETH Zürich, Switzerland

The formation of late magmatic dikes crosscutting previous plutonic voluminous bodies is a common feature. The textures of these rocks indicate similarity with volcanic rocks and general proximity to liquid compositions. The detailed study of zoning patterns of pheno- and xenocryst assemblages together with high-precision U-Pb ages allows us to get constraints on residence times and cooling rates of these magmas. Cooling rates obtained from diffusion patterns in minerals are linked to the thermal condition of the wallrock during emplacement of the dikes. Knowing the emplacement ages of the dikes and the plutonic wallrock could put constraints on cooling of the latter.

We show partially equilibrated zoning patterns of elements as Mg, Sr, and Ba in plagioclase pheno- and xenocrysts of basaltic-andesite to dacite post-plutonic dikes within the S-Adamello in Italy. Zoning patterns allow extraction of time constraints of diffusive processes under certain temperature conditions during temporary storage of magma or during ascent in dikes based on the continuity relation for the diffusive flux of these elements [1]. Hbl-Pl thermometry for the matrix and phenocrysts constrains the temperature during magma evolution. In earlier picro-basaltic to basaltic dikes Mg-Fe^{2+} interdiffusion patterns of chromite-spinel as inclusions in olivine provides further constraints on cooling rates of these magmas. Attainment of equilibrium of zoned phenocrysts for major and trace-elements was tested by analyzing the aphyric- to fine grained matrix by LA-ICP-MS, to determine actual liquid compositions.

The role of sulfur in triggering early Neoproterozoic oxygenation

M.T. HURTGEN[1], N.L. SWANSON-HYSELL[2], G.P. HALVERSON[3] AND A.C. MALOOF[2]

[1]Northwestern University, Evanston, IL 60208, USA (*correspondence: matt@earth.northwestern.edu)
[2]Princeton University, Princeton, NJ 08544, USA
[3]McGill University, Montreal, Quebec, H3A 2A7, Canada

Several lines of evidence suggest that Earth surface oxygen levels increased ~2300 million years ago [1]. While oxygen concentrations through the remainder of the Proterozoic (2500-542 million years ago) are poorly constrained, recent studies have linked an increase in the abundance of redox-sensitive elements and the difference between sulfur isotope ratios measured in sedimentary sulfate and contemporaneously deposited pyrite to a second oxygenation event ~580 million years ago—coincident with the diversification of macroscopic metazoa [2-5]. Here, we present paired sulfate and pyrite sulfur isotope data from two time-equivalent sections of the early Neoproterozoic (Tonian Period; 1000 to ~720 million years ago) Bitter Springs Formation, Australia. The $\delta^{34}S_{sulfate}$ record is obtained from anhydrite in drill core and carbonate-associated sulfate in drill core and outcrop samples. $\delta^{34}S_{sulfate}$ values are very similar between anhydrite and CAS in the drill core data set and between the drill core data and the CAS obtained from outcrop samples. These data suggest that an increase in microbial sulfide production in anoxic marine bottom waters and sediments enhanced nutrient recycling, thus sustaining elevated organic carbon burial rates and early Neoproterozoic oxidation. Our findings are consistent with evidence of eukaryotic diversification at this time [6] and suggest that oxidation of the atmosphere-ocean system occurred earlier in the Neoproterozoic than previously appreciated. These results highlight the role that sulfur plays in regulating the exogenic cycles of carbon and oxygen, particularly in low sulfate oceans of Earth's past [7].

New insights into gold transport in HCl-bearing vapour at elevated temperatures

N. C. HURTIG*, A. A. MIGDISOV AND A. E. WILLIAMS-JONES

Dept. of Earth & Planetary Sci., McGill Univ., Montréal, QC, H3A 2A7, Canada
(*correspondence: nicole.hurtig@mail.mcgill.ca)

Metal transport by vapour is an especially attractive hypothesis for explaining ore formation in shallow magmatic environments, where exsolution of fluid occurs in the stability field of vapour. Convincing evidence for the transport of high concentrations of metals by vapour in natural systems has been provided by quantitative analyses of fluid inclusions in porphyry Cu-Au deposists and associated epithermal Au-Ag deposits. Other evidence of metal transport by vapour in natural systems comes from metallic mineral deposits around high temperature fumaroles and in the pipelines from geothermal wells (scalings).

Experimental studies on metal solubility and speciation in water vapour at temperatures up to 400°C have emphasised the role of hydration in metal transport by vapour. These studies have shown that the concentrations of Ag, Au, Cu and Mo in vapour are comparable to those measured in hot fumarolic gas condensates. The high concentrations reported for fluid inclusions have not been observed experimentally. The current study was conducted for a range of fO_2 and at higher pressures than previous experimental studies, in order to approximate a little more closely the pressures of natural systems.

Experiments were carried out in batch-type Ti autoclaves at a temperature of 367°C and pressures up to 194 bars in HCl-bearing vapour. Oxygen fugacity was buffered either by the assemblage (MoO_2/MoO_3) or graphite. Gold concentrations ranged between 1.1 and 321 ppb in condensed samples of the reacted vapours. At pressures below 100 bar, gold concentration increased at a rate of 2-3 per log bar, similar to that observed previously. However, above this pressure, there was a sharp increase in the pressure dependency of gold solubility to approximately 8-14 per log bar. This suggests that at the lower pressures investigated, the hydration number was similar to that predicted by other studies, but increased sharply at higher pressure. Gold solubility increased with increasing fO_2 and was approximately one order of magnitude higher in the MoO_2/MoO_3 buffered system than in the system buffered by graphite.

Geothermobarometry of basaltic glasses from Tamu massif, Shatsky Rise oceanic plateau

A. HUSEN[1]*, R. ALMEEV[1], K. SHIMIZU[2], T. SANO[3], J.H. NATLAND[4], J. KOEPKE[1] AND F. HOLTZ[1]

[1]Institute of Mineralogy, Leibniz University of Hannover, Germany (*correspondence: a.husen@mineralogie.uni-hannover.de)
[2]IFREE, JAMSTEC, Yokosuka, Japan
[3]National Museum of Nature and Science, Tokyo, Japan
[4]Rosenstiel School of Marine and Atmospheric Science, University of Miami, USA

IODP Expedition 324 [1] recovered samples from Shatsky Rise oceanic plateau ranging from picritic basalts (15.6 wt% MgO) to more differentiated tholeiitic basalts (4.9 wt% MgO). In order to determine crustal magma chamber and magma evolution processes lava samples from several evolutionary stages should be investigated. We present results of the mineralogical study of lower MgO pillow and massive flow basalts (Site U1347). Major element glass and mineral compositions were analyzed by electron microprobe (JAMSTEC and University of Hannover). Glass H_2O and CO_2 determinations were performed by FTIR spectroscopy.

In general, basaltic glasses from Site U1347 are evolved tholeiitic basalts (5.2-6.8 wt% MgO), resembling typical EPR MORBs, located in the high-FeO and low-Al_2O_3 fields of EPR basalts. The CaO/Al_2O_3 ratios observed in U1347 basalts are amongst the highest known for all MORBs, probably indicating very low pressures of partial crystallization. H_2O contents in the glasses show MORB values, ranging from 0.18 to 0.6 wt%. CO_2 contents are usually below detection limit of the FTIR method (<50 ppm). The glass compositions and the H_2O concentrations were used to simulate conditions of multiply saturation [2]. Our calculations demonstrate that basaltic melts could have been last equilibrated with Ol-Pl-Cpx association at 1110 to 1170°C in the range of pressures between 1 atm to 3 kbar. These estimates represent the maximum values, since Ol is scarcely observed in natural Pl-Cpx-phyric lavas. The compositions of coexisting Pl and Cpx (~30 samples studied) show two compositional trends. One trend can be reproduced as a result of ideal fractional crystallization at pressures between (0.5-3 kbar). The second trend is the object for future investigations. Application of Cpx-melt and Pl-melt geothermobarometers [3] gives inconsistent results for the same samples and generally shows high P-T values using Cpx-melt (3.7-7 kbar, 1140-1220 °C) and low and negative pressure values using Pl-melt equilibria.

On the fate of ^{220}Rn in partially saturated media

STEPHAN HUXOL*[1], MATTHIAS S. BRENNWALD[1], EDUARD HOEHN[2] AND ROLF KIPFER[1,3]

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, CH-8600 Dübendorf, Switzerland (*correspondence: stephan.huxol@eawag.ch)
[2]Buchserstr. 44, CH-8157 Dielsdorf, Switzerland
[3]Institute of Isotope Geology and Mineral Resources, Swiss Federal Institute of Technology Zurich (ETH)

Thoron (^{220}Rn, half-life 55.6s) is a short lived isotope of the radioactive noble gas radon (main isotope: ^{222}Rn, half-life 3.58d). While ^{222}Rn is part of the ^{238}U-decay series, ^{220}Rn originates from the ^{232}Th-decay series. As $^{220,\ 222}$Rn are produced from alpha-decay of radium isotopes, $^{220,\ 222}$Rn emanate from minerals containing their precursors $^{224,\ 226}$Ra. As a result, both radon isotopes are found in soil gas and soil-near air, ^{222}Rn also in ground water. Hence, it is expected to find also ^{220}Rn in ground water. However, ^{220}Rn could not be detected in natural aquatic environments, although ^{220}Rn in water can be measured in laboratory experiments by a tailored improved radon- and thoron-in-water detection system.

In a field experiment, $^{220,\ 222}$Rn concentrations in various depths were continously monitored in the unsaturated soil. During a rain event, the lower most sampling port was flooded by the rising groundwater table. In response to saturation, the ^{222}Rn concentrations decreased by 40-50%, but the ^{220}Rn concentrations become virtually zero. After the event, e.g. the return to partly unsaturated conditions, the ^{222}Rn concentrations increased to former levels whereby the ^{220}Rn concentrations only slightly rose to 20% of the pre-event concentration. We conclude from the different response of $^{220,\ 222}$Rn, that the release of ^{220}Rn to soil air is controlled by the soil water content, i.e. the thickness of water films around the soil grains. As the diffusion length of ^{220}Rn is about 75 times smaller than that of ^{222}Rn, most of the short lived ^{220}Rn decays within the water film, if the layer reaches a certain critical thickness. In contrast, the long lived ^{222}Rn diffuses through the water film into the soil air.

We tested this hypothesis in laboratory experiments with Mn-coated sand, that emanates ^{220}Rn. In a closed vessel, the sand was sequentially wetted while the ^{220}Rn concentration in the surrounding air was analyzed. Preliminary results show that the release of ^{220}Rn from sand to air is effectively controlled by the water content of the sand: at a critical water content, the measured ^{220}Rn concentration dropped to almost zero, adding experimental support that the release of ^{220}Rn is controlled by the available humidity in the porous media.

A new highly effective silicagel emitter for lead isotopic measurements

MAGDALENA HUYSKENS*, TSUYOSHI IIZUKA AND YURI AMELIN

Research School of Earth Sciences, Australian National University, Canberra 0200 Australia (magda.huyskens@anu.edu.au, tsuyoshi.iizuka@anu.edu.au, yuri.amelin@anu.edu.au)

In modern U-Pb-geochronology a precision as high as 0.01% can be achieved in isotopic analyses using thermal ionization mass spectrometry. One of the prerequisites for achieving this high precision was the development of a highly effective ion emitter [1], which is based on a colloidal silicagel formerly produced by the chemical company Merck. Unfortunately this silicagel is not available for purchase anymore, and another ion emitter will be needed if the emitter efficiency of colloidal silica deteriorates with time. We tested colloidal silicagels from Alpha Aesar, Nissan Chemicals and Sigma-Aldrich as possible alternatives to the established Merck emitter. The gels were tested for U and Pb blanks and the ion yield (number of ions detected divided by number of atoms loaded) depending on the SiO_2 concentration and particle size using 300 pg Pb of the Pb isotopic standard SRM-981. For the most effective emitter, we also searched for the optimal mixing proportion of silicagel and H_3PO_4.

The Pb blanks of the gels from all three companies are below 0.7 pg/g and for Sigma-Aldrich ~0.15 pg/g. The U blanks from Nissan Chemicals are between 21 and 38 pg/g and for Alfa Aesar ~0.7 pg/g, rendering these silicagels unsuitable for U analysis. The gel from Sigma-Aldrich shows low U blanks below 0.1 pg/g. We found no correlation between ionisation efficiency and the particle size of SiO_2. The most effective emitter is from Sigma-Aldrich at a concentration of 0.4%. The average ion yield for this concentration is 5.8% (n=18), higher than the average ion yield of 4.1% (n=23) of the Merck gel. The accuracy and reproducibility of the isotopic ratios of both gels are comparable (^{207}Pb/^{206}Pb = 0.914740 ± 0.000041 for Sigma-Aldrich and ^{207}Pb/^{206}Pb = 0.914735 ± 0.000048 for Merck). Fractionation factors range between 1.0005 and 1.0012. The highest ion yield for Sigma-Aldrich gel was obtained using 92 µg of H_3PO_4 and 0.004 ml of gel.

From these observations we conclude that the Sigma-Aldrich silicagel is an excellent alternative for the established Merck silicagel for Pb isotopic measurements.

The uraniferous groundwaters and minerals in the two-mica granite of the Daejeon area, South Korea

J. HWANG[1]* AND S.H. MOON[2]

[1]Daejeon University, Daejeon 300-716, Korea
(*correspondence: jeongha@dju.ac.kr)
[2]KIGAM, Daejeon 305-350, Korea (msh@kigam.re.kr)

Daejeon is the most worrisome area for U-contaminated groundwater in South Korea. Many workers have deep concerns about the geological environment and sources of uranium in the groundwater of the Daejeon area. The regional geology is dominated by Mesozoic two-mica granite and Paleozoic meta-sedimentary rocks composed of metamorphic black slate, mica-schist, and carbonate rock. The black slate includes low grade U ore up to 0.11%, but has not been mined. The U concentration in groundwater is high in the two-mica granite area, but the U-minerals have not yet been described. To elucidate the source of U in groundwater, the geochemistry and environmental isotopes of the groundwater, as well as the U-minerals of the source rock, are examined in this study.

The groundwater in uraniferous meta-sedimentary rocks has a very low U concentration, less than 10μg/L. Meanwhile, the maximum level of U in two-mica granite is as high as 402μg/L. The ranges in Eh values of groundwater in granite and meta-sedimentary rocks are +202~+385 mV and -50~+225 mV, respectively. Granite aquifers are mostly subject to oxidizing conditions but meta-sedimentary aquifers are subject to relatively reducing conditions. Despite the high content of U in black slate, very little U is extracted into groundwater due to the reducing environment. The ranges in the $^{87}Sr/^{86}Sr$ ratios for groundwater in granite and meta-sedimentary rocks are 0.7111~0.7201 and 0.7112~0.7620, respectively. The consistent $^{87}Sr/^{86}Sr$ ratios of groundwater in granite indicate that the aquifer has remained a closed system. The $^{87}Sr/^{86}Sr$ ratios of uraniferous groundwater are similar to those of granite in the Daejeon area. The geochemical and isotopic data indicate that the U in groundwater in this area is genetically associated with the granite and not with the U-ores in black slate.

To examine the U-minerals in granite, a gamma ray spectrometry survey was conducted and U-count anomalies were identified along the contact zone between the two-mica granite and mica-schist, and fracture-filling quartz veinlet. The U-mineralization is dominated by uraninite, coffinite, uranophane and is commonly accompanied by hydrothermal alteration. The mica schist in contact with granite include graphite and sulphide, which provide a reducing environment favorable for U deposition. The redox condition is the critical factor for the formation of U-ores and uraniferous groundwater in the Daejeon area.

The charateristics of tremolite asbestos occurred in abandoned asbestos mines in South Korea

J. HWANG, J. OH, G. PARK AND H. LEE*

Pusan National University, Busan 609-735, Korea
(*correspondence: hmlee61@hotmail.com)

Recently, asbestos health risk and mining restoration become a big issue in the abandoned asbestos mine area. Tremolite asbestos has been known as the most toxic one causing lung cancer and mesothelioma. Tremolite asbestos mines are rarely found in the world, but four mines (Sinsuk mine and Daebosuksan mine in Boryeong area, Chungcheongnam-do, Bonghyeon mine in Yeongju area, Gyeongsangbuk-do and Ewha mine in Yeongwol, Gangwon-do) were operated up to 1980's in South Korea. The geological and mineralogical informations are needed for the asbestos health risk evaluation and mine restoration. In this study, the origin and characteristics of tremolite asbestos and the property changes by weathering process were examined with ores and soils in abandoned mine areas.

All the mines are formed in metamorphic rock strata consisting of the Precambrian mica schist and gneiss. Tremolite asbestos deposits are known to be formed by hydrothermal alteration of dolomitic limestone or ultramafic rocks intercalated in the Precambrian metamorphic rock strata. Associated minerals are significantly different with different mines. Tremolite in ores and soils were analyzed with optical microscope and SEM/EDS. Tremolite asbestos fibers have the average length of 12~38μm. The aspect ratio varies significantly and have range of 7.4~19. The significant morphological difference is observed with different mines. Tremolites found in soils of mine area shows similar morphological properties with ores. The distribution in soil is limited to the transportation ranges by stream water and sediments. The properties of tremolite asbestos are not varied with weathering process and closely related to the parent rock types. In all mines, prismatic tremolites are also commonly occurred with asbestos form tremolites. Although some of asbestos form tremolites may be formed by splitting through the cleavage of prismatic tremolite, those are mainly formed by crystal growth habit regulated by the environmental condition at the time of formation.

As described above, the associated minerals and crystal morphology are significantly different among the mines in the Boryeong area and the Yeongju and Yeongwol areas. It is considered that the differences in associated minerals and crystal morphology are caused by the degree of hydrothermal alteration and parent rock type.

We use thermodynamic calculations to show that high-temperature interaction between basaltic magma and organic matter can profoundly affect the redox state of the magma and of the gases in equilibrium with it. Our calculations simulate the incorporation into the gas-melt system of organic compounds like CH and CH_2 and take into account S-H-O-C gaseous species at temperatures and pressures in equilibrium with a basaltic liquid. We predict that the assimilation of less than 1 wt% organic matter produces gases with very unusual compositions that are CO-dominated and have H_2O and CO_2 as minor constituents. The crystallization of graphite and native iron is also predicted as a consequence of CH or CH_2 incorporation.

We combine our calculations with existing petrological observations on the Siberian Traps to assess the relevance of this process for the emplacement of voluminous magmatic intrusions in the coaliferous sediments of the Tunguska Basin. Critical is the presence of magmatic graphite and native iron in igneous mafic rocks, which allows to constrain the minimum amount of organic matter assimilated and the composition of the produced gases. We also present an estimation of the fluxes of the exceptional CO-dominated gas emissions, which are likely to have been produced by the emplacement of the Siberian intrusions. We finally evaluate the fate of such gases during their diffusion in the atmosphere, by using a regional 3D atmospheric model coupled to a tropospheric chemistry one.

The chemistry and the environmental impact of the Romanian phosphogypsum

A.M. IANCU, ŞT. MARINCEA, D.G. DUMITRAŞ, C. GHINEŢ AND N. CĂLIN

Geological Institute of Romania,Caransebes 1st., Bucharest 012721, Romania (aurash83@yahoo.com)

The aim of this paper is the mineralogical and geochemical description of phosphogypsum from a Romanian location for an accurate assessment of its environmental impact. Phosphogypsum is a technogenic (mineralurgic) by-product from the extraction of phosphoric acid from raw phosphate ore, consisting mainly of apatite [ideal formula: $Ca_5(PO_4)_3(F, OH, Cl)$]. The extraction technology uses normally the sulfuric acid to attack the apatite mineral. The phosphogypsum contains (in weight percentages) 32% CaO, SO_3 45% and 15% water of crystallization, with approximately 8% of impurities.

The chemical composition of phosphogypsum is influenced by three factors: 1) by the type of phosphate rock (apatitic rock) used as primary material, and olso by the nature and distribution of the trace elements of the rock; 2) by the processes of manufacturing of the phosphoric acid: the extraction process of the phosphogypsum, having as an intermediar product the calcium dehidrate, leads to the formation of some phosphogips, witch have a high level of contamination than their homologue, in some compounds as: Mn_2O_3, MgO, Fe_2O_3, Al_2O_3, Na_2O, K_2O, SiO_2, P_2O_5; 3) by the dumps age or stored phosphogypsum deposits, which, due to the percolation of the meteoric wather, have the tendancy of lousing, through solubilisation, a part of some trace elements. Some of the chemical, mineralogical and radiometric characteristics of the phosphogypsum, but also its use as a primary material can directly influence its impact on the environment and also on the human health collectivises.

The main factors, that have a major impact on the environmental safety, but also on the phosphogypsum recycling, are the radioactivity, the toxic elements contents, pore water acidity, mineral's impurity, the contents in rare elements.

The pollutants emitted from the phosphogypsum dumps have a potential impact on the environment, affecting both the people and the animals. The potential pathways of human exposure to these pollutants include: the irradiation with gamma rays; the content in toxic elements; contaminated dust and other elements which can provoce the cancer; the ingestion of contaminated groundwater.

Reliance of the rate of dissolution of the SON68 glass on SiO_2(aq): New quantification using interferometry

JONATHAN P. ICENHOWER,*[1] CARL I. STEEFEL,[1] ANDREAS LUTTGE,[2] JOE RYAN[3] AND ERIC M. PIERCE[4]

[1]Lawrence Berkeley National Laboratory, Berkeley, CA 94720 USA (*correspondence: jpicenhower@lbl.gov, cisteefel@lbl.gov)
[2]Rice University, Houston, TX 77005 USA (aluttge@rice.edu)
[3]Pacific Northwest National Laboratory, Richland, WA 99352 USA (joe.ryan@pnl.gov)
[4]Oak Ridge National Laboratory, Oak Ridge, TN 37831 USA (pierceem@ornl.gov)

At present, one of the most vexing problems confronting experimentalists and modelers alike is how nuclear waste glasses will react long-term in the repository environment. Many of the experiments that underpin modeling efforts have been conducted at conditions that are not germane to answering these questions. One of the most important constituents in natural subsurface waters is dissolved silica [SiO_2(aq)], and efforts are underway to understand the dependence of the dissolution rate on this component. A method to determine rates accurately in solutions containing high concentrations of SiO_2(aq) is needed.

We present evidence that rates of glass dissolution can be quantified by using a Vertical Scanning Interferometer (VSI) over a range of SiO_2(aq) concentrations. Polished glass monoliths (SON68) were exposed to solutions containing 0 to 5.46×10^{-3} mol/L SiO_2(aq) at 90°C and pH = 9. Both batch (static) and flow-through reactor systems were employed. In the former, the surface area of glass to volume of solution ratio (SA/V) was kept at a low value, ensuring that the system maintained a constant chemical affinity. In the flow-through systems, the SA/V ratio was higher and the release of elements into solution was monitored to ensure steady-state values. Dissolution rates by VSI were determined by comparing the height of the reacted surface to that of a pristine reference surface, and these rates were compared against those determined by assaying the effluent solutions from the flow-through experiments. The results revealed a close correspondence between the two methods for determining rates, and both methods indicated a linear dependence of the rates upon the concentration of SiO_2(aq) in solution [$\log R = -1.37 \times 10^{-2}(Si) - 5.41$]. This linear dependence shows that the rate can be quantified at conditions pertinent to the disposal environment and that a mechanistic basis for predicting rates can be realized.

Smoke aerosol emission source analysis from satellite and airborne measurements

CHARLES ICHOKU[1]*, CHARLES GATEBE[1,2] AND RALPH KAHN[1]

[1]Climate and Radiation Branch, NASA Goddard Space Flight Center, Greenbelt, MD 20771, USA (*correspondence: Charles.Ichoku@nasa.gov)
[2]GEST, University of Maryland Baltimore County, MD, USA

Accurate estimation of smoke emission source strength from active fires is essential for modeling smoke emission fluxes, transport, atmospheric interactions, and impacts on air quality and climate. For several decades, researchers have made efforts to estimate smoke emissions from ground-based measurements, but the spatial and temporal coverage is severely limited. The rapid growth of satellite measurement capability during the last decade has provided the potential to overcome these limitations by covering the entire globe for long periods of time. However, satellite remote-sensing methods are faced with new challenges as they attempt to use instantaneous observational snapshots to address continuous and highly variable processes such as fires and their emissions. The result is that, although the satellite enables more ground to be covered, uncertainties in quantifying emissions still remain, and may be even greater, compared to the ground-based methods. One of the promising ways to address this issue is the use of airborne measurements to bridge the spatial and temporal scales between the regional-scale satellite snapshots and landscape-scale, longer-duration processes of fire behavior and emissions. The ARCTAS summer campaign that was conducted in Canada in June–July 2008 provides a unique opportunity to demonstrate this approach with regard to closely exploring improved understanding of smoke emission mechanisms by remote sensing. In this talk, we will show preliminary results of using the vertical scans of plumes from the Cloud Absorption Radiometer (CAR) instrument aboard the NASA P-3 aircraft to complement the analysis of fire radiative power (FRP) and aerosol optical depth (AOD) measurements from MODIS aboard the Terra and Aqua satellites, and near-source plume-height measurements from MISR aboard Terra, to better understand the relationships between them, and elaborate the emission rates, spatial characteristics, and injection processes of smoke particulate matter.

Characteristics of the Ruwai base metal-Ag skarn in Tertiary middle Kalimantan volcanic arc, Indonesia

A. IDRUS[1]*, F.M. MEYER[2], S. SINDERN[2], L.D. SETIJADJI[1] AND I.W.WARMADA[1]

[1]Department of Geological Engineering, Gadjah Mada University, Yogyakarta, Indonesia (*correspondence: arifidrus@gmail.com)
[2]Institute of Mineralogy and Economic Geology, RWTH Aachen University, Aachen, Germany

This study is dealing with geology and characteristics of mineralogy, geochemistry and physicochemical conditions of hydrothermal fluid responsible for the formation of the Ruwai skarn base metal (Pb-Zn-Cu)-Ag deposit in Tertiary middle Kalimantan volcanic arc, Indonesia. The formation of Ruwai skarn is genetically associated with calcareous rocks consisting of limestone and siltstone (derived from marl?) and controlled by NNE-SSW-trending strike slip faults and localized along N 70° E-trending thrust fault, which also acts as contact zone between sedimentary and volcanic rocks in the area. The Ruwai skarn is mineralogically characterized by prograde alteration (garnet and clino-pyroxene) and retrograde alteration (epidote, chlorite, calcite and sericite). Garnet is of andraditic composition, whereas clino-pyroxene is identified as wollastonite, diopside and hedenbergite. Both garnet and clinopyroxene show a petrographic and chemical zonation. Ore mineralization is typified by sphalerite, Ag-rich galena and chalcopyrite, which formed at the early retrograde stage. Galena is typically enriched in silver up to 0.45 w t% and bismuth of about 1 wt %. Geochemically, SiO_2 is enriched and CaO is depleted in limestone, consistent with silicic alteration (quartz and calc-silicate) and decarbonatization of the wallrock. The measured resources of the deposit are 2,297,185 tonnes at average grades of 14.98 % Zn, 6.44 % Pb, 2.49 % Cu and 370.87 g/t Ag. Ruwai skarn orebody originated at moderate temperature of 250-266 °C and low salinity of 0.3-0.5 wt.% NaCl eq. The late retrograde stage formed at low temperature of 190-220 °C and low salinity of ~0.35 wt.% NaCl eq., which was influenced by meteoric water incursion at the late stage of the Ruwai base metal-Ag skarn formation. Further exploration of the skarn extension in the prospect area should consider the structural setting, lithologic distribution and the presence of the diagnostic calc-silicate minerals.

Pressure-induced phase transitions and H-D isotope effects in portlandite

R. IIZUKA[1]*, H. KAGI[1], K. KOMATSU[1], T. YAGI[2] AND S. NAKANO[3]

[1]Geochemical Research Center, Graduate School of Science, Univ. of Tokyo, Tokyo 113-0033, JAPAN (*correspondence: riizuka@eqchem.s.u-tokyo.ac.jp)
[2]ISSP, Univ. of Tokyo, Chiba 277-8581, JAPAN
[3]NIMS, Ibaraki 305-0044, JAPAN

$Ca(OH)_2$, portlandite, has a CdI_2 type structure and is one of the simple hydrous minerals. A crystal-to-crystal phase transition ocurrs around 10 GPa at room temperature in various pressure transmitting media [1, 2]. In brucite, which has an iso-structure of portlandite, H-D isotope effect on the compressibility was found from neutron diffraction [3]. In our study, the isotope effect on the pressure-induced responses was studied in order to clarify the phase transition mechanism accompanied by the geometrical change of hydrogen bonding for neutron diffraction studies in future.

Powder samples were synthesized by hydration of CaO powders with water (or D_2O) in a Teflon lined stainless steel autoclave at 240°C for one week. The single-crystals were obtained by recrystallizing from powder. These samples were loaded in clamped DACs with a few small ruby chips. As a pressure medium, 4:1 methanol-ethanol mixture or He gas was used. IR absorption spectra were measured at the IR synchrotron radiation beamline BL43IR at SPring-8. Angular-dispersive synchrotron X-ray diffraction experiments up to 25 GPa were performed on the BL-18C beamline in the Photon Factory (PF), KEK.

No remarkable difference between $Ca(OH)_2$ and $Ca(OD)_2$ samples was found in the compression behaviors from powder XRD patterns. They were consistent with the previous studies [4-7]. The OH(OD) vibration peaks of IR spectra were split at 6-7 GPa for single-crystals in He medium. No significant difference suggesting the isotope effect was found in the phase transition pressure. The hydrostaticity was found to contribute strongly to the process of the phase transition or amorphization. This implies that neutron diffraction of portlandite needs to be carefully measured under controlled stress conditions using large-volume presses.

Evolution of the African continental crust from Pb-Hf-O isotope systematics of detrital zircons

TSUYOSHI IIZUKA[1,2]*, IAN H. CAMPBELL[1] AND CHARLOTTE M. ALLEN[1]

[1]RSES, ANU, Canberra ACT 0200, Australia (ian.campbell@anu.edu.au, charlotte.allen@anu.edu.au)
[2]DEPS, Uni. Tokyo, Tokyo 113-0033, Japan (*correspondence: iizuka@eps.s.u-tokyo.ac.jp)

To better understand the evolutionaly history of the African continental crust, we have determined U-Pb ages, Lu-Hf and O isotopic compositions of ca. 450 detrital zircons from the Congo, Nile, Orange, Zambezi and Niger Rivers. The U-Pb isotopic data reveal the lack of >3.2 Ga zircons in the river sands, and distinct peaks at 2.7-2.5, 2.1-1.9, 1.2-1.0 and 0.9-0.6 Ga. The εHf(t) population shows that many zircons, even those having Archean U-Pb ages, crystallized from magmas involving an older crustal component (Figure 1). The O isotopic analyses reveal that ca. 70% of the zircons have $\delta^{18}O$ values higher than 6.5 (Figure 1), indicating that reworking of supracrustal material is important in the granitoid crust formation. However, no >2.0 Ga detrital zircons have $\delta^{18}O$ values higher than 8.0, suggesting restricted contribution of mature sediment to granitoid magma genesis in the Archean and early Proterozoic. We calculated Hf isotopic model ages for the zircons to estimate the mean mantle-extraction ages of their source materials. The oldest zircon Hf model ages of ca. 3.4 Ga suggest that some crust generation had taken place by that time, and that it was subsequently reworked into <3.2 Ga granitoid crust. The Hf model age distribution of the zircons having $\delta^{18}O$ values lower than 6.5 shows a prominent peak at 1.1-0.8 Ga, implying rapid generation of the continental crust at that time.

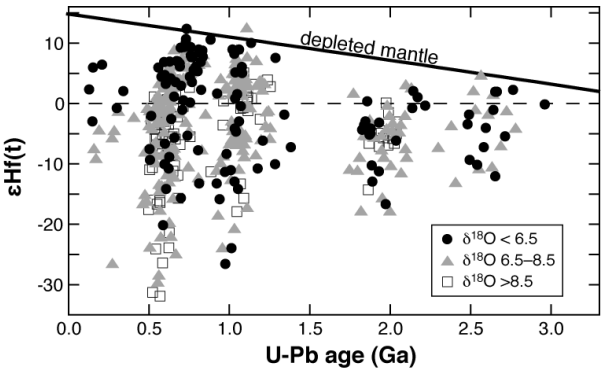

Figure 1: Plot of age vs. εHf(t) for African detrital zircons.

Biogeochemical processes in mud-volcano sediments from the Kumano forearc basin, Japan

[4]Tokyo Institute of Technology, Japan
[5]Hokkaido University, Japan
[6]National institute of Advanced Industrial Science and Technology, Japan

Remarkable populations of microbial life have been observed in global subseafloor environments. However, it remains largely unknown if the deep-derived diapiric structure provides potential habitats for subseafloor life or not. Here, we investigated microbial communities and biogeochemical processes in mud-volcano subsurface sediments down to 20 meters from the summit, obtained from the Kumano forearc basin in the Nankai Trough during the CK09-01 D/V *Chikyu* training cruise in 2009.

Pore water extracted from the cored sediments showed significantly low chlorinity to seawater (averaged in 23% of that in seawater), indicating that dehydrate reaction of clay minerals had previously occurred in the deeply buried sedimentary layer. The cored sediments contained relatively low population of microbial cells ($<10^4$ cells/cm^3). The $\delta^{13}C$ value of dissolved inorganic carbon ($\delta^{13}C_{DIC}$) increased with the coring depth, reaching +40‰ at 3 meters below the seafloor (mbsf). The highly ^{13}C-enriched values are possibly due to strong microbial reduction of DIC to ^{12}C-enriched products. The hydrogen isotopic composition of methane (-181±2‰) and magnitude of the carbon isotopic fractionation between DIC and methane (75.6±2.8‰) bellow 3 mbsf suggest the significant contribution of hydrogenotrophic methanogenesis as the source of methane. The $\delta^{13}C$ value of acetate was appeared to increase with the sediment depth (from -41 to -22‰), synchronous to the increase of $\delta^{13}C_{DIC}$. The significant isotopic fractionation between DIC and acetate (54.0±6.9‰) indicates that the principal process producing acetate is homo-acetogenesis via the reductive acetyl-CoA pathway. Radioactive tracer experiments exhibited relatively high activities of homo-acetogenesis (14–34,900 pmol/cm^3/day) and hydrogenotrophic methanogenesis (0.6–128 pmol/cm^3/day), consistently suggesting that autotrophy plays significant biogeochemical roles in the mud-volcano subseafloor microbial ecosystem.

Enhanced chemical weathering during early Triassic in response to the collapse of terrestrial ecosystem after the end-Permian mass extinction

M. IKEDA*, H. SAKUMA, R. TADA AND S. TAKAHASHI

Dept. of Earth and Planetaly Science, University of Tokyo, 113-0033, Japan
(*correspondence: m_ikeda@eps.s.u-tokyo.ac.jp

The vegetation recovery after the end-Permian mass extinction was delayed by > 5 m.y. until middle Triassic. It is demonstrated that the collapse of terrestrial vegetation enhanced physical weathering during early-middle Triassic, whereas its impact on chemical weathering intensity has not been investigated. Here, we investigate the variations of chemical weathering intensity and biogenic Si flux from lower to middle Triassic pelagic siliceous sequence of the equatorial Panthalassa in Japan, whose cyclostratigraphy is well established [1, 2]. Our results suggested that the chemical weathering intensity and the biogenic Si flux during early Triassic were extremely high relative to middle Triassic and decreased during middle Triassic. Also, the calculated biogenic Si budget on pelagic Panthalassa during early and middle Triassic was several times larger than total Si budget of global ocean today [3], suggesting that pelagic siliceous sequence at equatorial Panthalassa was the major sink of oceanic Si. Hence, the changes in biogenic Si flux on pelagic Panthalassa could reflect changes in global chemical weathering intensity in time scales larger than the residence time of Si in the ocean (> 10 kyr [3]). Therefore, the increase and following decrease in chemical weathering intensity during early to middle Triassic would have been related to the collapse of terrestrial vegetation and its recovery during early Triassic.

Trace metal concentrations and Pb isotopes of sediments from Barkley Sound, British Columbia

MARIKO IKEHATA*, ALYSSA E. SHIEL AND DOMINIQUE WEIS

PCIGR, EOS, University of British Columbia, Vancouver BC, V6T 1Z4, Canada
(*correspondence: mikehata@eos.ubc.ca)

Port Alberni is home to several industries (e.g., pulp and paper mills), responsible for releasing significant amounts of heavy metals (e.g., As, Cd, Pb and Hg) into Alberni Inlet every year [1]. Alberni Inlet may carry this metal effluent into Barkley Sound, located on the west coast of Vancouver Island, British Columbia (BC), home to economically important oyster farms. Alberni Inlet supplies freshwater to Barkley Sound and the headwaters are proximal to Port Alberni. Emissions associated with recreational boating in Barkley Sound and traffic in the lower mainland and on Vancouver Island are other potential sources of Pb pollution. We determined As, Cd and Pb metal concentrations and Pb isotopic compositions in sediment samples from Barkley Sound, collected from transects along Imperial Eagle Channel, Trevor Channel, and from Junction Passage, to assess metal contamination associated with local industries and trace the source of Pb pollution.

Metal concentrations for sediments from Barkley Sound range from 6.20 to 10.8 ppm for As, from 0.36 to 0.56 ppm for Cd, and from 4.91 to 17.5 ppm for Pb. The highest concentrations of As and Cd were observed in sediments from Junction Passage, directly downstream from Alberni outlet. In general, a decrease in Pb, As and Cd in the sediment was observed along NW-SE transects, i.e. towards the open ocean. Sediment $^{206}Pb/^{207}Pb$ ratios increase with increasing distance from Port Alberni, suggesting increasing natural contributions. The $^{206}Pb/^{207}Pb$ ratios (1.1783 to 1.1909) were primarily within the high end of the range reported for BC road dust [2], with the exception of that of sediment from the most distal site in Trevor Channel, with an isotopic composition closer to that of North Pacific sediments [3]. Our study shows that metal concentrations in Barkley Sound sediments are controlled in large part by anthropogenic activities and industrial inputs to Alberni Inlet.

High fluctations of suspended load in a tidal influenced river mouth, west coast of India

D. ILANGOVAN

National Institute of Oceanoraphy, Goa-403206, India

Suspended load of water bodies play a major role in studies related to pollution levels, turbidity, source and sink of sediments, sediment transport, etc. Proper sampling method brings out acceptable interpretations. Many times, one time observation of suspended sediment load is considered as representative of that aqueous ecosystem. However, one time observation of suspended sediment load may be less objectionable in substantiating the interpretation of the observation when aqueous body is a land locked lake or undisturbed fresh water river system. Therefore, the present study was carried out to check the validity of one time sampling. The study involved, every 2 hours observation of suspended sediment load at surface, mid depth and at near bottom of a tidally influenced river mouth (River Dahej), at west coast of India, for 2 days. The obtained data reveal high fluctuations in the volume of suspended sediment matter. Various parameters such as flood tide, ebb tide, slack period, spring tide, neap tide, fresh water-sea water mixing, water currents, etc., must be controlling the suspended sediment matter concentration in an environment which is influenced both by marine and riverine ecosystem. This study therefore, reveals the necessity of an acceptable sampling protocol considering all the controlling parameters so that interpretations of the observations are truly representative of the conditions of the involved aqueous ecosystem.

Effect of lake sediment application on soil structure assessed by means of X-ray computed microtomography

B. ILLERHAUS[1]*, M. JOSCHKO[2], D. BARKUSKY[3], J. REINHOLD[4], G. GLEIXNER[5] AND F. GERLACH[6]

[1]BAM Bundesanstalt für Materialforschung und –prüfung, Berlin, Germany (*correspondence:bernhard.illerhaus@bam.de)

[4]Stahnsdorf, Germany
[5]MPI-BGC Jena, Germany
[6]ZALF Komturei Lietzen, Germany

It is known that lake sediments applied to agricultural soils may improve soil fertility on dry sandy soils by increasing soil carbon storage and water holding capacity. In contrast, the effect of lake sediments on soil structure has not been well documented yet even though some of the documented effects must be linked to soil morphology. X-ray computed microtomography enables to characterize objects down to 50 μm or less and has recently successfully been applied to soil. The aim of this study was therefore to analyze, by means of X-ray computed microtomography, the structure of soil amended with lake sediments compared to a control.

At the long-term experimental site Lietzen in Brandenburg, lake sediments were applied to the soil after harvest at rates of 15 and 70 t/ha. At two locations within the 70 ha sized field, two undisturbed soil samples each (diameter 3.1 cm, height 4 cm) were taken from 0-4 cm soil depth. They were analysed with a 320 kV micro focus X-ray tube (spatial resolution 1/1000 of maximum sample diameter). The morphometric analysis included the determination of the overall pore volume and the local variance in the samples.

The morphological analysis showed that differences between amended and control soil were minor. In contrast, soil texture which differed strongly between the two sampling sites seemed to profoundly affect soil microstructure (pore volume, soil heterogeneity). It is assumed that the observed differences in soil structure are ultimately linked to soil texture-induced differences in soil biological activity.

The results show that more research is needed to entangle the effects of soil texture vs. management effects on soil microstructure and to identify mechanistical links between soil structure and soil biota under field conditions.

The Lomagundi-Jatuli $\delta^{13}C$-Event revisited

C.J. ILLING[1]*, R.E. SUMMONS[2], A.E. FALLICK[3], V.A. MELEZHIK[4] AND H. STRAUSS[1]

[1]Institut für Geologie und Paläontologie, WWU Münster, Münster, Germany (*correspondence: c.illing@uni-muenster.de)

[4]Geological Survey of Norway (NGU), Trondheim, Norway

The Lomagundi-Jatuli Event (LJE) is characterized by a positive carbonate carbon isotope ($\delta^{13}C_{carb}$) excursion [1, 2] in the aftermath of the Great Oxidation Event (GOE). Results reported from different successions, ranging in age from 2.4 to 2.2 Ga, imply that the LJE is global in nature [3, 4, 5, 6]. Assuming that the atmospheric/ oceanic dissolved inorganic carbon pool is faithfully archived in respective carbonate rocks, this carbon isotope excursion would indicate a shift in $\delta^{13}C$ of atmospheric CO_2 of at least ~5‰ for the duration of the LJE. The most likely explanation for this strong shift in $\delta^{13}C_{carb}$ is an enhanced biological CO_2-fixation and organic carbon burial leaving the residual pool enriched in ^{13}C. However, an alternative view has recently been proposed [7].

Here, we report paired analysis of $\delta^{13}C_{carb}$ and $\delta^{13}C_{org}$ for rocks capturing the LJE. These were obtained by the Fennoscandian Arctic Russia-Drilling Early Earth Project (FAR-DEEP). Carbonates show the typical positive $\delta^{13}C_{carb}$, values. In contrast, however, the organic matter does not record a corresponding positive shift in $\delta^{13}C_{org}$. Standard isotope mass balance provides no satisfactory explanation. Hence, alternative explanations are in need!

Coupled geochemical and foraminiferal response to environmental changes during the deposition of Upper Cretaceous oil shale in the Negev, Israel

P. ILLNER[1], S. ASHCKENAZI-POLIVODA[2], Z. BERNER[1], S. ABRAMOVICH[2], A. ALMOGI- LABIN[3] AND S. FEINSTEIN[2]

[1]Karlsruhe Institute of Technology (KIT), Institute for Mineralogy & Geochemistry, Karlsruhe, Germany (peter.illner@kit.edu)
[2]Ben Gurion University of the Negev, Beer Sheva, Israel
[3]Geological Survey of Israel, Jerusalem, Israel

The accumulation of a 40 m thick oil shale sequence during the latest Campanian marks a major change in the dynamics of the Late Cretaceous southern Tethys upwelling system. Based on the vertical distribution of foraminiferal taxa, Ashckenazi-Polivoda *et al*. [1] established a high resolution paleoenvironmental scheme, defining five planktic (P-Type) and five benthic foraminifera (B-Type) assemblages which thrived under distinct bottom-water aeration and surface water productivity conditions.

Principal component analysis of major and trace elements concentrations in the studied sequence allows distinguishing three factors. The first reflects the interplay between biogenic-carbonate (Ca, Sr) and terrigenous input (Al, Si, K, Ti, V, Fe, Ga, Nb, Ba, Pb, Th). The second mirrors the degree of bottom water oxygenation (C_{org}, S, Ni, Cu, Zn, As, Cd, Mo, U vs. Mn), while the third factor stands for conditions that promoted phosphorite deposition (P, Y, La, U). The comparison of these chemostratigraphic features with the distribution of the foraminiferal assemblage types as defined in [1] points to a strong interdependence between these geochemical and micropaleontological environmental indicators. The distribution of the planktic assemblages P-Types 1 and 4, and the benthic assemblage B-Type 4 parallels the variations in the degree of bottom water oxygenation and detrital input. P-Type 1 and 2 (high *Heterohelix*) assemblages coincide with a gradual decrease in biogenic carbonate production and a relative weak anoxic response to the increase in terrigenous input. In contrast, assemblages P-Type 4 (dominance of *Globigerinelloides*) and B-Type 4 (triserial buliminids and *Gavelinella*), limited to the base of the oil shale, are characterized by strong anoxia and high carbonate production, as reflected by scores of factors 1 and 2.

Mobility and bioavailability of some potentially harmful elements around an industrial contaminated environment (Estarreja, Portugal)

M. INÁCIO*, E. SILVA AND V. PEREIRA

University of Aveiro, Department of Geociences, Portugal (*correspondence: minacio@ua.pt)

Located in north central Portugal the industrial Chemical Complex of Estarreja (CQE) is composed of several chemical industries that could cause environment pollution. The most important inputs into the environment are chiefly related to past industrial activities, with the production of sulphuric acid from arsenopyrite roasting (e.g. As, Cu, Ni, Pb and Zn) and from a chloralkali plant (e.g. Hg).

The main purpose of this study was to evaluate the levels of some heavy metals and arsenic in soils and forage plants from Estarreja and from a reference site (Ouca, with no significant industry but a similar geology, pedology). These soils are sandy soils, often used as pasture and agricultural land. In Estarreja 90 topsoils and 27 forage plants were collected; in Ouca 20% of these numbers were sampled. Both soils and plants (separated into roots and green shoots) were analyzed in the same way, extraction with aqua regia and analysis by ICP/ES & MS, for 32 chemical elements. Three single extractants (water; ammonium acetate; EDTA) were used to assess the mobile and plant available fraction of some potentially harmful elements.

The first results show high levels of As and Hg in Estarreja compared to those given in the international guidelines. The maximum concentrations found in the soils are above 10.000 $mgkg^{-1}$ for As and above 100 $mgkg^{-1}$ for Hg. In green shoots, the maximum concentrations found are 255 $mgkg^{-1}$ for As and 5 $mgkg^{-1}$ for Hg. The spatial distribution of these elements shows a typical anthropogenic pattern, with the highest values near the factories and sewage outlets. It was possible to identify an area around the factories and sewage outlets where the median concentrations for As and Hg are more than 10 times higher than the median concentrations found in the reference area, which are close to the national backgrounds [1]. The EDTA was the most effective extractant for all the elements, except Zn, which was higher in the ammonium acetate extracts. However, the amounts extracted with these three extractants are low (less than 5%) for As, Hg, Pb, Cu and Zn, thus attenuating the impact of high metal contents in soils of green areas often used as pasture land and agriculture.

We have documented sediment sequestering of phosphorus in the Bothnian Bay, northern Baltic Sea, during the last 7000 years, using a paleomagnetic dating method. High resolution sampling and multi-element analyses coupled with ”absolute dating” of the sediment provides a powerful environmental record that can be used to foresee biogeochemical changes caused by climate-induced freshening of the Baltic and other silled marginal marine basins. Late Holocene freshening is pronounced in the Bothnian Bay, with a decline of surface salinity from 10-11‰ down to present day values between 1‰-3‰, consistent with the absence of a permanent halocline, and phosphorous limitation of primary production.

The P/Fe ratio in a 6-m-long piston core show distinct peaks above the time level 2500 years BP, closely related to temporal peak values for manganese, the Mn/Fe ratio and a major changes in magnetic susceptibility. We suggest that the changes in phosphorus sequestering in the core can be explained by the position of the suboxic zone at the time of deposition. A suboxic redox potential can be maintained in these layers if there is an excess of manganese that can oxidise formed sulphide in the sediment during burial. Particulate manganese maintains the suboxic redox level preventing dissolution of Fe-oxyhydroxides with associated phosphorus, at depth in the sediment. Today, the barrier between the sulfide zone and the sulfate zone is situated 0.5 m below the sediment surface. Trace metal data suggest that this zone has been located within the sediment during the whole lifetime of the core. Hence, a layer with high concentrations of Mn and Fe-oxyhydroxides, formed above the sulfide boundary, may pass through the sulfide barrier, leaving Fe-Mn oxyhydroxides in relative equilibrium below the active sulfide boundary.

Water content of lithospheres deduced from xenoliths: The example of Kerguelen Islands and South African craton

J. INGRIN[1], J. LIU[1,2], Q.-K. XIA[3], E. DELOULE[3] AND M. GRÉGOIRE[4].

[4]GET, UMR CNRS 5563, OMP, Univ. Toulouse III, 31400, Toulouse, France. (gregoire@get.obs-mip.fr)

The formation of the Kerguelen crust since 110 Ma, through magma underplating, may represent a good analogue for continental growth in oceanic environment like it was during the Archean period. The study of water content of granulite xenoliths representative of Kerguelen deep crust and related mantle xenoliths offers the opportunity to: 1) evaluate the distribution of water along the Kerguelen lithosphere; 2) compare it to the content of the older lithosphere like for instance the South African cratonic lithosphere.

We measured water content from 10 granulite xenoliths and 5 mantle xenoliths from alkali basaltic lavas erupted on Kerguelen Islands on the Northern part of the Kerguelen plateau. The xenoliths are composed of two-pyroxenes granulites with spinel or garnet [1]. The analysis of water dissolved as H-related point defects in the main anhydrous phases was done by micro-FTIR with a spot size of 50 microns, a spectral resolution of 4 cm^{-1} and with unpolarized beam following the procedure proposed by Kovacs *et al*. [2]. The water contents of pyroxenes from the granulite xenoliths (up to 180 and 330 ppm H_2O for orthopyroxenes and clinopyroxenes respectively) are significantly higher than those from the mantle xenoliths.

The Kerguelen xenoliths are less hydrous than the ones from the Kaapvaal Craton [3] suggesting that the mantle source at the origin of their formation is less hydrous than the ones at the origin of the older deep crust formed beneath South Africa or the North Chinese cratons [4].

Studies on annual variation of $^{14}C/^{12}C$ ratios in plant samples by AMS

A. INOUE[1*], Y. MURAMATSU[1], H. MATSUZAKI[2] AND S.YOSHIDA[3]

[1]Depertment of Chemistry, Gakushuin University, Mejiro1-5-1, Toshima, Tokyo, Japan (*correspondence: 10142005@gakushuin.ac.jp, yasuyuki.muramatsu@gakushuin.ac.jp)
[2]School of Engineering, University of Tokyo, Hongo1-3-7, Bunkyo, Tokyo, Japan
[3]National Institute of Radiological Sciences, Anagawa 4-9-1, Inage, Chiba, Japan

Carbon-14 ($T_{1/2}$; 5730yr) is one od the most impotant radionuclides produced by the reaction of cosmic ray with nitrogen in the upper atmosphere. Therefore, $^{14}C/^{12}C$ ratios in plant materials should provide information on the past atmospheric ^{14}C levels which might be related to the variation of solar activities. The ^{14}C levels in the atmosphere are also affected by the anthropogenic sources such as nuclear weapons testing and accident of nuclear facilities. In this study, we have determined $^{14}C/^{12}C$ ratios by AMS in three different plant materials, i.e. tree rings of Japanese Yaku-ceder, Japanese rice grains and tree rings of pine from Chernobyl area, for assessing the variation of atmospheric ^{14}C.

In order to know the natural variation of ^{14}C, we used tree rings of old Yaku-ceder (1139 year-old) and focused on a period between 1000-1100 A.D. As a result, we found a peak around 1050 A.D. This suggests that the solar activity was weak in this period.

Results obtained for rice grain samples (1950-2009 A.D.) showed that there was the highest peak around 1963 due to nuclear weapons testing and the values decreased gradually. Residence time of the produced ^{14}C was calculated to be about 11 years.

Tree rings of pine collected from the vicinity of Chernobyl NPP was used to assess the release of ^{14}C at the accident, which occurred in late April 1986. A peak of $^{14}C/^{12}C$ ratio clearly observed in the tree ring of 1986. However, the ratio varied widely within the tree ring. This heterogeneous distribution should be due to the short time releases (about 10 days) of ^{14}C during the accident. To examine this, we have separated early and rate wood and found that the early wood contained markedly high ^{14}C and the late wood contained low ^{14}C compared to whole ring of the same year .

Effects of thermal and salinity stresses on growth of aposymbiotic and symbiotic primary polyps

M. INOUE[1*], K. SHINMEN[1], H. KAWAHATA[1], T. NAKAMURA[2], A. IGUCHI[3], A. SUZUKI[4] AND K. SAKAI[3]

[1]AORI, Univ of Tokyo, Kshiwa 277-8564, Japan (*correspondence: mayuri-inoue@aori.u-tokyo.ac.jp)
[2] Univ of the Ryukyus, Nishihara, Okinawa 903-0213, Japan
[3]Sesoko Station, Univ. of the Ryukyus, Okinawa 905-0227
[4]GSJ, AIST, Tsukuba 305-8567, Japan

In order to better understand the effects of high thermal and low salinity stresses on coral calcification from the aspect of coral-algal symbiosis, aposymbiotic (lacking symbionts) and symbiotic coral primary polyps were experimentally exposed to several seawater temperatures (27 ~ 33˚C) and salinities (26 ~ 34 treatments). Calcification rates of polyp skeletons with zooxanthellate (symbiotic) were higher than those without zooxanthellate (aposymbiotic) in both the experiments even under high thermal and low salinity stresses.

Symbiotic polyps showed non-linear calcification responses to thermal stresses whereas aposymbiotic demonstrated linear increase of calcification responses according to the increase of temperature. Both aposymbiotic and symbiotic polyps showed the linear decreases of calcification rates according to the decrease of salinity. Our results suggest that future global warming may have negative impact on coral calcification at the primary polyp processing symbionts. In addition, low salinity stress, which would be caused by increase of the intensity of local floods related to future climate change, would certainly decrease coral calcification.

Peridotite xenolith inferences on the formation and evolution of the central Siberian cratonic mantle

D.A. IONOV[1], L.S. DOUCET[1*] R.W. CARLSON[2], N.P. POKHILENKO[3], A.V. GOLOVIN[3] AND I.V. ASHCHEPKOV[3]

[1]Univ. J.Monnet, CNRS-UMR6524, St Etienne 42023, France (*correspondence: dmitri.ionov@univ-st-etienne.fr)
[2]DTM-CIW, Washington D.C. 20015, USA
[2]Inst. Geology & Mineralogy, Novosibirsk 630090, Russia

Ongoing multi-disciplinary studies of large and fresh (LOI ≤1%) mantle xenoliths from the Udachnaya kimberlite in the central Siberian craton address the structure, composition and origin of cratonic lithospheric mantle. Petrographic data document successive deformation of coarse garnet peridotites (with strong crystal preferred orientation) to form: (1) olivine grains that are broken but not recrystallised, (2) porphyroclastic, (3) fluidal mosaic microstructures [1]. Extremely high sub-Moho velocities recorded in some seismic profiles in the craton may reflect strong anisotropy of foliated coarse peridotites [2]. Both sheared and coarse peridotites occur near the base of the lithosphere (≥1300°C, ~6.8 GPa). Oxygen fugacity decreases with depth. The major element composition of the majority of refractory peridotites is consistent with melt extraction at 1-5 GPa; Mg# is ≤0.929. These rocks are depleted in Pd, less commonly in Pt, relative to Os-Ir-Ru. Re-Os ages (T_{RD}) of the melt extraction residues range from 1.5 to 2.3 Ga (av. 1.8 Ga). 15-20% of coarse peridotites are enriched in opx and may have experienced silica addition in subduction settings.

The Proterozoic Re-Os T_{RD} ages of melt extraction residues from this and earlier [3] work indicate that most of the lithospheric mantle formed simultaneously with the assembly of the craton 1.8-2.1 Ga ago and is not coeval with the oldest exposed crustal rocks (2.6-3.5 Ga) [4]. More ancient mantle materials appear to come from volumetrically small terrains. The Siberian craton, and possibly other long-lived, thick, cold, diamond-bearing lithospheric domains, may have been created in the Paleoproterozoic rather than in the Archean.

Stacked SIMS Spectra: Unravelling ion production in geological materials

TREVOR R. IRELAND, PETER HOLDEN AND PETER LANC

Research School of Earth Sciences, The Australian National University (*correspondence: trevor.ireland@anu.edu.au)

Ion microprobe analyses rely on the production of secondary ions from solid target materials. In the material science community, complexity in ion production is noted for even simple targets comprised of only a few elements. In geological materials, complex mass spectra result from the large number of elements present and their propensity to form molecular ions. The analyses of molecular species is a cornerstone of zircon age determinations but resolution of unwanted interferences is also required.

We have developed a protocol to measure SIMS spectra under varying analytical conditions (mass resolution, energy filtering). These spectra can be stacked to allow identification of relevant species and custom built software allows individual peaks to be scrutinised. A reference lookup list means that isobars can be readily identified.

The spectra have been obtained on SHRIMP-RG, an instrument that allows mass resolution up to 20,000. A combined faraday – ion counter detection system is rapidly switched depending on count rates. Energy filtering can be changed to establish the nature of the molecular interferences based on the progressive exclusion of polyatomic intereferences with energy offset.

Thus far we have applied this technique to NIST glasses as well as minerals used for geochronology – zircon, monazite, and xenotime. For monazite, unresolved interferences in the Pb spectrum could potentially affect some analyses.

Having spectra from different matrices will also allow examination of ion production and speciation models, which will lead to a better understanding of zircon geochronology by SHRIMP.

Trans-lithospheric variations in highly siderophile elements beneath the Ontong Java Plateau

We determined highly siderophile element (HSE) concentrations and sulfur contents for 70 peridotite xenoliths from Malaita, Solomon Islands, which represent virtually the entire thickness (~120 km) of oceanic lithosphere beneath the Ontong Java Plateau. The major aim is to assess whether the fertile part of the suboceanic mantle yields suprachondritic Ru/Ir and Pd/Ir ratios and hence investigate the extent of non-chondritic HSE systematics in the Earth's mantle. To date, most constraints on PUM HSE characteristics come from subcontinental mantle due to the rarity of fertile samples from ophiolites and abyssal peridotites. In contrast, our Malaita sample set includes MORB source-like spinel lherzolites representing shallow lithosphere (<85 km) and garnet lherzolites from basal lithosphere (95-120 km), likely representing a deep-plume source [1]. A further aim is to examine the formation of an intralithospheric harzburgite layer (85-95 km). A previous Re-Os study revealed that the varying degree of Os-depletion uniquely recorded in this melt-depleted layer is intimately related to the ~122 Ma plateau magma production [2].

The new HSE data demonstrate that lherzolite and harzburgite, the two principal lithologies, display contrasting HSE patterns. Regardless of *P-T,* mineralogy and alteration indices, almost all lherzolites show coherent patterns with suprachondritic Ru/Ir and Pd/Ir, but chondritic Os/Ir and Pt/Ir. This supports the widespread occurrence of PUM-like compositions in Earth's mantle. In contrast, harzburgites display HSE depletion with decreasing sulfur content, coupled with highly fractionated patterns relative to PUM and systematically decreasing HSE/Ru, most likely resulting from progressive extraction of HSE residing in sulfide. We establish an order of HSE compatibility that may place key constraints on the mechanism and condition of formation of harzburgites and their extracted magma.

Possible high-PGE-Au silicate melt/aqueous fluid in mantle wedge: Inferred from Ni metasomatism in Avacha peridotite xenolith

SATOKO ISHIMARU[1,2]*, SHOJI ARAI[2], ANASTASSIA Y. BORISOVA[3,4] AND AKIHIRO TAMURA[2]

[1]Kumamoto Unv., Kumamoto 860-8555, Japan (*correspondence: ishimaru@sci.kumamoto-u.ac.jp)

[4]Geological Department, MSU, Moscow 119899, Russia

Platinum-group elements (PGE) and gold (Au) have highly siderophile features and favor to be partitioned into metals and sulfides (such as the Earth's core). Among them, IPGE (Os, Ir and Ru) are well partitioned into residues relative to PPGE (Rh, Pt and Pd) and Au during partial melting of mantle peridotite, although PGE are not mobile during low-temperature alteration processes. We found Ni-rich domains in a highly metasomatized mantle peridotite xenolith (#159) from Avacha volcano, the Kamchatka arc, composed of ordinary mantle minerals (olivine, orthopyroxene, clinopyroxene, chromian spinel, and monosulfide solid solutions; MSS) with high-Ni contents, around aggregates of clays rich in Fe, Ni and S [1]. The high-Ni, -Fe, -S clays at the center of the Ni-rich domain show varied colors under the microscope, from yellowish to brownish. Most of them fill interstitices or cracks, but some are observed as globluer inclusions in olivine (Fo_{93}). The MSS in this sample #159 rarely have quite thin hydroxide alteration rims. The Ni/(Fe + Fe) atomic ratio of the clays are varied (0-0.7) and show a good correlation with their color; when the Ni/(Fe + Ni) is low, the color of the clay is pale and yellowish. The S content of the clays also varies from below the detection to 66,000 ppm but does not show any correlation with the Ni/(Fe + Ni) ratio. Some clays have an extremely PGE- and Au-enriched feature, and the IPGE concentration is 100 times higher than the chondrite values. The presence of high-Ni halo and chemical zoning of NiO content of olivine from the center (5.3 wt%) to the outward (0.4 wt%) in the Ni-rich domain, the high-Fe, -Ni, -S clays are an alteration product of the metasomatic agent that drastically enhanced the Ni content of the surrounding minerals. We propose these clays were new type of S-rich silicate melt or silicate-bearing aqueous fluid to concentrate PGE and Au in addition to Ni and Fe within the mantle wedge.

The Izu-Bonin-Mariana (IBM) forearc is thought to be an excellent location for investigating the record of subduction initiation and subsequent arc evolution [1] because of the exposure of early-arc lavas on the forearc islands. Recent dredging and diving in the IBM forearc [2, 3] have revealed a bottom to top stratigraphy of: 1) mantle peridotite, 2) gabbroic rocks, 3) a sheeted dyke complex, 4) basaltic pillow lavas (forearc basalts: FAB), 5) boninites and magnesian andesites, 6) tholeiites and calcalkaline arc lavas. This forearc stratigraphy is remarkably similar to that found in many ophiolites.

The FAB and associated diabase overlying gabbros can be regarded as a first magmatic product produced by decompression melting associated with subduction initiation. $^{40}Ar/^{39}Ar$ ages of 48-52 Ma for these basalts as well as 51.6-51.7 Ma zircon U-Pb ages for the gabbros strongly imply that subduction initiation took place at 51-52 Ma. The change to flux melting and boninitic volcanism took 2-4 m.y., and the change to flux melting in counterflowing mantle and "Normal" arc magmatism took 7-8 m.y. This evolution from subduction initiation to arc normalcy occurred nearly simultaneously along the entire length of the IBM subduction system. The contemporaneousness of IBM forearc magmatism with the major change in plate motion in Western Pacific at ca. 50 Ma suggests that the two events are intimately linked. Mesozoic rocks found in the deep Bonin forearc suggest that the overriding plate at subduction initiation consisted of Mesozoic terranes.

The similarity between the IBM forearc stratigraphy and many ophiolites supports the hypothesis that the forearc crust section that is produced at subduction initiation and is preserved in the IBM system represents an in-situ section of supra-subduction zone ophiolite.

Organic geochemical analysis of the impact of cadaver burial on soil

SOFO S. ISMAIL[1,2]*, IAN D. BULL[1] AND RICHARD P. EVERSHED[1]

[1]School of Chemistry, University of Bristol, Cantock's Close, Bristol BS8 1TS, UK (*correspondence: chssi@bri.ac.uk)
[2]Faculty of Science & Technology, Universiti Malaysia Terengganu, 21030 Kuala Terengganu, Terengganu, Malaysia

A comparative study of soil lipids collected from eleven crime scenes across Malaysia, with different post-depositional intervals (PDI) of cadavers, was conducted. A laboratory degradation study of porcine flesh in soil was also carried out in parallel. The overall premise for this work was that organic molecular components in soil will be useful in determining the provenance of a cadaver and/or calculation of its post-mortem interval (PMI).

The results from the Malaysian samples show that the concentrations of palmitic (C16:0) and stearic (C18:0) acids are higher in the cases with a low PMI, In addition, their unsaturated analogues, palmitoleic (C16:1) and oleic (C18:1) acids are also present at high concentration. The higher concentration of cholest-5-en-3β-ol (cholesterol) in the cases with low PMIs indicates that this component is most likely derived from the decomposing body. The cases with longer PDI demonstrate a large shift towards plant-derived organic material. Differences observed are presumably due to the transformation of the cadaver derived lipids and can be associated with PMI and/or PDI.

Subsequently, porcine flesh was degraded in aerobic and anaerobic soil mesocosms, representative of tropical and temperate climates, for a year. Mesocosms were sampled throughout the experiment and target analytes were chosen to provide information about both materials derived from the flesh and the response of the microbial community to its presence in the soil environment. Initial results reveal that flesh derived triacylglycerol components degrade within the first 120 days resulting in a corresponding increase in concentration of free fatty acids, i.e. palmitic and stearic acids. Similar patterns of degradation are observed under both aerobic and anaerobic conditions. Preliminary analysis of phospholipid fatty acid distributions, derived from the soils, reveals a concentration increase in the region of 180-400% for soils incubated with porcine flesh after 121 days, with a currently unidentified C18:1 fatty acid moiety becoming the dominant component in the latter samples.

Role of acid mobilization in association of smaller particle size with higher iron solubility

AKINORI ITO

RIGC, JAMSTEC, Yokohama 236-0001, Japan (akinorii@jamstec.go.jp)

Iron (Fe) is an essential nutrient for phytoplankton. Iron-containing soil dust mobilized from arid regions supplies the majority of iron to the oceans, but primarily presents in an insoluble form. Since most aquatic organisms can take up iron only in the dissolved form, a key flux is the amount of soluble iron in terms of the biogeochemical response to atmospheric deposition. Atmospheric processing of mineral aerosols by anthropogenic pollutants may transform insoluble iron into soluble forms. We discuss the effect of the acid mobilization on a relationship between aerosol iron solubility and mineral particle size in an aerosol chemistry transport model [1]. The iron solubility from onboard cruise measurements [2, 3] over the Atlantic and Pacific Oceans in 2001 is used to evaluate the model performance in simulating soluble iron.

The association of smaller size with higher solubility as a role of the acid mobilization considerably improves the results of soluble iron in terms of ratio of fine to total particles, compared to constant iron solubility. The improvement of model-observation agreement provides strong evidence for faster iron dissolution in fine particles by anthropogenic pollutants. Accurate simulation of the ratio of fine to total aerosols of soluble iron has important implications with regards to the ocean fertilization because of a longer residence time of smaller particles, which supply nutrients to more remote ocean biome. The model reveals higher concentration of soluble iron in the coarse mode than that in the fine mode over the Southern Ocean except downwind regions of Australian dust, in contrast to the Northern Ocean. These results suggest that dust does not efficiently transport soluble iron to significant portions of the Southern Ocean. This corroborates hypothesis that phytoplankton blooms are not sustained by the supply of iron to surface waters from dust deposition in the Southern Ocean [4] except the Australian sector [5].

Zircon U-Pb and FT dating on clastic dykes in the Matsukawa Geothermal field, Japan, with reference to the Quaternary Kakkonda granite

H. ITO[1]*, A. TAMURA[2], T. MORISHITA[2] AND S. ARAI[3]

[1]Central Research Institute of Electric Power Industry, Chiba 270-1194, Japan (*correspondence: ito_hisa@criepi.denken.or.jp)
[2]Frontier Science Organization, Kanazawa Univ., Ishikawa 920-1192, Japan
[3]Department of Earth Sciences, Kanazawa Univ., Ishikawa 920-1192, Japan

We have determined both U-Pb and fission-track (FT) zircon ages from Quaternary clastic dykes in the Matsukawa Geothermal field, northeast Japan [1]. Since the dykes contain granitic xenoliths, the dated zircons may have derived from granitic basements underneath. A weighted mean LA-ICP-MS U-Pb (^{238}U-^{206}Pb) age of 1.30±0.04 Ma (1σ error) and a weighted mean FT age of 1.0±0.1 Ma (1σ error) were obtained from the zircons. This indicates that if zircons are of granitic origin, the granite intruded ~1.3 Ma and cooled to ~300 ºC at ~1.0 Ma, considering closure temperatures of both the dating methods.

Adjacent to the Matsukawa geothermal area, the Quaternary Kakkonda granite with K-Ar ages of 0-0.2 Ma resides below 1.5-3 km depths. The intrusion of the Kakkonda granite is assumed to be ~1.0 Ma based on geological and geochronological evidence [2]. Therefore strong correlation is plausible between the two granites.

U-Pb zircon dating of the Kakkonda granite is now under way. We will report the dating results and the relevance of the Quaternary granite for the related geothermal systems.

Sample code	Number of grains	Dosimeter number	Dosimeter density x 10^5 cm^{-2}	Spontaneous number	Spontaneous density x 10^5 cm^{-2}	Induced number	Induced density x 10^6 cm^{-2}	P(χ^2) %	T ± 1σ Ma
SP-2	30	2270	3.487	88	1.27	2096	3.03	75	1.0 ± 0.1

Ages are calculated using ζ=142.1±5.7 (1σ error). Dosimeter glass CN-1 used.

Two flood basalt events and contemporary granites within the same LIP: Siberian Traps case study

A.V. IVANOV[1], H. HE[2], L. YAN[2], V.V. RYABOV[3], A.Y. SHEVKO, S.V. PALESSKY AND I.V NIKOLAEVA[3]

[1]Institute of the Earth's Crust SB RAS, Irkutsk, Russia, (aivanov@crust.irk.ru)
[2]Institute of Geology and Geophysics CAS, Beijing, China, (huaiyuhe@mail.iggcas.ac.cn)
[3]Institute of Geology and Mineralogy SB RAS, Novosibirsk, (Russia, trapp@igm.nsc.ru)

Siberian Traps LIP contains effusive, intrusive and volcanoclastic rocks of variable composition from ultrabasic to acidic, though low-Ti basalts and their intrusive analogues are predominant rock types. Our new ^{40}Ar/^{39}Ar results combined with published values suggest that basaltic magmatism appeared during different periods of time (Fig. 1). Among four episodes, at least two (at the Permo-Triassic boundary and one at the Early/Middle Triassic) can be considered as flood basalt events on merit of the volume and geochemistry. Two other episodes of basaltic volcanism were probably less voluminous. U-Pb data for granites show that granites in peripheral parts of the Siberian Traps LIP were contemporaneous to the two flood basalt events, but the latest Bolgokhtokh intrusion is younger than any of basalt. Thus Siberian Traps LIP is much more complex then usually considered.

Fluid processes in subduction zones and global water circulation

HIKARU IWAMORI

Tokyo Institute of Technology: (hikaru@geo.titech.ac.jp)

Water within the Earth, including OH and H in minerals, may play an important role in the planetary evolution, yet its distribution and circulation are poorly constrained. Seismic observations, e.g., those based on dense networks over the Japan arcs, suggest deep subduction of water and dehydration of the slab [1 and the refs. therein]. Geochemistry of volcanic rocks is useful for quantifying the amount and composition of slab-derived fluid, and suggests a typical range from 0.1 to 1 wt.% H_2O in the mantle wedge with regional variations according to the tectonic settings [2]. Numerical models provide a consistent view, in which fluid flow with local chemical equilibration explains the above observations [3]. In addition, these models and water solubility to minerals at high pressures [4] imply that a boundary layer with several 1000 ppm H_2O hosted by NAMs subducts to depths greater than 300 km.

The deeply subducted water, especially in the lower mantle, is not well mapped by geophysical means: seismic velocity may be influenced by major element compositions and temperature, while electrical conductivity is sensitive to the amount of water but provides a poor spatial resolution at depths [5]. Geochemistry of oceanic basalts can be used as a probe for the subducted components. Statistical analysis on the mantle isotopic variability suggests that such a component is in fact inherited in the mantle and forms geographical domains, possibly related to the extensive subduction having surrounded the supercontinents in the past, Pangea, Gondwana and Rodinia [6]. Repeated formation-breakup of supercontinents seems to be recorded in the mantle geochemistry, controlling the global material circulation.

Mantle compositional variability constrained from arc and oceanic basalts

HIKARU IWAMORI

Tokyo Institute of Technology: (hikaru@geo.titech.ac.jp)

Mantle compositional variability has been extensively studied using oceanic basalts, including mid-oecan ridge basalts (MORB) and ocean island basalts (OIB), as geochemical 'messages' from the mantle [1]. However, the spatial coverage of ridges and ocean islands is insufficient for resolving even a global distribution of compositional variability (Fig.1). Here we discuss the mantle compositional variability in subduction zones that extend over a long distance comparable to mid-ocean ridges, mostly around the Pacific Ocean (Fig.1). As a result, we are able to map global geochemical domains, when combined with the mantle compositional variability obtained from MORB and OIB.

Arc basalts associated with subduction are the products of interaction between slab-derived materials and mantle wedge beneath the arcs. In order to extract the compositional variability of the mantle, influence of the subducted materials needs to be evaluated. Based on Sr, Nd and Pb isotope ratios mainly from the GEOROC and PetDB databases, and using the multivariate analyses, in particular, Independent Component Analysis, it has been found that depleted portions of the arc basalts well represent the compositions of mantle wedge that has not been fluxed by slab-derived materials. These portions lie on a compositional plane that is well defined by MORB and OIB, and can be decomposed into two independent components. Consequently, geographical domains in terms of 'anciently subducted component' ('IC2' in [2]) have been found and its implications on mantle dynamics are discussed.

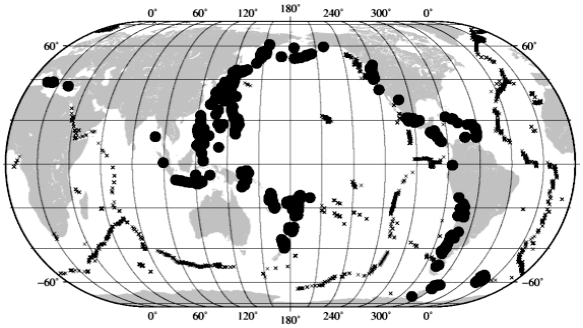

Figure 1: Distribution of oceanic basalts (small crosses) and arc basalts (solid circles) used in this study.

$\delta^{13}C$ evidence of conodont evolution as a response to bioproduction perturbations

O.P. IZOKH

Sobolev Institute of Geology, and Mineralogy SB RAS, Novosibirsk, Russia (izokhop@gmail.com)

Usually $\delta^{13}C$ variations in marine sediments are related to the mass extinction in the Earth's past, and explained as reflection of the changes in primary bioproduction of the paleooceans, but sometimes the $\delta^{13}C$ excursion coincide with important evolutionary changes in biosphere. One of examples is radiation of polygnathid conodonts at the lower Emsian (Devonian), where negative $\delta^{13}C$ excursion (from +2 to -0.7 ‰) is aligned with the appearance of well-developed Pa element of the *Polygnathus kitabicus*, *Pol. pannonicus* and *Pol. sokolovi*.

Apart of bioproduction decrease, carbonates secondary changes also may cause negative excursion. To exclude the diagenetic nature of these isotopic signals, investigations of geochemical criteria of primary carbonate material safety (Fe/Sr and Mn/Sr) have been done. Together with the petrographic studies they are very effective for allocation of diagenetically altered samples.

All studied lower Emsian samples from Zinzilban section (Zeravshan Ridge, Kitab State Geological Reserve, Uzbekistan) are characterized by the low concentration of Fe (<100 ppm) and Mn (<22 ppm) with Sr contents from 150 to 400 ppm. Thus, Fe/Sr and Mn/Sr not exceed 0.5 and 0.07 accordingly, that evidence absence of carbonate material alteration. Also, it was controlled by petrographic studies. Thus, $\delta^{13}C$ negative excursion with high probability is a primary signal and the correlation of this event with the complication of conodont Pa element can reflect changes in their nutrition type, induced by the decreasing of the simple food.

Mo-isotopes as tracers of Cretaceous ocean anoxia

G.J. IZON[1]*, A.S. COHEN[1], A.L. COE[1], S.W. POULTON[2] AND T. WAGNER [2]

[1]Department of Earth and Environmental Sciences, The Open University, Milton Keynes, MK7 6AA, UK. (*correspondence: G.Izon@open.ac.uk)

[2]School of Civil Engineering and Geosciences, Newcastle University, Newcastle upon Tyne, NE1 7RU, UK.

Recent observations and modelling have shown that ocean warming and stagnation, driven by global climate change, may lead to widespread ocean deoxgyenation with direct impacts on marine biogeochemistry and ecosystems. Measurements of marine oxygen levels extend back no more than *c*. 50 years, whilst accurate predictions of future deoxgyenation trends are difficult and uncertain. In contrast, the geological record of past abrupt global warming events can provide insights into the entire earth system response - the mechanisms, extent, duration and consequences of - seawater deoxgyenation that are associated with CO_2-induced global warming.

The Cretaceous oceans were particularly susceptible to transient widespread deoxygenation, containing as many as 6 discrete intervals known as Ocean Anoxic Events (OAEs). Of these, OAE 1a (~120 Ma) and OAE 2 (~93 Ma) may have been global in extent and are marked by a sudden increase in organic C accumulation in conjunction with broad positive carbon isotope excursions.

We present new Mo-isotope, trace element and Fe-speciation analyses of samples from OAE 1a (the Selli event) and OAE 2 (the Bonarelli Event). Mo-isotope data can, under certain circumstances, provide quantitative estimates of how the extent of seawater anoxia may have fluctuated in the past. Our data from Gorgo a Cerbera, Italy, indicate that local conditions became progressively more reducing during OAE1a. $\delta^{98/95}Mo$ ratios show pronounced stratigraphic variations, consistent with diminished oxic sedimentation globally. Laminated sediments from Demerara Rise are enriched in redox sensitive trace metals (RSTM) throughout much of the Cenomanian. However, OAE 2 is marked by relatively low levels of RSTM consistent with the global expansion of anoxic sedimentation and the drawdown of the RSTM inventory. Our sample specific Fe-speciation data show that the water column was periodically euxinic, allowing us to use Mo-isotope data to critically test ideas on the timing, extent and duration of one of the most prounced deoxgyenation events of the Mesozoic.

[3]AGES Austrian Agency for Health and Food Safety, CC Radiation Protection and Radiochemistry, Spargelfeldstr. 191, A-1226 Vienna, Austria

Iodine is an important element in oceanic, atmospheric and terrestrial systems. Atmosphere is one of the most important compartments for natural and anthropogenic changes and provides rapid response to disequilibrium. Iodine is transferred between compartments on different time scales and in different chemical forms (species). However, the dominant transfer pathway is either through the atmosphere as reactive gases (e.g. I_2, CH_2I_2, CH_2ICl, CH_3I), bound to aerosols or in the aqueous phase (i.e. rain, rivers, lakes and oceans).

^{129}I has received increased attention in recent years as unique atmospheric and environmental tracer. ^{129}I is a long lived ($T_{1/2}$ = 15.7 Ma) radionuclide whose concentration in environment has been elevated by several orders of magnitude, mainly by emission from reprocessing plants [1]. However in spite of environmental relevance, there is still little knowledge about temporal variability of the ^{129}I anthropogenic fallout over Europe. One of the main goals of this study is to trace transport path of ^{129}I released from reprocessing plants in atmosphere by measuring its concentration.

This study deals with temporal changes of iodine isotopes (^{127}I and ^{129}I) in aerosols collected within two years in Vienna, Austria (202 m a. s. l). The data shows isotopic ratios of the order of 10^{-8} to 10^{-7}. The predominant basis for the higher ratios in the aerosols appears to be upcurrent sources of ^{129}I from nuclear fuel reprocessing plant at Sellafield. Apart from this, short term variability of ^{129}I concentrations was associated with air mass transfer and wind pattern.

Mineral composition of particulate matter in human lung samples from Upper Silesia (Poland) – Preliminary results

M. JABLONSKA

University of Silesia (mariola.jablonska@us.edu.pl)

The aim of this study is to compare the mineral composition of airborne particles to mineral composition of particles inhaled by humans who lived in highly urbanized and industrialized region of Upper Silesia (S Poland). The characterization of mineral particles in samples of lung tissues of 40 subjects by TEM and ASEM revealed the presence of quartz, aluminosilicates including feldspars, Ca carbonates, iron oxides, Ca sulphates, and kaolinite as major components.

All of those minerals are major mineral constituents of dust particles in Upper Silesia in addition to soot. Some of them may serve as tracers of the source of inhaled particles. For instance, barite particles in lung tissues may be related to the abundant airborne barite resulted from the combustion of the uniquelly Ba-rich Silesian coal. The lung tissues lack of Pb-particles, which are common in airborne soot particles. Their fast dissolution in lung fluids is a possible explanation of their absence in lung tissues.

Additionally, Ca-phosphates (perhaps of the apatite group) and zinc oxide were observed on rare occasions in lung tissues.

This work is supported by research project N306314439 of the Polish Ministry of Science and Higher Education.

Direct ventilation of the North Pacific did not reach 2300 m during the last glacial termination

S.L. JACCARD[1]* AND E.D. GALBRAITH[2]

[1]D-ERDW, ETHZ, Zurich, Switzerland (*correspondence: samuel.jaccard@erdw.ethz.ch)
[2]Earth and Planetary Sciences, McGill University, Montreal, Canada (eric.galbraith@mcgill.ca)

It has recently been argued that the North Pacific circulation during HS1 (18-14.6 kyr) was distinct from both the LGM and the warmer intervals that followed, with a greater formation of 'deep waters' sinking to 2500-3000 m. This intriguing conjecture appears to be inconsistent with a number of geochemical proxies measured at multiple North Pacific core sites from this depth range.

'Ventilation' involves the input of atmospherically-equilibrated waters to the ocean interior. Well-equilibrated waters have high concentrations of oxygen and relatively low concentrations of dissolved carbon dioxide. Bottom waters with high oxygen concentrations inhibit the diagenetic enrichments of some redox-sensitive trace metals in underlying sediments, while low concentrations of carbon dioxide (relative to alkalinity) produce high carbonate ion concentrations, encouraging preservation of calcium carbonate ($CaCO_3$) microfossils in sediment. Thus, poorly ventilated bottom waters are likely to show both sedimentary authigenic U enrichments and poor $CaCO_3$ preservation. Measurements at sites from the NW Pacific and in the Bering Sea show that, at 2393 m and 2209 m water depth, respectively, these twin hallmarks of poor ventilation reigned throughout the LGM and HS1, to finally disappear after ~15 ka. This sequence of change is consistent with a poorly ventilated deep ocean throughout this interval that extended from the abyss to within < 2500 m of the surface. The assembled evidence does not appear to provide an opening during the deglaciation during which the North Pacific water could have pumped oxygenated waters into the deep.

A new starting point for the mantle's geochemical reservoirs

M.G. JACKSON[1] AND R.W. CARLSON[2]

[1]Dept. Earth Sciences, Boston University, 675 Commonwealth Ave., Boston, MA 02215 (jacksonm@bu.edu)
[2]Department of Terrestrial Magnetism, Carnegie Institution of Washington, 5241 Broad Branch Road, NW, Washington, DC 20015 USA (rcarlson@ciw.edu)

The present-day terrestrial mantle, as sampled by melts that erupt at the surface, is chemically and isotopically heterogeneous. The discovery of a surviving portion of the early-formed silicate Earth that existed immediately after formation of the core—referred to as primitive mantle—would place constraints on the earliest chemical evolution of the Earth. Such a discovery would also provide a starting point to understand the origin and long-term evolution of the various geochemically-distinct mantle reservoirs that now make up Earth's interior. Earth's primitive mantle has long been thought to be compositionally similar to primitive chondrites, at least for the refractory, lithophile elements. However, the recent discovery that modern terrestrial lavas have $^{142}Nd/^{144}Nd$ ratios ~18 ppm higher than chondrites suggests that the Earth's primitive mantle has a Sm/Nd ratio that is ~5% higher than chondrites [1], and that all modern terrestrial mantle and crustal reservoirs ultimately were derived from this reservoir with superchondritic Sm/Nd. Today, the $^{143}Nd/^{144}Nd$ of the primitive (albeit non-chondritic) reservoir would be ~0.5130, a ratio that is closer to the depleted MORB mantle than to chondritic. In order to extract the continents from the non-chonditic primitive mantle, the depleted mantle reservoir must comprise > 50% of the mass of the mantle, thus extending into the lower mantle. Another implication of a non-chondritic Earth is that it provides a new reference for the composition of primitive mantle (e.g. $^{143}Nd/^{144}Nd$ = 0.5130), and reservoirs that were once considered depleted relative to chondritic (e.g. HIMU, with $^{143}Nd/^{144}Nd$ = 0.51285) are actually enriched relative to the postulated non-chondritic mantle. The observation that the most frequently-occurring $^{143}Nd/^{144}Nd$ ratio (0.5130, PREMA) in ocean island basalts (OIB), including lavas with high $^{3}He/^{4}He$, overlaps with the value suggested for a non-chondritic mantle (0.5130) suggest that large portions of the mantle sampled by OIB remain little-modified with respect to $^{143}Nd/^{144}Nd$. If the Earth's primitive mantle is not chondritic and a portion has survived in the deep Earth to the present-day, we consider the best candidate to be the mantle reservoir sampled by lavas with the highest $^{3}He/^{4}He$.

A 'hotspot highway' in the S. Pacific

M.G. JACKSON[1]*, S.R. HART[2], J.G. KONTER[3], A.A.P. KOPPERS[4], H. STAUDIGEL[5], M.D. KURZ[2], J. BLUSZTAJN[2] AND J. SINTON[6]

[6]Department of Geology and Geophysics, University of Hawai'i at Mānoa, Honolulu, Hawaii 96822, USA

New deep-sea dredges from the Samoan region provide evidence for three seamounts (Malulu, Papatua [PPT], Waterwitch) and one atoll (Rose) that are not geochemically related to the Samoa hotspot track. We use a plate motion model to show that three non□Samoan hot spots, currently active in the Cook□Austral Islands, are responsible for 10–40 Ma volcanism in the Samoan region. The four 'interloping' volcanoes in the Samoan region exhibit geochemical affinities with the three hot spots. All three hot spots would have left a depleted, viscous, refractory keel that is coupled to the base of the Pacific lithosphere that has been 'rafted' to the Samoan region. Without major modification of the current 'propagating lithospheric cracks' model, it is not clear how such cracks could yield melts from the refractory keel present under the Samoan lithosphere. Instead, a region of buoyantly upwelling mantle, or plume, is suggested to generate the shield stage volcanism in the Samoan region.

Another implication of the Cook-Austral interlopers in the Samoan region is that they may provide the "missing link" to what may be a third long hotspot track in the Pacific, in addition to the Hawaii and Louisville chains. The Hawaii and Louisville hotspots exhibit very different behavior at ~45-50 Ma (the Hawaiian hotspot exhibits a clear "kink", and Louisville exhibits a gradual bend), and it is important to establish a third long-lived hotspot for comparison during this critical time in Pacific tectonics. Plate reconstruction models suggest the Rurutu hotspot track—one of the three hotspots in the Cook-Austral Islands—bends at ~45 Ma and emerges from the Gilbert Islands before trending through Samoa and toward the present-day hot spot location beneath Rurutu. Deep-sea dredging the seamounts in the region predicted to be the ~45 Ma Rurutu "bend" is necessary for evaluating a genetic and temporal link to the Rurutu hotspot.

Quantitative determination and mapping of trace element concentrations in sulfide minerals using LA-ICP-MS

S.E. JACKSON[1], S. SHUTTLEWORTH[2] AND L.J. CABRI[3]

[1]Geological Survey of Canada, Ottawa, ON K1A 0E8, Canada (*correspondence: simon.jackson@nrcan.gc.ca)
[2]Photon-Machines Inc., 15030 N.E. 95th St., Redmond, WA 98052, USA (shutts@photon-machines.com)
[3]Cabri Consulting Inc., 99 Fifth Avenue, Suite 122, Ottawa, Ontario, K1S 5P5 (lcabri@sympatico.ca)

Quantitative trace-element analysis of sulfide minerals has a number of important applications, including: empirical indication of deposit setting, geo-thermometry and geo-barometry, ore paragenesis studies, indicator mineral surveys, and deportment investigations. However, progress in this field has been hindered by the lack of multi-element sulphide mineral standards for trace-element microbeam techniques and methods for mapping trace element concentration distributions in samples with complex mineralogy.

In this study, element distribution maps have been constructed from time-resolved LA-ICP-MS signal intensity data acquired during multiple, continuous parallel line ablations and lines of edge-to-edge, square spot ablations across selected areas of petrographic sections. The data were deconvoluted, calibrated and digitally combined using in-house software to generate elemental concentrations maps, which provide detailed information on spatial variations of elements within and between sulfide grains and their enclosing minerals.

Determining concentrations in mono-mineralic sampling areas was perfomed using conventional calibration protocols involving external standardization and normalization using an internal standard, performed on a (mass) scan-by-scan basis. External standardization was achieved using a multi-element synthetic pyrrhotite standard that was prepared by reaction in an evacuated quartz tube of elemental iron and sulfur doped with multi-element aqueous standards. This has been shown to be homogeneous (r. s. d. <10%) for the majority of the 30 doped elements. For complex mineralogies, both sulfide and silicate external standards were employed, together with normalization using different internal standard elements and/or concentrations for different minerals, and algorithms that automatically detected the mineral phase being analyzed.

The effect of different laser sampling strategies and algorithms for data smoothing and interpolation, and assignment of colours to element maps will be demonstrated.

Polycrystalline diamonds witness redox processes in the Earth's mantle

D.E. JACOB[1]*, R. WIRTH[2] AND F. ENZMANN[1]

[1]Johannes Gutenberg-Universität, D-55099 Mainz, Germany (*correspondence: jacobd@uni-mainz.de)
[2]Helmholtz Centre Potsdam, D-14473 Potsdam, Germany (wirth@gfz-potsdam.de)

Polycrystalline diamond aggregates (framesites) from the Orapa kimberlite (Botswana) contain a syngenetic micro- and nano-inclusion suite of magnetite, pyrrhotite, omphacite, garnet, rutile and C-O-H fluid in order of abundance. This suite of inclusions is distinctly different from those in fibrous diamonds, although the presence of sub-micrometer fluid inclusions provides evidence for a similarly important role of fluids in the genesis of polycrystalline diamond. High resolution μ-Computed Tomography (resolution 1.3μm per voxel) combined with Focused Ion Beam assisted Transmission Electron Microscopy reveals epigenetic replacement coatings of hematite and late stage sheet silicates around magnetites showing that magnetites are often (but not always) interstitial to the diamond and, thus, were open to late stage more oxidized overprinting. We present evidence that the primary paragenesis preceding this late stage event formed from a reduced, water-rich C-O-H fluid oversaturated in carbon upon entering the base of the subcratonic lithosphere along opening cracks. Precipitation of diamond increased the water content of the fluid, fluxing melting of surrounding rocks (eclogitic silicates, Fe-sulfides, oxides), which re-precipitated in the interstices between diamonds and as nano-inclusions. Pyrrhotite crystallization led to a rise in fO_2 in the small-scale Fe-O-S melt, which is amplified by the precipitation of diamond from the C-O-H fluid, moving the whole system towards more oxidizing conditions. Thus, fO_2 conditions were more reducing at the start of diamond precipitation and evolved towards more oxidizing conditions upon cooling and solidification. The inclusion paragenesis was generated in a local small-scale equilibrium system, and is representative only for the redox conditions towards the end of diamond precipitation. It is generally acknowledged that sulfide melts are relatively immobile in the Earth's mantle. Formation of polycrystalline diamond would require only local remobilization and small-scale transport of pre-existing material. Cratonic roots have been episodically impregnated with carbon-rich fluids - small volume melts from mantle sources as well as subducted basaltic material - since Archean times. This process leads to diamond formation at a range of spatial scales.

Diamond-graphite transformation: A NanoSIMS isotope study of diamond-graphite inclusion in zircon from the Kochetav massif

B. JACOBSEN[1]*, J. MATZEL[1], I.D. HUTCHEON[1], H.W. GREEN[2] AND L.F. DOBRZHINETSKAYA[2]

[1]Lawrence Livermore National Laboratory, CA 94550, USA (*correspondence: jacobsen5@llnl.gov)
[2]University of California, Riverside, CA 92521, USA

Diamond from ultrahigh-pressure metamorphic terrains (UHPM) is an important mineralogical indicator of deep lithospheric slab subduction (>150 km) into Earth's mantle. Details about diamond-to-graphite transition occurring during subsequent exhumation are not well understood. Because the structures of diamond and graphite are so dissimilar, it is unlikely that a direct phase transformation would occur in the graphitization process. Heating experiments at T=1500-1800°C and ambient pressure showed that diamond is replaced by disordered graphite along planes with a high concentration of dislocations.

In order to better understand the process of diamond-to-graphite transformation we measured C, and N isotopes in an inclusion, comprising graphite with a diamond core, in zircon from the Kokchetav massif, Kazakhstan. The inclusion is ~ 10 μm in diameter and consists of a ~3 μm diamond core that is surrounded by a graphite rim ~7 μm in thickness. The C and N isotopes were measured with a Cameca NanoSIMS-50. Diamond and graphite in the inclusion are isotopically indistinguishable (i.e. $\Delta^{13}C_{diamond\text{-}graphite}$ and $\Delta^{15}N_{diamond\text{-}graphite} \approx 0$). The C and N isotopic composition for the entire inclusion is $\delta^{13}C = -30 \pm 1$ ‰ and $\delta^{15}N = +0.5 \pm 3$ ‰ respectively, which is in the range of carbon of organic origin.

The distinctive geometry of the diamond-graphite inclusion – the diamond core mantled by graphite – suggests a retrogressive reaction that probably occurred due to decompression during the host rock's exhumation to the Earth's surface from depths > 120-150 km. The lack of intra-mineral isotope fractionation between diamond and graphite for both C and N isotopes suggests that the retrogressive diamond-to-graphite transformation occurred at temperatures above 500 °C and pressures less than 4 GPa. Raman spectroscopy studies of this diamond by Smith *et al*. (2011) show the presence of 1624 -1647 cm-1 bands which are close to those of disordered graphite. We thus hypothesize that during exhumation diamond was gradually replaced by graphite through an intermediate phase of disordered graphite.

CO_2 evasion from the Greenland Ice Sheet: A new carbon-climate feedback

ANDREW D. JACOBSON[1] AND JONG-SIK RYU[1,2]

[1]Department of Earth and Planetary Sciences, Northwestern University, USA, (adj@earth.northwestern.edu)
[2]Division of Earth and Environmental Sciences, Ochang Center, Korea Basic Science Institute, South Korea, (jsryu@kbsi.re.kr)

Rising greenhouse gas levels may increase global surface temperatures between 1 and 6°C by 2100. Even greater increases are expected for the Arctic, where sea ice reduction, organic matter decomposition in lakes and thawed permafrost, and other positive feedbacks can potentially amplify the global trend. Melting of the Greenland Ice Sheet (GIS) figures prominently in climate change predictions because it will impact albedo, sea level, and possibly, ocean circulation. However, direct carbon cycle feedbacks are poorly constrained. Here, we show that melting of the GIS yields a previously unknown flux of CO_2 that will likely increase in a warmer world. Water emerges from the Russell Glacier in West Greenland with CO_2 partial pressures (pCO_2) 3 – 10X supersaturated with respect to atmospheric equilibrium. This CO_2 likely originates from microbial respiration beneath the GIS. During downstream transport, the chemical weathering of glacial till sequesters 70% of the excess CO_2 as HCO_3 – a carbon sink on human timescales – and the remaining 30% evades to the atmosphere. Scaled to all rivers draining the GIS, the evasion flux of 0.13 Tg C/yr is small by comparison to other atmospheric CO_2 inputs; however, we hypothesize that significant increases could occur as retreat of the ice sheet margin and expansion of moulins exposes meltwater to basal ice with pCO_2 values up to 340X higher than the current atmospheric value. Worst-case model predictions yield evasion fluxes of 100 – 180 Tg C/yr by 2100 depending whether melting increases linearly or exponentially with time. These CO_2 fluxes surpass those reported for Arctic Lakes (20 Tg C/yr) and would increase by 23% those predicted for permafrost thaw (800 – 1100 Tg C/yr). Our findings suggest that Arctic climate change could have a more significant feedback on global climate than currently anticipated.

Along-arc geochemical variations in the Southern Volcanic Zone, Chile

G. JACQUES[1]*, K. HOERNLE[1,2], H. WEHRMANN[1], D. GARBE-SCHÖNBERG[3], P. VAN DEN BOGAARD[1,2], F. HAUFF[2], J. MAHLKE[2], K. SCHUMANN[2] AND L.E. LARA[4]

[1]Sonderforschungbereich 574, IFM-GEOMAR, 24148 Kiel, Germany (*correspondence: gjacques@ifm-geomar.de)

[4]Servicio Nacional de Geología y Minería, 0104 Santiago, Chile

The origin of enriched isotopic signatures in volcanic rocks from the northern segment of the Southern Volcanic Zone (SVZ) in Chile is controversial. Hildreth and Moorbath [1] argued for crustal assimilation in the context of their MASH model. Stern [2] and recently Kay *et al*. [3], however, proposed that subduction erosion can best explain the increasing enrichment of the magmas from the Miocene to present. We present new trace element and isotope data from young olivine-bearing volcanic rocks along the volcanic front of the SVZ in Chile. We observe systematic spatial variations in Sr, Nd, Hf and Pb isotopic compositions along the arc with the northern part of the Southern Volcanic Zone (NSVZ) having the most enriched signatures. Oxygen isotope data, with one exception, show uniform compositions, close to that expected for the upper mantle. Mixing calculations using O and Sr isotope ratios suggest that the enriched signature of the NSVZ lavas is primarily acquired in the mantle, favoring the subduction erosion model. Crustal assimilation, however, could also affect the composition of these lavas.

Role of three-dimensional mantle flow in magmatism at slab edges

MARGARETE JADAMEC[1]*, PATRICIA DURANCE[1], KEN MCLEAN[1], MAGALI BILLEN[2] AND LOUIS MORESI[1]

[1]School of Mathematical Sciences, Monash University, Clayton, Victoria, Australia 3600 (*correspondence: margarete.jadamec@monash.edu)
[2]Geology Department, University of California, Davis, CA, 95616, USA

Adakitic volcanics associated with subduction-transform plate boundaries have been identified in numerous localities, including the eastern Alaska slab edge, the Kamchatka-Aleutian plate boundary corner, the Cascadia-San Andreas transform fault juncture, and the New Hebrides trench-Hunter Ridge [1, 2]. Three-dimensional (3D) models investigating the solid state flow in the mantle due to subduction of a slab edge predict toroidal flow around the slab edge and an upward flow component, which could lead to decompression melting within several hundred kilometers outward of the slab edge as well as contribute to melting of the slab edge. However, the position of the volcanics with respect to the slab edge and associated upwelling in the mantle has only recently been tested in 3D geodynamic models [3, 4]. We use 3D numerical models to investigate the role of rheology and slab geometry on the mantle flow and its implications for anomalous arc volcanism near two slab edges: the eastern Alaska slab edge and the slab edge in the easternmost New Hebrides [3, 5]. In the eastern Alaska region the Aleutian trench terminates at a near right angle into the Fairweather-Queen Charlotte transform boundary. In the eastern New Hebrides, the subduction zone makes a nearly 90 degree arcuate turn, such that the slab edge intersects with the back arc spreading center. The models predict localized rapid mantle velocities (greater than 80 cm/yr), which may contribute to the preservation of primitive magmas that can be brought to the surface. These models do not investigate the link between melt migration and solid state flow of the mantle, which is an important and complex process, but rather aim to place a framework for interpreting how the 3D solid state flow field may influence migration patterns in subduction zones.

The magnitude and composition of the delamination flux in arcs during continental crust formation

OLIVER JAGOUTZ[1] AND MAX W. SCHMIDT[2]

[1]EAPS, MIT (jagoutz@mit.edu)
[2]ETH Zürich (max.schmidt@erdw.ethz.ch)

As the bulk continental crust is not in equilibrium with a mantle assemblage significant volumes of mafic/ultramafic composition counterbalancing the andesitic bulk composition of the crust are missing. Significant volumes of such complementary compositions are exposed in the Kohistan Arc, NE Pakistan. We constrain the bulk composition of the Kohistan arc and constrain the volume and composition of rocks needed to balance the andesitic crust composition to a mantle derived melt using the cumulates exposed in Kohistan. The Kohistan bulk arc composition results very similar to global continental crust estimates indicating that modern arc activity is the dominant process that formed the (preserved) continental crust. Fitting the bulk Kohistan arc crust and the ultramafic cumulates exposed at base of the arc (dunites, wehrlites, websterites, cpx-bearing garnetites and hornblendites, and garnet gabbros) to primitive arc melts with calc-alkaline/tholeiitic, alkaline, and boninitic affinity from various island arcs demonstrates that delamination of wehrlites + garnet hornblendites ± garnet gabbros perfectly explains the evolution from a tholeiitic/calc-alkaline primitive high-Mg basalt to the continental crust. Mass balance demonstrates that volumes of delaminate similar or larger to the continental crust are required. Including these ultramafic cumulates into the estimates of mass fluxes at convergent margin significantly increases the volume of magma production rates in convergent magin setting. Compared to depleted mantle, the delaminate is enriched in Pb and low U concentrations (low mue composnent) and may compensate for the depleted mantle radiogenic lead composition.

[3]ILL, 38042 Grenoble Cedex 9, France

The structural characterization of multicomponent liquids is a challenging problem. From the experimental perspective, measurements need to be performed *in situ* at high temperature (and possibly high pressure). Furthermore, a single method such as x-ray or neutron diffraction, Raman or NMR spectroscopy is usually not sufficient to provide a reliable structural model. On the other hand, molecular modeling approaches using classical interatomic potentials often lack accuracy and computationally expensive first-principles simulations suffer from finite size and time effects. It appears attractive to combine the strengths of different techniques to investigate the structure of chemically complex melts and the relation between their structure and their physical or thermodynamic properties.

Calcium aluminosilicate melts and glasses are important in both geological and technological context. Here, we employ advanced classical interaction potentials that were parametrized using electronic structure calculations [1] to predict the structure of representative liquids of the CaO-Al_2O_3-SiO_2 system at ambient pressure and a temperature of 2500 K as a function of chemical composition. The quality of the simulation model is assessed by comparing the computed total static structure factors to data from x-ray and neutron diffraction experiments (e.g. [2]). In this presentation, we will focus on structural changes across the binary CaO-SiO_2 and CaO-Al_2O_3 as well as the metaluminous ($CaAl_2O_4$)-SiO_2 joins. Similar to the MgO-Al_2O_3 system [3], the average Al coordination decreases from about 4.4 in pure Al_2O_3 melt to 4.0 in Ca-rich melts. At the same time, the number of OAl_3 triclusters is reduced significantly. The distributions of Ca coordination are rather broad but they are dominated by a sixfold octahedral geometry and show a decreasing average coordination towards the Ca-rich melts. In the glass-forming region of the CaO-Al_2O_3 system, a maximum in the melt viscosity is observed well above the glass transition temperature.

Role of microbe in the formation of illite from nontronite: Mesophilic and thermophilic bacterial reaction

DEB P. JAISI[1,2], DENNIS D. EBERL[3], HAILIANG DONG[1] AND JINWOOK KIM[4]*

[1]Department of Geology, Miami University, Oxford, OH 45056, USA
[2]Department of Plant and Soil Sciences, University of Delaware, Newark, DE 19716, USA
[3]US Geological Survey, Boulder, CO 80303, USA
[4]Department of Earth System Sciences, Yonsei University, Seoul, Korea (*correspondence: jinwook@yonsei.ac.kr)

The formation of illite through the smectite-to-illite (S-I) reaction is considered to be one of the most important mineral reactions occurring during diagenesis. In biologically catalyzed systems, however, this transformation has been suggested to be rapid and to bypass the high temperature and long-time requirements. To understand the factors that promote the S-I reaction, the present study focused on the effects of pH, temperature, solution chemistry, and aging on the S-I reaction in microbially mediated systems. Fe (III)-reduction experiments were performed in both growth and non-growth media with two types of bacteria: mesophilic (*Shewanella putrefaciens* CN32) and thermophilic (*Thermus scotoductus* SA-01). Reductive dissolution of NAu-2 was observed and the formation of illite in treatment with thermophilic SA-01 was indicated by X-ray diffraction (XRD) and high-resolution transmission electron microscopy (HRTEM). A basic pH (8.4) and high temperature (65°C) were the most favorable conditions for the formation of illite. A long incubation time was also found to enhance the formation of illite. K-nontronite (non-permanent fixation of K) was also detected and differentiated from the discrete illite in the XRD profiles. These results collectively suggested that the formation of illite associated with the biologically catalyzed smectite-to-illite reaction pathway may bypass the prolonged time and high temperature required for the S-I reaction in the absence of microbial activity.

Solar noble gases in Tagish Lake

T. JAKUBOSWKI[1], U. OTT[2]*,
S. HERRMANN[2] AND P.J.A. MCCAUSLAND[3]

[1]Balonowa 5/2, Wroclaw 54-129, Poland (illaenus@gmail.com)
[2]Abteilung Biogeochemie, Max-Planck-Institut für Chemie, Postfach 3020, DE-55020 Mainz, Germany (*correspondence: uli.ott@mpic.de)
[3]Department of Earth Sciences, University of Western Ontario, London, Ontario K7L 3N, Canada

Tagish Lake fell in January 2000 [1] and is an ungrouped C2 meteorite and a 'breccia at all scales' [2]. Originally two different lithologies, a carbonate-rich one and a carbonate-poor one [2] were recognized, but additional work has revealed that there are even more distinct lithologies [3-5].

Analysis of the carbonate-rich lithology by [6] found abundant primordial noble gas, but solar noble gases were absent. A similar result was obtained by [7] in the analysis of a 'whole-rock' sample. Here we report noble gas data for a carbonate-poor sample of Tagish Lake, which, besides the primordial noble gases contains abundant solar gas.

We analyzed two samples. A smaller sample (#1; 20.2 mg) was heated in three temperature steps (600, 1000, 1800 °C), while a larger sample (#2; 93.9 mg) was heated in 200 °C increments from 400 °C to 1800 °C. Results for He, Ne and Ar are summarized in the Table below. Primordial Kr and Xe were also found at typical abundance levels relative to Ar (^{36}Ar/^{84}Kr/^{132}Xe ~ 80/0.85/1).

#	^{3}He	^{4}He	^{22}Ne	20/22	21/22	^{36}Ar
1	5.99	16774	7.77	10.12	0.0851	90.3
2	8.35	22745	11.45	10.42	0.0853	96.4

Based on the presence of texturally and mineralogically distinct clasts, Nakamura *et al*. [6] concluded that the carbonate-rich lithology they studied is a breccia, however distinct from an asteroidal regolith breccia which would be characterized by the presence of solar noble gases. Our results indicate that there are other lithologies of Tagish Lake that in fact show solar wind gases. This and also the difference in cosmogenic ^{21}Ne (in 10^{-8} cc/g units: 0.46 and 0.64 in our samples vs. 0.114 in [6]) indicate that different lithologies / clasts of Tagish Lake may have experienced quite different irradiation histories.

Investigation the use of ozonation column for phenol removal

H. JALAYERI[1]*, R. MARANDI[2] AND F. DOULATI[1]

[1]Dept of Mining, Shahrood Univ of Tech (*correspondence: hjalayeri@yahoo.com)
[2]Dept of chemical, Islamic Azad Univ, North Tehran

The phenol and this compound are highly toxic and carcinogenic. This pollutant can be observed in the effluents of many industries such as petroleum refining, coal tar distillation and coke in steel mills [1-3]. Advanced oxidation specific ozonation was considered for water treatment as the potential research interest in recent years. Ozonation has a high capacity and suitable for remove phenol. Effective factors were evaluated initial phenol concentration, pH, H_2O_2 volume and Duration ozonation. The results of ozonation were shown that the percentage removal of phenol was related to time. Increased phenol concentration decrease phenol removal rate so that maximum of the percentage removal was obtained for 100, 200 and 300 ppm phenol respectively after 20, 35 and 55 min (Figure 1). The experiments were carried out in pH of 2, 4, 7 and 9. The results were illustrated in table 1.

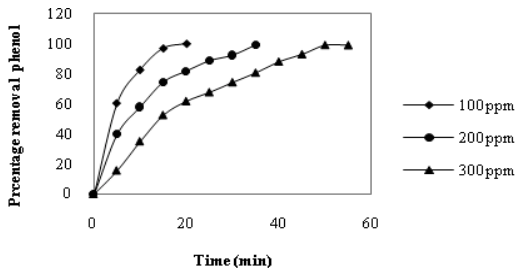

Figure 1: Effect of initial phenol concentration on removal

pH	2	4	7	9
Percentage removal 10 min (%)	55.18	65.12	70	95.3

Table 1: Effect of pH on phenol removal after 10 min

The most advantages of this study were the design of ozonation column and using a ozone diffuser that led to increase the percentage phenol removal in the shortest time possible. The optimum pH was 9 for remove phenol from wastewater and also increased H_2O_2 had little effect on removal.

[4]U. of Massachusetts, Amherst, USA

Active hydrothermal systems on the ocean floor provide modern analogues for the formation of ancient VMS deposits. Seafloor hydrothermal processes are also an important mechanism for the transfer of heat and chemicals between the underlying crust and oceans. However, the rates at which these processes occur remain poorly constrained.

Here, we present radioisotope ages and volume estimates of hydrothermal sulfides from the Endeavour Segment, an intermediate rate ocean spreading center along the Juan de Fuca Ridge that hosts 5 active high-temperature vent fields. The ridge is currently undergoing a period of tectonic extension and volcanic quiessence. A suite of 43 sulfide samples, collected by manned submersible from the active fields and extinct/inactive sites, have been dated using ^{226}Ra/Ba ratios from hydrothermal barite that precipitates along with sulfide minerals. Radium-226 has a half-life of 1,600 years, making it an ideal chronometer for samples younger than ~20, 000 years. Results indicate that venting within the current axial valley of the Endeavour segment was initiated at least 2, 500 years ago. Venting within the Main Endeavour Field, the largest field by area, has been continuous for this period of time.

Using a GIS-based volume calculator developed at MBARI, the total volume of hydrothermal sulfide (including active and inactive/extinct structures) is determined from high-resolution bathymetry of the entire ridge segment. By combining volume data with the age of venting at Endeavour, the mass accumulation rates of sulfide can be determined at the segment scale. These results can be used to calibrate the efficiency of sulfide deposition from hydrothermal vents, and provide a time-integrated history of heat, fluid and chemical fluxes at the ridge-segment scale. The comparison of time-integrated rates with real-time estimates, based on fluid and chemical fluxes, as well as heat flow measurements, allow for an estimate of the episodicity of venting at Endeavour.

Porosity evolution, fracturing and Liesegang-banding during spheroidal weathering

BJØRN JAMTVEIT*, MAYA KOBCHENKO AND ANDERS MALTHE-SØRENSSEN[1]

Physics of Geological Processes, University of Oslo, Norway
(*correspondence: bjorn.jamtveit@geo.uio.no

A 10-meter thick andesitic sill intrusion from the Neuquen Basin, Argentina, shows spectacular examples of spheroidal weathering and Liesegang banding. The Liesegang patterns demonstrate how andesite blocks, initially cut out by a pre-weathering joint set, are subdivided by fractures forming during the spheroidal weathering process. The stresses causing fracturing originate from the growth of ferrihydrite and calcite in the pore space of the andesite, partly at the expense of original ilmenite, amphibole, and plagioclase. Fresh andesite has a porosity of ca. 8%. The porosity evolution and fracture formation during progressive weathering has been characterized in 3D by X-ray computed tomography (CT). The extent of pore filling increases with pore-size. Pores > 10^6 μm^3 are almost completely filled, whereas pores < 10^3 μm^3 are < 50% filled. More than 85% of the pore volume is comprised of pores < 10^3 μm^3, and thus the overall porosity is only slightly reduced during weathering. The fracturing associated with spheroidal weathering is caused by growth in pores comprising the largest 10% of the total porosity. We suggest that variation in growth rate with pores size is controlled by more effective transport of externally derived components to the larger pores. Models for diffusive transport in a porous rock with a pore size distribution similar to the observed will be presented, along with a fracturing model where stresses are generated by growth in pores.

New isotopic constraints on Amsterdam-St. Paul hotspot activity: Evidence for a deep-seated mantle plume and implications for the DUPAL anomaly origin

M. JANIN[1]*, C. HEMOND[1], M. MAIA[1], A. AGRANIER[1], K.T.M. JOHNSON[2] AND E. PONZEVERA[3]

[2]School of Ocean and Earth Science and Technology, University of Hawaii, Honolulu, Hawaii 96822, USA
[3]Département Géosciences Marines, Ifremer, 29280 Plouzané, France

The Amsterdam-St Paul oceanic plateau (ASP) results from the interaction between the ASP hotspot and the Southeast Indian ridge. A volcanic chain, named the chain of the dead Poets (CDP), lies to its northward tip and is related to the hotspot intraplate activity.

The ASP plateau and CDP study reveals that ASP plume composition comes from oceanic crust and pelagic sediments recycled in the mantle through a 1.5 Ga subduction process. The ASP plateau lavas have a composition (major and trace elements and Sr-Nd-Pb-Hf isotopes) reflecting the interaction between ASP plume and the Indian MORB mantle, with some clear DUPAL input [1].

The Indian upper mantle below ASP plateau is heterogeneous and made of a depleted mantle with lower continental crust strips probably delaminated during the Gondwana break-up. The lower continental crust is one of the possible reservoirs for the DUPAL anomaly origin [2-3-4-5] and our data support it. The three endmembers involved (plume, upper mantle and lower continental crust) and their mixing in different proportions enhances an important geochemical variability in the plateau lavas.

[4]WISMUT GmbH, 09117 Chemnitz (j.meyer@wismut.de)

As a residual of microbial ferrous iron oxidation, large amounts of schwertmannite (Fe_8O_8 $(OH)_6SO_4$) were produced in a pilot plant for lignite mine water treatment in Tzschelln (Lusatia, Germany). The secondary mineral has excellent properties for removal of arsenic and other oxoanions from mine water and rapidly transforms into ferric hydroxides of high specific surface area once exposed to water containing at least some alkalinity. Therefore, the research project SURFTRAP was carried out to investigate the applicability of schwertmannite for the treatment of ground- and surface water contaminated with arsenic.

Following to fundamental, hydrochemical and structural investigations in the laboratory, a pilot scale test was performed in the bypass of an active water treatment plant for contaminated flooding water from uranium ore mining. About 25 mg Fe/L as schwertmannite were necessary to undershoot the governmental described effluent limits (0.3 mg As/L and 0.5 mg U/L). The costs of the higher demand of schwertmannite compared to the conventional $FeCl_3$ additon (10 mg Fe/L) could be compensated by a reduction of lime milk requirement of about 25%.

Furthermore, dumping experiments with arsenic-loaded schwertmannite-sludges were performed. A discontinuous irrigation scenario and a continuous groundwater equilibration scenario was investigated. After one year, no significant arsenic release was observed.

Pb-Sr-Nd-Hf isotope variations of megacrysts from Mesozoic Southern African kimberlites reflect mixing of HIMU melts with deep lithosphere

P.E. JANNEY[1] AND D.R. BELL[1,2]

[1]School of Earth & Space Exploration, Arizona State University, Tempe AZ 85287 (pjanney@asu.edu)
[2]Department of Chemistry and Biochemistry, Arizona State University, Tempe AZ 85287 (david.r.bell@asu.edu)

Clinopyroxene (cpx) megacrysts are abundant in southern African kimberlites and most have compositions that are not in equilibrium with normal mantle peridotite. Cpx megacrysts constitute a major part of the Cr-poor megacryst fractionation sequence. Although much of their major element variation is attributable to simple fractional crystallization, deflection of the frationation trends in many cases toward Cr- and Mg-rich compositions suggests that crystallizing megacryst parental magmas are not closed systems. We present Pb-Sr-Nd-Hf isotope data for cpx megacryst samples at regular intervals along evolution paths. The two localities we have examined in detail thus far, Pofadder and Monastery, display illuminating similarities and differences. Mg- and Cr-rich compositions dominate the cpx megacryst population at Pofadder, with only a minority of Cr-poor varieties. These megacrysts describe wide variations in all isotope systems (e.g. $^{206}Pb/^{204}Pb$ = 18.3 to 19.6) with the Cr-poor megacrysts having the most radiogenic Pb (although with lower Δ7/4 and Δ8/4), Nd and Hf isotope ratios. At Monastery, Cr-poor varieties dominate the cpx megacryst assemblage, with a small population of only moderately Cr-rich megacrysts. Here, isotope ratios display a much smaller variation (e.g. $^{206}Pb/^{204}Pb$ = 20.3 to 20.8) and encompass HIMU compositions comparable to the most extreme OIB at St. Helena. Pb becomes progressively less radiogenic as Cr# gradually drops with decreasing Mg#, and this progression continues as the evolution path is deflected toward higher Cr# and mildly increased Mg#. Our isotope data are consistent with an increasing degree of mixing between megacryst parental magmas having HIMU isotopic characteristics and deep lithospheric peridotite (having relatively unradiogenic $^{206}Pb/^{204}Pb$, Nd and Hf) with increasing magma evolution, the extent of assimilation appearing to be much greater at Pofadder than at Monastery. The nearly monotonic changes in the isotope ratios of cpx megacrysts from Cr-poor to Cr-rich compositions at these localities confirms that the two suites are petrogenetically related. Moreover, such mixing may be partly responsible for the lack of strong HIMU compositions directly observed in southern African kimberlites

Geochronological, geochemical and growth constrains of Alpine clefts from U-Th-Pb in monazite

EMILIE JANOTS[1], ALFONS BERGER[2], EDWIN GNOS[3], MARTIN WHITEHOUSE[4] AND ERIC LEWIN[1]

[1]ISTerre, Grenoble, France (*correspondence: emilie.janots@ujf-grenoble.fr)
[2]Museum of Natural History, Geneva, Switzerland
[3]University of Kopenhagen, Denmark, [4]Museum of Stockholm, Sweden

Monazite is a powerful U-Th-Pb chronometer of geological processes. Although conditions that drive its dissolution and precipitation remain unclear, monazite occasionally occurs in hydrothermal veins. Recent studies showed that hydrothermal monazite is successful to date mineralization. The originality of the present work is to evaluate if compositional and isotopic signature of monazite can record the geochemical environment and duration of rock-fluid interaction.

For this study, the selected monazite crystals satisfy two criteria: they are geologically young to ensure a Ma-resolution in age, and large enough (~mm-sized) to detect an age evolution over a grain profile. Studied monazite come from two distinct Alpine clefts from Central Alps (Griesserental and Blauberg, Switzerland). U-Th-Pb isotopic data were measured using ion microprobe.

In the two hydrothermal monazite crystals, U-Th-Pb isotopic signature gives indications about the ages, duration, fO_2 and geochemical environment (close vs open system) of the mineralization. Geochronologically, the Th-Pb age is preferred to the U-Pb age (s), because of (1) the unusually low U/Th contents, (2) significant contribution of common Pb and (3) ^{206}Pb excess in the Griesserental crystal, related to significant incorporation of ^{230}Th. Blauberg and Griesserental crystals show similar Th-Pb ages ~12 Ma, with no significant variations. However, one younger analysis point (~10 Ma) suggests possible crystallization over 2 Ma in the Blauberg crystal. Compositionnally, both crystals show unusually high Th/U values, indicating oxidizing conditions and dominant hexavalent U. Blauberg monazite is rather homogeneous displaying some sector zoning. The Griesserental crystal has a rim with higher Th/U and ^{206}Pb excess (up to 80% of the ^{206}Pb) than in its core. This zoning is coherent with a two-stage crystallisation in a closed system. While ^{230}Th was in disequilibrium with the U-series when the core precipitates, the fluid had time to reach equilibrium when the rim crystallized.

Nature, origin and causes of Jurassic felsic igneous activity in the Victory Glacier area (Eastern Graham Land)

V. JANOUŠEK[1,2]*, A. GERDES[3], J. ŽÁK[2,1], I. SOEJONO[1], Z. VENERA[1], V. ERBAN[1,2], O. LEXA[2,1] AND P. MIXA[1]

Geochemical signatures of felsic igneous rocks (biotite granites and rhyolite dykes) from the Victory Glacier area (eastern Graham Land, Antarctic Peninsula) are mutually indistinguishable, corresponding to high-K calc-alkaline, subaluminous to slightly peraluminous rocks. The NMORB-normalized spiderplots show strong LILE/HFSE enrichment typical of magmas generated at active continental margins or having originated by anatexis of mature continental crust. Characteristic are also fractionated chondrite-normalized REE patterns with deep negative Eu anomalies. The Sr–Nd isotopic signatures are those of fairly evolved crust ($^{87}Sr/^{86}Sr_{175}$ = 0.7084–0.7107, ε^{175}_{Nd} = -4.4 to -4.8). Taken together, the felsic rocks most likely originated from highly differentiated magmas derived by low-P (residue lacking Grt), low-T (Mnz and Zrn saturation temperatures ~770 °C) anatexis of metapsammites or orthogneisses. The widespread crustal anatexis took place within attenuated crust, as a part of the Chon Aike silicic large igneous province [1] magmatism.

New U–Pb Zrn dating shows that the Jurassic magmatic flare-up was rather short-lived (Toarcian–Aalenian). The two recognized Bt granite generations (~185/~166 Ma) both pre- and post-dated the rhyolitic volcanism (~174–179 Ma).

Field relationships indicate that the rhyolite dykes were emplaced in a biaxial extension deformation regime. The appropriate tectonic setting was either rifting accompanying mantle-plume-assisted Gondwana break-up [2] or extension behind the emerging Antarctic Peninsula arc [3]. The two scenarios do not have to be mutually exclusive, though [1, 4].

A physiochemical analysis of the mechanisms for transport and retention of Technetium (^{99}Tc) in unsaturated Hanford sediments

D.P. JANSIK, [1]*,2 D.M. WELLMAN[1], E.A. CORDOVA[1], D. DAGE[1] AND J. ISTOK[2]

[1]Pacific Northwest National Lab, Richland, WA 99352, USA (*correspondence: Danielle.Jansik@pnl.gov)

[2]Oregon State University, Corvallis, OR 97330, USA

The transport of technetium (^{99}Tc) is of interest due to the potential for human exposure and impact on ecosystems. Technetium has been released to the environment predominantly through nuclear fuel processing; as a result, further spreading of ^{99}Tc is a concern at DOE sites across the US. Specifically, technetium is a contaminant of concern at the Hanford Site in southeastern Washington, due to the magnitude of material that was disposed. The current body of work conducted on ^{99}Tc has provided a wealth of information regarding the redox relationships, sorption, solubility, and stability of the mineral phases [1], however little work has been conducted on the transport of technetium under vadose zone conditions.

The current conceptual model for technetium transport in the Hanford deep vadose zone is driven by two dominant hypotheses. The first component, proposes technetium movement is dominated by anisotropy and capillary forces; with the mobile technetium spreading laterally across higher conductivity saturated zones and being resisted by low saturation high conductivity zones. Within these regions technetium transport is considered highly dependent on the unsaturated hydraulic conductivity and capillary pressure. Thus, understanding saturation dependent technetium transport is critical for estimating the vertical fluxes of technetium and predictive modelling. The second premise assumes that technetium is in the form of the oxic pertechnetate species. Using an integrated testing approach we examined the mechanisms for physical and chemical retention and transport of technetium in unsaturated sediments. By employing transport and breakthrough curve analysis as well as pore water and sequential extractions, we evaluated transport behaviour, technetium mineral association, and technetium leachability with regard to pore size distribution.

Pushing the limits of AMS measurements of cosmogenic radioisotopes in natural systems

M. JANZEN[1] AND A. GALINDO-URIBARRI[1,2]

[1]Department of Earth and Planetary Sciences, University of Tennessee, TN 37996, United States (mjanzen1@utk.edu)
[2]Physics Division, Oak Ridge National Laboratory, P.O. Box 2008, MS 6368, Oak Ridge, TN 37831, United States (uribarri@ornl.gov)

Pushing the detection limits of cosmogenic radioisotopes using Accelerator Mass Spectrometry (AMS) techniques will be extremely advantageous to the field of earth sciences. In the late 1970's research in earth sciences was revolutionized by the use of AMS to achieve isotopic levels many orders of magnitude lower than conventional mass spectrometers. In earth sciences AMS techniques are most commonly employed for the measurement of cosmogenic radioisotopes. These isotopes are most useful for quantifying processes at Earth's surface. At the Holifield Radioactive Ion Beam Facility (HRIBF) we have exceptional capabilities owing to the unique set up including the highest operating voltage electrostatic accelerator in the world, the 25-MV Tandem, as well as unique beam transport components and peripheral equipment. This system allows for the detection of extremely rare isotopes and effectively remove isobar interferences. Recent measurements on $^{36}Cl/Cl$ ratios within seawater samples have shown that the levels of detection can be pushed as far as 10^{-16} [1]. Recent developments of new AMS methods such as photodetachments of negative ions may allow us to push the limits even further and increase the range of radioisotopes that can be detected [2]. I will describe an on-going research program at HRIBF that includes identifying natural systems where this extra sensitivity could make a difference. Measurements at the limit of sensitivity will contribute to constrain the predictions from cosmogenic production models at Earth's surface.

Linking geochemistry to microbial community structure and function in sulfidic geothermal systems of Yellowstone National Park

Z.J. JAY[1], B. PLANER-FRIEDRICH[2], D.B. RUSCH[3] AND W.P. INSKEEP[1]*

[1]Department of Land Resources & Environmental Sciences, Montana State University, Bozeman, MT 59717, USA (*correspondence: binskeep@montana.edu)
[2]University of Bayreuth, Bayreuth, Germany
[3]J. Craig Venter Institute, Rockville, MD 20850, USA

Analysis of metagenome sequence from high-temperature microbial communities in Yellowstone National Park (YNP) suggests the importance of heterotrophic, S-respiring crenarchaeal populations in sub-oxic sulfidic sediments. The primary goal of this study was to determine the role of Thermoproteales and Desulfurococcales populations in S and C cycling in these communities using both molecular and culture methods. Metagenome sequence was obtained from three sub-oxic, elemental S-dominated hot springs in YNP: Monarch Geyser (80° C, pH 4), Cistern Spr. (CS; 76° C, pH 5) and Joseph's Coat HS (JCHS; 80° C, pH 6). Major sequence assemblies from these sites resulted in nearly complete consensus genomes of *Acidilobus*, *Vulcanisaeta* and *Caldivirga*-like organisms in all sites, *Thermoproteus*/*Pyrobaculum* spp. in JCHS and CS, and two different Sulfolobales phylotypes in CS. Several enzymes and transporters involved in protein, carbohydrate, and lipid catabolism were identified. The predominant community members all contain bd-ubiquinol oxidase genes and lack any evidence for heme-copper oxidases often associated with aerobic respiration. The expression of genes involved in anaerobic respiration, including novel S reductases in the dimethylsulfoxide (DMSO) molybdopterin family, NAD(P)H:S^0 oxidoreductases, and nitric oxide reductases, was studied using RT-PCR to estimate the activity of these processes in each habitat. Results from molecular analyses of field samples were compared to controlled experiments using a *Pyrobaculum* sp. isolated from JCHS that is capable of growing anaerobically on S^0, using yeast extract as a C and energy source. This organism contains a novel DMSO reductase, highly related to gene sequences identified in the JCHS metagenome. The effect of S^0 particle size on microbial growth was evaluated in concert with the expression of novel DMSO reductases. These data provide insight regarding the structure and function of high-temperature microbial communities, and the role of specific phylotypes in S and C cycling in sub-oxic, sulfidic geothermal systems.

Chemical speciation of airborne mineral dust in the Middle East

R.K.M. JAYANTY[1]*, J.B. FLANAGAN[1] AND J.P. ENGELBRECHT[2]

[1]RTI International, 3040 East Cornwallis Road, Research Triangle Park, NC 27709, USA (*correspondence: rkmj@rti.org, jamesf@rti.org)
[2]Desert Research Institute, 2215 Raggio Parkway, Reno, NV 89512, USA (johann@dri.edu)

Background

On July 8, 1997, the U.S. Environmental Protection Agency (EPA) promulgated a new national ambient air quality standard (NAAQS) for particulate matter with an aerodynamic diameter less than 2.5 μm (PM2.5). In response to the new NAAQS, EPA established two networks: the larger network monitors total mass to assess compliance with the standard. The second, smaller network, the PM2.5 Chemical Speciation Network (CSN) provides data to support attainment activities, and supplies a broad-based dataset to support human health studies and other research. RTI International has provided analytical services and other support to the chemical speciation network since early 2000.

Project Description

Desert Research Institute (DRI) contracted with RTI to provide analytical services for the U.S. Army's Enhanced Particulate Matter Surveillance Program (EPMSP), which began sampling in late 2006. The primary objective of EPMSP was to gather information on the chemical and physical properties of ambient PM in the Middle East. Ambient air samples were collected over a period of approximately one year at 15 sites, which included Djibouti, Afghanistan, Qatar, United Arab Emirates, Iraq, and Kuwait. Three particulate size fractions were sampled: PM2.5, total suspended particulates (TSP), and particulate matter less than 10 μm (PM10). Teflon, nylon, and quartz filters were used for sampling, and all filters were subsequently analyzed by RTI. Analyses included: trace elements (by X-ray Fluorescence Spectroscopy), anions and cations (by ion chromatography), total mass (by gravimetry), and elemental, organic, and carbonate carbon (by Thermal-Optical Transmittance).

Discussion

Because of the high levels of mineral dust found in the deserts of the Middle East, the levels of crustal elements found in the EPMSP samples were significantly higher than in CSN samples from the U.S., which posed some analytical challenges that will be discussed in this presentation.

Trace element geochemistry of soils in fluoride-rich shallow groundwater sites in Sri Lanka

D.T. JAYAWARDANA[1]*, A. PITAWALA[2] AND H. ISHIGA[1]

[1]Shimane University, Department of Geosciences, 690-8504, Matsue, Japan (*correspondence: taranga23@yahoo.com)
[2]Peradeniya University, Department of Geology, 20400, Peradeniya, Sri Lanka

Higher groundwater fluoride is a controversial issue in dry zone of Sri Lanka. This study described the geochemistry of residual soil from higher (< 8 mg/L) and lower (< 1 mg/L) water fluoride sites in dry zone to identify possible sources for fluoride. Twenty two major and trace elements have been determined for seventy four soil samples by means of X-ray fluorescence. Results denote that soil fluoride is lower than upper continental crust and basement rocks in both higher (<411 mg/kg) and lower (<277 mg/kg) water fluoride sites. Negative linear correlation exists between fluoride in the soil and the water suggested that fluoride readily leaching to water rather than retaining in soils due to unconsolidated sandy clay loam texture. Weathering of heavy minerals such as zirconium, apatite, fluorite, monazite and garnet are the main source for the soil in high water fluoride area. Consequently, stable extent of Zr, Nb and Th and depletion of F together with CaO and P_2O_5 than basement is occurred, hence loss of CaO provides favourable condition to leach F to water. Conversely, lower water fluoride area soils show enrichment of TiO_2, Fe_2O_3, MnO, Cr, V and Sc denote the weathering of biotite, hornblende, garnet and pyroxenes in the basement. Primary minerals present in that soil is the main cause for the enrichment of those elements. Further, fluoride levels in the soil and subsequently in water show close link with magmatic differentiations along the geological formations. Thus soil geochemistry evident that meta-igneous rocks of the higher water fluoride area may have associate with a fluoride rich residual melt while lower water fluoride area associate with acidic meta-igneous rocks with concordant meta-sedimentary rocks.

Transfer of uranium isotopes, thorium and their decay products to edible plants

M. JEAMBRUN[1], L. POURCELOT[1], C. MERCAT[2], F. GAUTHIER-LAFAYE[3] AND B. BOULET[4]

[1]Institut de Radioprotection et de Sûreté Nucléaire, Bat 153 BP3 13115 St Paul lez Durance cedex, France (marion.jeambrun@irsn.fr , laurent.pourcelot@irsn.fr)
[2]AREVA NC, BP44 26701 Pierrelatte Cedex, France (catherine.mercat@areva.com)
[3]Université de Strasbourg, EOST, 1, rue Blessig 67000 Strasbourg, France (fgl@unistra.fr)
[4]Institut de Radioprotection et de Sûreté Nucléaire, Bat 501 Bois des Rames 91400 Orsay, France (beatrice.boulet@irsn.fr)

Some of the primordial radionuclides (uranium, thorium and their decay products) are the main source of both external and internal radiation for humans. They can be incorporated metabolically into plants and can be transferred to animals and humans via the foodchain. However, there is a lack of data concerning the Earth crust derived actinides measured in edible plants. Furthermore their main sources as well as their mechanisms of transfer are still misunderstood. Indeed, whereas radionuclides such as uranium and radium would be transferred by root uptake, others radioelements like ^{210}Po and ^{210}Pb are preferentially carried by atmospheric particles. The aim of this work is firstly to understand the differences in activity between various plants species. The appreciation of the equilibriums and the disequilibriums between radionuclides in the decay series as well as the uptake of radionuclides by roots and the inputs by the atmosphere and irrigation should be taken into account to clarify the transfer mechanisms responsible of these differences. Secondly, the objective consists in studying the variability of natural radioactivity in edible plants, according to uranium content in soils from various areas with different geological characteristic and anthropic influence like the nuclear fuel cycle which may enhance the activity in local foodstuffs.

Fluid-mobile element enrichment in mantle wedge of subduction zones

MARLON M. JEAN AND JOHN W. SHERVAIS

Geology Department, Utah State University, Logan Utah 84322-4505

Our previous work has shown that supra-subduction zone ophiolites, which form in the mantle wedge of nascent subduction zones, preserve mantle lithologies that formed in response to hydrous melting and represent the refractory residuum of that process [1-3]. In this study we document the a new algorithm for using fluid-mobile element (FME) concentrations in unaltered residual pyroxenes to calculate the composition and flux of slab-derived fluids in the mantle wedge during melting.

We use high-precision laser ablation ICP-MS analyses (Element 2 ICP-MS with 213 nm laser) of relic pyroxenes in supra-subduction zone peridotites for B, Be, Rb, Th, Ba, Li, and Pb – analyzed in conjunction with a suite of non-fluid mobile elements including the REE and high-field strength elements, which are used to assess melt extraction and melt percolation. Pyroxenes in all SSZ ophiolite samples display enrichments in the FME relative to depleted MORB mantle. In contrast, melting models based on the MREE-HREE and HFS elements show that the FME should have concentrations that are effectively zero after significant melting. We derive an alogrithm may be used to calculate the FME:

$$C_{wr,\,add}=[C_{cpx\text{-}obs}/[[D_{cpx}/(D_{bulk}-PF)]*[1-(PF/D_{bulk})]^{(1/P)}]]-[C_{0,\,wr}]$$

Where $C_{wr,\,add}$ =concentration of FME added to mantle wedge, $C_{cpx\text{-}obs}$=observed pyroxene, D_{cpx} and D_{bulk} = mineral and bulk partition coefficients, P=melt proportion, and F=melt fraction.

Melt models require enormous fractions of FME if the peridotite and fluid are 'mixed' prior to melting. However, if the calculated fluid is added continuously so that it is in equilibrium with the observed refractory pyroxenes, fluid addition models provide reasonable results.

Our results show that high concentrations of fluid-mobile elements in supra-subduction peridotites can be attributed to a flux of aqueous fluid or fluid-rich melt phase derived from the subducting slab. Further, our calculated FME-enriched source yeilds model melts with the trace element signatures of the arc volcanics.

Raman spectroscopic identification of evaporitic minerals and biomarkers using miniaturised portable devices

J. JEHLICKA[1]*, P. VITEK[1], A. OREN[2] AND H.G. M. EDWARDS[3]

[1]Institute of Geochemistry, Mineralogy and Mineral Resources, Charles University in Prague, 12843 Prague, Czech Republic (*correspondence: jehlicka@natur.cuni.cz)

[2]The Alexander Silberman Institute of Life Sciences, The Hebrew University Jerusalem 91904, Israel

[3]Centre for Astrobiology and Extremophiles Research, University of Bradford, Bradford BD71DP, UK

Raman spectroscopy for exobiological applications

It is advocated that in the frame of forthcoming probes planned within future exobiological missions on Mars, Raman spectroscopy will play an important role. It is planned to use this non-destructive tool to identify both minerals and potential organic compounds – possible biomarkers of preexisting life. In this work, minerals from four groups (halides, sulphates, carbonates and borates), examples of pigments known from bacteria, as well as selected osmotic biochemicals (betaine, ectoine), were investigated to estimate the potential of miniaturised spectrometers to work under complex Earth conditions to detect these compounds. Raman spectra were obtained outdoors using a portable Raman spectrometer (DeltaNu, Inspector Raman, excitation 785 nm). Collection specimens and reference compounds were investigated, as well as white evaporitic crusts from two dry evaporitic lakes (Bristol Lake, Owens Lake, California, U.S.A.) and saltern evaporation ponds (Eilat, Israel).

Results

Generally speaking, excellent identificaton of minerals and associated biomaterials through their Raman band positions was achieved on mineralogical specimens from collections. Good results were obtained using the portable spectrometer outdoors on native white evaporitic crusts under ambient atmospheric conditions. Shielding of the measurement area against insolation was nevertheless necessary. Although the recording of weaker Raman features was sometimes problematic, this did not compromise the precise identification of the mineral concerned. Raman spectra of investigated pigments and halophile osmotic compounds obtained permit their reliable identification as well.

Chalcophile element systematics in the North West Lau backarc basin

FRANCES E. JENNER, JOHN A. MAVROGENES*, RICHARD J. ARCULUS AND HUGH ST.C. O'NEILL

Research School of Earth Sciences, Australian National University, ACT Australia 0200 (*correspondence: john.mavrogenes@anu.edu.au)

The Lau Backarc Basin hosts numerous individual spreading centers, including the 70 km-long Northwest Lau Spreading Center (NWLSC) located ~500km west of the northern Tonga Arc volcanic front. Submarine volcanic glasses with from 9 to 2 wt.% MgO (49-62 wt.% SiO_2) were recovered from the NWLSC. These samples show no evidence of a subducted slab component. There is no indication of S loss by degassing. Fractional crystallization of olivine and clinopyroxene drives the liquid to high FeO* with decreasing MgO until the appearance of magnetite on the liquidus at ~4 wt.% MgO. S parallels FeO* but the S levels are initially below those of sulfide-saturated MORB, indicating undersaturation in sulfide. Consequently Cu, Se and Ag also initially increase with decreasing MgO. The apogee in Cu, Ag and Se contents, attributable to sulfide saturation, is at ~5.5 wt% MgO, notably earlier than the maximum in FeO* and S. Because S simply tracks FeO* at sulfide saturation, the Cu-Ag-Se trend reveals the onset of sulfide saturation better than S itself. The behaviour of Cu, Se and Ag in the basaltic to andesitic suite from the NWLSC is intermediate between MORB and oxidised backarc basin magmas; it contrasts with that from the Pual Ridge back arc basin by reaching sulfide saturation prior to the onset of magnetite fractionation. Therefore, chalcophile elements in the NWLSC are removed by continuous pyrrhotite fractionation whereas the more oxidised Pual Ridge magma fractionates to very high chalcophile element abundances before massive precipitation of Cu-Ag (and Au) sulfide at the magnetite crisis.

Characterization of magma from inclusions in zircon: Apatite and biotite work well, feldspar less so

E.S. JENNINGS[1], H.R. MARSCHALL[1,2], C.J. HAWKESWORTH[3] AND C.D. STOREY[4]

[1]Department of Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK (eleanor.jennings@bristol.ac.uk)
[2]Department of Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA (hmarschall@whoi.edu)

[4]School of Earth and Environmental Sciences, University of Portsmouth, Burnaby Road, Portsmouth PO1 3QL, UK (craig.storey@port.ac.uk)

Detrital zircon grains are frequently employed to decipher sediment provenances and crustal evolution throughout Earth history, and they provide unique evidence of Hadean crust-mantle differentiation. However, interpretation of detrital zircon is hampered by the remarkably restricted range of geochemical characteristics of zircon derived from a range of igneous source rocks. Mineral inclusions in zircon are an underexploited resource and provide valuable additional petrologic information on the condition under which zircon crystallised. Zircon grains from a range of plutonic rocks (diorite-monzonite-granite sequence) contain inclusions of apatite and mafic phases (biotite, amphibole, pyroxenes) which accurately reflect the chemical compositions of the equivalent phases in the matrix of the host rocks. Chemical characteristics of the inclusions, such as Mg/Fe ratios of mafic phases, and Sr abundances in apatite, correlate well with the compositions of the whole rocks. High concentrations of Y_2O_3 (>0.4 wt%) and low concentrations of SrO (<0.02 wt%) in apatite inclusions in zircon are diagnostic of evolved, felsic granitoid host rocks. In strong contrast, the relative abundances and compositions of plagioclase and alkali feldspar inclusions in zircon are decoupled from the composition of the whole rock, and are generally indicative of chemically evolved, granitic melts, regardless of the bulk rock composition. This is best explained by the late crystallization of zircon relative to the bulk of the feldspars.

We conclude that inclusions of apatite and mafic phases in zircon constrain the potential source rocks of detrital zircon, whereas feldspar inclusions do not. This ability to differentiate between grains from primitive and evolved sources has important applications to the interpretation of Hadean zircons.

Secular trends in granite zircon εHf–$\delta^{18}O$, Australian Tasmanides

HEEJIN JEON[1]*, IAN S WILLIAMS[1], BRUCE W CHAPPELL[2] AND VICKIE C BENNETT[1]

[1]Research School of Earth Sciences, Australian National Univ., Acton, ACT 0200, Australia (*correspondence: heejin.jeon@anu.edu.au)
[2]Department of Earth Sciences, Univ. of Wollongong, Wollongong, NSW 2522, Australia

The possible role of arc/back-arc accretionary processes in generating continental crust has recently been highlighted [1]. In this context, it has been argued that the Phanerozoic Tasmanides (~3000 x 6000 km) comprising the eastern third of the Australian continent formed during repeated opening and closing of sediment-filled back-arc basins triggered by alternating slab rollback and advances in a long-lived Cambrian to Triassic subduction system [2]. Kemp *et al*. [3] attempted to correlate additions of newly formed juvenile crust to the Tasmanide igneous rocks with the pattern of deformational/tectonic events during three orogenies (Delamerian, Lachlan, New England) using isotope signatures (whole rock Nd, zircon U/Pb, Hf and O). They proposed S-type granite emplacement in thickened crust followed by increasing juvenile contributions during back-arc rifting. The limited data set did not fully define the long-term Tasmanide isotopic trend, however, and few data represented the key Carboniferous event between the main crust forming episodes in the Lachlan (LFB) and New England (NEO) orogens.

New zircon U-Pb, Hf and O isotopic data from Carboniferous-Early Triassic granites in the LFB and NEO have been used to test the Kemp *et al*. [3] tectonic model. The I-type LFB Carboniferous granites show a trend from juvenile to more crustal (higher) $\delta^{18}O_{Zrn}$ with time, but a step from strongly to weakly positive εHf (t). Permian S-type granites of the NEO have very high, crustal $\delta^{18}O_{Zrn}$, but uniformally moderately positive εHf (t). Most analysed NEO I-type granites have moderate $\delta^{18}O_{Zrn}$, except for the oldest, in which the range of $\delta^{18}O_{Zrn}$ is similar to that in the LFB S-types. All have moderately to strongly positive εHf (t).

The zircon Hf and O isotopic compositions in the post-Devonian granites of the LFB and NEO are decoupled. Further, emplacement of the NEO S-type granites did not coincide with any recognised deformation episode. These features are not consistent with current models of arc/back-arc accretion.

Lead isotopic compositions for Pb-Zn deposits in the Eastern South Korea

Y.-J. JEONG[1], C.-S. CHEONG[1], H.-J. JO[1], J.Y. CHOI[1], D.-B. SHIN[2], M.-S. HAN[3] AND J.-J. HWANG[3]

[1]Korea Basic Science Institute, Daejeon 305-333, Korea (hero0123@kbsi.re.kr)
[2]Department of Geoenvironmental Sciences, Kongju National University, Kongju 314-701, Korea
[3]Division of Conservation Science, National Research Institute of Cultural Hertage, Daejeon 305-380, Korea

In this paper, the lead isotopic compositions of galena, collected from 15 lead-zinc deposits in the eastern part of South Korea were analyzed, mainly aiming at understanding the regional variation and the geochemical evolution of Pb isotopic composition of lead-zinc deposits in Korea.

For 9 lead-zinc deposits in the Ogcheon system and the Yeongnam massif, Pb isotopic compositions of galena are ranging 18.562-19.784 for $^{206}Pb/^{204}Pb$, 15.729-15.934 for $^{207}Pb/^{204}Pb$, and 38.849-39.859 for $^{208}Pb/^{204}Pb$.

In contrast, for galena samples collected from 6 lead-zinc deposits in Gyeongsang basin, the lead isotopic composition varies in a relatively small range; those isotopic compositions of $^{206}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ are in the range of 18.265-18.441, 15.581-15.726 and 38.332-38.993, respectively, which are slightly lower than those observed in the Gyeongsang basin.

Based on our observations, it seems that lead isotopic compositions in Korea can be classified according to the tectonic boundary between the Gyeongsang basin and the Yeongnam massif. Also, it appears that Pb for lead-zinc deposits in the Ogcheon system and the Yeongnam massif seems to have been originated from upper crustal materials of old continental, because they fit well onto the general trend of lead isotopic compositions of Precambrian basement rocks in South Korea.

Ni and Cr speciation in soils formed on ultramafic rocks from Barberton Greenstone Belt (South Africa)

I. JERZYKOWSKA* AND M. MICHALIK

Jagiellonian University, Institute of Geological Sciences, Oleandry 2a, 30-063 Kraków, Poland (*correspondence: irena.jerzykowska@uj.edu.pl)

Five soil samples were collected by Jolanta Mesjasz-Przybyłowicz (from the depth of about 10 cm) near the Agnes Mine in Mpumalanga Province, the Republic of South Africa. Soils are formed on amfibole-talc shists and serpentinites of Onverwacht Group in Barberton Greenstone Belt. Soils are characterised by mean Mg/Ca ratio 4, 27 and mean pH_{H2O} value 5, 43 [1].

Soil samples and the bedrock fragments were analyzed using optical microscope, SEM EDS and X-ray diffraction. Seven-step sequential extraction (exchangeable ions, carbonates, manganese oxides, amorphous iron oxides and hydroxides, crystalline iron oxides, organic matter and sulfurs, residual fraction) was executed on 4 soil samples. Chemical composition of soils and extracts was determined using IPC MS and ICP AES.

Soils are composed mainly of amfibole, talc, serpentine, chlorite, quartz and various clay minerals. According to EDS measurements of weathered rock fragments form soils, the most important Ni and Cr bearing phases are rarely occurring Mn-oxides, Fe-oxyhydroxides and commonly occurring various phyllosilicates. Mean and maximal values are listed in Table 1.

wt.%	Phyllosilicates		Fe-oxyhydroxides		Mn-oxides	
	NiO	Cr_2O_3	NiO	Cr_2O_3	NiO	Cr_2O_3
Mean	0,12	0,21	0,43	1,76	9,69	0,05
SD	0,58	1,11	1,25	2,7	4,28	0,15
Max.	12,53	3,85	6,81	16,74	17,74	0,42

Table 1: Mean and maximal concentrations of NiO and Cr_2O_3 (wt.%; EDS results) in weathered rock fragments

Sequential extraction experiment results agree with EDS studies. About 50% of Ni and Cr are bound to residual phases which are mainly silicates. Almost 50% of Cr is accumulated in crystalline Fe-oxides. Very important Ni containing phases are crystalline and amorphous Fe-oxides (respectively 27% and 8%) and to a lesser amount Mn-oxides (5%).

Today's rapid global warming of oceans together with eutrophication appears to promote a deoxygenation of some of the world's water bodies [1, 2], which eventually leads to hypoxia and even anoxia in regions of low oxygen supplies. With less than 60 μM oxygen most animals are negatively impacted and microorganisms dominate benthic energy fluxes [3]. As a result, it can be expected that in zones with oxygen dynamics around this tipping point benthic and microbial community structure will vary considerably in space and time, with repercussions on the flux of energy and matter trough the ecosystem. Here we present effects of varying hypoxic conditions on benthic microbial communities. Sediments from a series of transects across oxic to hypoxic conditions at the Crimean shelf of the Black Sea were analysed by community fingerprinting using ARISA (Automated Ribosomal Intergenic Spacer Analysis), in order to asses the connections between oxygen supply and benthic microbial community structure.

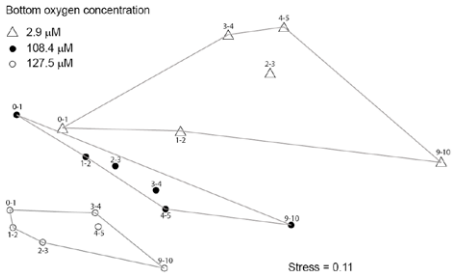

Figure 1: NMDS ordination plot (Bray-Curtis distance matrix) of ARISA profiles for the upper 10 cm layer sediment. Numbers represent each horizon sampled (cm).

Our data clearly exhibited a strong change in benthic bacterial community structure along a sampling transect including oxic, anoxic and highly dynamic hypoxic zones (Fig. 1), indicating an effect of temporal dynamics in oxygen supply at the microbial scale. This study is supported by the EU project HYPOX.

Sulfur, carbon and nitrogen isotopic variation in the drinking water source of Beijing

JI HONGBING[1,2,3]*, ZHU XIANFAN[2], LI HUIYIN[2], LU FENGYUN[2] AND XING XIN[2]

[1]School of Civil and Environmental Engineering, University of Science and Technology Beijing, Beijing 100083, China (*correspondence: hongbing.ji@yahoo.com)
[2]The Key Laboratory of Metropolitan Eco-Environmental Processes, College of Resource Enviroment and Tourism, Capital Normal University, Beijing 100048, China
[3]State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China

Samples of water, suspended particulate matter and sediments were collected in the drinking water source of northern Beijing and analyzed for sulphur, carbon and nitrogen isotopic compositions. The results showed that: (1) The ratios of sulphur isotope were between 4.9‰ and 10.7‰ in water samples; (2) The carbon and nitrogen isotopic ratios in suspended particulate matter were -29.34‰–-25.91‰ and -0.96‰–6.73‰ in summer, and -30.75‰–-25.75‰ and -0.83‰–9.67‰ in winter, respectively; (3) The sulphur, carbon and nitrogen isotopic ratios in surface sediments were -11.8‰–6.1‰, -27.25‰–-21.58‰ and 1.32 ‰–6.74‰, respectively. The differences of sulphur isotopic compositions in surface sediments from different sampling sites show the differences in the sources of sulphur. The suspended particulate organic matter was derived mainly from SOM-C_3 and macrophyte in summer, while it was derived from SOM-C_3 and plankton in winter. Surface sedimentary organic matters were mainly derived from SOM-C_3. Nitrogen isotopic ratios reflected the combined results of materials source and it can be used to trace some special biogeochemical processes. This study reveals that the source of organic matter has a close relationship with the situation of soil erosion in the areas.

This study was supported by the program of "One Hundred Talented People" of the CAS.

Research on chronology and formation mechanism of Xiaorequanzi Cu-Zn field in Tianshan Orogenic Belt, Western China

JI HONGWEI[1,2]*, SUN JINGBO[2], LI JIE[1,2], LI HUAQIN[1,3], CHEN FUWEN[3] AND CHEN WEN[2]

[1]China University of Geosciences, Beijing, 100083 China (*correspondence: jhw5566@163.com)
[2]Institute of Geology CAGS, Beijing, 100037 China
[3]Wuhan Center of Geological Survey, Wuhan, 430223 China

A large number of VHMS deposits have developed within Tianshan orogenic belt in western China, and Xiaorequanzi Cu-Zn field, consisting of several sulphide deposits, is more typical. There are three perspectives on the genesis of the deposit. First, according to the phenomena that intermediate-acid porphyry veins usually emerge near the ore body, the copper amount of porphyries is several times higher than the Clarke value of similar rocks, it is a porphyry copper deposit. Second, based on the features that the deposit occurs in the Xiaorequanzi volcanic rocks, ore body is layered and like-layered, it is a VHMS deposit. Third, on the basis of the traits that oxide ores in the surface and deep primary ores are more veins, it is volcanic hydrothermal-type deposit.

In order to identify the mineralization age and genesis of Xiaorequanzi Cu-Zn deposit, the metallogenetic and magmatic events in mining area were systematically researched by Rb-Sr isotopic geochronology. The whole-rock Rb-Sr isochron age of ore-bearing rocks, andesite, is 313Ma; the Rb-Sr isochron age of quartz fluid inclusion in copper-bearing quartz veinlets is 297Ma; the age of albite porphyry is 267Ma; the Rb-Sr isochron age of quartz fluid inclusion in stockwork copper ore, which formed in the period of magmatic hydrothermal, is 264 Ma. Isotopic dating results show that Xiaorequanzi Cu-Zn field belongs to the composite deposit, consisting of volcanic exhalation sedimentation and post-magmatic hydrothermal reworking. The mineralization should be divided into two phases: the main occurred in the late Carboniferous, 313~297Ma, which is consistent with the time of volcanic eruptions. Superimposed mineralization of the late magmatic hydrothermal occurs in the middle to late Permian, about 264Ma, which is roughly the same as the emplacement time of subvolcanic rocks in the region.

Mineralogic and climatic interpretations of the Late Miocene-Pliocene Red Clay Formation on the Chinese Loess Plateau

JUNFENG JI, TONG HE, LIANG ZHAO, YANG CHEN AND JUN CHEN

Institute of Surface Geochemistry, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China (jijunfeng@nju.edu.cn)

The closest past analog to the contemporary global warming is the Pliocene. Its climate reconstruction has been focused on continuous sedimentary records and terrestrial eolian deposits. The late Miocene-Pliocene Red Clay Formation on the Chinese Loess Plateau is among the best archives of the Pliocene paleoclimate change. In this study, we examined three classic Red Clay profiles at Lingtai, Duanjiapo and Bajiazui on the Chinese Loess Plateau with X-ray diffraction, Fourier transform infrared spectroscopy, diffuse reflectance spectrophotometer and scanning electron microscopy. Compared to the overlying Pleistocene loess-paleosol sequences, the Red Clay profiles show the following different mineralogical features: (1) carbonates are composed of both calcite and protodolomite; (2) the protodolomite are rhombic euhedral crystals growing in soil voids and coexisting with secondary calcite and palygorskite; (3) smectite is one of the dominate clay minerals; (4) the hematite/goethite (Hm/Gt) ratio varies from 0.30 to 0.52, and is much higher than that of Quaternary loess and paleosol. The occurrences of protodolomite and palygorskite as well as abundant hematite and smectite in the Red Clay sequence may indicate that it was formed under a prevailing warm and dry climate condition, which is probably a response of the inner Asia continent to the Pacific permanent El Niño and global high temperature climate in the late Miocene to Pliocene.

Thermodynamic study for CO_2 storage in deep saline aquifers

XIAOYAN JI[1]* AND CHEN ZHU[2]

[1]Division of Energy Engineering, Lulea University of Technology, 97187 Lulea, Sweden (*correspondence: xiaoyan.ji@ltu.se)

[2]Department of Geological Science, Indiana University, USA (chenzhu@indiana.edu)

Storage of CO_2 in deep saline aquifers is one proposed option to limit the continuing buildup of greenhouse gases in the atmosphere. To reduce the capture costs, co-injection of CO_2 and H_2S is proposed. To predict the sequestration capacity and the fate of injected gases as well as for other geochemical applications, it is necessary to study the thermodynamic properties and phase equilibria for the CO_2 sequestration-related systems at temperatures up to 200 °C and pressures up to 600 bar.

A new thermodynamic model, on the basis of statistical associating fluid theory equation of state, is developed to represent the phase equilibria and thermodynamic properties for CO_2-H_2O-NaCl, H_2S-H_2O-NaCl, and CO_2-H_2S-H_2O-NaCl systems. The parameters of pure components are obtained from the fitting of their saturated vapour pressure and liquid density data, and the cross parameters are obtained from the fitting of the phase equilibrium data of H_2S (CO_2)-H_2O-NaCl system.[1-4] With the available parameters, the phase equilibria and thermodynamic properties for CO_2-H_2S-H_2O-NaCl are predicted. The prediction shows that the solubility of the H_2S-CO_2 mixture increases with increasing pressure, decreasing concentration of NaCl and decreasing temperature. The mixture of H_2S-CO_2 is more soluble than pure H_2S under certain conditions and also more soluble than pure CO_2.

This thermodynamic model will be further implemented into a dynamic model to investigate the process of gas diffusion and dissolution in brine and the process of mineral dissolution and precipitation with dissolved CO_2 and H_2S. It is expected that the coupling of the dynamic model with the thermodynamic model will provide reliable long-term predictions pertaining to geochemical carbon sequestration, such as sequestration capacity, CO_2 leakage, the mechanics of CO_2 trapping, and environmental impacts, etc.

Detrital zircon provenance of late Ordovician-Silurian sandstones in the Lower Yangtze foreland basin of South China

DONG JIA, HAIBIN LI, LONG WU AND YIQUAN LI

Dept. of Earth Sciences, Nanjing University, Nanjing 210093, China (djia@nju.edu.cn)

The Lower Yangtze foreland basin is situated northwest of the early Paleozoic (ca.460–400Ma) Wuyi orogenic belt in South China [1]. In this basin, the upper Neoproterozoic-Ordovician strata are composed of shelf carbonates, slop limestones as well as mudstones [2]. Significant changes of lithofacies, and depositional environment took place during latest Ordovician–Silurian, which were coincident with the timing of the Wuyi orogeny. In order to demonstrate the basin development was in response to the orogenic event, seven sandstone samples were collected from upper Ordovician and Silurian strata. U–Pb ages of 604 detrital zircon grains yield remarkable peaks at ca. 2500Ma, 1200–900Ma, 860–740Ma and 458–425 Ma. The early Paleozoic zircons (458–425 Ma) correspond to the granitic rocks within the Wuyi orogenic belt to south or southeast, suggesting exhumation of syn-orogenic rocks. Besides, the Precambrian zircons (ca. 2500Ma, 1200–900Ma, 860–740 Ma) are most likely recycled from pre-orogenic strata in the Wuyi orogenic belt due to their similarity in age distribution [2]. The predominant Neoproterzoic (860–740Ma) zircons indicate the Yangtze basement had been involved in the orogenic belt. The youngest zircons at the top of the succession yield a maximum depositional age of ca. 425 Ma.

Aeolian deposition in the central north Pacific has been well recognized to originate from arid Asian interior. However, works on terrestrial organic tracers therein are rare. In this work, higher plant leaf wax n-alkanes from ODP Site 1208 in the northwest Pacific since the middle Miocene were analyzed to explore the source region vegetation and climate changes. Both average chain length of wax n-alkanes and their accumulation rates showed a general increasing trend, consistent with the well recognized climatic drying trend of the Asian interior. The record of isotopic fractionation factor between plant and atmospheric CO_2 ($\varepsilon_{plant-CO2}$), calculated from $\delta^{13}C$ values of n-alkane and atmospheric CO_2, showed a prominent decrease from 12.4 to 9.3 Ma, and displayed a general pattern of higher values prior ~8 Ma and lower values post ~8 Ma. Although all values of $\varepsilon_{plant-CO2}$ (−18.5 to −16.8‰) were well within the range of C_3 plants, adjustment of isotopic discrimination of C_3 plants was rule out as the main cause of the observed $\varepsilon_{plant-CO2}$ variations. Therefore, relative abundances of C_3 vs. C_4 plants were invoked to interpret the $\varepsilon_{plant-CO2}$ record, and higher C_4 contributions (13.8 ± 2.0%) were inferred due to slightly warmer climate in the source region prior to ~8 Ma. The suggested major C_4 decline from 12.4 to 9.3 Ma was concurrent with evidences supporting a prominent uplift of northern Tibetan plateau [1], demonstrating close relationships of Tibetan uplift, drying and cooling climates, and vegetation changes of the Asian interior.

Introduction

According the regional geological information, the sedimentation of southwestern margin of the Yangtze plate was of platform type, its sedimentation in the Xuanwei Group was series of marine to land transformation association [1]. The Upper Permian Emeishan basalt group underlying contact with Xuanwei Group, is continental flood basalt [2], as an eruption of the Emeishan large igneous province magmatism [3]. Sedimentary environment is very useful to understand activities in the Emeishan large igneous province and geological event of great significance to the changed environmental process.

Methods and Results

Trace elements and strontium isotopes are measured of samples from the Xuanwei Group, west Guizhou, and we also collected data from publications from the Emeishan Group and its adjacent regions [1-3]. Based on analyses of petrochemistry and strontium isotopes of carbonaceous shale and sandy shale rocks, geochemical characteristics indicate that sedimentary environments show hydrothermal activity, accomanyed with normal sedimentary participation. The fluctuations in Ce anomaly represent conversion process from oxidative environment and deoxidized environment. Strontium isotopic ratios $(^{87}Sr/^{86}Sr)_{t0}$ manifesting that materials of the Xuanwei Group may be derived from Emeishan basalts mixed with marine carbonate from chemical weathering. It conclude that sedimentary sources were not only by Emeishan basalt weathering, but also causes of hot water sedimentary display.

A 700-year record of accumulation rates at Dome A, Antarctica

S. JIANG[1], Y.S. LI[1], J.H. COLE-DAI[2] AND D.G. FERRIS[2]

[1]Polar Research Institute of China, Shanghai, China (jiangsu@pric.gov.cn)
[2]Department of Chemistry and Biochemistry, South Dakota State University, Brookings, South Dakota, USA

Dome A, located along the dividing line of East Antarctica, has the highest altitude in Antarctica. Preliminary evidence indicates that Dome A holds high potential for 'oldest ice' cores [1].

During the 21st Chinese Antarctic Research Expedition in 2004/2005 austral summer, a 109.91 m ice core (hereafter DA2005 ice core) was recovered at the site about 300 m away from the summit of Dome A. Chemical analysis of the DA2005 core has been used to construct continuous, detailed glaciochemical record. And time stratigraphic horizons from known volcanic eruptions were used for dating. Several clearly visible sulfate peaks in the top 35 m part of DA2005 were identified by comparison with common volcanic chronologies from Antarctica [2, 3]. These include the well-known volcanic events in the last millennium: Agung 1963, Krakatoa 1883, Tambora 1815 and an unknown eruption 1809, Unknown 1693, Kuwae 1453 and Unknown 1259. A mean accumulation rate was calculated according to the time stratigraphic horizons between two adjacent events and was assumued constant to date the intervening snow layers. Results show that the mean accumulation rates during different time periods are quite constant, ranging from 21.5 to 24.5 $mmH_2O{\cdot}yr^{-1}$. And the resulting dates for other volcanic events during the period of 1259-1963 A.D. are in good agreement with those in previous Antarctic ice core volcanic records. The mean accumulation rate between Agung and 1259 A.D. is 23.2 $mmH_2O{\cdot}yr^{-1}$, which is the same as the value between 1966 and 2004 A.D. measured from snow blocks collected at Dome A [4]. It seems that there is neither an indication of a change nor a trend in the accumulation rate apparent during the period of 1259-1963 A.D. which may indicate no drastic change in deposition has occurred at Dome A within this time period.

Analysis of microbial molecular ecology techniques in constructed rapid infiltration system

XIN JIANG[1,2] *, MING-CHAO MA[2], JUN LI[2] AND ANHUAI LU[1]

[1]School of Earth and Space Sciences, Peking University, Beijing 100871, China (*correspondence: jiangxinmail@yahoo.com.cn)
[2]Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agriculture Science, Beijing 100081, China

The microbial molecular ecology techniques, which were developed on the basis of molecular, were applied in studying the bacteria in Constructed Rapid Infiltration system (CRI). These techniques are very efficient in better describing the bacterial diversity, microbial community distribution and the relations between microbial group structure and nitrogen contamination through the analysis of microbial nucleic acid sequence fragment in CRI. The results further revealed the removal mechanism of contamination, which are essentially for the improvement of wastewater treatment in CRI.

In this study, a series of microbial molecular ecology techniques were applied in studying the bacteria in CRI. The microbial community distribution of bacteria was analyzed by PCR-DGGE qualitatively and a bacterial 16S rDNA gene clone library was constructed to analyze the bacterial diversity quantitatively. The anaerobic ammonium oxidation bacteria were proved to exist in CRI by phylogenetic analysis with a DNA sequence similarity of 97 %. The relations between microbial groups' structure and nitrogen contamination, and the removal mechanism of contamination were revealed.

Granularity and geochemistry of olivine in Jinchuan Ni-Cu-PGE magmatic sulfide deposit

JIAO J G[1,2], LIU M W[2], DUAN J[1] AND JU H[1]

[1]Chang'an University, Xi'an 710054, China (*correspondence: (jiangang@chd.edu.cn)

[2]Key Laboratory of Western China's Mineral Resources and Geological Engineering, Ministry of Education of P.R.C, Xi'an 710054, China

The Jinchuan Ni-Cu-PGE deposit is the third largest magmatic Ni deposit in the world, hosted by a small ultramafic intrusion in the Longshoushan terrane located in the south-western part of the North China Craton.

Granularity of olivine in the Jinchuan complex is from 1-8mm in diameter.Those olivine with 6-8mm distributes in ore-body 24, only contains disseminate sulfide; the olivine with 3-6mm still mainly lies in ore-body 24 contain partial net-texture sulfide; the olivine with 1-3mm in diameter distributes all mine, including most net-texture ore and no-sulfide rocks.

Our datum prove forsterite contents (mol. % Fo) of olivine in the Jinchuan rocks are in the range of 83.9-85.5% in pyroxene-bearing peridotite (no sulfide, olivine 1-2mm in diameter, at the surface of ore-body 2), 82-83.5% in dunite and lherzolite (mostly net-texture sulfide, olivine 1-3mm or 6-8mm in diameter, in ore-body 1, 24), and 78-81% in olivine pyroxenite (partial net-texture sulfide or no sulfide with tremolite, olivine 1-2mm in diameter, in ore-body 1, 2) (Fig.1). Little variation within one sample is observed for olivine.

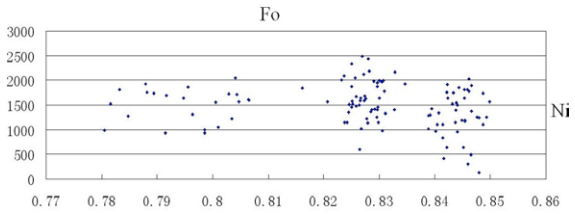

Figure 1: Compositional variations of different types of olivine from the Jinchuan rocks

So Granularity and forsterite contents of olivine have no accordant variation; Most net-texture sulfide ore holds forsterite contents from 82-83.5%, indacating the main ore-forming condition; 83.9-85% in pyroxene-bearing peridotite with no sulfide and stabilized Ni contents in olivine means olivine has partially crystalized before sulfur saturation as the decrease of temperature.Three type of forsterite contents means three types of rock-forming conditions, maybe three middle magma chambers.

An Atomic Force Microscope study of the microstructure of 'barkinite' liptobiolith

KUN JIAO[1], SUPING YAO[1]* AND KE ZHANG[1]

[1]State Key Laboratory for Mineral Deposits Research (Nanjing University), School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China (*correspondence: spyao@nju.edu.cn)

Using Atomic Force Microscope (AFM) to observe the surface of 'barkinite' and vitrinite in nanoscale, reveal the surface microstructures of 'barkinite' and vitrinite, that is, the netlike structure of vitrinite macromolecular clusters and the fiberlike, granular, and netlike structure of 'barkinite' macromolecular clusters. With increasing maturity, the structure of 'barkinite' macromolecular clusters are fiberlike - granular - irregular netlike - netlike in sequence (Fig.1), while the structure of vitrinite macromolecular clusters change from loose, irregular network to highly orient arranged, regular network. Quantitative analysis of the structure of macromolecular cluster and arrangement in maceral by using cross - section analysis tool of Atomic Force Microscope provide a new approach to study the structure evolution of maceral molecule and hydrocarbon generation mechanism.

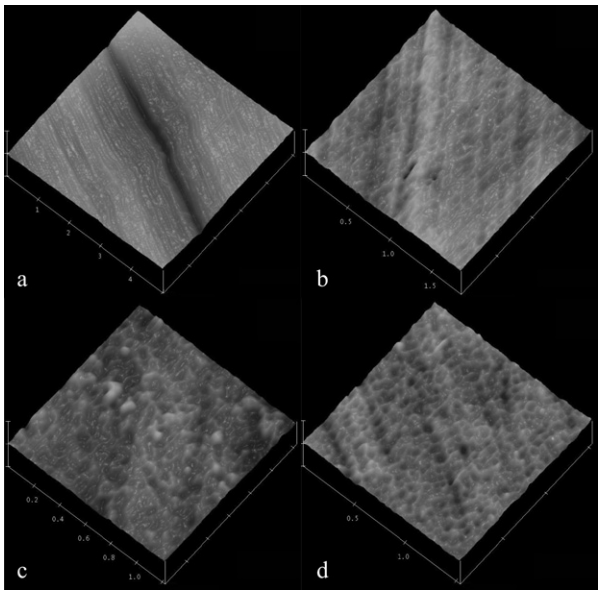

Figure 1: Microstructure evolution model of "barkinite" (a-gas coal, b-gas-fat coal, c-fat coking coal, d-anthracite)

Enhanced phosphorus regeneration in low oxygen marine settings: insights from modern and ancient sediments and implications for the future ocean

TOM JILBERT[1], CAROLINE P. SLOMP[1], PETER KRAAL[2], ANNE K. STEENBERGH[3] AND VIRGINIA PALASTANGA[1]

[1]Department of Earth Sciences (Geochemistry), Faculty of Geosciences, Utrecht University, P.O. Box 80.021, 3508 TA Utrecht, The Netherlands

[3]Netherlands Institute of Ecology, Droevendaalsesteeg 10, 6708 PB Wageningen, The Netherlands

Phosphorus (P) is a key nutrient for marine productivity and its availability plays a crucial role in the development of oxygen deficiency in marine systems. Most importantly, enhanced release of phosphate from seafloor sediments under low-oxygen conditions can drive a positive feedback loop between increased productivity, oxygen depletion and marine P availability. This feedback loop helps to sustain low oxygen conditions in restricted basins such as the Baltic Sea and may have contributed to the development of large-scale oceanic anoxia and massive burial of organic matter in the Earth's past. Here, we first summarize the field evidence for enhanced regeneration of P relative to organic carbon (C) from modern and ancient sediments. We then briefly review the responsible mechanisms, including enhanced regeneration of P from organic matter under low oxygen [1], and limited retention of P in inorganic minerals. We also present the results of an experimental investigation into the bacterial controls on P regeneration. Finally, we discuss the role that enhanced regeneration of P from sediments can play at the regional and global scale. We show that enhanced regeneration of P can account for the underestimation of phosphate concentrations in existing nutrient budgets of the Baltic Sea. Using biogeochemical ocean modeling, we show that oxygen depletion in the global ocean is also highly sensitive to the rate of enhanced regeneration of P. These results underline the need for improved quantitative and mechanistic understanding of the P cycle to better understand past changes in ocean oxygenation, and to predict those which may occur in the future.

Ripening processes during crystallization of natrojarosite

AMALIA JIMÉNEZ*, ANA HERNÁNDEZ, ÁNGELES FERNÁNDEZ-GONZÁLEZ AND MANUEL PRIETO

Facultad de Geología, C/ Jesús Arias de Velasco s/n, 33005, Oviedo, Spain. (*correspondence: amjimenez@uniovi.es)

The crystallization behavior of jarosite type compounds $MFe_3(SO_4)_2(OH)_6$ (M = Na^+, H_3O^+, K^+, Ag^+, NH_4^+) has received increasing attention due to the formation of these minerals in acid mine water drainage environments during the oxidation of sulphide minerals. The fact that jarosites were identified on Mars gives these minerals an additional interest as indicators of water-limited chemical weathering on that planet. Although different jarosite-type compounds have been synthetised by precipitation at temperatures close to 100°C [1], the genesis of these minerals in environmental conditions needs to be studied in depth. In this work, natrojarosite was synthesized by mixing 60 ml of $Fe_3(SO_4)_2$ (1N) and 40 ml of NaOH (1N) parent solution at 25 ± 0.1°C. Similar experiences were performed using 0.5N concentrations for both parent solutions (50:50 ratio). The experiments were carried out for specific reaction periods (1 day to 7 weeks) by keeping the solutions at constant agitation. The aging process of natrojarosite was followed by monitiring the precipitate crystallinity (X-ray diffraction), the aqueous solution composition (ICP-AES), and the pH.

Using 1N parent solutions, a low-crystallinity precipitate was obtained in the early stages of the experiments. However, as the reaction time passes by, the main XRD reflections (012, 021 and 113) of natrojarosite become more apparent and undergo a progressive decrease of widthness (FWHM) and an increase of intensity which indicate an increasing degree of crystallinity. In contrast, using 0.5N parent solutions the precipitate remained amorphous during the whole aging process. The pH values varied between 2.6 and 2.2, in all experiments. The aqueous solution exhibited a slight increase of both Fe and Na concentrations that is consistent with the development of the crystalline phase. Aqueous solution modellization (phreeqc code) evidenced higher saturation indices for hematite than for natrojarosite, which indicates that the formation of natrojarosite was governed by kinetic factors.

Comparison of different evaluation schemes and optimization of instrumental parameters for chlorine isotope analysis of organic compounds using GC-qMS

B. JIN, C. LASKOV, M. ROLLE AND S.B. HADERLEIN

Center for Applied Geosciences, University of Tübingen, Sigwartstrasse 10, D-72076 Tübingen, Germany (biao.jin@uni-tuebingen.de)

Compound specific chlorine isotope analysis is a valuable tool to detect and quantify biodegradation processes and abiotic transformation of chlorinated organic compounds in the subsurface. The new GC-qMS method avoids tedious off-line sample pretreatments and offers a quick and sensitive method for on-line determination of chlorine isotope ratios. In this study, the GC-qMS method for chlorine CSIA of chlorinated hydrocarbons was evaluated and validated. We compared the existing evaluation schemes to determine chlorine isotope ratios with newly proposed and/or modified ones. Besides, we tested the important instrumental settings such as split ratio, ionization energy and dwell times. Chlorinated ethenes were selected as model organic contaminants. Headspace sample of tetrachloroethene (PCE), trichloroethene (TCE) and cis-dichloroethene (cisDCE) at aqueous concentrations in the range of 20-500 μg/L were analyzed using GC-qMS. The results showed good precisions (relative standard deviation: 0.4‰ - 2.1‰, n=5). We also found that the precison of the GC-qMS method depends on the applied evaluation schemes, instrumental parameters and target compounds. A systematic test and evaluation of these important factors enabled us to optimize the GC-qMS technique to determine the chlorine isotope ratios of chlorinated organic contaminants.

In situ Pb and U isotope analysis of single ostracod shells from Nam Co, Tibet

K.P. JOCHUM[1]*, D. SCHOLZ[2,1], P. FRENZEL[3], G. GLEIXNER[4], F. GUENTHER[4], A. SCHWALB[5], B. STOLL[1], U. WEIS[1] AND M.O. ANDREAE[1]

[1]Max-Planck-Institut für Chemie, Postfach 3060, 55020 Mainz, Germany (*correspondence: k.jochum@mpic.de)
[2]Universität Mainz, 55128 Mainz (Germany)
[3]Universität Jena, Burgweg 11, 07749 Jena (Germany)
[4]MPI für Biogeochemie, 07701 Jena (Germany)
[5]Techn. Universität, 38106 Braunschweig (Germany)

We have developed a new LA-ICP-MS technique for combined *in situ* trace element, Pb and U isotope analysis of single ostracod shells. High spatial resolution is achieved by using spot sizes of 12 - 100 μm. We analyzed very small (ca. 0.5 mm) and thin (about 0.05 mm) shells from eight levels of a Holocene lake sediment core from Nam Co, Central Tibetan Plateau, deposited within the last 7700 a BP [1]. *In situ* measurements of ($^{234}U/^{238}U$), $^{208}Pb/^{206}Pb$ and $^{207}Pb/^{206}Pb$ yielded a precision (RSD) of about 2 % for U = 10 – 20 μg g^{-1} and 0.2 % for Pb = 10 – 40 μg g^{-1}.

Our results show identical ratios for ostracods from the same core depth indicating that they reflect the composition of the lake water. ($^{234}U/^{238}U$) and $^{208}Pb/^{206}Pb$ show significant variability with age: Ostracods from the upper core section show uniform isotope ratios (1.42 ± 0.01 and 2.134 ± 0.003, respectively). The older samples show lower and more variable isotope ratios. These findings are in agreement with investigations of the sediments [1] and suggest that the isotope ratios of the ostracod shells reflect past climate variability: reduced precipitation and runoff, low lake level and maximum salinity since ca. 800 a BP, more humid conditions and a positive precipitation/evaporation balance between 5400 and 7200 a BP [1]. The lowest ratios (($^{234}U/^{238}U$) = 1.13, $^{208}Pb/^{206}Pb$ = 2.112) are observed in a 6000 a old ostracod shell, where a high intensity of monsoonal precipitation, associated with elevated lake levels in Tibet, is recorded [1].

On the duration and rates of fluid release from a dehydrating slab

T. JOHN[1], Y. PODLADCHIKOV[2], N. GUSSONE[1], G. BEBOUT[3], R. HALAMA[4], T. MAGNA[1] AND R. KLEMD[5]

[1]Institut für Mineralogie, Universität Münster, Germany (timm.john@uni-muenster.de)
[2]Institut de Géophysique, University of Lausanne, Switzerland
[3]Lehigh University, Bethlehem, PA 18015, USA
[4]Institut für Geowissenschaften und SFB 574, Universität Kiel, Germany
[5]GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Germany

At subduction zones, seawater-altered oceanic lithosphere recycles back into the mantle, heats up during descent and releases fluids by devolatilization of hydrous minerals. Large-scale fluid flow resulting from this dehydration is implicit in recent models for the formation of arc magmas and appears to be linked to intraslab seismicity and non-volcanic tremors. However, the mechanisms as well as spatial and temporal scales of this fluid flow are only poorly known.

Exposures of veins (mineralized fractures) in oceanic lithosphere, metamorphosed at high pressures in subduction zones, provide direct evidence for fluid mobility within subducting slabs. We quantify the duration of dehydration-related fluid flow through subducting oceanic plates by investigating a high-pressure vein and its reaction selvage. Using a novel approach employing an array of radiogenic (Sr) and stable (Li, Ca) isotope data combiend with Li-diffusion and reaction kinetic modelling, we demonstrate that large amounts of fluid can be transported along major conduits over km distances in a pulse-like manner through slabs over surprisingly short time periods of ~170 to as little as ~6 years.

This indicates that even though the overall slab dehydration is a continuous process, dehydrating slabs release their fluid by short-lived, channelized fluid-flow events, involving aseismic mobile hydraulic fractures that rapidly traverse the subducting slabs. Furthermore, the time for mineral reactions to reestablish thermodynamic equilibrium in rocks along the flow pathways is estimated to be at least three times shorter than that of the overall fluid-rock interaction. This indicates that local thermodynamic equilibrium is indeed a valid assumption for understanding fluid-mediated processes at high fluid-rock ratios and sluggish reaction kinetics are negligible.

Sedimentary basin acid sulfate weathering: Its recognition and palaeo-environmental implications in the Eucla Basin, South Australia

ASHLYN JOHNSON[1]*, S.M. HILL[1], D. CHITTLEBOROUGH[2] AND D. MITCHELL[3]

[1]Deep Exploration Technologies Cooperative Research Centre. School of Earth and Environmental Sciences. University of Adelaide. SA 5005 (*correspondence: ashlyn.johnson@adelaide.edu.au)
[2]School of Earth and Environmental Sciences. University of Adelaide. SA 5005
[3]Iluka Resources Limited, 11 Dequetteville Tce, Kent Town, Adelaide, SA 5067

'Acid Sulfate weathering' broadly describes soil and regolith materials that typically had an abundance of iron sulfides that have oxidised to sulphates. This redox process as well as other processes such as ferrolysis and microbiological functions are important producers of protons and therefore acidity within the regolith. Although previous studies have tended to focus on the soil management and sediment diagenesis and weathering geochemical implications, this study considers the significance of these processes from a sedimentary basin geochemical perspective. As such, further insights into basin-hinterland palaeo-environments and controls and the stratigraphic implications for the resulting regolith materials are gained. The study basin is the Eucla Basin, which is one of the world's largest on-shore Cainozoic basins, extending across Australia's central southern continental margin.

One of the major controls on palaeo- and contemporary acid-sulphate weathering within the Eucla Basin is the setting of regional groundwater systems within the Eocene marginal marine sediments in the basin. In geochemically reduced settings, typically below the watertable, the sediments contain an abundance of pyrite, whereas where these sediments have been oxidised, typically above the watertable, the pyrite has been oxidised and sulphates (which are now widely expressed as alunite found under many playa lake beds) and iron oxides (especially hematite but also goethite) are prevalent. These processes also have a profound influence on the mobility and reorganisation of Al and Si, largely derived from clay minerals such as smectite and kaolinite. This has resulted in the formation of authigenic clays (e.g. halloysite) and phreatic silicification (ie. groundwater silcretes) hosting abundant termite bioturbation preserved in the basin's geological record. Palaeo-watertables that may be linked to eustatic, climatic and tectonic variations are now being interpreted across large parts of this basin.

Redox transformations of iron in extremely low pH environments: Environmental and industrial implications

D. BARRIE JOHNSON[1]*, SABRINA HEDRICH[2] AND TADAYOSHI KANAO[3]

[1]Bangor University, Bangor, LL572UW, UK (*correspondence: d.b.johnson@bangor.ac.uk)
[2]2Bangor University, Bangor, LL572UW, UK (s.hedrich@bangor.ac.uk)
[3]Okayama University, Okayama, 700-8530, Japan (tkanao@cc.okayama-u.ac.jp)

Iron is a particularly important microbial resource in extremely acidic (pH <3) environments, where it serves not only as a micronutrient, but also as a major electron donor and/or acceptor. This is due primarily to the much greater stability of ferrous iron (even in oxygen-saturated liquors) and solubility of ferric iron in extremely acidic compared to neutral pH waters. Many different species of acidophilic prokaryotes are known to either catalyze the dissimilatory oxidation of ferrous iron or the dissimilatory reduction of ferric iron, while some can do both, depending on the prevailing environmental conditions.

Measurements of specific rates of iron oxidation by acidophilic bacteria have revealed significant differences between species. In general, specialized chemolithotrophs, such as *Leptospirillum* spp., exhibit significantly faster rates than more generalist mixotrophic and heterotrophic species, such as *Sulfobacillus* spp. and *Ferrimicrobium acidiphilum*. Measurement of specific rates of dissimilatory reduction of soluble ferric iron by *Acidiphilium cryptum* str. SJH have shown that these are often much greater than values recorded for neutrophiles. Rates of reductive dissolution of ferric minerals by acidophilic bacteria appear to depend on the relative acid-solubilities of the former. Acidophilic iron-reducing bacteria appear to use the often small amounts of ferric iron in solution, thereby causing the equilibrium between mineral-phase and solution-phase iron to move in the direction of the latter. Reductive dissolution (and concommitant release of associated metals and metalloids) of a wide range of ferric iron minerals, including jarosites, schwertmannite and goethite, has been demonstrated *in vitro*.

Recent developments that harness redox transformations of iron for industrial applications include remedation of mine waters using the recently characterised species *Ferrovum myxofaciens*, and the extraction of nickel from oxidized ores by causing the reductive dissolution of goethite. The latter represents a major development in 'biomining'.

Oxygen isotope exchange between H_2O and super critical CO_2: Lab experiments and field evidence

G. JOHNSON, B. MAYER*, M. NIGHTINGALE AND M. SHEVALIER

Applied Geochemistry Group, Department of Geoscience, University of Calgary, 2500 University Drive N.W., Calgary, Alberta, Canada T2N 1N4 (*correspondence: bmayer@ucalgary.ca)

Traditionally, the application of stable isotopes in Carbon Capture and Storage (CCS) projects has focused on $\delta^{13}C$ values of CO_2 to trace the migration of injected CO_2 in the subsurface. More recently the use of $\delta^{18}O$ values of both CO_2 and reservoir fluids has been proposed as a method for quantifying *in situ* CO_2 reservoir saturations due to oxygen isotope exchange between CO_2 and H_2O and subsequent changes in $\delta^{18}O_{H2O}$ values in the presence of high concentrations of CO_2. To verify that oxygen isotope exchange between CO_2 and H_2O reaches equilibrium within days, and that $\delta^{18}O_{H2O}$ values indeed change predictably due to the presence of CO_2, a laboratory study was conducted to measure the isotope composition of H_2O, CO_2, and dissolved inorganic carbon (DIC) at representative reservoir conditions (50°C and 19 MPa) and varying CO_2 pressures. Results obtained showed that $\delta^{18}O$ values of CO_2 were on average 36.4 ± 2.2 ‰ (1σ, n = 15) higher than those of water at all pressures up to and including reservoir pressure (19 MPa), in excellent agreement with the theoretically predicted isotope enrichment factor of 35.5 ‰ for the experimental temperature of 50°C. Since the fraction of oxygen sourced from CO_2 is related to the total volumetric saturations of CO_2 and water as a fraction of the total volume of the system, we conclude that changes in $\delta^{18}O$ values of reservoir fluids can be used to calculate reservoir saturations of CO_2 in CCS settings given that the $\delta^{18}O$ values of CO_2 and water are sufficiently distinct. This was confirmed by field data obtained from eight observation wells at the Pembina Cardium CO_2 Monitoring Pilot in Alberta (Canada). Arrival of injected CO_2 caused changes in the $\delta^{18}O$ values of reservoir fluids of up to 4 ‰, as well as increasing DIC, Ca and Fe concentrations in the reservoir fluids.

Updated dust-iron dissolution mechanism: Effects of organic acids, photolysis, and dust mineralogy

M.S. JOHNSON AND N. MESKHIDZE

Deptartment of Marine, Earth, and Atmsospheric Sciences, North Carolina State University, Raleigh, North Carolina, USA (msjohns2@ncsu.edu, nmeskhisze@ncsu.edu)

Aeolian dust deposition to remote oceanic regions is a major atmospheric supply pathway of essential nutrients (e.g. iron (Fe) and phosoporus (P)) which have a controlling effect on marine primary productivity. The soluble/bioavailable fractions of Fe and P in mineral dust are minor at the source regions and increase during the transport. Nutrient mobilization from mineral dust is a complex process; in the atmosphere it is thought to be controlled by dust mineralogy, atmospheric chemical composition, and meteorological variables. Therefore, quantitative predictions for the formation of these important nutrients should be included in global-scale coupled biogeochemical cycle models for improved prediction of future climate.

Here, the global 3-D chemistry transport model GEOS-Chem with a state-of-the-art Fe- and P-dissolution scheme is used to generate comprehensive global datasets for nutrient concentrations and deposition (Fig. 1). The model improvements include source-specific dust-mineralogy, organic ligand-promoted Fe dissolution, the photolytic redox cycling of Fe (II)/Fe (III), and acid-based P dissolution. Preliminary results indicate that Fe bound in clay minerals and the presence of oxalate significantly increases soluble Fe production in mineral dust. Photolysis can further increase the amount of soluble Fe by converting Fe (III)-species into the more bioavaliable ferrous Fe (Fe (II)) form. Model predicted diurnal variations in Fe (II)/Fe (III) are consistent with available data.

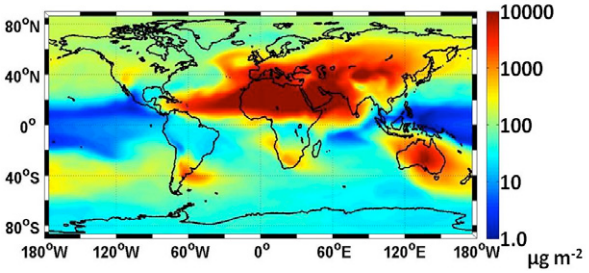

Figure 1: Model-predicted total column burden of soluble Fe (μg m^{-2}) between June-August 2009.

Adsorption of organic ligands on silicate mineral surfaces in the presence of CO_2 and water: Insight into olivine dissolution rates

The dissolution of magnesium silicates releases magnesium cations (Mg^{2+}) into solution, which in the presence of dissolved carbon dioxide (CO_2) can, under certain conditions, precipitate as magnesium carbonates. This process results in the mineralization of CO_2, a safe, long-term storage strategy to control rising CO_2 concentrations in the atmosphere. However, the kinetics for these processes are slow and the mechanisms are not fully understood. Previous work by this group and others has found the dissolution rates of silicates to be enhanced by the presence of organic acids in some cases, but reduced in other cases. This study seeks to understand the factors that determine whether an organic compound acts as an activator or an inhibitor. Organic ligands may adsorb to silicate surfaces as outer-sphere complexes, likely passivating active sites and reducing dissolution rates, or as inner-sphere complexes, drawing electron density away from the mineral surface, weakening near-surface bonds, and increasing dissolution rates. The nature of the adsorbed complexes depends on mineral surface charge and ligand charge, both of which are controlled by pH. X-ray photoelectron spectroscopy has been used to examine the organic carbon adsorbed on olivine and quartz surfaces after reaction with organic acids, water, and CO_2. Initial results show additional carbon on the surfaces exposed to the organic-containing aqueous phase but none on surfaces exposed only to the supercritical CO_2-H_2O phase. Mineral surfaces exposed to both the CO_2 and H_2O phases also showed increased superficial carbon.

Calibrating S isotope fractionation in sulfate reducing bacteria

DAVID T. JOHNSTON[1]*, ALEXANDER S. BRADLEY[2]*, RENATA CUMMINS[1], WILLIAM D. LEAVITT[1] AND PETER R. GIRGUIS[2]

[1]Department of Earth and Planetary Sciences, Harvard University, Cambridge MA 02138 USA (*correspondence: johnston@eps.harvard.edu)
[2]Department of Organismic and Evolutionary Biology, Harvard University, Cambridge MA 02138 USA (bradley@fas.harvard.edu)

The sulfur isotopic composition of sedimentary sulfate and sulfide minerals throughout Earth history is a reflection of the activity of dissimilatory sulfate-reducing bacteria (SRB). The magnitude of the fractionation between sulfur compounds is intrepreted as a biochemical consequence of changing environmental conditions. However, quantitatively understanding the isotopic variability within the geological record requires calibrating the physiological controls on dissimilatory sulfate reduction (e.g. sulfate concentrations, relevant electron donor, etc.). We have interrogated these controls with three complementary approaches.

First, through the incorporation of recent biochemical and crystal structure data, we have rexamined the reaction network involved in dissimilatory sulfate reduction. Our revised network adequately describes previous observations, and is experimentally testable.

Second, we measured the production of intermediates in pure cultures of *D. desulfuricans* grown on sulfate/sulfite and lactate/formate. In these experiments we observe the systematic production and consumption of sulfite and thiosulfate. We have tracked the isotopic consequences of each experiment, including the measurement of the site-specific isotopic composition of thiosulfate. These data reinforce our model predictions and provide valuable constraints on the fractionations associated with thiosulfate production and consumption.

Third, we performed community scale experiments in quasi-chemostat microbial reactors to better quantify changes in fractionation in response to sulfate concentrations. Whereas the pure culture work investigates the internal cycling, the reactor work assesses the first-order controls on sulfate uptake.

Through this broad combination of experimental and conceptual approaches, we provide unprecidented insight in the operation of the sulfate reduction pathway: information that can be used to better calibrate and inform our interpretation of sulfur isotopes in the sedimentary record.

Constraining magma-carbonate interaction at Vesuvius, Italy: Insights from stable isotopes and experimental petrology

[5]Dip. Sci. Fis., Università 'Federico II', Napoli, Italy

At Vesuvius volcano, Italy, abundant high temperature calc-silicate (skarn) xenoliths have been found in many eruptive deposits and, provide evidence for intense interaction between magma and carbonate crust. In order to understand magma-carbonate interaction and to quantify carbonate assimilation processes, we present a combined stable isotope study of natural samples and piston cylinder de-carbonation experiments.

The sample study shows that $\delta^{18}O$ and $\delta^{13}C$ isotope values of igneous-, skarn- and carbonate rocks indicate that significant crustal contamination of Vesuvius magmas has taken place. Calc-silicate xenoliths define variable degrees of decarbonation and interaction processes between magma and crust, producing progressively more lava-like values [1].

In the experiments, we simulated the processes of carbonate assimilation under magmatic pressure and temperature conditions (0.5GPa and 1200°C) with Vesuvius magma composition and local crust as starting material. We have constructed a high-resolution time-sequence of magma-carbonate interaction in our experimental products with short but increasing dwell run-times (t_d), of 0, 60, 90 and 300 sec [2]. We observe a progressive carbonation of the host melt, and rapid liberation of large quantities of CO_2 coming from the breakdown of the enclosed carbonate. Variable degrees of carbonate assimilation and chemical mixing between carbonate and silicate melts are observed, with diffusion processes playing an important role at melt interfaces.

The combination of petrological evidences and experimental products allows insights into the processes and time-scales of magma-crust interaction and reinforces the hypotheses that carbonate assimilation is an ongoing and significant magmatic process at Mt. Vesuvius.

Causes and timing of tropical glacier fluctuations during the Holocene are poorly understood. We present a chronology for the past 11, 000 years of the Bolivian Telata glacier. We show that Telata glacier retreated irregularly. A rapid and strong melting from the maximum extent, at 10.8 ka ± 0.9, to 8.5 ka ± 0.4 ^{10}Be years was followed by a slower retreat until the Little Ice Age (LIA) while a dramatic acceleration occurred over the 20th century. A glacier-climate model and additional climate constraints indicate that annual temperatures for this region were -3.3±0.8 °C cooler at 11 ka BP and were -2.1±0.8 °C below the present value until the end of the LIA. We suggest that low-frequency warming of the eastern tropical Pacific and increased atmospheric temperature in response to enhanced austral summer insolation were the main drivers for the long-term Holocene retreat of the glacier. Future temperature projections estimate a 4°-5°C warming in the tropical Andes by 2100, a warming close to our estimate for the whole Holocene.

Mineral composition of the metallurgical slag after steel production

I. JONCZY

Silesian University of Technology, Faculty of Mining and Geology, Institute of Applied Geology, 44-100, Gliwice, Poland (iwona.jonczy@polsl.pl)

Introduction

Metallurgical slags are increasingly often used as material in production of aggregates, but there are also attempts made to recover metals from them. That is why it is important to carry out research on their mineral and chemical composition, which may deliver much valuable information during an economic exploitation of slags, e.g. connected with new phases forming in a metallurgical furnace, forms of metal occurrence in slag components and possibilities of their release from slag components and migration to the environment [1, 2].

Research results

The conducted mineralogical research of slags after steel production proves that among their phase components, apart from metal concentrations (including up to 98% Fe) and glaze, oxide and silicate phases are especially interesting because of their heterogeneous chemical composition.

Oxide phases are represented by iron oxides (magnetite, hematite, wustite), chromite, ilmenite and phases with compound chemical composition. We can recognize among them oxides Ca-Mg or Ca-Ti with elements of: Cr, Mn, Fe, Zn. A common component is also a solid solution od compounds: FeO, MgO, MnO occuring in variable quantity relations, with admixtures: V, Zn, Cr, Ti and Ca.

Among silicate phases there are distinguished, among others, pyroxenes from a series of augite, monticellites, wollastonite, dicalcium silicates (larnite). Their chemical composition is considerably diversified, and often differs from the chemical composition of the same phases forming in natural conditions. Silicate phases are also carriers of heavy metals, which may be included in their internal structures or form micro-inclusions. For instance, a considerable group consists of calcium silicates with admixtures of Ti, Cr, Mn, V, Mg and P, as well as calcium silicates and aluminosilicates Ca-Fe.

The scientific work is financed as a research project from the means allocated for science in the years 2010-2011.

A Precambrian manganous sea?

C. JONES*, S.A. CROWE AND D.E. CANFIELD

NordCEE, Institute of Biology, Syddansk Universitet (*correspondence: carriayne@biology.sdu.dk)

Differences in the biogeochemical behavior of Fe and Mn can lead to their physical separation and a variation in the Fe:Mn ratio in sedimentary rocks. The mechanisms controlling the Fe:Mn ratios of Precambrian sedimentary rocks remain understudied. Using previously published data from the Mt. McRae shale deposit [1, 2] and the biogeochemical characteristics of Fe and Mn, we evaluate the potential controls on Fe and Mn co-deposition in this succession. We suggest that before the 'whiff' of oxygen, as recorded in the Mt. McRae shale, Fe and Mn were deposited together as carbonate minerals at a ratio reflecting their supply from hydrothermal fluids. During the 'whiff', iron likely precipitated and was sequestered in the sediments as sulfide minerals. This sulfide resulted from a global increase in the flux of sulfate to the oceans due to increased oxidative weathering on the continents [2]. We propose that this led to a global enhancement of Fe removal as Fe sulfides, preferentially enriching seawater in dissolved manganese relative to iron. In the Mt. McRae shale, we find evidence for this in the sediments deposited after the 'whiff', which exhibit a Mn enrichment relative to Fe with respect to both a hydrothermal source and continental weathering. These observations support the hypothesis of a transitional manganous ocean that punctuates intervals of ferruginous and euxinic ocean redox states [3]. We propose that enrichments of Mn relative to Fe in marine sediments deposited under anoxic conditions are a sensitive proxy for increased oxidative weathering.

Ecological niches of Fe-oxidizing acidophiles in a coal mine discharge

D. JONES[1]*, J. BROWN[2], L. LARSON[2], D. MILLS[1], W. BURGOS[2] AND J. MACALADY[1]

[1]Dept. of Geosciences, Penn State Univ., University Park, PA 16802, USA (*correspondence: djones@psu.edu, dbm5029@psu.edu, jlm80@psu.edu)

[2]Dept. Civil Environ. Eng., Penn State Univ., University Park, PA 16802, USA (jfb213@psu.edu, lnl5053@psu.edu, wdb3@psu.edu)

Low pH iron oxidation is a promising strategy for cost effective bioremediation of acidic mine drainage (AMD). To effectively utilize the iron-oxidizing potential of naturally-occurring microbiota in AMD discharges, knowledge of the diversity, iron-oxidizing efficiency, and natural distribution of acidophilic communities is required. Here we used full-cycle rRNA analyses to describe the composition of sediment communities at Red Eyes, an AMD site in Somerset County, PA, USA. Near anoxic emergences, the dominant microbial communities are green benthic *Euglena* biofilms and associated populations of *Gamma-* and *Betaproteobacteria*. As pH and Fe^{2+} concentrations decrease downstream, the dominant iron oxidizers shift first to (i) a close relative of *Gallionella spp*., followed by (ii) *Ferrovum spp*., and finally to (iii) *Acidithiobacillus ferrooxidans*. Archaea and *Leptospirillum spp*. are less than 2% of cells.

In previous research using laboratory reactors [1], we found that normalized iron-oxidation rates were 1.5-2x faster for the *Ferrovum*-dominated communities compared to the *Acidithiobacillus*-dominated communities. We have since extended our sampling and analyses to identify environmental variables that control the distribution of these and other iron-oxidizers at Red Eyes. Overall, turnover among communities is related to changes in pH and Eh. Results so far suggest that the transition between *Ferrovum-* and *Acidithiobacillus-*dominated communities depends on iron concentration rather than pH. Ongoing analyses will further define the ecological niches of these and other important AMD populations.

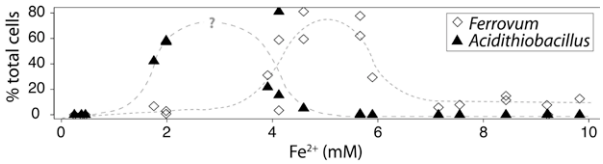

Figure 1. Fluorescence *in situ* hybridization cell counts of *Ferrovum* and *Acidithiobacillus* versus Fe^{2+} concentration.

Differential changes in Ni^{2+}, Co^{2+} and Fe^{2+} coordination in silicate melt with pressure

J. JONES[1]*, H. STC. O'NEILL[1] AND A. BERRY[2]

[1]Research School of Earth Sciences, Australian National University, Canberra, ACT 0200, Australia (*correspondence: jesse.jones@anu.edu.au)

[2]Department of Earth Science and Engineering, Imperial College London, South Kensington, UK

It is currently debated whether siderophile element abundances in the Earth's mantle reflect single-stage metal-silicate equilibration at high pressure at the base of an extensive magma ocean (homogeneous accretion), or the mixing of differentiated protoplanets each with a core formed at low pressures (heterogeneous accretion). This question has been addressed by parameterizing metal/silicate partition coefficients of siderophiles such as Ni, Co and Fe as a function of pressure, temperature and other variables, and extrapolating these parameterizations to determine P-T conditions that reconcile observed mantle abundances. Implicit in these parameterizations is that the partial molar volumes vary monotonically with pressure. XANES spectroscopy shows that the average coordination of Ni^{2+} in silicate glasses recovered from melts quenched at pressure, changes from tetrahedral to octahedral between 1 and 4 GPa, while that of Co^{2+} and Fe^{2+} remain unchanged. The effects of this transition are clearly mirrored in the distribution coefficients between iridium metal and silicate melt measured over the same range, showing that the quenched glasses reflect the liquid state at P and T. The partitioning can be modelled using different values of the partial molar volume of tetrahedral and octahedral NiO in the silicate melts. Changes in coordination environment of each siderophile in silicate melts will generally occur over different pressure intervals, preventing simple extrapolation of metal/silicate partitioning. The results enable an improved parameterization of the pressure dependence of Fe-Ni-Co partitioning, which excludes the simple single-stage magma-ocean hypothesis.

Martian magmatic volatiles recorded in olivine-bearing melt inclusions and matrix of shergottite Y-980459

J.H. JONES[1], T. USUI[1], C.M. O'D. ALEXANDER[2], J. WANG[2] AND J.I. SIMON[1]

[1]KR, NASA/JSC, Houston, TX 77058 (john.h.jones@nasa.gov)

[2]Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington DC, 20015

Martian basaltic meteorites [shergottites] contain a wealth of information about Mars. Of particular interest is the geochemical record contained in melt inclusions from the most primitive shergottite, Yamato 980459 (Y98). Using polished sections of Y98 mounted in indium to avoid volatile contamination from epoxy, our ion- and electron-microprobe study aims to constrain the volatile contents of primary Martian magmas generated by mantle melting. This record is also used to track the subsequent melt evolution of shergottite magmas. We report preliminary results for volatile abundances (H_2O, CO_2, S, Cl, F) in olivine-hosted melt inclusions (MI) and groundmass glasses (GG).

Unlike other shergottites, MIs in Y98 have remained glassy because of rapid cooling following eruption. Volatile concentrations of MI and GG in Y98 were analyzed by a Cameca ims-6f at DTM following the techniques of [1]. MIs contain distinctly higher contents of H_2O (~200 ppm) and CO_2 (600-1600 ppm) than GGs (<100 ppm H_2O and <20 ppm CO_2). In contrast, the MIs contain lower amounts of F (~15 ppm) and S (~900 ppm) than those in the GGs (~25 ppm F and 2200-3000 ppm S). Cl contents are almost constant among the MIs and GGs (~50 ppm). The CO_2 solubility in basaltic magmas suggests that the MIs were trapped at a depth of ~3 kbar. The pre-erupted magmatic water contents recorded in the Y98 MIs are ~2 orders of magnitudes lower than those proposed by the wet shergottite magma hypothesis (e.g. 1.8 % [2]), although the absolute water abundances in the MIs may have been changed by post-entrapment modifications. By using Na as an indicator of the degree of crystal fractionation (mainly olivine + pyroxene), the degree of degassing between pre-erupted (MI) and erupted (GG) Y98 melts are estimated as follows: CO_2 (~100 %) > H_2O (>80%) > Cl (50-70 %) > F (~0 %) ≈ S (~0 %, probably saturated with sulfide). Likewise, we estimate that the bulk Y98 liquid contained <30 ppm H_2O, 200-500 ppm CO_2, ~20 ppm Cl, ~5 ppm F, and ~300 ppm S.

Incongruent dissolution of volcanic riverine particulate material in seawater: Consequences for global element cycling

M.T. JONES[1]*, C.R. PEARCE[2], C. JEANDEL[3] AND E.H. OELKERS[4]

[1]Institute of Earth Sciences, University of Iceland, Sturlugata 7, Reykjavik, Iceland (*correspondence: morgan@hi.is)

[3]LEGOS-Université de Toulouse-CNRS-IRD-OMP, 14 Avenue Edouard Belin, 31400 Toulouse, France
[4]GET-Université de Toulouse-CNRS-IRD-OMP, 14 Avenue Edouard Belin, 31400 Toulouse, France

The world's rivers transport material from the land to the oceans in dissolved form and as particulate matter. Although particulate fluxes dominate over dissolved fluxes for the majority of elements relatively little attention has been paid to the role of riverine particulate material, both in the fluxes of elements to the oceans and moderating global climate [1]. The degree to which riverine particulate matter plays a role in the compositional evolution of seawater depends on its dissolution rate after arrival in the ocean. Volcanic islands supply the most easily weathered material to the oceans and are an important component of the global suspended flux. However, the apparent dearth of original volcanic minerals in oceanic drill cores suggests that the dissolution of riverine particulate material in seawater may be an important component of land-to-ocean element fluxes.

This study measured directly the initial element release rates of riverine particulate material in seawater through a series of closed-system batch reactor experiments. Large changes to the concentrations and isotopic ratios of elements are observed in seawater when mixed with riverine particulates. Elements such as Si, Ca, Mn and Ba show marked increases in seawater concentrations, indicative of particulate dissolution. Other elements such as Li become rapidly depleted in seawater, suggesting element exchange reactions or the formation of secondary phases. Sr and Nd display comparatively little change in seawater concentrations, but have large changes in isotopic ratios. Taken together, these results demonstrate a significant role of seawater weathering of riverine particulate material to the fluxes of elements to the oceans and have important consequences for the use of isotopes as tracers of global processes.

Fluid and temperature conditions in an oceanic detachment fault footwall: Insights from late-stage mineral veins (ODP Leg 304/305)

N. JÖNS[1]*, W. BACH[1], M. ROSNER[1,2,3] AND B. PLESSEN[2]

[1]Dept. of Geosciences, University of Bremen, Germany (*correspondence: njoens@uni-bremen.de)
[2]Helmholtz-Zentrum Potsdam/ GFZ, Potsdam Germany
[3]FB Geowissenschaften, Freie Universität Berlin, Germany

The Atlantis Massif is an oceanic core complex located at the Mid-Atlantic Ridge at ca. 30°N. During IODP Leg 304/305 Hole U1309D the footwall of the detachment fault, which is related to exhumation of the Massif, was drilled. It consists mainly of gabbros and troctolites, with minor amounts of basaltic and ultramafic rocks. The 1416 m long drilled section is fractured and shows a retrograde overprint recorded by granulite- to zeolite-facies mineral assemblages. Late-stage mineral veins (consisting of anhydrite, calcite, prehnite or zeolite) formed from sub-seafloor fluid-rock interactions. These veins were examined to further our understanding of the fluid regime and temperature conditions in detachment fault systems.

Abundant syn- to postkinematic calcite has low concentrations of incompatible elements (e.g. U, Sr, Li) as well as flat chondrite-normalized REE+Y pattern with a positive Eu anomaly. This indicates that the calcite precipitating fluids are similar to basalt-hosted hight-T vents and indicate no affinity to the nearby serpentinization-derived Lost City vent field. The deep origin of the fluids is highlighted by low $^{87}Sr/^{86}Sr$ (0.704 to 0.708), mantle-like $\delta^{7}Li_{LSVEC}$ (+0.8 to +9.4‰) and $\delta^{13}C_{PDB}$ (-6 to -2‰). From $\delta^{18}O$ values, minimum calcite precipitation temperatures of 150-220°C are derived.

Anhydrite and anhydrite + zeolite veins have $^{87}Sr/^{86}Sr$ values consistent with anhydrite formation from down-flowing seawater which had leached only minor amounts of Sr from the basement. The REE pattern of anhydrite veins indicate that admixed hydrothermal fluids at depth played a minor role.

Silicate minerals (prehnite, quartz, plagioclase) predominate veins in the deepest section of Hole 1309D and indicate precipitation temperatures ranging from 270 to 145°C (estimated from $\delta^{18}O$ values). They are comparatively unradiogenic in $^{87}Sr/^{86}Sr$ (0.7033-0.7046) and demonstrate (in contrast to anhydrite) enhanced intensity of reactions between infiltration seawater and basement with increasing depth.

Surface properties and complexation on titanium dioxide nanoparticles

C.M. JONSSON*, J. PEREZ HOLMBERG, J. GALLEGO-URREA, Z. ABBAS, E. AHLBERG, J. BERGENHOLTZ AND M. HASSELLÖV

Department of Chemistry, University of Gothenburg, SE-41296 Gothenburg, Sweden (*correspondence: caroline.jonsson@chem.gu.se)

There is an increasing amount of synthetic nanoparticles in the environment. Due to their small size, they have properties that result in higher reactivity compared with larger particles and bulk materials. Interactions that occur at the surface of nanoparticles are important for understanding and predicting nanoparticle fate and behavior, as well as characterizing the potential risks for the environment and human health.

Surfactant-free TiO_2 nanoparticles were synthesized and characterized according to [1]. Temperature during synthesis reaction, dialysis and storage was found to strongly influence the particle size and crystal structure. Potentiometric titrations were used to determine the surface charge of the particles at varying pH and ionic strength.

In order to mimic the interactions of nanoparticles with natural organic matter (NOM), surface complexation on TiO_2 was studied using model organic substances possessing carboxyl and hydroxyl groups. Results show that the adsorption of 2, 3-dihydroxybenzoic acid (2, 3-DHBA) was influenced by pH, and the amount adsorbed varied greatly with initial TiO_2 particle size. The size dependent surface complexation is investigated further in order to obtain a mechanistic understanding of the processes that occur at the molecular level when TiO_2 nanoparticles interact with NOM.

Further, the stability of TiO_2 nanoparticle dispersions in presence and absence of well-characterized macromolecules (sodium alginate, humic acid, and fulvic acid) was studied in different electrolyte environments and at varying pH. The aggregation behavior was investigated by monitoring the changes in particle size using dynamic light scattering.

Stable carbon isotope chemostratigraphy and implications for global carbon cycling, Cretaceous Western interior basin

YOUNG JI JOO*, MATTHEW HURTGEN AND BRADLEY B. SAGEMAN

Department of Earth and Planetary Sciences, Northwestern University, Evanston, IL 60201, USA (*correspondence: yjoo@earth.northwestern.edu)

The Late Cretaceous provides a critical analog for the anthropogenic greenhouse world. Strata of 100 Ma±20 myr record one of the warmest times in Earth history and are characterized by high-resolution time control, global correlation of deposits from deep ocean to epicontinental seas, and a series of global scale perturbations of the land-ocean-climate system. These perturbations include major changes in carbon cycling, surface temperatures, glacial ice volumes, sea level, and marine redox conditions over geologically short intervals (10's – 100's of kyr, similar to durations predicted for an anthropogenic greenhouse forced by combustion of all fossil fuel reserves). Recent findings from the Cenomanian-Turonian Ocean Anoxic Event 2 (OAE2), one of the largest Cretaceous events, have implicated active volcanism from emplacement of the Caribbean large igneous province as a trigger. One approach to testing this hypothesis involves carbon isotopes, since a volcanically triggered OAE should leave a characteristic signal. This study reports a new Cenomanian to Campanian carbon isotope record for the central Western Interior basin linked to a carbon isotope mass balance model. Major perturbations in the isotope record, such as Mid-Cenomanian Event and OAE2, are correlated to other carbon isotope records and analyzed with a series of model experiments. The new d13C record contributes to Late Cretaceous chemostratigraphy and allows testing of the volcanic initiation hypothesis, as well as the role of regional variations in organic matter burial.

Speciation of trivalent metal ions at the silica/water interface studied by second harmonic generation

DAVID S. JORDAN, SARAH A. SASLOW AND FRANZ M. GEIGER

Department of Chemistry, Northwestern University, 2145 Sheridan Rd. Evanston, IL 60208 (*correspondence: geigerf@chem.northwestern.edu)

The nonlinear optical technique of second harmonic generation (SHG) is used to study the interactions of Al (III), Y (III), La (III), and Gd (III) with the fused silica/water interface. Specifically, the Eisenthal $\chi^{(3)}$ technique [1] is employed in order to quantify several thermodynamic binding parameters of these ions as a function of background electrolyte concentration. Using this highly surface specific technique, we are able to quantify binding contants, adsorption free energies, absolute number densities, and interfacial charge densities in real-time and without the use of labels. We also examine the relationship between the measured adsorption free energies and the electric double layer interfacial potential at each electrolyte concentration to elucidate the charge state and possible binding pathways for each ion at the fused silica surface.

Our results show that the binding of each trivalent ion is fully reversible under the experimental conditions employed in this study. Adsorption isotherms are measured under dynamic flow conditions and fit using the Triple Layer model. We employ an analysis that takes advantage of the additive adsorption free energy expression in which the observed free energy is modeled as a sum of the electrostatic free energy and the intrinsic chemical free energy [2]. From this analysis, we find that the Al (III) ion binds to the fused silica surface as a fully hydrated trivalent species in a bidentate geometry. In contrast, the Y (III), La (III), and Gd (III) ions are each shown to adsorb to the silica surface in a reduced valence state. Despite identical oxidation state, the extent and mode of binding varies between each ion. These SHG studies provide valuable data that can be used to predict the transport these metal ions are throughout the environment.

Hydrate destabilization and methane release events during last glacial episode in Bay of Bengal

R.K. JOSHI AND A.MAZUMDAR*

Geological Oceanography, National Institute of Oceanography, Donapaula, Goa, 403004, India (*correspondence: maninda@nio.org)

We report here for first time episodic methane expulsion events in the Krishna-Godavari basin, Bay of Bengal during the marine isotope stage 4 (MIS-4) and at the transition of MIS-4 and MIS-5. We have observed sharp negative carbon isopote excursions in the isotope profiles of planktonic (*G. ruber*) and benthic (*Uvigerina sp.*) foraminifera in a core MD161-8, recovered on board *Marion Dufresne* as part of our gas hydrate exploration program in 2007. Depleted carbon isotope excursions in both benthic (B_1, B_2 and B_3) and planktonic (P_4, P_5 and P_6) foraminifera suggest that the methane expulsion events not only altered the carbon stable isotopic composition of the bicarbonate pool near the sediment waters interface, but also that of the shallow water column. A significant fraction of methane gets oxidized to HCO_3^- via anaerobic methane oxidation (AMO) at or below the sediment water interface. Depletion in carbon stable isotope ratios of the dissolved inorganic carbonate (DIC) pool depends on the carbon stable isotope ratios of methane advecting from deeper layers. Reported[1] $\delta^{13}C_{CH4}$ values (-75 to -85 ‰ VPDB) and C1/C2+C3 ratios (1110 to 3354) suggest presence of biogenic hydrocarbon gases within the methanogenic zone at the site MD161-8. Carbon stable isotope ratios of infaunal benthic foraminifera like *Uvigerina sp.* may get significantly influenced by incorporation of isotopically depleted carbon as HCO_3^- in the calcitic shell during growth and considered as a potential proxy for paleo-methane seepage. On the other hand, the depleted carbon isotope excursions recorded for the corresponding planktonic foraminifera, *G. ruber,* suggests that a part of the expelled methane reached the upper mixed layer (0-25m) where aerobic methanotrophy resulted in the depletion of carbon stable isotope ratios of the DIC reservoir.

We attribute the methane emission events to destabilization of the base of gas hydrate stability zone (BGHSZ) due to shale tectonics induced focused fluid flow. Fluid released from the over-pressured mud, possibly played important role in creating fractures as well as advection of the gases in K-G basin.

Clumped isotope measurements to reveal diagenetic histories

A.-L. JOURDAN*, C.M. JOHN AND S. DAVIS

Qatar Carbonates and Carbon Storage Research Centre (QCCSRC), Department of Earth Science & Engineering, Imperial College London, London SW7 2AZ, United Kingdom (*correspondence: a.jourdan@imperial.ac.uk)

Clumped isotope geochemistry is a growing field, and more particularly the 'carbonate clumped isotope paleothermometer' is becoming more widely applied. Isotopologues are molecules that are identical except for their isotopic composition. Clumped isotopes are isotopologues where two or more heavy isotopes are clumped together; the effects of clumping are enhanced with decreasing temperatures, the zero point energy of the system being lowered. However, calibrating clumped isotopes is still a novel and challenging field of research, and more importantly measuring isotopologues requires skills and high sensitivity mass spectrometry.

So far, clumped isotopes have been used mainly in paleoclimate research. Here, we intend to calibrate the carbonate clumped isotope paleothermometer for diagenetic material. Carbonates are reactive minerals that can easily be modified during burial and exhumation. Post-depositional diagenetic processes such as dissolution and re-precipitation of new minerals are common and result in modified mineralogical and petro-physical characteristics of the initial carbonate rock. Temperature at which those transformations occur is a fundamental parameter in diagenesis: given a known geothermal gradient and burial history, the temperature of precipitation of carbonate cements can be translated into depth and timing of the event, assuming a thermal equilibrium between the fluids and the rock. Because it is thermodynamically based, the clumped isotope paleo-thermometer is independent of the isotopic composition of the diagenetic fluid and therefore can be applied with greater confidence.

We are currently implementing the technique at Imperial College London, both in a manual and in an automatic manner. Our aim is to improve the technique in order to be able to measure smaller sample sizes of diagenetic material (such as cement and crack infills) and to lower the associated error down to ± 1°C. We are therefore running a wide range of calibrations, on calcite and dolomite, and from different synthetically precipitated carbonate materials.

Ultimately, we aim to constrain the depositional and diagenetic environments of selected outcrops in Oman in the context of a wider study on Carbon Capture and Storage.

We would like to acknowledge that the QCCSRC is funded jointly by Qatar Petroleum, Shell, and the Qatar Science & Technology Park.

A ~3.63 Ga major impact recorded by the Bunburra Rockhole anomalous basaltic achondrite

F. JOURDAN[1]*, P.A. BLAND[2], A. BOUVIER[3] AND G. BENEDIX[4]

[1]Western Australian Argon Isotope Facility, and JdL-CMS, Curtin University of Technology, GPO Box U1987, Perth, WA 6845, Australia (*correspondence: f.jourdan@curtin.edu.au)
[2]Impacts and Astromaterials Research Centre (IARC), Imperial College London, SW7 2AZ, UK
[3]School of Earth and Space Exploration, Arizona State University, Tempe, AZ 85287, USA
[4]Meteoritics and Cosmic Mineralogy, Natural History Museum, Cromwell Road, London SW7 5BD

The Bunburra Rockhole (BR) meteorite is an anomalous basaltic achondrite recovered in Western Australia [1]. BR mineralogy, petrology [1] and mineral composition [2] resemble classical brecciated basaltic eucrites, generally associated with asteroid 4 Vesta. However, BR oxygen isotopic composition is distinct from the general HED fractionation line, suggesting that BR, along with 3 other anomalous eucrites, belongs to a distinct differentiated parent asteroid. Previous chronology studies indicate a reset of the ^{26}Al-^{26}Mg system and a ~4.1 Ga ^{207}Pb-^{206}Pb whole-rock reequilibration age for BR [2].

The ^{40}Ar/^{39}Ar chronometer has typical low closure temperature of few hundred °C and has the potential to record heating events such as large collisions between asteroids. We have analyzed 4 groundmass (fine-grained) and 5 breccia (medium- to coarse-grained) single-grain aliquots of BR using the ^{40}Ar/^{39}Ar laser step-heating technique. All samples yielded well-defined plateau ages. 7 grains yielded a weighted mean age of 3634±18 Ma (P=0.53) suggesting that BR recorded a major impact event on its parent body at this time. 2 breccia grains suggest a secondary minor heating event at 3538±24 Ma (P=0.54).

Generally, eucrites ^{40}Ar/^{39}Ar analyses yield complex age spectra with ambiguous apparent ages between 3.4 and 4.1 Ga [3]. Here, a unique well-defined age at 3.63±0.02 Ga based on several flat age spectra indicate that BR had a simpler history than eucrites from Vesta 4 and may suggest that BR belongs to a different parent asteroid.

Cu isotopes suggest Cu reduction during acquisition in higher plants

DELPHINE JOUVIN[1]*, DOMINIK WEISS[2], MATTHIEU N. BRAVIN[3], PASCALE LOUVAT[4], PHILIPPE HINSINGER[5] AND MARC F. BENEDETTI[6]

[6]Géochimie & Cosmochimie, IPGP - Université Paris Diderot, Sorbone Paris Cité, UMR 7154, Paris, France

Evidences from recent studies suggest that studying the natural isotope fractionation of metals in plants offers great potential to elucidate acquisition and translocation mechanisms. We conducted controlled hydroponic studies with lettuce, tomato, rice and durum wheat and tested the effect of copper (Cu) speciation and iron (Fe) supply in the nutrient solution. Next to Cu isotopes, we studied the zinc (Zn) isotopes since Zn is not sensitive to redox processes and a model of Zn isotopic fractionation in plants has been proposed [1].

Isotope fractionation patterns between nutrient solution, roots and shoots differ for Cu and Zn. Roots are enriched in ^{63}Cu (light isotope) but slightly enriched in Zn heavier isotopes compared to the nutrient solutions, suggesting that different processes occur for Cu and Zn at the root-solution interface. Different physical, chemical and biological processes can contribute to the isotopic fractionation during acquisition of Cu and Zn by plants. Abiotic processes, mainly complexation in the nutrient solution or adsorption onto root binding site, are expected to fractionate similarly for Cu and Zn. On the contrary, plant behaviour differs for Cu and Zn, as seen with the concentrations and isotopic ratios data.

The enrichment in light isotopes for Cu is associated with significant reduction of Cu at the root-solution interface, suggesting that this biogeochemical mechanism is predominant for the acquisition of this metal into plants. This is similar to mechanism of Fe uptake for strategy I plant species [2].

How are oceanic $\delta^{18}O$ changes imprinted in ice core records?

J. JOUZEL[1]*, G. HOFFMANN[1], A. LANDAIS[1], B. STENNI[2], V. MASSON-DELMOTTE[1] AND C. WAELBROECK[1]

[1]LSCE/IPSL CEA/CNRS/UVSQ, CEA saclay 91191, Gif/Yvette (*correspondence: jean.jouzel@lsce.ipsl.fr)
[2]Department of Geosciences, University of Trieste, 34127 Trieste, Italy

The deuterium and oxygen 18 composition of a precipitation and thus its deuterium-excess, $d = \delta D - 8\ \delta^{18}O$, depends, amongst other parameters, on the isotopic composition of surface waters in the oceanic source regions. As a result, the glacial-interglacial $\delta^{18}O$ change of surface oceanic waters is imprinted in the ice core d-excess record with, in Central Antarctica, a 3 to 4 ‰ d-excess increase directly attributable to the oceanic source. In the same line, changes in oceanic $\delta^{18}O$, globally averaged in this case, influence the $\delta^{18}O$ composition of atmospheric oxygen directly through oceanic productivity and indirectly over the continent. Obviously there are many other processes, most of them however relatively well identified, which govern the $\delta^{18}O$ oceanic record derived from foraminifera, on the one hand, and the d-excess and the air $\delta^{18}O$ measured respectively in polar ice and entrapped air bubbles, on the other. In this context, we will compare the amplitude and time sequence of these three isotopic signals from one deglaciation to the next, thanks to the d-excess and air $\delta^{18}O$ records now available on nine terminations from the EPICA Dome C ice core.

Nucleation and growth mechanisms and kinetics of environmentally important oxides and carbonates

YOUNG-SHIN JUN[1]*, BYEONGDU LEE[2], YANDI HU[1], JESSICA R. RAY[1], GLENN A. WAYCHUNAS[3] AND ALEJANDRO FERNANDEZ-MARTINEZ[3]

[1]Department of Energy, Environmental and Chemical Engineering, Washington University, St. Louis, MO 63130, USA (*correspondence: ysjun@seas.wustl.edu),
[2]Argonne National Laboratory
[3]Lawrence Berkeley National Laboratory

Nucleation and growth of hydrous oxide or carbonate nanoparticles can significantly influence the fate and transport of organic and heavy metal contaminants in the environment. Their particles' formation and tranport can alter the porosity and permeability of geo-media. Therefore, more accurate quantitative and qualitative information about mineral nucleation and growth is required.

In this work, we used a time-resolved simultaneous small angle x-ray scattering (SAXS)/grazing incidence (GISAXS) setup for real-time monitoring of water-mineral interfacial reactions. To observe the size, shape, distribution, and phase of hydrous iron oxide and calcium carbonate nanoparticles on quartz and mica surfaces as well as in solutions, we also used complemetary techniques, such as atomic force microscopy, high resolution transmission electron microscopy, high resolution X-ray diffraction, and grazing incidence wide angle x-ray scattering. The solutions included different ionic strengths of sodium nitrate, arsenate, aluminum, and polyaspartate. The mineral nucleation and growth modes were monitored as a function of exposure time. We delineated the quantitative contributions between homogenous and hetergeous mechanisms at varied environmental conditions. Hydrous iron oxide nanoparticles formed preferrentially along steps rather than terraces, while amorphous calcium carbonate did not show any clear preference. Under aqueous conditions, newly formed nanoparticles did not exhibit any facets. The presence of arsenate and aluminum ions significantly influenced the sizes and crystallinities of hydrous iron oxide nanoparticles and altered their nucleation and growth kinetics. This study provides more accurate depiction of nucleation and growth of environmentally important minerals in solution as well as at active interfaces. Our findings have implications not only for hydrous oxide- or carbonate-containing biogeochemical systems, but also for environmental remediation (heavy metal removal and nuclear waste deposition site remediation) and geoengineering applications (geologic CO_2 sequestration).

Effects of organic ligands on supercritical CO_2–induced phlogopite dissolution and secondary mineral formation

YOUNG-SHIN JUN* HONGBO SHAO, AND JESSICA R. RAY

Department of Energy, Environmental and Chemical Engineering, Washington University, St. Louis, MO 63130, USA (*correspondence: ysjun@seas.wustl.edu) (shaoh@seas.wustl.edu, jrr5@cec.wustl.edu)

To evaluate the long-term and short-term risks associated with geologic CO_2 sequestration (GCS), we need to understand both the reactions at supercritical CO_2 ($scCO_2$)-saline water-rock interfaces and the environmental factors affecting these interactions.[1, 2] This research investigated the effects of four organic ligands (oxalate, malonate, acetate, and propionate) on the dissolution and surface morphological changes of phlogopite [$KMg_{2.87}Si_{3.07}Al_{1.23}O_{10}$ (F, $OH)_2$] under GCS conditions (in particular, 95ºC and 102 atm). Phlogopite was chosen as a model clay mineral in potential GCS sites.

After CO_2 injection, the dissolution of CO_2 causes a pH decrease in saline water, which increases phlogopite dissolution, but this effect can be minimized by the buffering capacity of organic ligands. However, in this study, for ligands forming a strong complexation with surface metals, phlogopite dissolution rates (especially for Al) are increased by ligand-promoted dissolution, even though the pH increases. The experimentally observed dissolution rates of phlogopite were in the order: oxalate > malonate > acetate ≈ propionate. Based on results from ion-exchange chromatography, oxalate and malonate were stable in our reaction system; however, acetate and propionate concentrations continuously decreased due to the solvent exaction of acetic acid and propionic acid by $scCO_2$ at 95ºC and 102 atm. After 159 h, all of the acetate and propionate had disappeared from the aqueous solutions.

Interestingly, in the presence of oxalate, nanoscale precipitation of amorphous silica and fibrous illite was observed only three hours after CO_2 injection. At this early reaction time, illite fibers formed a honeycomb structure on phlogopite basal surfaces, but at a later reaction time these structures detached from the surface and triggered the formation of dissolution channels. In addition, kaolinite, boehmite, diaspore, and gibbsite were also identified. These results provide new information for understanding reactions at $scCO_2$–saline water–rock interfaces in deep saline aquifers.

Laser-induced breakdown detection (LIBD) of uranium and silica colloids

E.C. JUNG*, H.-R. CHO AND M.R. PARK

Nuclear Chemistry Research Division, Korea Atomic Energy Research Institute, P.O. Box 105, Yuseong, Daejeon 305-600, Republic of Korea
(*correspondence: ecjung@kaeri.re.kr)

Introduction

Laser-induced breakdown detection (LIBD) is a well established technique using plasma formation in the high irradiance of a focused laser beam for measuring small size of colloidal particles in an aquatic environment. Over the last decades, several different LIBD systems which adopt different detection schemes by using a piezoelectric transducer, a charge-coupled device camera, and an optical probe beam were developed. These LIBD systems enable to detect extremely low concentration of nanoparticles. Thus, the LIBD technology can be applied in various fields such as, *in situ* observation of colloid mediated transport of polluants and measurement of solubility of radio-active elements.

Although LIBD methods allow one to determine a particle size in principle, until now, particle sizing capabilities in most LIBD experiments were inspected only for polystyrene particles of a well-defined size as a reference material. Therefore, it should be certified that these LIBD methods are whether suitable or not to determine the particle size for different materials.

Discussion of Results

In the present work, particle sizing capability using LIBD has been investigated for three different materials: uranium, polystyrene, and silica nanoparticles. It was observed that spatial distribution of breakdown events generated by laser pulse of 532 nm wavelength along the laser beam propagation axis was directly correlated with particle size for uranium and polystyrene, while there was no correlation between the spatial distribution of breakdown events and particle size for silica. The reason for these phenomena is understood based on the ionization potential (IP) of each material. IPs of these materials are about 6.17, 7.8, and 11.7 eV for UO_2, polystyrene, and SiO_2, respectively. When a focused laser pulse of 532 nm wavelength is used to generate laser-induced plasma, simultaneous three or four photon absorption is required to induce multiphoton ionization (MPI) of uranium and polystyrene. However, at least five photon absorption is required to induce MPI of silica. The result suggests that determination of particle size of silica particles with the aid of calibration curve obtained from the polystyrene reference particles may give incorrect values.

Seismic anisotropy produced by serpentine in the mantle wedge

H. JUNG*

School of Earth and Environmental Sciences, Seoul National University, Seoul 151-747, Korea
(*correspondence: hjung@snu.ac.kr)

Trench-parallel seismic anisotropy has been observed in many subduction zones in the upper mantle. In this study, crystal-preferred orientation (CPO) and seismic anisotropy of natural serpentine from Val Malenco in northern Italy and Punta Bettolina in western Italy were studied. It is found that [001] axes are aligned subnormal to the foliation but [010] axes of serpentine are aligned subparallel to the lineation which is significantly different from that produced in a recent high-pressure experiment. I show that the CPOs of serpentine found in this study can be used to explain trench-parallel seismic anisotropy in the mantle wedge, not only for serpentine deformed at high angles greater than 45° from the surface but also for serpentine deformed at low angles such as in horizontal shear, demonstrating that the CPO of serpentine has much broader implications for interpreting the seismic anisotropy than previously thought. It is also found that seismic anisotropy caused by the CPO of serpentine depends on the degree of serpentinization and flow geometry. Current data suggest that trench-parallel seismic anisotropy in the forearc mantle wedge in subduction zones can be attributed to the CPO of serpentine.

Wadi as collectors of drinking water in South Mongolia

DAVID JUŘIČKA[1], MAJIGSUREN YONDON[2], JITKA NOVOTNÁ[1] AND JINŘICH KYNICKÝ[1]

[1]Mendel University in Brno, 613 00 Brno, Czech Republic (25389@node.mendelu.cz)
[2]University of Science and Technology, Ulaanbaatal 46, Mongolia (majigsuren@yahoo.com)

Current drinking water resources of south Mongolia do not yield suitable quality and quantity to often. Solution of the drinking water deficit issue can partially solve the large wadi evaluation, such as drinking water collectors. We constructed the first evaluation of wadi water capacity for Khan Bogd complex, which is one of the largest known intrusions of peralkaline granite (*ca*. 1500 km^2). Watersheds and stream network and profiles carefully identified in the field were verified by comparison of supervised classifications of Landsat TM images. The possible sources yield almost 5.0×10^6 m^3 and average annual recharge rate for the Khan Bogd wadi aquifers is estimated at 1.892×10^6 m^3. The only risk of the aquifer contamination presents stock, but comparing the chemical composition of the water from wells used for animals feeding and samples of groundwater, we didn't observe any important contamination (ammonium up to 10 mg/l). Present study is the first attempt to describe and evaluate the potential wadi Khan Bogd as a source of drinking water in the Mongolia. Implication for use of this new water source accessible for drinking water in whole arid region of South Mongolia is clear.

Distinguishing mantle derived contributions at a continental arc volcano: Tatara-San Pedro

J. JWEDA[1], S.L. GOLDSTEIN[1], M.A. DUNGAN[2], C.H. LANGMUIR[3] AND J.P. DAVIDSON[4]

[1]Lamont-Doherty Earth Observatory, Columbia Univ., 61 Rt. 9W, Palisades, NY 10964, USA (*correspondence: jjweda@ldeo.columbia.edu)

[3]Harvard University, 20 Oxford Street, Cambridge, MA 02138, USA
[4]University of Durham, South Road, Durham DH1 3LE, UK

Subduction recycling plays a key role in the distribution of elements between the mantle and crust. One of the important challenges in the study of arc magma genesis is identifing contributions from the subducted slab and mantle, and distinguishing them from crustal contamination at relatively thick crust continental arc volcanoes [1, 2]. The Quaternary Tatara-San Pedro complex (TSPC) of the Southern Volcanic Zone (SVZ) is a large, compositionally diverse frontal arc volcanic complex. High-density sampling has yielded one of the most complete eruptive chrono-stratigraphies (spanning over 930 kyr) of any arc volcano [3, 4, 5]. This provides us with a unique opportunity to elucidate magma source heterogeneity and the effects of recycled slab, mantle, and crustal input at a continental arc volcano.

This study augments an extensive XRF geochemical dataset with new isotope and ICP trace element analyses. Although most TSPC lavas appear impacted by crustal input, we distinguish three distinct mantle-derived magma types: (1) one derived from 'depleted mantle' fluxed by slab-derived hydrous fluids (high Sr/Nd, Zr/Nb and low $^{87}Sr/^{86}Sr$), (2) one from 'enriched mantle' (high incompatible elements, HFSE, and $^{87}Sr/^{86}Sr$), and (3) another that appears prevalent to the SVZ mantle wedge (subduction modified) with generally intermediate but still distinct chemistry (broadly similar to parental magmas at other SVZ volcanoes). Extensive MASH processing is precluded by the absence of significant garnet fractionation in the endmembers and by eruption of diverse parental magmas over short time intervals.

Role of Hydrogen and Oxygen fugacity in incorporation of Nitrogen in reduced magmas of the early Earth's mantle

A.A. KADIK[1]* AND Y.A. LITVIN[2]

[1]Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, 19, Kosygin str., Moscow, Russia (*correspondence: kadik@geokhi.ru)
[2]Institute of Experimental Mineralogy, Russian Academy of Sciences, Chernogolovka, Moscow district, 142432, Russia

In a series of experiments in the system Fe-bearing melt + molten Fe phase + N + H conducted at 4 GPa, 1550 °C, and fO_2 from 2 to 4 log units below IW buffer we have characterized the nature and quantified the abundance of N and H species dissolved in a model silicate melt (FeO + Na_2O + Al_2O_3 + SiO_2). To elucidate the mechanisms of nitrogen and hydrogen dissolution in magmas, we studied the glasses produced by quenching the melts using infrared and Raman spectroscopy's in a manner similar to that reported by [1]. Experiments indicate that under the reduced conditions corresponding to the fO_2 path during metal segregation and self-oxidized of mantle [2] and magma ocean [e.g. 3, 4] the silicate melt would contain species with N-H bonds (NH_3, NH^{4+}, NH^{2-}, NH^{2+}) as well as N_2 and oxidized H species (OH- and H_2O). Some hydrogen is present in the melt in molecular form. The formation of N–H bonds in the reduced silicate melts results in a significant increase in nitrogen solubility that can reach 1–2 wt. %. It is suggested that significant amounts of nitrogen, comparable to those estimated for the present-day mantle, could have been incorporated in the early Earth by dissolution in reduced magma ocean.

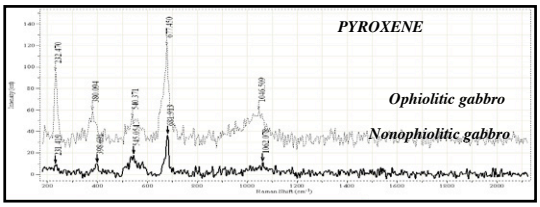
Differentiation of ophiolitic and nonophiolitic gabbros using confocal Raman spectroscopy: Central Anatolia Turkey

Y.K. KADIOĞLU, T. KORALAY, O. ZOROĞLU, B. GULLU, M.A. AKÇE, K. DENIZ AND B. YILDIRIM

Ankara Univ., Dept., of Geol., Eng., & YEBIM Ankara, Turkey (*correspondence: kadi@ankara.edu.tr)

Ophiolitic gabbros are mostly exposed at west of Tuz Lake and nonophiolitic gabbros are exposed at east of Tuz Lake in Central Anatolia. Ophiolitic and nonophiolitic gabbros have almost same mineral and geochemical compositions. Discrimination of the ophiolitic and nonophiolitic gabbros was carried out using the Raman spectra of the pyroxene minerals. Based on Raman peak positions, the major-element composition of the (Mg, Fe, Ca)-pyroxenes are determined and classified.



Results and Discussion

Raman vibrational modes were observed for the pyroxenes in the wave number range between 200 and 1200 cm^{-1} (Figure 1). The Raman modes showing the greatest variation in frequency with the $Fe^{2+}$and OH^{+}content are potentially capable of being used as an index for determining the ophiolite and nonophiolite pyroxenes of the gabbro series. The best Raman modes for this purpose in the ophiolite pyx series are ν_6 (232–540 cm^{-1}) and (677–1046 cm^{-1}) pairs that show about 60 cm^{-1}across the series. The ν_{15} (931–950 cm–1) mode can also serve as a supplementary mode for the determination of the composition. These modes are characteristic and fairly intense. However, in the nonophiolite pyx series, because only the ν_3 (231–545 cm^{-1}) and ν_3' (681–1046 cm^{-1}) pairs show a variation more than 20 cm^{-1}. These provide a weaker basis for the composition indices. The uncertainties in the determination of the Fe content with the Raman modes are of the order of 3 and 7%.

Polyphase serpentinization history of Mariana forearc mantle: Observations on ultramafic clasts from ODP Leg 195, Site 1200

W.-A. KAHL[1]*, N. JÖNS[1], W. BACH[1] AND F. KLEIN[2]

[1]University of Bremen, 28359 Bremen, Germany (*correspondence: wakahl@uni-bremen.de)
[2]Woods Hole Oceanographic Institution, Woods Hole, USA

In the forearc of the Mariana subduction zone system, abundant seamounts form from extrusion of blueschist and serpentine mud. ODP Leg 195 drilled the South Chamorro seamount, where ultramafic clasts occur within the mud matrix. These clasts show a complex serpentinization history, which bears the potential for tracking the fluid history during uplift and cooling of mantle wedge rocks to the seafloor.

Highly serpentinized harzburgites, which are crosscut by different generations of late-stage veins, were examined. Preserved primary minerals include olivine (X_{Mg}= 0.91-0.92) and orthopyroxene ($X_{Mg}\approx$ 0.92). Magnesium-rich (X_{Mg}= 0.92-0.95) clinopyroxene is present as exsolution lamellae in orthopyroxene and in symplectitic intergrowths with spinel (X_{Cr}= 0.48-0.59).

Multiple serpentinization steps are documented: (I) Pervasive serpentinization led to ubiquitous breakdown of olivine and formation of serpentine (X_{Mg}= 0.92-0.94) and magnetite. Orthopyroxene was replaced to lesser extent by serpentine ($X_{Mg}\approx$ 0.90). Clinopyroxene remained stable during this stage. (II) The second hydration stage was bound to fractures crosscutting earlier serpentinization textures and is manifested as veins consisting of Mg-rich serpentine (X_{Mg}= 0.90-0.93). (III) Veins from stage II were re-activated and overprinted by serpentine + brucite assemblages. Replacement of magnetite is observed, leading to brucite with $X_{Mg}\approx$ 0.80 and serpentine with $X_{Mg}<$ 0.90. Furthermore, clinopyroxene breaks down and Fe-rich brucite ($X_{Mg}\approx$ 0.60) forms. (IV) Finally, late discontinuous serpentine veins formed perpendicular to the stage II and III veins.

Pervasive serpentinization (stage I) likely marks a comparatively high-T (i.e. T= 250-350°C) hydration that took place within the mantle wedge. The lower density of the hydrated rocks led to diapiric rise and associated fracture-bound serpentine formation (stage II). Formation of Fe-rich brucite as well as breakdown of magnetite and clinopyroxene (stage III) occurred after considerable cooling (T<< 200°C) during uplift. Petrography and mineral chemistry point to low-temperature demagnetization, which is in agreement with density-susceptibility relations and results of reaction-path modelling.

Incomplete recovery of mineral-bound lignin phenols

K. KAISER[1], P.J. HERNES[2], R.Y. DYDA[2], C. CERLI[3]

[3]Institute of Biodiversity and Ecosystem Dynamics, Earth Surface Science, University of Amsterdam, 1098 XH Amsterdam, The Netherlands (c.cerli@uva.nl)

Intimate associations with minerals is one mechanism involved in the accumulation and stabilisation of organic matter (OM) in soils. Phenolic compounds derived from partial degradation of polyphenols such as lignin are among the most surface-reactive organic compounds. However, we still do not know to which extent lignin-derived phenols associated with soil minerals can be analytically assessed.

Here, we tested the extractability of mineral-bound lignin-derived phenols by alkaline CuO oxidation.

We used tree aqueous litter (blue oak, pine, annual grass) leachates and five minerals (ferrihydrite, goethite, kaolinite, illite, montmorillonite). In a first step, we determined the sorption capacity for dissolved organic carbon for each mineral, as well as the changes in specific UV absorption during the sorptive interaction between organic matter and minerals. Then, we produced organic–mineral associations under conditions well below the sorption maximum of the contained mineral. The mineral–organic associations, the dried out leachates and the equilibrium solutions were then subjcted to CuO oxidation. The amount of sorbed and not CuO-exctractable lignin-derived phenols were calculated by difference.

CuO-oxidation extracted lignin-derived phenols bound to ferrihydrite completely and without changes in composition, presumably due to complete dissolution of the mineral. For all other minerals, up to 44% of the bound phenols could not be extracted. The incomplete recovery of sorbed phenolic compounds was accompanied by different ratios of extracted individual phenols, suggesting different bonding strengths.

The results show that a substantial portion of lignin-derived phenols binds irreversibly to minerals, even escaping harsh extraction unless the mineral is completely dissolved. The difference in extractability of individual phenols suggests that abiotic processes, such as sorption/desorption, should be taken into account when using CuO oxidation data for assessing organic matter transformation in mineral matrixes.

Different paths of chemical alteration during grusification of granites from S Poland

B. KAJDAS* AND M. MICHALIK

Institute of Geological Sciences, Jagiellonian University, ul. Oleandry 2a, 30-063 Kraków, Poland (*correspondence: bartlomiej.kajdas@uj.edu.pl)

Four type of grusified granites were taken under consideration. Three of the investigated gruses were developed on the Variscan granites from Karkonosze Mts. (Kowary Średnie [KS] and Głębock [GL]) and Tatra Mts. (Skrajna Turnia Mt. [ST]), one on the Early Paleozoic (ca. 500 Ma) Izera Granite (Siedlęcin [SI]).

Each of studied gruses shows significant variation in the LOI (loss of ignition) value, what can be connected with degree of alteration of parent granite. Changes in contents of major elements differ for each grus localization. ST grus shows significant changes of amount of major elements in relation to degree of alteration of rock (decreasing trends in SiO_2, Na_2O, and CaO, and increasing trends in Al_2O_3, K_2O, MgO and Fe_2O_3 contents versus LOI); SI grus shows increasing trend for Fe_2O_3 and MgO and decreasing trend for SiO_2 (vs. LOI); in KS grus increasing trends occur for Fe_2O_3 and MgO, and decreasing trends for Na_2O and CaO, whereas SiO_2, Al_2O_3 and K_2O content variation is non-systematic in relation to LOI. In GL grus the only slightly increasing content of Fe_2O_3 is visible (vs. LOI).

Using several indices of alteration [1, 2] we were able to notice differences in the paths of chemical alteration during grusification. Because the main alteration process during grusification is connected with decomposition of plagioclase, chemical alterations can be observed on plots based on changes of alkali and Al_2O_3 content (e.g. CIA and PIA; [1, 2]). CIA and PIA plots for ST are steeper, for SI more flattened, and for KS and GL trends are less uniform (vs. LOI). The WPI [3], which use all major elements, shows most uniform plots for each of the investigated gruses, but PI [3] shows trends only for Tatra and Izera granites, what indicate, that silica was immobile during grusification of Karkonosze granite.

The Alteration Box Plot [4] used for hydrothermal and diagenetic alteration of rocks reveals sericitization and chloritization trends in ST, KS and GL and carbonatization trend in SI.

Fluid-fluid phase separation under metamorphic conditions: MD simulations of a generalized composition H_2O-CO_2-NaCl

ANDREY G. KALINICHEV

Laboratoire SUBATECH, UMR 6457 / Ecole des Mines de Nantes / IN2P3-CNRS / Université de Nantes, 4 rue Alfred Kastler, BP 20722, 44307 Nantes Cedex 03, France (kalinich@subatech.in2p3.fr)

Water and carbon dioxide are two most abundant volatile species in the Earth's crust and mantle. They represent the common solvents which, under high-temperature, high-pressure thermodynamic conditions, dissolve various amounts of other volatiles to form complex hydrothermal and metamorphic fluids. Thus, aqueous mixtures in the system H_2O-CO_2-NaCl can be considered a good approximation for most crustal and mantle fluids. Although there are many experimental thermodynamic data for this generalized system, the molecular-level understanding of their thermodynamic, transport, and phase equilibria properties is still inadequate in many respects. We performed molecular dynamics (MD) computer simulations of the H_2O-CO_2-NaCl fluids along three high-density isochores (1.0, 1.1, and 1.2 g/cm3) to systematically study their thermodynamic, structural, and transport properties in the range of temperatures from 400 to 1000ºC and pressures from 3 to 18 kbar.

The composition of H_2O/CO_2/NaCl = 60/28/12 mol%) was chosen to probe both homogeneous and heterogeneous regions of the phase diagram. It has been predicted from experimental data [1-3] and model calculations [4-5] that such fluid would undergo phase separation at approximately 700ºC by forming a CO_2-rich phase of low-salinity (H_2O/CO_2/NaCl ~ 50/48/2 mol%) and a concentrated brine (H_2O/CO_2/NaCl ~ 66/20/14 mol%). We try to uncover the molecular-level mechanisms driving this heterogenization process and to rationalize the properties of decompressing H_2O-CO_2-NaCl fluids under metamorphic conditions in terms of the effects of temperature and density on the molecular clusterization and ion pairing in the system controlled by the electrostatic and hydrogen-bonding interactions among the fluid species.

Hydrogen bonding and molecular ordering of water at mineral-solution interfaces

ANDREY G. KALINICHEV[1]*, JIANWEI WANG[2] AND R. JAMES KIRKPATRICK[3]

[1]Laboratoire SUBATECH, UMR 6457 / Ecole des Mines de Nantes / IN2P3-CNRS / Université de Nantes, 4 rue Alfred Kastler, BP 20722, 44307 Nantes Cedex 03, France (*correspondence: kalinich@subatech.in2p3.fr)
[2]Department of Geological Sciences, University of Michigan, Ann Arbor, MI 48109, USA
[3]College of Natural Science, Michigan State University, East Lansing, MI 48824, USA

Aqueous interfaces play crucial roles in many geochemical systems, and the atomic scale details of the mineral substrate structure and composition are essential to understanding and predicting their chemical and physical properties. Here we compare the results of molecular dynamics (MD) simulations for the atomic density profiles, atomic surface density distributions, hydrogen bonding configurations, and orientational ordering of H_2O molecules at interfaces with several minerals, which may be considered typical for many hydrophobic and hydrophilic inorganic oxide and hydroxide surfaces [1, 2]. The atomic density profiles of water show substantial layering at all surfaces, with the details significantly different and strongly dependent on the composition and crystal structure of the mineral substrate. Relative to bulk water, the average density of water at the hydrophobic talc (001) surface is reduced by about 9-15% within 6-10 Å from the interface, which is equivalent to a 0.8Å-thick depletion layer compared to the similar but hydrophilic (001) surface of muscovite.

At the hydroxide surfaces, both cations and anions are effectively stabilized in their adsorbed state via the development of an integrated hydrogen-bonding network among the ions, H_2O molecules, and surface OH-groups, even if the substrate does not charged. For organic anions, such as amino acids, the deprotonated carboxylate groups are the primary strong H-bond acceptors, whereas the deprotonated amine groups serve as only weak additional H-bond acceptors from the surface. The organic species preferably accept H-bonds from H_2O molecules rather than from surface OH-groups due to structural restrictions on the development of tetrahedrally coordinated H-bonding environments for the carboxylate groups at the surface.

[4]MARUM, Leobener Str., 28359 Bremen, Germany (twesterhold@marum.de)

IODP Expeditions 320 and 321 (Paleocene-Eocene Age Transect, PEAT) recovered a continuous Cenozoic record of the equatorial Pacific by drilling at the paleopositions of the Equator at successive crustal ages on the Pacific plate. The drilled sites passed the high productivity area of the equatorial upwelling at different times.

Microbial cell abundance in several PEAT cores strongly deviates from the expected steady decrease with depth. We compared cell count profiles with several sedimentological, physical and geochemical parameters. Several of the observed excursions in cell abundance correlate with distinct sedimentological and geochemical horizons, which are ultimately caused by changes in paleoproductivity.

Colour changes in the sediment indicate changes in redox conditions from more oxidized to reducing, they also mark the time intervals during which the site was in the high productivity zone of the equatorial upwelling.
Also, distinct turning points in the cell count profiles correlate well with redox fronts, being indicated by peaks in dissolved porewater constituents like Fe^{2+} and Mn^{2+}.

The new PEAT data allow an insight into how past changes in productivity are influencing current patterns of microbial abundance and activity.

Revised ages of angrites

A. KALTENBACH[1]*, C.H. STIRLING[1] AND Y. AMELIN[2]

[1]Dept. of Chemistry, University of Otago, Dunedin, NZ (*correspondence: akaltenbach@chemistry.otago.ac.nz)
[2]RSES, The Australian National University, Canberra, Australia

Angrites are a small group of 18 differentiated achondrites and are among the oldest known rocks of our Solar System. These meteorites have low metamorphism and shock effects, are enriched in refractory elements and are well suited as anchors for short-lived nuclide chronology. Therefore it is crucial to accurately measure their ages according to the Pb-Pb chronometer, the only absolute geochronometer with sufficient precision to resolve age differences in the early Solar System processes.

To determine accurate ^{207}Pb-^{206}Pb ages, the isotopic ratio of ^{238}U/^{235}U must be known. This number was assumed to be invariant at 137.88 for several decades but recent studies [1, 2] have shown that variations occur not only in terrestrial rocks but also in meteorites. In this study, we analysed six bulk angrite samples: three quenched angrites and three plutonic angrites, for their uranium isotopic ratios using the double-spike MC-ICPMS procedure after [3]. The ratios are reported relative to the recently published value of 137.837 ± 0.015 (2σ) for the uranium isotopic standard CRM145 [4]. The ^{238}U/^{235}U ratios for the analysed angrites are uniform within error of each other, ranging from 137.763-137.802. Analytical errors are 0.018-0.049 (2σ), depending on the sample size. These data, combined with ^{206}Pb-^{207}Pb analysis by TIMS, are used to revise previously reported Pb-Pb ages to values with a higher accuracy, leading to a more reliable early Solar System chronometer.

The causes of variations in the ^{238}U/^{235}U ratios in meteorites are currently debated, including the possible decay of extant ^{247}Cm to ^{235}U. Th and Nd are used as present day proxies for the extinct Cm. Therefore, the correlation between Th/U or Nd/U and uranium isotopic ratios is used to find evidence for the decay of ^{247}Cm in the early stages of the Solar System [1, 2]. In addition to ^{238}U/^{235}U values, we analysed the rare earth element (REE) pattern and the U and Th concentrations of the samples to determine the environment in which the meteorites formed and the plausibility for Cm being present during angrite formation.

Mineralogy of atmospheric particles deposited on cypress leaves close to a nuclear plant

R. KALTENMEIER[1]*, R. GIERÉ[1] AND L. POURCELOT[2]

[1]Albert-Ludwigs-Universität, D-79104 Freiburg, Germany (*correspondence: giere@uni-freiburg.de)
[2]Institut de Radioprotection et de Sûreté Nucléaire, Cadarache, F-13115 St Paul lez Durance, France

Enhanced activity of actinides and some decay products has been reported for the leaves of cypress trees (*Chamaecyparis nootkatensis*) at the edge of the Malvési uranium-processing facility, SW France. The enhanced activity is due to the release of actinides via the smokestacks and artificial ponds inside the facility. This study was conducted to characterize the particulate matter deposited on the leaf surfaces from the atmosphere and to investigate whether or not radioactive particles may be identified.

Air-dried leaf samples were examined by scanning electron microscopy (SEM), in combination with energy-dispersive X-ray spectrometry (EDX). The samples were scanned systematically in both secondary and backscattered electron modes. EDX spectra were collected from particles and from areas devoid of particles (background spectra). These background spectra as well as the signals resulting from the C or Au coating were taken into account for the interpretation of the qualitative EDX spectra of the individual particles trapped on the leaf surface.

Particles ranging in size from <200 nm to ~40 μm were found on most portions of the adaxial leaf surface, but they are especially abundant at the boundary between facial and lateral leaves. We classified the particles chemically according to the most prominent peaks in the EDX spectra, yielding the following five principal classes: carbonates, silicates, sulfates, oxides/hydroxides, and halides. Approximately 80% of all analyzed particles could be attributed to these five classes. In addition, other types of particles were found, including Fe alloys; scheelite-group phases; phosphates; sulfides; and fly ash spheres.

Of special interest are U-rich particles, which were identified as U oxides, except for one particle, which was an U-oxide-fluoride. Clearly, these particles were released into the atmosphere by the nuclear facility prior to their deposition on the leaf surfaces. As most of the U-rich particles are ≤1 μm across, they are respirable.

Once inhaled, particles containing alpha-emitting isotopes represent a potentially long-term source of ionizing radiation inside the lungs and thus, pose a threat to the health of the people living nearby.

Petrogenetic implications of two contrasting granite types in the Çataldag Plutonic Complex, NW Turkey

O. KAMACI* AND S. ALTUNKAYNAK

Department of Geological Engineering, Istanbul Technical University, 34469, Maslak, Istanbul, Turkey (omer.kamaci@itu.edu.tr)

In late Oligocene and Early Miocene time, western Turkey was the site of extensive magmatic activity that produced voluminous plutonic associations. This magmatic activity was followed the continental collision between the Sakarya continent and Tauride-Anatolide carbonate platform along the Izmir-Ankara-Erzincan suture zone prior to middle Eocene. The Çataldag plutonic complex (CPC), one of the biggest plutonic associations, is a composite intrusive body consisting of both I- and S type granitic intrusions of similar age. $^{39}Ar/^{40}Ar$ dating obtained from CPC yields ages between 20 and 22 Ma as their cooling ages. These two intrusive groups display different textural, structural and also geochemical features. S-type, peraluminous granitic intrusion in CPC is represented by synkinematic, sheet like bodies situated in the eastern border of the plutonic complex. It includes leucocratic two-mica granites and milonitic granites which show petrographical features indicating ductile shear zone deformation. They are composed of quartz, feldspar with minor biotite, muscovite, epidote and garnet. Combined petrographical and geochemical features of this group reveal crustal origin for their genesis. I type granitic intrusion is made up of granite and granodiorite-quartz diorite showing gradational contact to each other. This group is late kinematic weakly deformed intrusion and displays hipidiomophic granular and porphyric textures. Geochemically, it has medium to high-K calc-alkaline and metaluminous compositions. Major and trace element compositions, and Sr-Nd-Pb isotope data indicate collectively that the I type granitic group of CPC has been originated from hybrid magma (s) including mantle and crustal components. Geochronological and petrological findings combined with bimodal character of CPC suggest that CPC is synextensional and therefore there was a close spatial and temporal relations between magmatism and extensional tectonics during the late Cenozoic geodynamic evolution of Turkey.

A combined U/Pb and Hf-isotope study of up to 4.0 Ga detrital zircon from the Wyoming Province

BALZ S. KAMBER, MARTIN J. WHITEHOUSE AND JON D. WOODHEAD[1,2,3]

[1]Laurentian University, Sudbury, Ontario, Canada
[2]Swedish Museum of Natural History, Stockholm, Sweden
[3]School of Earth Sciences, Melbourne, Australia

An extensive dataset (n=750) of new zircon U-Pb dates is presented for two quartz-rich metasediments from the eastern Beartooth Mountains, northern Wyoming craton, Montana. Both rocks yielded detrital zircon dates with comparable age populations, ranging from just under 4.0 Ga to the likely deposition age of ca. 3.0 Ga. Among the Meso-, Paleo-, and Eoarchean zircon there are age groupings. The most prominent population occurs between 3200 and 3325 Ma, followed by less abundant groupings at 3500, 3625, 3725, 3850 and 3950 Ma. A representative selection of grains (n=50) were subsequently analysed for Hf-isotopes by *in situ* MC-ICP-MS. Of these, 44 grains define a clear linear array in a Hf-isotope evolution diagram. The oldest zircon have chondritic initial Hf-isotope composition, with all younger grains defining a clear trend towards less radiogenic compositions. At 3.25 Ga, this trend averages -12 E_{Hf}.

Whereas no rocks of Eoarchean age have yet been found in the Wyoming craton, Pb-isotope signatures of 2.8 Ga ganodiorites have long been known to require involvement of an ancient high U/Pb silicate source. This could have been subduction zone modified mantle or a cratonic substrate. We discovered inherited Mesoarchean zircon in the 2.8 Ga granodiorites and heterogenous Hf-isotopes in zircon from one granodiorite, collectively favoring the *in situ* existence of a cratonic nucleus from the Hadean/Archean boundary but with no isotopic evidence for involvement of even older crust.

In agreement with most other Eoarchean and Hadean detrital zircon occurrences, it appears that the oldest zircon-bearing lithologies of the Wyoming craton became part of the erosional cycle only after a very extensive (ca. 1 Ga) period of residence in the crust. The internal structures of the oldest studied zircon grains reveal repeated reworking, testifying to a long and complex thermal history of the crust. This is consistent with a model of an originally quite zircon-poor mafic crust, whose internal heat, generated by radioactive decay, led to episodic remelting and reworking into a more evolved upper crust in which zircon became more abundant and a more refractory, depleted lower crust.

Volatiles in the kimberlite melt – What drives ascent and causes explosive eruption?

V.S. KAMENETSKY

School of Earth Sciences and CODES, University of Tasmania, Australia (Dima.Kamenetsky@utas.edu.au)

Existing reconstructions of the kimberlite melt emphasise carbonate-bearing ultramafic compositions with significant amounts of dissolved volatiles CO_2 and H_2O (10-20 wt%). These volatiles are considered to be a major factor in reducing viscosity of the kimberlite melt, governing fast ascent from mantle depths. The exsolution of these volatiles from the melt during ascent and emplacement is viewed as being responsible for violent eruption of the magma and related brecciation of country rocks and the kimberlite itself. Magmatic volatiles and groundwaters have an unequivocal role in present models of kimberlite emplacement (fluidisation and phreatomagmatism, respectively).

Studies of the diamondiferous Udachnaya-East pipe (Siberia) kimberlites [1-3] show that neither of major magmatic volatiles in the form of degassing fluids was responsible for well-known 'explosivity' of kimberlites. Exceptionally fresh kimberlites from the Udachnaya-East pipe have low H_2O (<0.5 wt%), but high CO_2 (up to 14 wt%), Cl and alkalis. The carbonatite-chloride composition of the Udachnaya-East kimberlite [1, 2] and similar compositions in olivine-hosted melt inclusions in other kimberlites worldwide [4] strongly support the previously assumed low viscosity and density of kimberlite magmas. Massive degassing of H_2O and CO_2 is unlikely in the case of the Udachnaya-East kimberlite, because the melt is poor in H_2O, whereas CO_2 is bonded in the carbonatitic melt. After crystallisation of olivine the kimberlite melt evolves towards essentially dry carbonate-chloride compositions [3]. The gravitational separation of silicate solids within the kimberlite pipes drives light, low viscosity carbonate-chloride melt to the top. The hydrogen species, such as H_2 and CH_4, some of magmatic origin, but mostly produced by post-magmatic serpentinisation of olivine in the kimberlite, are the main cause of explosions. Detonation of these gases at near-surface levels of the pipe can result in brecciation and even evacuation of already solid kimberlite and country rocks.

Real composition of the Earth's lower mantle

FELIX V. KAMINSKY

KM Diamond Exploration Ltd., 2446 Shadbolt Lane, West Vancouver, BC, V7S 3J1 Canada (felixvkaminsky@cs.com)

Real composition of the Earth's lower mantle is based on a study of mineral inclusions in lower-mantle diamond from Brazil, Guinea, Canada and Australia. Three associations were established among them: juvenile ultramafic, analogues to eclogitic, and carbonatitic. The juvenile ultramafic association strongly predominates; it is composed of ferropericlase, MgSi-, CaSi- and CaTi-perovskites, stishovite, tetragonal almandine-pyrope phase (*TAPP*), and some others. The mineralogical composition of the lower mantle is now understood to be more complex than had been suggested in theoretic and experimental works. The frequencies of the lower mantle minerals for all areas are similar to each other, deviating from the average by only 10-15 %.

These figures differ drastically from the composition of the lower mantle as suggested from experimental data. In that the most common mineral is ferropericlase, which comprises 48.0-63.3 % (average 55.4 %) of all minerals in the lower mantle. This is in contrast to an abundance of ~ 18 % as suggested by experimental data, i.e. approximately three times higher. In contrast to ferropericlase, MgSi-perovskite comprises, in all studied regions, only 5.0-10.2 % (average 7.5 %), i.e. approximately ten times lower than has been suggested as an average composition in the lower mantle (~ 77 %); and its composition is more iron-rich (mg = 0.36-0.90) as compared to experimental and theoretical data. CaSi-perovskite, according to geological data, is more than twice as common compared to experimental data (10.0-14.3 % with an average of 12.0 % against ~ 5 %). The most important feature of the real composition of the lower mantle is a permanent presence, in all regions and areas, of free silica (as stishovite), in the lower mantle. Stishovite frequency, among the lower mantle minerals, is 2.1-15.0 % (average 8.4 %). The other minerals (CaTi-perovskite, *TAPP*, a phase with the composition of that of olivine, spinel, ilmenites, titanite, native nickel and iron, magnetite, and sulphides), have frequencies 0.1-4.3 % each. These discrepancies suggest that the composition of the lower mantle differs to that of the upper-mantle, and experiments based solely on 'pyrolitic' compositions are not, therefore, applicable to the lower mantle. These data indicate a probability of an alternative to the CI-chondrite model of the Earth's formation, for example, an enstatite-chondrite model.

Short-term CO_2-fluid-mineral interactions in a CO_2 injection experiment, Wyoming

N. KAMPMAN[1]*, M.J. BICKLE[1], A. GALY[1], H.J. CHAPMAN[1], Z. ZHOU[2], B. DUBACQ[1], M. WIGLEY[1], O. WARR[2], T. SIRIKITPUTTISAK[2] AND C.J. BALLENTINE[2]

[1]Dept. Earth Sciences, Downing Street, Cambridge CB2 3EQ, UK (*correspondence: nkam06@esc.cam.ac.uk)
[2]University of Manchester, M13 9PL, UK

During geological CO_2 storage short-term geochemical processes will be dominated by dissolution of CO_2 into the formation fluid and by the reaction of this acidic fluid with soluble minerals (e.g. carbonate, oxide, sulphide and organics) in the reservoir. Modelling the progress of the fluid-mineral reactions is frustrated by uncertainties in the absolute mineral surface reaction rates [1] and the significance, in natural systems, of CO_2 dissolution and transport in formation fluid as an overall rate limiting step.

We present preliminary results of water chemistry from an artificial noble gas tracer study in a commercial CO_2-EOR reservoir located in Wyoming, USA. In this study a noble gas spike (^{3}He & ^{129}X) was introduced to a single CO_2 injection well [2], and fluids and gases collected from the surrounding four-point production well pattern, from September 2010 to February 2011. Preliminary results from fluid chemistry measured over this period reflect: (1) mobilization and mixing of formation water, driven by the injection of CO_2; (2) the arrival of co-injected water and CO_2 at the production wells and; (3) dissolution of the CO_2 and subsequent reaction of this acidified fluid with soluble minerals in the reservoir. The spatial changes in fluid chemistry are consistent with the reservoir geology; the updip producers are dominated by processes related to the early arrival of the CO_2 front whereas changes in downdip fluid chemistry are dominated by the arrival of dense saline fluid from the injection well. Sigmoidal fronts in fluid chemistry are observed in the updip production wells, and correlate with changes in fluid temperature, a measure of CO_2 breakthrough. Elevated concentrations of divalent cations (Ca^{2+}, Mg^{2+}, Sr^{2+}, Fe^{2+} and Mn^{2+}), in excess of the original pore fluid and injected water, are thought to represent dissolution of carbonate minerals in the reservoir which drives neutralization of fluid acidity and progressively increasing fluid alkalinity.

[5]School of Civil Engineering and Geosciences, Newcastle University, Drummond Building, Newcastle upon Tyne, NE1 7RU, England, UK

Sub-millimolar concentrations of sulfate likely prevailed in the Archean Ocean. We studied the concentrations and quadruple isotope fractionation of sulfur species in the warm, monomictic Lake Kinneret (Tiberias), which has sulfate concentrations of <600 μM. The highest concentrations of zero-valent sulfur (ZVS), thiosulfate and sulfite occurred in the redox-transition zone (RTZ, c. a. 28 m depth), and were 5.0 μM, 1.35 μM and 0.76 μM, respectively.

In the vicinity of the RTZ, the δ^{34}S fractionations between sulfide and sulfate are small (-17 – -21‰), with large positive Δ^{33}S values (0.067 – 0.086 ‰), and can be attributed to sulfate reduction. ZVS is 0.1 – 4.7‰ more enriched in ^{34}S than sulfide, consistent with equilibrium isotope effects between sulfide – polysulfide – rhombic sulfur and fractionation via phototrophic sulfide oxidation.

In the deeper waters, δ^{34}S fractionations between sulfide and sulfate are larger (-37 – -44‰), with smaller differences in Δ^{33}S (0.009 – 0.073‰). Sulfur isotope values near the bottom of the lake can be explained by a combination of sulfate reduction and sulfur compounds disproportionation. High sulfur isotope fractionation is supported in this system even at very low sulfate concentrations by both the absence of sulfide scavenging by dissolved Fe (II) and the presence of the RTZ, where sulfide oxidation supplies zero-valent sulfur to deeper sulfidic waters.

Mineralogical and geochemical studies of the metasomatic rocks within Gachin, Kalat, Pohl and Hormuz Island salt plugs, Iran

A. KANANIAN[1], S. TAGHIPOUR[1], R. NEMATI[1] AND M.A. MACKIZADEH[2]

[1]School of Geology, College of science, University of Tehran, Tehran, Iran (kananian@khayam.ut.ac.ir)
[2]Mineralogy Department, College of Science, University of Isfahan, Isfahan, Iran (ma_mackizadeh@yahoo.com)

The Gachin, Kalat, Pohl and Hormuz Island salt domes are located in the Bandar Abbas province. They are a part of the Hormuz formation which situated in the Iran-Pakistan salt basin. The studied area centered at 25 ° 24´-27 ° 08´ N and 53 ° 55´-59 ° 15´ E at the geology map of the area [4]. The studied area is composed of some Infracambrian–Cambrian igneous and evaporites rocks. The igneous rocks composed of mafic to felsic composition and involve basalt, andesite, rhyolite, rhyolitic tuff and some hypabyssal bodies and occur in the within plate continental rift. On the basis of petrographic studies mineral assemblage has formed in magmatic (I) and metasomatic (II) stages. Clinopyroxene, amphibole, biotite, plagioclase, feldspar and quartz is the main magmatic minerals. Tremolite-actinolite, garnet, albite, epidote, sphen have occur in the metasomatic stage. According to the EPM analysis the chemical composition of the pyroxene is salite-frrosalite to augite. The composition of garnet is andradite-grossular ($An_{29.21}$ $Gros_{70.78}$), feldspar is albite ($An_{4.03}$-$Ab_{95.36}$-$Or_{0.60}$), epidote is pistachit. Clinopyroxene thermo-barometers range from 1060≤ T≤1290 °C and 1 ≤ P≤10 kbar [5], also chlorite [3] and plagioclase [2] geothermometer yielded a temperature of 330 °C and 500 °C for them respectively. Fluid inclusion studies have documented vapor bubbles, fluid and solid (cube halite) inclusions in the hydrothermal vein quarts. The salinity of the studied samples is 35-45 wt % NaCl and the homogenization temperature range 205 °C-320 °C. Fluid inclusion data on the salinity-temperature diagram [1] have plotted on the mixing magmatic-meteoric field. On the basis of field, petrography, mineral chemistry, thermo-barometery and fluid inclusion data we could proposed following conclusions:

At first stage, magmatic and evaporate rocks have formed in the within plate continental crust in the striking an aborted rift. At latter stage, meteoric water entering igneous-evaporite assemblage and a hydrothermal system has created so Na, Ca, Fe metasomatism occurred in the system and metasomatic minerals have formed.

Carbon cycling in the Pliocene Velenje Coal Basin, Slovenia, inferred from stable carbon isotopes

T. KANDUČ[1,], S. ŽIGON[1], M. MARKIČ[2], S. ZAVŠEK[3] AND J. MCINTOSH[4]

[1]Jožef Stefan Institute, Jamova 39, 1000 Ljubljana, Slovenia (*correspondence: tjasa.kanduc@ijs.si)

[3]Velenje Coal Mine, Partizanska 78, 3320 Velenje, Slovenia
[4]University of Arizona, Department of Hydrology and Water Resources, 1133 E. James E., Rogers Way, Tucson, Arizona

Introduction

In this study, stable isotopes of carbon were used to trace organic and inorganic carbon cycles and biogeochemical processes, especially methanogenesis within different geological media of the Pliocene lignite-bearing Velenje Basin in northern Slovenia. The study is based on investigations of carbon isotopic composition of the following geological media: 1) lithotypes of lignite, 2) coalbed gasses, 3) calcified woods and carbonate-rich sediments, and 4) groundwaters in various aquifers.

Discussion of Results

For different lignite lithotypes it was found that $\delta^{13}C$ values ranged from -28.1 to -23.0‰, the variability is being a consequence of original isotopic heterogeneity of the source plant ingredients and of biogeochemical processes (gelification, fusinitization, mineralization of organic matter). In the lignite seam the major gas components were found to be CO_2 and CH_4 with small amounts of N_2. The carbon isotope compositions of carbon in CO_2 ($\delta^{13}C_{CO2}$) and CH_4 ($\delta^{13}C_{CH4}$) were very variable and ranged from -9.7 to 0.6‰ and from -70.5 to -34.2‰, respectively. The presence of thermogenic gases is unlikely due to the low rank of the coal and lack of higher chain hydrocarbons. Calcified xylite enriched with ^{13}C ($\delta^{13}C$ values up to 17.1‰) indicated that CO_2 reduction process was present at the time of formation of the basin. The $\delta^{13}C_{DIC}$ values (from -17.4 to -3.2‰) of groundwaters recharging the basin from the Triassic aquifer were consistent with degradation of organic matter and dissolution of dolomite. Groundwaters from the Pliocene sandy and Lithotamnium carbonate aquifers had $\delta^{13}C_{DIC}$ values (from -9.1 to 0.2‰) suggestive of degradation of organic matter and biogenic CO_2 reduction.

Physical and chemical state of Fe-phases in Chinese aeolian dust

MAKOTO KANEKO[1], YUKI NAKAMATSU[1], ZHOUQING XIE[2] AND SATOSHI UTSUNOMIYA[1]*

[1]Department of Chemistry, Kyushu University, Fukuoka 812-8581, Japan (utu@chem.rc.kyushu-u.ac.jp)
[2]University of Science and Technology of China

Iron supplied by aeolian dust is a factor controlling the biomass of phytoplankton in high nutrient low chlorophyll (HNLC) regions, and dissolved Fe-stimulated biogeochemical activity can consume a large amount of CO_2 in atmosphere, which may have a significant impact on the global C-cycle. In order to understand the physical and chemical state of Fe in the asian dusts, aerosol samples collected in Fukuoka, Japan and Hefei, China in March 2010 have been investigated in detail from nano to bulk scale. The analytical techniques include an inductively coupled plasma mass spectrometry (ICP-MS), X-ray diffraction (XRD), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). A sequential extraction of the Fe-phase was also perfomed based on the previous method [1].

The Fe concentrations in the Hefei and Fukuoka samples during the dust event are 11.8 and 4.31 times higher than that in the Fukuoka sample in the non-dust period. The fraction of Fe-phase (in wt.% = mass of Fe in each Fe-phase/total mass of Fe) in the Fukuoka dust samples determined by the sequential extraction is Fe-bearing sheet silicate (59-61 %), hematite and goethite (23-28 %), ferrihydirte (7.5-12 %), magnetite (3.0-4.3 %). The XRD pattern indicates that illite and chlorite are the major Fe-bearing minerals in all samples. TEM observation reveals that aggregates of nano-sized ferrihydrite are present on the surface of illite.

Based on the the solubilities of clays (4 %) and Fe oxides (<1 %) reported in the previous study [2] combined with our data, it is suggested that the clay minerals in the Chinese dust contribute predominantly to the Fe flux to the HNLC, which can potentially supply >6 times greater amount of Fe than that from Fe oxides [2]. It should be also noted that the ~10 % of Fe present as ferrihydrite may be an important contribution because it is readily consumed by some photosynthetic algae species [3]. Still, quantitative investigation of highly bioavailable and soluble minerals in dust materials such as demonstrated in the present study should be essential to the appropriate evaluation of the impact of atmospheric Fe input into HNLC region.

Uniqueness of kimberlite magma: Its source characteristics and transportaion systems revealed by isotope signatures

ICHIRO KANEOKA

Earthquake Research Institute, University of Tokyo, Tokyo 113-0032, Japan (ikaneoka@aol.com)

Since kimberlite magma carries diamonds as xenoliths, it has been regarded to be formed at a depth of at least more than 150km and extruded to the surface within a few hours from the bottom of continental lithosphere. Based on Sr-Nd isotope systematics, kimberlites are classified into Group I and Group II [1]. Among them, Group I kimberlites show especially significant isotope signatures, which would reflect quite unique source characteristics and transportaion systems.

In the Sr-Nd and Nd-Hf isotope diagrams expressed as delta values, Group I kimberlites from different sites cluster close to the Bulk Earth values [2], while chondrite-normalized REE patterns show highly fractionated trend with L-REE enrichment. This implies that such high L-REE enrichment in a kimberlite magma should have occurred in the latest stage of magma transportaion system before eruption. To explain such high enrichment of L-REE, very small amount of partial melting of less than 1% is required. On the other hand, cluster of isotope signatures in Sr-Nd and Nd-Hf diagrams needs homogenization of magma source materials. Those isotope values mentioned above are often regarded to be a result of mixture between depleted (asthenosphere) and enriched (lithosphere) components. However, it seems quite difficult to attribute the cluster of isotope values of kimberlites with different sites and times to the process of small degree of partial melting. Our findings of high $^3He/^4He$ for Greenland kimberlites [3] and Ne isotope systematics for Russian kimberlites [4] definitely suggest that kimberlite (Group I) magma source materials have similar isotope sigantures with those of OIBs and would possibly be located in the lower mantle. Although He and Ne isotopes show a sign of interaction with lithospheric components before eruption, it would be only effective for He and Ne due to their higher diffusivity compared to that of solid elements. Hence, the cluster of Sr, Nd, Hf isotopes of kimberlites (Group I)would reflect the chratacteristics of source materials of magma in the less fractionated deep mantle.

Seasonal distribution and effects of herbicides on coral reefs around Okinawa, Japan

A. KANESHIRO[1], H. FUJIMURA[1]*, T. OOMORI[1], S. GIMA[1], T. HIGUCHI[2], B.E. CASARETO[2], Y. SUZUKI[2] AND T. SAGAWA[3]

[1]Univ. of the Ryukyus, 1 Senbaru, Nishihara, Okinawa 903-0213, Japan (*correspondence: fujimura@sci.u-ryukyu.ac.jp)
[2]Shizuoka Univ., 836 Ohya, Suruga-ku, Shizuoka-shi, Shizuoka 422-8529, Japan
[3]WWF Coral Reef Conservation and Research Centre, 118 Shiraho, Ishigaki, Okinawa 907-0242, Japan

Introduction

It is apprehensive about future degradation of coral reef caused by artificial chemicals such as herbicide and pesticides. Diuron [N'-(3, 4-dichlorophenyl)-N, N-dimethylurea] is one of the active substance contained in a herbicide. The used amount of diuron in Okinawa is the second highest in Japan [1]. Moreover, diuron has been using recently for antifoulant of ships as a replacement for organotin compounds. We investigated seasonal variation of herbicide contained in water and sediment around coral reef area in Ishigaki Island in Okinawa Japan, and carried out experiments to see the effect of the herbicide on coral metabolisms of photosynthesis and calcification.

Materials and Methods

Samples from twelve stations in the Shiraho lagoon and five in the Todoroki river were taken seasonally from August 2010 to May 2011. Diuron and other active substances were extracted using a solid-phase column and measured with a liquid chromatography with tandem mass spectrometry (LC–MS/MS).

Results and Discussion

Higher diuron of 222 ng/L was detected at the headwater of the Todoroki river in August. It decreased to 85 ng/L toward the river mouth. However, diuron in seawater and sediments at lagoon were significantly low level compared to the river. Because herbicide is mainly used in July to September in Okinawa and ground water from the catchment area flows geometrically to the headwater, the highest concentration was detected during summer season. The concentration in the lagoon has not reached to the level at which metabolic activity of coral colony is degraded.

Coral records of ocean acidification and physiological processes in the southern Great Barrier Reef

J.O. KANG[1,3]*, M.T. MCCULLOCH[2,3], S.M. EGGINS[1], M.K. GAGAN[1] AND G.E. MORTIMER[1]

[1]Research School of Earth Sciences, Australian National University, Canberra, ACT 0200, Australia (*correspondence: jung.kang@anu.edu.au)
[2]School of Earth and Environment, University of Western Australia, Crawley, WA 6009, Perth, Australia
[3]ARC Centre of Excellence in Coral Reef studies, Australia

Ocean acidification, the process of declining seawater pH due to increased uptake of CO_2 from anthropogenic emissions, is likely to have severe impacts on marine calcifiers and related ecosystems. However, long-term records of ocean acidification from marine biota have rarely been evaluated. Here, we present high-resolution records of boron isotopic compositions ($\delta^{11}B$) as a paleo-pH proxy and calcification rates from two *Porites* corals (over 150 year old) from the southern limits of the Great Barrier Reef, Australia.

Carbon isotopes ($\delta^{13}C$) and trace element ratios (Mg/Ca and Sr/Ca) were also determined. The results from coral boron isotopic systematics show the obvious impact of enhanced uptake of anthropogenic CO_2 on the ocean chemistry, resulting in a trend of decreasing seawater pH (-0.0016 ± 0.0002 pH unit yr^{-1}) and decreasing $\delta^{13}C$ compositions (-0.015 ± 0.002 ‰ yr^{-1} since 1960) due to fossil fuel burning (Suess effect). Ocean warming is also observed in the coral skeleton Sr/Ca record with slightly increased measured annual calcification from both corals during the observed period. This indicates that warming of the surface oceans may be countering the effect of decrease in carbonate ion concentration on coral calcification rates. Evidence of kinetic effects during coral calcification was also found in the long-term record; strong negative and positive correlation of coral growth with detrended $\delta^{13}C$ and Mg/Ca. This suggests that CO_2 hydroxylation is a dominant reaction in high calcifying conditions resulting in depleted $\delta^{13}C$. Also higher rate of coral growth could generate the kinetic effect on Mg partitioning and lead to greater incorporation into the aragonite skeleton of corals.

Validation of saltation flux parameterization with observation

J.-Y. KANG[1]*, M. MIKAMI[1], Y. SHAO[2], S.-C. YOON[3], T.Y. TANAKA[1] AND T.T. SEKIYAMA[1]

[1]Meteorological Research Institute, Tsukuba, Ibaraki, 305-0052, JAPAN (*correspondence: jykang@mri-jma.go.jp)
[2]University of Cologne, Cologne, D-50923, GERMANY (yshao@meteo.uni-koeln.de)
[3]Seoul National University, Seoul, 151-747, KOREA (yoon@snu.ac.kr)

Introduction

The estimation of natural dust emission amount is important to understand the effects of dust on climate. Many dust emission parameterizations have been developed and it is required to investigate emission parameterizations and validate them with observation data.

Results and Discussion

In this study, the saltation flux formulation given by White [1] is used and it is as follows:

$$Q=C\times\rho_a/g\times u_*^3\times(1-u_{*t}/u_*)\times(1+(u_{*t}/u_*)^2)$$

where C is coefficient, ρ_a and g are air density and gravity, respectively, and u_* is friction velocity, u_{*t} is threshold friction velocity. The White equation [1] is compared with observation data collected during the Japanese Australian Dust Experiment (JADE) [2]. The coefficient C is obtained by the iterative method to make the difference between observed and calculated fluxes minimize. Figure 1 shows the comparison of calculated flux using new linear coefficient with observation data. The result indicates that the saltation flux equation has a good ability to predict sand flux with tuning the linear coefficient only.

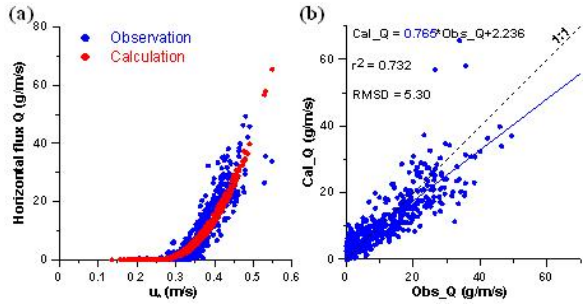

Figure 1: (a) Observed and calculated Q with friction velocity, (b)Scatter plot of observed Q versus calculated Q.

[1] White (1979) *J. Geophys. Res* **84**, 4643–4651. [2] Ishizuka *et al.* (2008) *J. Geophys. Res* **113**, D24212.

Geochronology and geochemistry of Hongqilapu granite in eastern Pamirs, China

LEI KANG, PEI-XI XIAO, XIAO-FENG GAO, REN-GANG XI, ZENG-CAN DONG AND LEI GUO

Xi'an Center of Geological Survey (Xi'an Institute of Geology and Mineral Resource), CGS, Xi'an, Shaanxi 710054, China (kang844@163.com)

Hongqilapu granite is distributed in the boundary of China and Pakistan, composed o f granodiorite and quartz dioite which developing dioritic enclave. The granite belongs to the sub-aluminum to peraluminous and calc-alkali series, and is characterized by rich in Al, Fe, Ca, and LILEs (Rb, Ba, Th), poor in Hf, Zr, Y, Yb. In particular, partial rock have the geochemistry character of adakite, such as SiO_2= $60.41\times10^2\sim72.02\times10^2$, $A1_2O_3$=$15.53\times10^2\sim16.13\times10^2$, MgO=0.66 $\times10^{-2}\sim2.56\times10^6$, Y=$9.61\times10^6\sim18\times10^6$, Yb=$0.8\times10^6\sim1.44\times10^6$, Sr=$393\times10^6\sim560\times10^-$, riching LREE, HFSEs' (Ti, Nb, Ta)content is as much as, Eu have negative anomaly faintly. In addition, these rocks' $K_2O/Na_2O>1$ and Sr-Y×10-Zr diagram show that them belong to C-form adakite with high kalium, proving that Hongqilapu granite is the production of thickened lower crust partial melting. LA-ICP-MS zircon U-Pb dating of the granite indicate that the weighted mean $^{206}Pb/^{238}U$ age are 107.20±0.76Ma (n=29, MSWD=1.09), which belongs to Early Cretaceous Epoch. In conclusion, these information show Bangonghu-Nujiang ocean basin of Neotethys had closed earlier than lower cretaceous, which provide a new valuable information on the time limit of colliding between Gangdise block and Qiangtang massif.

The Paleozoic minimum in $^{87}Sr/^{86}Sr$ ratio in the Capitanian (Middle Permian): Records from the mid-Panthalassa paleo-atoll limestones

T. KANI[1]*, D. KOFUKUDA[2] AND Y. ISOZAKI[2]

[1]Dept. of Earth Sci., Kumamoto Univ., Kumamoto, 860-8555, Japan (*correspondence: kani@sci.kumamoto-u.ac.jp)
[2]The University of Tokyo, Meguro, Tokyo 153-8902, Japan

We report a detailed secular change of the Middle-Late Permian seawater $^{87}Sr/^{86}Sr$ ratio with the unique 'Permian minimum' interval detected in mid-Panthalassa (superocean) paleo-atoll carbonates. The analyzed limestones at Kamura and Akasaka sections in Japan occur as exotic blocks within the Jurassic accretionary complex. On the basis of fusuline biostratigraphy, both sections span across the Middle-Upper Permian or the Guadalupian-Lopingian (G-L) boundary characterized by a major biotic crisis. Two sections are separated from each other for 500 km at present, thus were likely derived from different paleo-seamounts existed in mid-Panthalassa.

A 30 m-thick interval with low $^{87}Sr/^{86}Sr$ value (< 0.7070) was detected in the Capitanian (Upper Guadalupian) interval, i.e. the *Yabeina* (fusuline) Zone, *Lepidolina* Zone, and the barren interval in the Kamura section. Data from Akasaka section comfirm that extremely low $^{87}Sr/^{86}Sr$ values (0.70688) similarly characterize the *Yabeina* Zone and the barren interval. A remarkable rise in $^{87}Sr/^{86}Sr$ values for 0.00073 up to 0.70761 occurred in the barren interval after the 'Permian minimum' in both sections, suggesting a general isotopic trend in the superocean. This increase in Sr isotope after the 'Permian minimum' likely suggests that a huge amount of highly radiogenic terrigenous clastics have been shed into Panthalassa by connecting intra-Pangean drainage systems directly to the superocean. The development of the new drainage systems might be related to large-scale continental rifting, thus the initial breakup of Pangea. It is noteworthy that carbonate stable carbon isotope ratio ($\delta^{13}C_{carb}$) also shifted dramatically in the latest Capitanian barren interval immediately before the G-LB.

Fe(II) oxidation under very low O_2 conditions: New rate law and its implication

YOSHIKI KANZAKI* AND TAKASHI MURAKAMI

Department of Earth and Planetary Science, the University of Tokyo, Tokyo 113-0033, Japan
(*correspondence: kanzaki@eps.s.u-tokyo.ac.jp)

Many geological proxies point the great rise of atmospheric oxygen in the Paleoproterozoic (Great Oxidation Event). The proxies including mass independent fractionation in sulfur isotopes reveal that atmospheric oxygen increased from very low concentration (< ~10^{-6} atm of pO_2) to low concentration (> ~10^{-3} atm of pO_2) between 2.5 and 2.0 Ga. However, many of the proxies are useful for deciphering the timing of the transition in pO_2 levels rather than its quantitative pattern. On the other hand, paleosols formed during the Paleoproterozoic have recorded the ratios of Fe (III)/Fe (II) at the time of their formation and these kinetical data can give more quantitative estimates of pO_2. To quantitatively estimate pO_2 through the ratios of Fe (III)/Fe (II), the rate law of Fe (II) oxidation should be understood.

Experimental data of Fe (II) oxidation have been obtained under the conditions of $pO_2 = 10^{-3}$ - 10^{-5} atm and pH = 7.57 - 8.12. Combined with previous oxidation data at $pO_2 > 10^{-3}$ atm, newly discovered is that the rate law changes its form from $d[Fe(II)]/dt = -k[Fe(II)][OH^-]^2[O_2]$ at $pO_2 > \sim 5 \times 10^{-3}$ atm to $d[Fe(II)]/dt = -k'[Fe(II)][OH^-]^2[O_2]^{0.55}$ under the conditions of $pO_2 = 5 \times 10^{-3}$ - 10^{-5} atm.

In interpretation of this new rate law, especially the change in the power of $[O_2]$ from 1 to 0.55, we suggest that under the very low O_2 conditions intermediate oxygen species (superoxide, hydrogen peroxide and hydroxyl radical) attack Fe (II) more effectively, which results in faster Fe (II) oxidation rate than previously considered. Out of possible reactions that produce oxygen species from oxygen, the reaction,

$$O_2 + (18/11)H_2O = (16/11)H_2O_2 + (4/11)HO_2$$

gives the power of $[O_2]$ of 0.55. Combination of this reaction and those proposed by Haber and Weiss reproduces the experimental results well under the conditions of 10^{-5} - 0.2 atm of pO_2.

The new rate law was applied to the ratios of Fe (III)/Fe (II) of paleosols formed during the Paleoproterozoic, revealing that atmospheric oxygen increased gradually, linearly on the logarithmic scale, from < ~ 10^{-6} to > ~ 10^{-3} atm of pO_2 between 2.5 and 2.0 Ga.

Primary structures, petrography and geochemistry of Deccan flood basalts at Anantagiri Hills, Andhra Pradesh, India

ARCHANA B. KAOTEKWAR* AND S.N. CHARAN

National Geophysical Research Institute (CSIR) Hyderabad-500007, India
(*correspondence: archana.ngri@gmail.com)

The Cretaceous age Deccan flood basalts of Anantagiri Hills in south India represented by six lava flows show formation of columnar joints as the most conspicuous feature in each basalt flow unit. These flow units, exhibiting columnar structures, enable division into three well defined zones namely: Lower Colonnade Zone (LCZ); Middle Entablature Zone (MEZ) and Upper Colonnade Zone (UCZ). The columns in UCZ are five sided; MEZ separating the UCZ and the LCZ displays four sided intersecting, fanning and fragmented columns while the underlying LEZ has four to five sided vertical columns. These basalts show a mild affinity towards basaltic andesite on the TAS (Na_2O+K_2O vs. SiO_2) diagram, while in the Al-Fe+Ti-Mg ternary plot these basalts plot in the iron rich tholeiitic field. The major and trace element signatures of these tholeiitic basalts are similar to that of the Ambenali Formation basalts, suggesting possible extension of this Formation in SE Deccan Volcanic Province. REE plots define a nearly flat pattern with mild LREE enrichment and negative Eu anomaly. Primitive mantle normalized multielement patterns show mild LREE, LILE troughs positive Ba, Nb and Pb peaks and negative K, Sr and P anomalies in similarity with plume type CFB'S. The well developed sequence of colonnade structures in the different basalt flow units in Anantagiri Hills appear to have formed due to conductive cooling initiated both from the top and bottom portions of these flows. Geochemical signatures shown by these tholeiitic basalt flows suggest that the precursor was probably generated by low degree partial melting of an enriched mantle source.

Ectomycorrhizal fungi and silicate mineral weathering: Characterising nanoscale interactions using AFM

D. KAPITULČINOVÁ*, R.C.T. HOWE, S. JACKSON, S.A. GAZZE AND TERENCE J. MCMASTER

H.H. Wills Physics Laboratory, University of Bristol, Bristol, BS8 1TL (*correspondence: glxdk@bristol.ac.uk)

Ectomycorrhizal (ECM) fungi substantially affect mineral weathering [1, 2]. In order to understand the nanoscale processes occurring at the fungi-mineral interface, we have used Atomic Force Microscopy (AFM) to investigate the interactions of three *Suillus* ECM fungi, *S. bovinus*, *S. luteus* and *S. variegatus*, with sheet silicate minerals.

After 2-3 months of incubation under controlled laboratory conditions, the fungal hyphae and the mineral surface were imaged to nanometre resolution. To assess the effect of the fungi-mineral interaction on the mineral surface, a cleaning procedure was applied to biotite flakes colonised with *S. luteus*; this removed the organic material and exposed the 'reacted' mineral surface for further analysis. The cleaning protocol was also perfomed on a biotite control.

Our results show that all three *Suillus* species generate a large amount of organic material, forming typically a 1-5 nm thick coating on the mineral surface extending over many tens of microns. We have previously observed a similar 'biolayer' with *Paxillus involutus* [3]. AFM images of the cleaned biotite surface (Fig 1a), and the control biotite surface (Fig. 1b), show that both displayed a domain-like surface morphology. However, only on the fungi-colonised surface were round pits found, about 100 nm across and 5 nm in depth (Fig. 1a). These results indicate that the surface pitting is linked to the colonisation of the mineral with *S. luteus*.

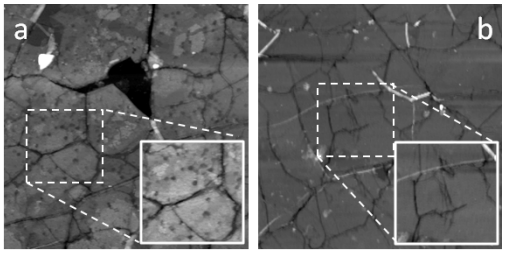

Figure 1: AFM images of a cleaned biotite surface: a) previously *Suillus luteus* colonised flake, note the pitting; b) control flake; field of view 8×8 μm, inserts 2.5×2.5 μm.

A ^{13}C DOC tracer approach to estimate the contribution of semi-labile dissolved organic carbon to stream ecosystem metabolism

LOUIS A. KAPLAN*, J. DENIS NEWBOLD AND ANTHONY K. AUFDENKAMPE

Stroud Water Research Center, 970 Spencer Rd, Avondale PA, 19390 (*correspondence: lakaplan@stroudcenter.org)

13C Tracer Method

In streams and rivers, dissolved organic carbon (DOC) supplies energy and carbon (C) to heterotrophic bacteria. The complexity of the DOC pool combined with simultaneous processes that continually produce, transform and consume DOC molecules in transport, makes *in situ* measurements of DOC uptake challenging. A tracer approach is a logical solution and we prepared a ^{13}C tracer of semi-labile DOC from soil-aged ^{13}C-labeled *Liriodendron tulipifera* tissues with a chemical composition reflective of the heterogeneity of terrestrially produced C that has been modified by sorptive fractionation onto mineral surfaces and oxidation by soil bacteria.

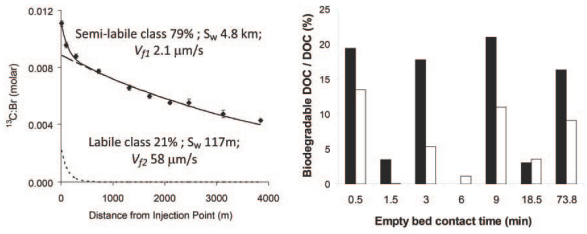

Figure 1: A. Whole-stream addition ^{13}C uptake; B. Lability profiles of stream water DOC (open) and ^{13}C tracer (solid).

Results

We used the tracer in a whole-stream injection coupled with bioreactor-based lability profiling to measure an uptake length of 4.5 km for semi-labile DOC constituents in a headwater piedmont stream and estimate support of ~10% of ecosystem metabolism.

Biogenic Fe(III) minerals lower the efficiency of iron-mineral-based commercial filter systems for arsenic removal

A. KAPPLER[1]*, S. KLEINERT[1], E..M. MUEHE[1], N.R. POSTH[1], U. DIPPON[1] AND BIRGIT DAUS[2]

[1]Geomicrobiology, University of Tuebingen, Germany (*correspondence: andreas.kappler@uni-tuebingen.de)
[2]Helmholtz-Zentrum für Umweltforschung GmbH – UFZ, Department Grundwassersanierung, Leipzig, Germany

Millions of people worldwide are affected by As-contaminated groundwater. Since abiogenic and biogenic Fe (III) (oxy)hydroxides sorb/co-precipitate As efficiently [1], filter systems containing Fe (III) minerals are applied to purify As-contaminated water. However, commercial filters containing abiogenic Fe (III) (oxy)hydroxides (granular ferric hydroxide, GFH) showed varying As removal efficiency depending on groundwater geochemistry and it was unclear whether Fe (II)-oxidizing bacteria influenced their efficiency. We found up to 10^7 Fe (II)-oxidizing bacteria/g dry weight in GFH-filters and determined the performance of the filters in the presence and absence of Fe (II)-oxidizing bacteria. GFH-material sorbed 1.7 mmol As (V)/g Fe. This was ~8 times more efficient than biogenic Fe (III) minerals alone that sorbed 208.3 μmol As (V)/g Fe. It was also ~5 times more efficient than a 10:1 mixture of GFH-material and biogenic Fe (III) minerals that bound 322.6 μmol As (V)/g Fe. Co-precipitation of As (V) with biogenic Fe (III) minerals in the absence of GFH-material removed 343.0 μmol As (V)/g Fe. As removal by co-precipitation with biogenic Fe (III) oxides in the presence of GFH-material bound 1.5 mmol As (V)/g Fe. This was slightly less efficient as by GFH-material alone. Since the formation of biogenic Fe (III) minerals lowers rather than increases the As removal efficiency of the filters, we recommend to exclude microorganisms from the filters (e.g. by activated carbon filters) to maintain their high As removal capacity.

Pressure-temperature diagenesis of Fe minerals and biomass produces hematite, siderite and magnetite as present in Banded Iron Formations

A. KAPPLER[1]*, N.R. POSTH[1], I. KOEHLER[1], C. SCHRÖDER[1], K.O. KONHAUSER[2], U. NEUMANN[1], C. BERTHOLD[1] AND M. NOWAK[1]

[1]University of Tuebingen, Germany (*correspondence: andreas.kappler@uni-tuebingen.de)
[2]Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Alberta, Canada, T6G 2E3

The reconstruction of microbial life in ancient sedimentary deposits is complicated by the influence of temperature and pressure during diagenesis and metamorphism. While minerals and persistent organic molecules may be evident in ancient rock formations such as Banded Iron Formations (BIFs), the specific primary minerals, their (trans-)formation mechanisms and proposed microbial processes involved are not certain. Understanding the transformation of biogenic iron minerals is the key to constraining models of BIF deposition that occurred between 3.8-0.8 billion years ago [1]. Thermal and barometric transformations of Fe (III) minerals associated with organic carbon (biomass, e.g. microbial cells) have not yet been systematically tested in laboratory experiments. Here, we present experimental results of mineral transformations of Fe (III) hydroxide and organic matter (glucose as a proxy for biomass) in gold capsules at elevated pressures and temperatures. Iron speciation and mineralogical analysis show the conversion of ferrihydrite [Fe $(OH)_3$, ferric hydroxide] into hematite ($Fe_2^{III}O_3$), magnetite ($Fe^{II}Fe_2^{III}O_4$), and siderite ($Fe^{II}CO_3$). Our results suggest that the joint precipitation of biomass with primary Fe (III) hydroxides followed by pressure/temperature diagenesis produces minerals found in BIFs today. Moreover, this study shows that siderite and magnetite form, i.e. Fe (III) is partially reduced, under diagenetic conditions decoupled from conditions in the ocean/atmosphere. The experimental system presented herein offers a means to bridge the gap between geological evidence from the field and laboratory experiments with modern microbe analogues.

Source rock-oil correlation in the Sinop Basin (Northern Turkey)

REYHAN KARA-GÜLBAY* AND SADETTIN KORKMAZ

Karadeniz Technical University, Department of Geological Engineering 61080, Trabzon, Turkey (kara@ktu.edu.tr)

Lower Cretaceous aged Çağlayan Formation is exposed in the Sinop Basin consists of black coloured claystone, siltstone, shale and marl, and has source rock characteristics. An oil seep from Çağlayan Formation is located in the Ekinveren region of the Sinop Basin.

The average total organic carbon (TOC) values of the shale samples from the Çağlayan Formation in the Ekinveren and the Bürnük areas are 1.48, 1.26 % and HI values are 190, 244 mg HC/g TOC, respectively. The potential yield values of the sample from the Ekinveren and the Bürnük are >2 mg HC/g rock and these potential yield values indicate fair hydrocarbon potential for the Çağlayan Formation.

The unimodal n-alkane distribution with lower carbon number dominant is observed in the gas chromatograms of the shale samples from the Çağlayan Formation in the Ekinveren and the Bürnük locations. Low TAR, $(C_{19}+C_{20})/C_{23}$ tricyclic terpane ratios and type II kerogen content indicate that the shale samples from the Çağlayan Formation comprise dominantly marine organic matter. Pr/Ph ratios for the Ekinveren and the Bürnük shale samples are 1.39 and 0.89, respectively.

Average T_{max} values for the Ekinveren and the Bürnük locations are 429 and 433°C, respectively. According to T_{max} data, Çağlayan Formation has immature-early mature characteristics in the Ekinveren location and early mature-mature characteristics in the Bürnük location. CPI values, isoprenoid/n-alkane ratio, 20S/(20S+20R) and ββ/(ββ+αα) C_{29} sterane, 22S/(22S+22R) C_{32} homohopane ratios for the Ekinveren and Bürnük shale show that Bürnük shale are more mature than those of the Ekinveren shale.

A large UCM and n-alkanes, isoprenoids that were recorded in low amount in gas chromatogram for oil sample from the Ekinveren seep indicate that the Ekinveren oil seep were heavily biodegraded. Similar tricyclic terpane, C_{24} tetracyclic terpan, norhopane, hopane and homohopane distributions were recorded in m/z 191 and m/z 127 mass chromatograms of samples from the Çağlayan Formation and the Ekinveren oil seep. Higher diasterane and pregnane content is typical for oil and shale samples. C_{27}, C_{28}, C_{29} sterane distribution for oil and shale samples is similar. According to biomarker data, Çağlayan Formation and Ekinveren oil seep are well correlated to each other.

Mineralogical and chemical variations in kaolin and alunite deposits in vicinity of the Aksaray region (Central Anatolia, Turkey)

NECATI KARAKAYA AND MUAZZEZ ÇELIK KARAKAYA*

Selçuk Universitesi Muh.-Mim. Fakültesi Jeoloji Mühendisliği Bölümü, Konya, 42079, Türkiye
(*correspondence: mzzclk@hotmail.com)

The kaolin-alunite deposits were formed in Lower Miocene volcanic and volcanoclastic, mostly dacitic, rhyodacitic, and andesitic rocks. The deposits were derived from by supergene and hypogene alteration processes. Kaolinite/halloysite is clay minerals, sometimes pure and sometimes associated with α-quartz, K-feldspar, plagioclase, alunite, natroalunite and hematite, whereas other kaolinite accompanies smectite, which represents a moderate kaolinization. Massive zones of alunite deposits sometimes pure, and show gradational passing to kaolinite/halloysite, and they were cut by gypsum and native sulphur veins and contain partially cinnabar and realgar mottles and/or veinlet. Tridymite and rarely low-cristobalite are the dominant silica mineral in these kaolins. Barite, pyrophyllite, minamiite, hematite, and geotite/lepidocrosite are rarely observed. Bentonite deposits composed mainly of nearly pure Ca-montmorillonite, observed as gradually or sharply at the uppermost levels or lateral sides of the alunite and kaolinite deposits. The alunite and most of kaolinite are products of hypogene alteration. Alunite, kaolinite, and gypsum samples show very similar chondrite-normalized REE trends, suggesting that they may be linked to common source. The REE patterns of the alunite and kaolinite samples are characterized by strong LREE enrichment ((La/Lu)cn=54.7 and 170.5, whereas gypsum and bentonite samples show moderate enrichment (9.2 and 7.2), respectively. Most of the alunite and kaolinite samples have pronounced positive Eu anomalies (1.08) and gypsum and bentonite samples negative and/or weakly negative Eu anomalies ranging from 0.77 to 0.89. All of the samples have positive Ce anomalies. Alunite and native sulphur samples from the deposits have $\delta^{34}S$ values of 5.03-6.62%, and 5.97-7.49%, respectively, with values for gypsum of 4.5-5.24%. Therefore, the sulphur-rich minerals may have been formed by steam-heated hydrothermal environments. The isotopically slightly heavy sulphur in the minerals could be derived from H_2SO_4. Development of the hydrothermal alteration contemporaneous with extensional tectonic and strike-slip faulting movements have resulted in hypogene alunite and kaolinite deposits. Hydrothermal alteration strongly affected along fault zones but subsequent weathering (supergene) away from the fault zones, and much of the volcanoclastic rocks have been altered to a more smectite-rich and less kaolinite-bearing assemblage.

A new model of the asthenosphere

SHUN-ICHIRO KARATO

Yale University, Department of Geology & Geophysics, New Haven, USA, (shun-ichiro.karato@yale.edu)

Although the classic model of asthenosphere = a layer of partial melt has been questioned for more than two decades, such a model is revived recently based on seismological observations showing a sharp and large reduction in seismic wave velocity. In this presentation, I will argue that such a model is not consistent with physics of behavior of partailly molten materials nor with the seismological observations. First, in the gravity field, it is difficult to maintain a substantial amount of melt for a geologic time scale. Layering observed in some lab experiments is often invoked to explain the persistency of a mlet-rich layer, but the lab experiments show ~20° tilt and hence the melt-rich layer will be compacted. Second, if a large reduction of velocity (~5-10%) were to be due to the presence of sub-horizontal melt-rich layer, then the asthenosphere should show large anisotropy in SH/SV waves (5-10%), which is not observed.

I propose that the basic properties of the asthenosphere is best explained as a residue of partial melting near the 410-km discontinuity. Partial melting removes a large fraction of incompatible elements leading to the 'depleted' homogenous composition, and also leads to ~0.01 wt% of water in the asthenosphere. The lab data show that this much of water is consistent with the observed electrical conductivity of the asthenosphere including its regional variation. If water reduces the strength of grain-boundaries, it can easily exlpain the sharp drop in velocity as much as ~10%.

Sequential extraction of Pb, Zn, Cd, and Cu in contaminated soils due to mining operation in Isfahan-Iran

L. KARIMZADEH

(l_karimzad@yahoo.de)

Sequential extraction was applied on 6 soil samples collected from metal contaminated site due to Gooshfil mining operation (20 km south west of Isfahan) to evaluate the level of contamination and bioavailability of Pb, Zn, Cd, and Cu. The sequential extraction method which was used in this research has been introduced by Tesser *et al*. in 1979 and modified by Salbu *et al*. in 1998. This method separates metals in six operationally defined fractions: water soluble, exchangeable, carbonate bonds, oxides bonds, organic bonds and residual fractions.

From the results of this study it can be concluded that the study area is contaminated with led. Zn is lower but near the contamination level. Mining operation in the area is the major source of metal contamination. The results obtained from the sequential extraction indicate that up to 90 % of metals in soil samples were associated to low soluble and high stable fraction such as oxide, organic and residual fraction. Metal distribution in soil samples generally followed the order oxide fraction> residual fraction> organic fraction> carbonate fraction> exchangeable> water-soluble.

Metal mobility and bioavailability

Ratio of relatively metal bioavailable and mobile fractions to stable and less mobile fractions is defined as mobility factor.

Metal mobility factor (Mf) defined as the following equation:

MF = (water-soluble + exchangeable + carbonate fraction)/ total metal content *100

The high MF values have been interpreted of relatively high biological availability and bioaccessibility of metals in soils. Mobility factor for six soil samples was determined by using the result of sequential extraction. Results are presented in Table 1.

Table 1: Mobility factor for metals

Soil	Pb	Cd	Zn	Cu
S1	1.8	7.8	1.7	2.0
S2	0.7	6.9	0.6	0.7
S3	3.0	9.7	1.0	3.6
S4	3.9	10.2	1.4	8.1
S5	1.9	9.7	2.0	7.1
S6	3.1	10.2	1.0	4.1

Bioavailability for metals found to be very low. Metal mobility factor for four studied metals were lower than 12%. The highest mobility was measured for cadmium and the lowest obtained for Zn. The results of bioavailability and mobility factor for the studied metals in the soil samples generally show the following order: Cd>> Cu> Pb> Zn

Viscosity of MgO-SiO_2 melt system from first principles simulations

BIJAYA B KARKI

Department of Computer Science, Department of Geology and Geophysics, Center for Computation and Technology, Louisiana State University, Baton Rouge (karki@csc.lsu.edu)

Transport properties of silicate melts are crucial to our understanding of chemical and thermal evolution of Earth. In recent years, we have performed density functional theory-based molecular dynamics simulations to study from first principles several key properties including viscosity (η) of relevant melts in the MgO-SiO_2 system. Numerous simulations of durations from a couple of tens of picoseconds to a few nanoseconds were completed to sample the pressure-temperature-composition (P-T-X) space accurately. The calculated results show that the viscosity is strongly dependent on pressure and temperature showing large deviation from the normal Arrhenian behaviour. The melt viscosity varies by two to three orders of magnitude across the entire mantle pressure regime. The predicted anomaly (i.e. viscosity increasing on compression) becomes more pronounced in silica-richer melts. Such dynamical changes can be associated to the structural changes. The simulations results were used to derive a viscosity model, η (PTX), applicable for the parameter space considered. The predicted viscosities compare favourably with the available measured data.

Putting constraints on the life cycle of organic carbon based on ecosystem scale flux measurements

THOMAS KARL

National Center for Atmospheric Research, 3090 Center Green Drive, Boulder, CO, 80301, USA (tomkarl@ucar.edu)

Large quantities of volatile organic compounds (VOC) enter the atmosphere. The annual production of VOC (600 - 2000 TgC/a) likely exceeds that of methane and CO (~500 TgC/a each). Together these gases fuel tropospheric chemistry. Oxidation of VOC leads to the formation of aerosol [1] via complex organic chemistry [2, 3] in the gas and aerosol phase thereby modulating the oxidation capacity of the atmosphere [4]. It is currently believed that a large fraction of VOC originates from biogenic sources (e.g. >80%). The life cycle of organic carbon is ultimately controlled by emission and deposition processes at the surface. Uncertainties in budgets of VOC and potential ramifications for organic aerosol production in the atmosphere will be discussed based on a synthesis of direct VOC flux measurements performed in a range of different ecosystems. These direct flux measurements will be used to address some outstanding questions concerning (1) the amount of reactive biogenic organic aerosol precursors, (2) the magnitude of deposition processes and (3) the lifetime of reactive biogenic organic aerosol precursors in the atmosphere.

Molecular-level studies of Fe(III) in aquatic systems

T. KARLSSON[1]*, U. SKYLLBERG[2] AND P. PERSSON[1]

[1]Dept. of Chemistry, Umeå Univ., 901 87 Umeå, Sweden (*correspondence: torbjorn.karlsson@chem.umu.se)
[2]Dept. of Forest Ecology & Management, Swedish Univ. of Agri. Sci., 901 83 Umeå, Sweden

The fate and behavior of iron (Fe) in aquatic environments is highly dependent on chemical interactions with natural organic matter (NOM). There is however still limited knowledge about the molecular structure, strength and hydrolysis of the Fe species formed in association with aquatic NOM and few studies that present results obtained by molecular-level probes (e.g. [1, 2]). In this study we have used extended X-ray absorption fine structure (EXAFS) and Fourier transformed infrared (FTIR) spectroscopy in combination with chemical speciation modeling to characterize Fe (III) in different types of aquatic NOM and in dissolved and colloidal material in different size fractions from a boreal stream.

Our results show that Fe in association with NOM and fulvic acid from river water forms two predominant species; mononuclear Fe (III)-NOM complexes and polymeric Fe (III) (hydr)oxides. The distribution of the two species is largely dependent on pH and Fe concentration. The speciation in the boreal stream water is dominated by mononuclear organic Fe (III) complexes irrespective of pH and size fraction. In the organic complexes Fe is coordinated by carboxylic functional groups forming a structure consisting of five-membered chelate rings and these complexes are sufficiently strong to prevent hydrolytic polymerization of Fe even at pH 7.0.

Thus, in oxic aquatic environments, with organic matter present, the fate of Fe will to a large extent be controlled by the properties of the organic Fe (III) complexes. In addition, the stable Fe (III)-NOM complexes formed will have important implications for the biogeochemistry of other elements, such as phosphorus and arsenate, that are known to be strongly associated with Fe (III).

Temporal trend in anthropogenic sulfur aerosol transport from central and Eastern Europe to Israel

A. KARNIELI[1]*, D. YEVGENY[1,2], R. INDOITU[1], N. PANOV[1], R.C. LEVY[3], L.A. REMER[3] W. MAENHAUT[4] AND B.N. HOLBEN[3]

[1]Ben-Gurion University, Israel (*correspondence: karnieli@bgu.ac.il, panov@bgu.ac.il, indoitu@bgu.ac.il)
[2]Laboratoire d'Optique Atmospherique, France (derimian@loa.univ-lille1.fr)
[3]NASA/GFSC, Maryland, USA (robert.c.levy@nasa.gov, Lorraine.A.Remer@nasa.gov, Brent.N.Holben@nasa.gov)
[4]Ghent University, Gent, Belgium (Willy.Maenhaut@UGent.be)

Decrease of sulfur emissions in central and eastern Europe over the past 3 decades is well documented. These changes result in a decreasing trend of sulfate aerosol and aerosol forcing over the source region, but also at a receptor site located in southern Israel, thousands of kilometers downwind. A combination of several independent observations, namely, satellite and ground-based remote sensing, *in situ* aerosol sampling, and backward trajectory analysis, was implemented to show significant downward trends in fine particle aerosol optical thickness (AOT), in general, and sulfur aerosol, in particular. MODIS-Terra observations over central Europe show 38% reduction of fine AOT. At the reception site in southern Israel, 43% reduction of fine AOT was observed by a sunphotometer and 25% reduction of sampled fine aerosols was obtained. During the corresponding observation periods, the coarse mode AOT has remained constant. The majority of the backward trajectories, where meaningful sulfur events were observed at the receptor site, are originated from eastern and central Europe. The aerosol radiative effect at top of the atmosphere has become less negative during the past decade, decreasing by 30% in Europe and 67% in Israel.

Neoproterozoic ice ages, boron isotopes, and ocean acidification

S.A. KASEMANN[1]*, A.R. PRAVE[2], A.E. FALLICK[3], C.J. HAWKESWORTH[3] AND K.-H. HOFFMANN[4]

[1]Department of Geosciences, Univ. Bremen, 28334 Bremen, Germany (*correspondence: skasemann@marum.de)
[2]Earth Sciences, University of St Andrews, St Andrews KY16 9AL, UK (ap13@st-andrews.ac.uk, deputyprincipal@st-andrews.ac.uk)
[3]Scottish Universities Environmental Research Centre, East Kilbride G75 OQF, UK (T.Fallick@suerc.gla.ac.uk)
[4]Geological Survey of Namibia, P.O. Box 2168, Windhoek, Namibia (khhoffmann@mme.gov.na)

The Neoproterozoic Earth underwent at least two severe glaciations, each extending to low paleomagnetic latitudes and punctuating warmer climates. The two widespread older and younger Cryogenian glacial deposits in Namibia are directly overlain by cap carbonates deposited under inferred periods of high atmospheric carbon dioxide concentrations [1]. Oceanic uptake of carbon dioxide decreases ocean pH and here we present a record of Cryogenian inter-glacial ocean pH, based on boron isotopes in marine carbonates. Our data document characteristically different B isotope profiles of the two Cryogenian carbonate transects that are consistent with the presence of two 'pan-glacial' climate states, but indicate that each had its own distinct environmental conditions. The Marinoan interglacial $\delta^{11}B$ profiles are systematic and remarkably consistent, and they vary by up to 11‰. This yields a relative pH variation of up to 1.5 pH units, and implies a pH of 8.5 at the onset of cap carbonate deposition, followed by a decrease in pH to ~7 and then a return to pH ~8 for the upper part of the section. The transient ocean acidification excursion and the alkaline pH condition near the start and termination of the inferred greenhouse state suggests a rapid draw-down of CO_2 initiated at the start of the deglaciation and supports inferences of a thick, global sea-ice shield with minimal air-sea gas exchange during glaciation. In contrast, largely constant B isotope values for the Sturtian-aged glacial aftermath do not indicate extreme ocean pH (~8.3) conditions and do not support a contemporaneous major ocean acidification event and associated high pCO_2 at the time of the older Cryogenian glaciation and deglaciation. That leads us to speculate that the ocean during the older glaciation was not totally frozen and that the hydrological cycle was functioning [2].

Molecular-scale mechanism of Mo isotopic fractionation during adsorption on ferromanganese oxides

TERUHIKO KASHIWABARA[1]*, YOSHIO TAKAHASHI[2] AND MASAHARU TANIMIZU[1]

[1]Japan Agency for Marine-Earth Science and Technology (JAMSTEC)
(*correspondence: teruhiko-kashiwa@jamstec.go.jp)
[2]Hiroshima University

Molybdenum (Mo) shows a large mass-dependent isotopic fractionation during adsorption on ferromanganese oxides, which is responsible for isotopic composition of Mo in modern oxic seawater [1]. The aim of this study is to reveal the fractionation mechanisms of Mo isotopes during adsorption on natural ferromanganese oxides. We investigated surface complex structures of Mo on various Fe/Mn (oxyhydr)oxides, key factors for the isotopic fractionation, and compared them with previously-reported isotopic fractionation.

Our XAFS analysis showed that symmetry of surface Mo species is different from MoO_4^{2-} (*Td*) in seawater in the case of its adsorption on some solids. This structural information showed the excellent correlation with the degree of isotopic fractionation of Mo reported in previous studies: the proportion of *Oh* species or their magnitude of distortion in surface Mo species becomes larger in the order of ferrihydrite < goethite < hematite < δ-MnO_2 [2], a trend identical to the degree of isotopic fractionation [3]. Based on the comparison with previous reports for surface Mo species on various oxides such as MgO, Al_2O_3, and TiO_2, the symmetric change from *Td* to *Oh* is suggested to be driven by the formation of inner-sphere complexes on specific sites of the oxide surfaces. In addition, the mode of attachment (inner- or outer-sphere) of surface Mo species is well correlated with the hydrolysis constant of the cation (e.g. Fe^{3+} and Mn^{4+}) in oxides.

EPMA study of sulfides in ultramafic suites of J.C.pura belt, Western Dharwar craton, India

NAMRATHA R. KASHYAP* AND B.C. PRABHAKAR

Department of geology, Bangalore University, Bangalore 560056, India
(*correspondence: namratharkashyap@gmail.com)

Significant ultramafic magmatism has been recorded in the western part of the Dharwar craton, southern India. J.C.Pura schist belt is one such ultramafic milieu with abundant dunite and peridotite which have been extensively serpentinised. Their komatiitic nature and extrusive mode of formation is evident from the field study. Some of the dunite bodies are chromitte in nature and contain veins and stringers of chromite. Highly altered bodies of chromitite show strong development of magnesite veins. They contain complex nickel sulfides which have been studied by ore microscopic method, besides analysing by EPMA. Camica (France Make) EPMA system was used for EPMA. Polished thin sections were prepared for this study and through a preliminary study the mineral-spots were marked for the EPMA studies. Selected representative samples from different rock types of dunite/peridotites, pyroxenites and cumulus schistose rocks were identified for this study. The chemical composition of different ore phases and the identified mineral phases are presented. From the analysis it is deciphered that cobalt–nickel-pyrite and pentlandite make the most abundant ore phase among the sulfides followed by pentlandite-pyrrohite-chalcopyrite assemblage. Occurrence of sulfides within the oxide phase (Chromite-Magnetite-ilmenite) is also noticed infrequently. This suggests to the possibility of sulfide evolution progressively with magma cooling. Strong immiscible and solid-solution relation are evident in the entire sulfide phase. The disseminated nature of them suggests to the possibility of poor sulfidation process during their formation i.e. either there was poor endowment of sulfur at the time of partial melting or during the ascent of magma through the crustal rocks. This is being reported for the first time for the J.C.Pura area. However detailed volcanic stratigraphy of the belt when studied, which is underway, and whole rock geochemistry including elemental ratios integrated, it will provide more insight in to the actual potential of the sulfides especially Ni sulfides in the said belt.

Microbial activity in gas field fluids and in laboratory experiments simulating geological CO_2 storage

ANDREA KASSAHUN[1]*, CLAUDIA GNIESE[2], MICHAELA HACHE[1], THOMAS MUSCHALLE[3] AND NILS HOTH[3]

[1]Dresdner Grundwasserforschungszentrum, 01217 Dresden, Germany (*correspondence: akassahun@dgfz.de)
[2]TU Bergakademie Freiberg, Inst. of Biosciences, 09599 Freiberg, Germany (claudia.gniese@ioez.tu-freiberg.de)
[3]TU Bergakademie Freiberg, Inst. of Drilling and Fluid Mining, 09596 Freiberg, Germany

Microbial activity in gas field fluids from two natural gas fields in Germany was assessed for evaluation of possible biochemical transformation of injected CO_2. 16S rDNA clone library construction revealed the presence of bacteria (*Thermoanaerobacterium* sp., *Petrotoga* sp. *Desulfotomaculum* sp.) in both gas fields and archaea (*Methanolobus, Methanoculleus*) in one gas field [1]. Gas field fluids of both fields contain free amino acids, polysaccharides, carbonic acids (formic acid, acetic acid) and alcohols (methanol, ethanol). Bio-molecules and metabolites form 25 to 50% of the total dissolved organic carbon of 2 to 10 μM. Moreover, both gas field fluids contain 0.1 to 250 μM dissolved H_2.

Laboratory experiments for simulation of geological CO_2 storage were conducted in high-pressure reactors (autoclaves) for 6 to 12 months. Gas field fluids and milled rock material from exploration drilling cores were reacted at p_{CO2}=6.5 bar, p_{H2}=3.5 bar, p_{N2}=4 bar and T=40°C. During the experiments, cell numbers of the reactor fluids rose and CO_2 and H_2 were consumed. DOC concentrations increased up to several hundred mM, while its composition remained comparable to the gas field fluid DOC. For one gas field, sulphate reduction was observed. Fatty acids, saturated hydrocarbons and elemental sulphur (in sulphate reducing systems) were detected in the sediments after the experiment. Fluorescence microscopy was used for visualisation of polysaccharides, proteins and calcium in the sediment samples. Both protein-calcium and polysaccharide-calcium associations were detected. REM-EDX analysis revealed biogenic sulphides and carbonates in sulphate reducing systems. Microbial activity at simulated CO_2 geological storage resulted in elevated concentrations of dissolved organic carbon, production of EPS and precipitation of biogenic minerals and thus might influence CO_2-storage capacities and rock physical properties of CO_2 storage units.

Analysis and application of water-rock-CO_2 reaction using basalt to underground CO_2 sequestration

T. KATAYAMA[1], N. SHIKAZONO[1], Y. TAKAYA[2] AND Y. KATO[2]

[1]Department of Science for Open and Environmental Systems, School of Science and Technology, Keio University, Kanagawa-ken, 223-8522, Japan (*correspondence: tomohirokatayama2487@yahoo.co.jp)
[2]Department of Systems Innovations, School of Engineering, the University of Tokyo, 113-8656, Tokyo, Japan

Water-rock-CO_2 reaction attract attention in many parts of science. It consists of three following reactions:

$CO_2 + H_2O = H_2CO_3 = H^+ + HCO_3^-$ (1)

$MSiO_3 + 2CO_2 + H_2O = M^{2+} + H_4SiO_4 + 2HCO_3^-$ (2)

$M^{2+} + 2HCO_3^- = MCO_3 + CO_2 + H_2O$ (3)

where M is bivalent metal ion.

There are two steps. First, CO_2 dissolves in the water by (1) or mineral and water react CO_2 by (2). Next, bivalent metal ion and hydrogen carbonate ion generate and carbonate minerals (MCO_3) precipitate by (3).

We are applying them to the CO_2 underground sequestration and the estimate of atmospheric CO_2 concentration of Archean and formation of mineral water, and global carbon cycle in earth system. In this paper we will focus on CO_2 underground sequestration based on experimental water-basalt-CO_2 reaction and computer simulation.

Assessment of the nanoscopic dissolution rate of basic lead carbonate (hydrocerussite)

D. KATSIKOPOULOS[1]*, A. GODELITSAS[2] AND J.M. ASTILLEROS[3]

[1]University of Oviedo, Spain (*correspondence: dionisis@geol.uniovi.es)
[2]University of Athens, Greece
[3]Complutense University of Madrid, Spain

Hydrocerussite (Pb_3 $(CO_3)_2$ $(OH)_2$), related to shannonite and plumbonacrite phases, is reported to be a characteristic secondary mineral [e.g. 1] particularly associated with the weathering of industrial metallic Pb (e.g. bullets, shots, pipes) and the oxidation of Pb-Zn-Ag ore deposits. Such processes exhibit a straightforward connection between the dissolution-precipitation of hydrocerussite ($\log K_{sp}$=-43.7) and the mobility of Pb contaminants in the environment. Synthetic hydrocerussite (basic lead carbonate known as 'white lead' [e.g. 2]) has been broadly used in pigments and cosmetics. In this study, we present *in situ* AFM experiments that provide evidence of the nanoscopic reactivity behaviour of hydrocerussite {0001} surfaces in contact with deionized water. The AFM study shows that the edge pits, with initial depth ~1 nm, exhibit random shapes with flattened bottoms. However as the dissolution proceeds, terrace adatoms, corresponding approx. to the *c* unit cell parameter of hydrocerussite, appear near the edges of deeper etch pits (~3 nm, Fig. 1).

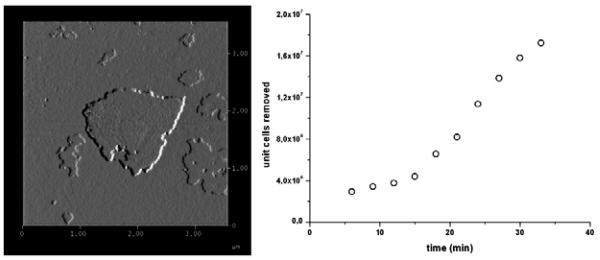

Figure 1: Nanoscopic dissolution rate of hydrocerussite

Following the methodology described by Rufe & Hochella [3], an assessment of the nanoscopic dissolution rate of hydrocerussite was obtained (**Fig. 1**) for the first time in the literature.

The origin of Naxos migmatites: SIMS U-Pb and O isotope analysis of zircon

Y. KATZIR[1]*, Y. BE'ERI-SHLEVIN[2], J.WOODEN[3], J.W. VALLEY[4], K. KITAJIMA[4] AND C. GRIMES[5]

[1]Ben-Gurion University of the Negev, Be'er-Sheva 84105, Israel (*correspondence: ykatzir@bgu.ac.il)

[4]University of Wisconsin, Madison, WI 53706, USA
[5]Mississippy State University, Starkville, MS 39762, USA

The Naxos (Aegean Sea, Greece) structural and thermal dome is cored by migmatites that record the peak P-T conditions (6-8 kbar; ≤700°C) of a late Alpine (18 Ma) Barrovian type metamorphism [1]. The 'leucogneiss core' comprises various types of anatectic gneisses thought to derive from either 'pre-Alpine basement' or Mesozoic sedimentary protoliths or both. Early Miocene intense deformation and metamorphism has obliterated most prior evidence, leaving zircon as the major tool for unveiling the pre- and early-Alpine history of the Naxos core. SIMS U-Pb dating of zircons from the four major types of gneisses in the core shows that oscillatory zoned domains yield concordia ages of ca. 326, 315, 312 and 300 ± 5 Ma with inherited cores of ca. 500-2500 Ma. Clear overgrowths yield ages between 17 and 20 Ma. Intermediate ages between ca. 300 and 17 Ma are restricted to blurred or porous zircon domains and are aligned on discordia lines connecting these end points. The age data indicate that the protoliths of the migmatites were Variscan igneous intrusions with inheritance of Pan-African and older detritus. Zircons from a pelite raft within the core yield the same age pattern as the migmatites suggesting that these sediments were derived from a similar basement.

SIMS O isotope analysis of oscillatory zoned zircon domains of Variscan age yielded $\delta^{18}O$ (Zrn) of 6.5-8.5‰. However in each sample these values vary within a 1‰ range, further supporting the igneous origin of the Naxos migmatites.

Noble gases used as an indicator of groundwater mixing in Azraq, Jordan

T. KAUDSE* AND W. AESCHBACH-HERTIG

Institute of Environmental Physics, Heidelberg University, 69120 Heidelberg, Germany (*correspondence: Tillmann.Kaudse@iup.uni-heidelberg.de)

Several sources contribute to the noble gas content in groundwater. One component arises from an equilibrium between soil air and percolating water. Excess air (EA) accounts for an additional noble gas contribution [1]. This applies to all noble gases. Helium has additional sources: ^{4}He is generated by radiogenic production within the aquifer matrix, while ^{3}He originates from tritium decay in young groundwater. A mantle helium component can shift the ^{3}He/^{4}He ratio to higher values. To determine the excess helium component all other noble gases need to be measured in order to separate the excess from the equilibrium and the EA component.

As part of an interdisciplinary research initiative to study water issues in Jordan, we use noble gases to investigate groundwater origin and recharge. In the region of Kerak in Western Jordan, a groundwater recharge estimation project is being conducted, based on tritium-^{3}He dating.

Here a study of groundwater origin in the Azraq Basin in Eastern Jordan, which is affected by groundwater depletion, is presented. The excess of ^{4}He as well as the ^{3}He/^{4}He ratio are used to identify groundwater mixing near the Azraq Oasis. In this area groundwater is used only from the upper aquifer, since the deeper one consists of highly saline water. However, a few production wells in the upper aquifer have shown a rising salt content over the past years. A correlation between the salinity and the ^{4}He excess is detected which argues for an inflow of water from the saline and old aquifer below. In the case of Azraq also the ^{3}He/^{4}He ratio seems to corroborate the above finding, as a ^{3}He/^{4}He vs. Ne/^{4}He isotope plot indicates mantle helium in the saline wells.

Implications of U-Pb-Hf detrital zircon data on the Precambrian crustal evolution of NW India

PARAMPREET KAUR[1]*, ARMIN ZEH[2], NAVEEN CHAUDHRI[1], AXEL GERDES[2] AND MARTIN OKRUSCH[3]

[1]Centre of Advanced Study in Geology, Panjab University, Chandigarh-160 014, India (*correspondence: param.geol@gmail.com)
[2]Institut für Geowissenschaften, Goethe-Universität, Altenhöferallee 1, 60438 Frankfurt am Main, Germany
[3]Lehrstuhl für geodynamik und Geomaterialforschung, Universität Würzburg, 97074 Würzburg, Germany

We have integrated *in situ* U-Pb-Hf data for 217 zircon grains from two quartzite samples of NW Indian plate to understand the Precambrian crustal evolution of this region. The U-Pb data unravel prominent probability age peaks at ca. 1.77, 1.85, 2.2, 2.5, 2.7 and 2.9 Ga. Barring 1.77 and 2.2 Ga age peaks, others are correlatable with most of the magmatic events identified in the basement of NW India.

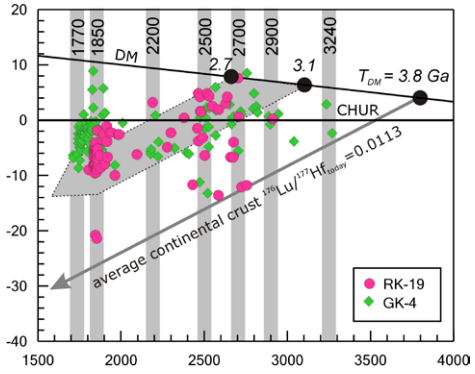

Figure 1: $\varepsilon Hf_{(t)}$ versus $^{207}Pb/^{206}Pb$ diagram showing results of detrital zircons from NW India.

The Lu-Hf isotope analyses indicate that at 1.77 and 1.85 Ga, reworking of Neoarchaean crust dominated over juvenile input as indicated by their largely subchondritic εHf values. At 2.5 Ga the zircons show a wide scatter in εHf values but the dominace of subchondritic values also indicate substantial reworking of older crust at this time. On the contrary, during 3.1–2.7 Ga, variable but mostly superchondritic to nearly chondritic εHf values suggest the dominant production of juvenile crust. The Hf model ages for Neoarchaean zircons also signify that the oldest crust in the NW Indian plate was formed from a depleted mantle source at around 3.8-3.7 Ga.

Impact of ferrihydrite coating and aeration conditions on microbial selenium (Se) reduction and retention in artificial soil aggregates

M.F. KAUSCH* AND C.E. PALLUD

ESPM, University of California at Berkeley, Berkeley, CA 94720, USA (*correspondence: mkausch@berkeley.edu)

Soils display large variations with respect to their physical, geochemical and biological characteristics at scales ranging from nanometers to kilometers. The impact of this heterogeneity on biogeochemical processes is as of yet poorly understood. In structured soils, the aggregate scale (mm-cm) is of particular interest due to the sharp transition in pore size at the surface of aggregates. Small intra-aggregate pores limit advective transport thus facilitating the formation of chemical concentration gradients that promote spatial variation in biogeochemical processes. One such process is the microbial reduction of selenium (Se), both an essential micronutrient and a toxicant. A mechanistic understanding of Se reduction within soil aggregates may lead to improved prediction of its transport and attenuation in soils of contaminated areas.

In order to investigate the coupling of physical and biogeochemical processes controlling Se reduction at the aggregate scale, we used artificial aggregates in flow-through reactor cells, mimicking the interface between soil micropores and macropores. Aggregates were constructed using either uncoated sand or ferrihydrite-coated sand homogenously inoculated with Se-reducing bacteria (*Thauera selenatis* and *Enterobacter cloacae* SLD1a-1 were compared). Saturated flow of aerobic or anaerobic artificial groundwater medium containing selenate and an electron donor, was initiated. Concentrations of selenite and total Se were measured in the outflow solution and in concentric sections of the aggregates' air dried solid phase.

Selenite export rates from aggregates increased by a factor of 600 between aerobic *T. selenatis* reactors with low selenate and acetate input and anaerobic *E. cloacae* reactors with high selenate and pyruvate input. Aerobic input solution significantly decreased Se reduction, however, the presence of a selenite signal indicates the occurrence of anaerobic/microaerobic microzones within aggregates. Solid phase selenite concentrations increased from the exterior to the core under aerobic as well as anaerobic conditions within both sand and ferrihydrite-coated sand aggregates. This is an indication that soil structure can impact Se retention in soils under a diverse set of conditions and that consideration of aggregate scale reactive transport may be essential for a complete understanding of field dynamics.

Metal mobility in clay formations – From batch experiments with mineral suspensions to column setup with compacted clay

R. KAUTENBURGER*, C. MOESER AND H.P. BECK

Institute of Inorganic and Analytical Chemistry and Radiochemistry, Saarland University, Saarbrücken, Germany
(*correspondence: r.kautenburger@mx.uni-saarland.de)

Nowadays, there is a broad consensus on the technical merits of the disposal of high-level nuclear waste (HLW) in deep and stable geological clay formations. For the long-term disposal of radioactive waste, detailed information about geochemical behaviour of radioactive and toxic metal ions under environmental conditions is necessary.

In our project europium, gadolinium (homologues of americium and curium) and uranium were used and their sorption and desorption behaviour onto Opalinus clay was studied [1]. Natural organic matter (NOM) can play an important role in the immobilisation or mobilisation of metal ions due to complexation and colloid formation. This complexation could interfere the sorption of metal ions onto clay. In addition to humic acid (HA) we used other natural appearing organics in Opalinus clay like lactate, formiate or propionate [2]. Therefore, we investigated the complexation behaviour of the metals with NOM as well as the influence of present NOM on the metal sorption onto clay [3].

Capillary electrophoresis hyphenated with inductively coupled plasma mass spectrometry (CE-ICP-MS) has been used to study the complexation behaviour of Eu (III), Gd (III) and U (VI) with HA. The influences of metal concentration as well as the presence of competing cations from clay dissolution as well as cations from clay porewater on the complexation behaviour was analysed [4]. For the sorption/desorption behaviour common batch experiments with mineral suspensions are performed, and in comparison a miniaturised column setup with compressed clay was used to study the influence of NOM on the metal mobility in compact Opalinus clay.

The authors thank the BMWi for financial support (grant no. 02E9683 and 02E10196).

Boron isotope geochemistry of subseafloor hydrothermal ore deposits, Agrokipia B, in Troodos ophiolite, Cyprus

H. KAWAHATA[1]*, K. YAMAOKA[2], S. MATSUKURA[1] AND T. ISHIKAWA[3]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, 5-1-5 Kashiwanoha, Kashiwa, Chiba, 277-8564 Japan (*correspondence: kawahata@aori.u-tokyo.ac.jp)
[2]Geological Survey of Japan, National institute of Advanced Industrial Science and Technology, 1-1-1 Higashi, Tsukuba, Ibaraki 305-8567 Japan
[3]Kochi Institute for Core Sample Research, JAMSTEC, 200 Monobe Otsu, Nankoku, Kochi, 783-8502 Japan

Cyprus-type ore deposits in many ophiolites are regarded as fossil examples of ore forming processes occurring at modern hydrothermal vent area. Hole CY2A was drilled into stockwork zone of the subseafloor Agrokipia B deposit. Boron is a useful tracer for understanding geochemical mechanism of fluid-related processes because of its chemical properties of high incompatibility and fluid mobility.

Basalts altered at low temperature (Zone A) are relatively enriched in boron (6.2–31.7 ppm) and give the average value of 21.1 ppm. On the other hand, mineralized basalts and dolerites altered at high temperature (Zones B, C, and D) have lower boron contents (0.92–17.0 ppm) and show no trend with stratigraphic depth. The $\delta^{11}B$ values of basalts from upper 450 m slightly increase with depth from 2.4 to 4.8‰, whereas those of basalts and dolerites below 450 m show a significant decrease with increasing depth. The lowermost dolerite and sulfide-enriched part of dolerite have as low as –6‰ of $\delta^{11}B$. We conclude that the rocks around Agrokipia B experienced relatively low temperature in recharge zone when Agrokipia A deposits was formed and that high temperature alterations overprinted boron content and isotopic composition of altered rocks to form the subseafloor Agrokipia B deposit. This demonstrates that boron is a good new proxy to analyze and trace hydrothermal alteration and its stages.

Continental materials around the bottom of the mantle transition zone

[5]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo Japan (smaruyam@geo.titech.ac.jp)

Recent progress in our understanding of the consuming plate boundary indicates the ubiquitous occurrence of tectonic erosion of the hanging wall of the continental margin, sediment-trapped subduction, and direct subduction of immature oceanic arcs into deep mantle. Geological studies have estimated the volume of subducted tonalite–trondhjemite–granodiorite (TTG) materials to about seven times the surface total volume of continental crust. To reveal the fate of subducted crusts and how they recycle within the Earth, we studied high-pressure densities and elastic properties of TTG by means of the first principles computation method and compared them to those of peridotite. We found that TTG is gravitationally stable and its seismic velocities are remarkably faster than peridotite in the depth range from 270 to 800 km, especially from 300 to 670 km. We, therefore, propose SiO_2-rich second continents around the bottom of the mantle transition zone, which used to form the TTG crust on the Earth's surface. Our proposed model may provide reasonable explanations of seismological observations such as the splitting of the 670 km discontinuity and seismic scatterers in the uppermost part of the lower mantle. The difference in seismic velocities between PREM model and experimental results in the lower part of the transition zone can be explained by 25 volumetric% of TTG, which would correspond to about several times the present volume of the continental crust. Formation and dynamics of those second continents would have controlled the Earth's thermal history over geologic time.

Zircon behavior in the upper amphibolite facies polymetamorphic terrane, Ryoke belt, Japan

T. KAWAKAMI*, I. YAMAGUCHI[1,2], T.D. YOKOYAMA[1], K. MAKI[1], T. HIRATA[1] AND T. SHIBATA[1]

[1]Dept. of Earth and Planetary Sciences, Kyoto Univ., Kyoto 606-8502, Japan (*correspondence: t-kawakami@kueps.kyoto-u.ac.jp)
[2]Dowa Holdings Co. Ltd., Tokyo 101-0021, Japan

In the Ryoke metamorphic belt at the Aoyama area, SW Japan, pelitic schists and migmatites are widely outcropped, and the *P-T* condition of the regional metamorphism by which they were formed is estimated to be 3.0–4.0kbar, 615–670ºC for the Sil-Kfs zone at the north, and 4.5–6.0kbar, 650–800ºC for the Grt-Crd zone at the south [1]. The U-Th-Pb dating of the monazite in migmatites yielded 96.5±1.9Ma mainly preserved in the monazite core, and domains and rims of 83.5±2.4Ma. Although the contact metamorphism by the Ao granite at the south (79.8±3.9Ma) was not detected from the major metamorphic minerals, the coincidence of the age suggests that the Younger Ryoke granite including the Ao granite caused the contact metamorphism to the regional metamorphic rocks [2].

In the Grt-Crd zone where metamorphic temperature increases toward the south, zircon grains larger than 20 μm in diameter were abundant in the north than in the south. The comparison between the modal amount of zircon larger than 20μm and the whole-rock Zr concentration suggests that most of the whole-rock Zr was resided in zircon larger than 20μm in the north, whereas zircon larger than 20μm can account for only 20-30% of the whole-rock Zr in the south. The U-Pb dating of zircon by LA-ICPMS showed that most of the zircon larger than 20μm from the northernmost part of the Grt-Crd zone are detrital in origin. On the other hand, in the pelitic migmatite from the area where metamorphic temperature of 720 °C is estimated, several grains of ~100Ma zircon larger than 20μm were found.

These observations suggest that upper amphibolite grade metamorphism that potentially lasted about 5Ma [3] is not sufficient enough to (re)crystallize new zircon larger than 20μm, although monazite is almost completely rejuvenated. It is necessary to date tiny-grained zircon less than 20μm, or instead, use monazite in order to date upper amphibolite facies metamorphism.

Increased stable carbon isotopic ratios of oxalic, malonic, and glyoxylic acids in the Arctic aerosols during polar sunrise and after

KIMITAKA KAWAMURA[1] AND LEONARD A. BARRIE[2]

[1]Institute of Low Temperature Science, Hokkaido University, Sapporo 060-0819, Japan (kawamura@lowtem.hokudai.ac.jp)
[2]The Cyprus Institute (CyI), P.O. Box 27456 CY-1645 Nicosia, Cyprus (barrie@cyi.ac.cy)

Low molecular weight dicarboxylic acids such as oxalic acid (C_2) are present abundantly in aerosols. Because they are water-soluble, dicarboxylic acids can enhance the hygroscopic properties of atmospheric particles. During the polar sunrise season at Alert, Canadian Arctic, we observed photochemical production and loss of small diacids [1]. Although C_2 is the dominant diacid species in winter to spring, it was replaced by succinic acid after polar sunrise in May. Oxalic acid was preferentially decomposed when a solar radiation was intensified and the atmospheric transport from mid latitudes was ended in May. In this study, we applied compound-specific stable isotope analysis for diacids and related compounds isolated from the Arctic aerosols collected from late winter to early summer including dark winter and polar sunrise seasons.

Stable carbon isotopic ratios ($\delta^{13}C$) of small dicarboxylic acids and ketoacids were measured in the Arctic aerosols after derivatization to butyl esters and/or dibutoxy acetals using a capillary gas chromatography combined to on-line combustion/isotope ratio mass spectrometer [2]. We found that $\delta^{13}C$ of C_2 increased from -23‰ in early March (before polar sunrise) to -5‰ in May (after polar sunrise). Malonic acid (C_3) also showed an increase of $\delta^{13}C$ from late February (-25‰) to early May (-17‰). Glyoxylic acid (HOC-COOH), a precursor of C_2, showed similar increase from -18‰ in late February to -10‰ in May. Glyoxal (HOC-CHO), another precursor of C_2, showed very high isotopic ratios up to +15‰. In contrast, isotopic composition of succinic acid (-32‰ to -24‰) did not show a systematic trend. An increase in $\delta^{13}C$ values is probably associated with photochemical ageing of aerosols. It is likely that ^{12}C-^{12}C bonds of oxalic and other species decompose preferentially over ^{12}C-^{13}C bonds during photochemical ageing. Isotopic fractionation of C_2 and its precursors may also be likely during the gas/particle portioning. Here, we propose that $\delta^{13}C$ of oxalic acid can be used as a photochemical tracer for the ageing of organic aerosols.

[2]Shizuoka Univ., 836 Ohya, Suruga-ku, Shizuoka-shi, Shizuoka 422-8529, Japan

Introduction

Barred mudskipper *Periophthalmus argentilineatus* is an amphibious gobioid fish, inhabiting in mudflats, mangroves and port. Mudskippers are known as a carnivorous fish that feed insects as well as benthic animals such as small crustacea on intertidal area [1, 2]. While adult males of the mudskipper have territory around their nests, adult females move along with tidal migration front without their nests. Because the adult individuals have not been observed to move wide range habitats (e.g. between river systems), food differences of barred mudskippers are expected to reflect food availability of each habitat. Stable isotope is one of the powerful tools for studies of food chain in an ecosystem. This study is to reveal food differences attributed to differences of habitat environment and feeding behavior between males and females, using stable isotopic methods.

Materials and Methods

Mudskipper, other benthic animals, particulate matter and sediments were taken from intertidal area of mudflats and mangroves around tropical coral reefs of Okinawa, Japan. Mudskipper samples were separated into gut and muscular tissues. Then, all the organic tissue were freeze-dried and analyzed $\delta^{13}C$, $\delta^{15}N$, $\delta^{34}S$ using a continuous flow EA/IRMS (Delta V advantage, Thermo).

Results and Discussion

Muscular tissues of mudskipper showed $\delta^{13}C$ = -17.4‰ and $\delta^{15}N$ = 7.4‰ at Iriomote Island; $\delta^{13}C$ = -21.3‰ and $\delta^{15}N$ = 11.8‰ at Okinawa Island. These results suggested significantly different food sources and availabilities of the two islands.

Assessment of cloud droplet growth based on the measurements of hygroscopicity and CCN activity of aerosol particles in Nagoya, Japan

K. KAWANA[1]*, M. MOCHIDA[1] AND N. KUBA[2]

[1]Graduate School of Environmental Studies, Nagoya, University, Nagoya, Japan (*correspondence: kawana.kaori@d.mbox.nagoya-u.ac.jp)
[2]Research Institute for Global Change, Japan Agency for Marine-Earth Science and Technology, Yokohama, Japan

To better understand the aerosol-cloud relationship in the atmosphere, we investigated hygroscopicity and CCN activity of aerosol particles by ground-based observation, and performed model calculations to predict the concentrations and the effective radii of cloud droplets (N_d and R_{eff}, respectively) formed from the observed particles. The field observation was conducted in the city of Nagoya, from 29 July to 3 August, 2010. The hygroscopic growth of aerosol particles were measured using a Hygroscopicity Tandem Differential Mobility Analyzer (HTDMA). The aerosol particles were classified by the dry mobility diameter in the first DMA, and were further classified by the diameter under the condition of 85% relative humidity in the second DMA. A CCN counter (CCNC) and a condensation particle counter to measure CCN and condensation nuclei were connected to the second DMA. The CCN were measured at supersaturations of 0.17%, 0.48%, and 0.93%. The hygroscopic growth factors (HGFs) of studied particles were 1.0, 1.1, 1.25, and 1.4.

The measured CCN activation diameters (d_{act}) were smaller than those predicted; i.e. the actual CCN activity was higher than that predicted. Whereas the differences between predicted and measured d_{act} were not very large for more hygroscopic particles, they were remarkable for particles with HGF of 1.0. Based on the HGF data, we performed model calculations to investigate how the differences of particle hygroscopicity and the differences between predicted and measured d_{act} for particles with HGF of ~1.0 affect the cloud droplet formation. If less hygroscopic aerosol particles in addition to more hygroscopic particles are considered in the cases of large updraft velocity conditions, N_d and R_{eff} are, respectively, substantially larger and smaller than those calculated with consideration of only more hygroscopic particles. Further, if we correct the model inputs based on the differences between predicted and measured d_{act}, N_d increase and R_{eff} decrease slightly. These results suggest that less hygroscopic aerosol particles in the urban area could contribute to the cloud droplet formation, and play an considerable role in the formation of clouds.

Högbomite from West Ongul Island, Lützow-Holm Complex, East Antarctica

TOSHISUKE KAWASAKI* AND SYOTA HAMADA

Ehime University, Matsuyama 790-8577, Japan
(*correspondence: toshkawa@sci.ehime-u.ac.jp)

Högbomite has been found within magnetite megacrysts (5 cm × 3 cm) from the upper amphibolite- to granulite-facies pegmatite cutting the medium-grained quartzo-feldspathic garnet-biotite gneiss at West Ongul Island, Lützow-Holm Complex, East Antarctica. Associated minerals included in magnetite are biotite, plagioclase, hercynite, sillimanite, corundum, quartz, rutile, ilmenite, hematite, and zircon. Högbomite occurs as very fine euhedral to subhedral crystal (5-20 μm) along grain boundaries between magnetite and ilmenite or less commonly enclosed in hercynite (Fig. 1) and in magnetite. Quartz is found in hercynite. Högbomite is in direct contact with hercynite. Ilmenite contains hematite exsolution lamellae. Hematite also forms exsolution lamellae in rutile, which is trapped in ilmenite. Corundum is in direct con-tact with magnetite, hercynite or sillimanite. Electron microprobe analyses of högbomite yield 2.6-7.9 wt% TiO_2, 60-64 wt% Al_2O_3, 0-0.1 wt% Cr_2O_3, 18-25 wt% Fe (as FeO), 0.3-0.6 wt% MnO, 2.9-4.4 wt% MgO, 4.8-10 wt% ZnO, 0.61-0.01 wt% SnO_2, and 0.20-0.36 X_{Mg}. Hercynite varies 4.9-14 wt% ZnO and 0.23-0.36 X_{Mg}. Sillimanite contains 0.6-3.6 wt% Fe_2O_3 from rim to core and < 0.1 wt% TiO_2. Textures and mineral chemistry suggest that the reaction, Mag + Ilm + H_2O + O_2 → Hög + Hc + Qtz, took place at retrograde stage (T < 600 °C) whereby magnetite and ilmenite contained impurities Si, Al, Zn and Mg. Hydrous and oxidized fluid, possibly supplied by crystallization process of pegmatite, were sufficiently enough to form högbomite and biotite. Subsequent cooling processes hematite crystallized as exsolution lamellae from ilmenite and rutile, and sillimanite and corundum became Fe_2O_3-poor at the rim.

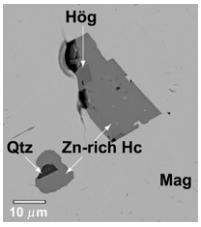

Figure 1: Backscattered image of högmatite + hercynite and her-cynite + quartz in magnetite.

Neogene Central Andean adakites, frontal arc migration and forearc subduction erosion at 27°-28.5°S

S. MAHLBURG KAY[1]*, A.R. GOSS[2] AND C. MPODOZIS[3]

[1]Dept. Earth Atm. Sci., Snee Hall, Cornell Univ., Ithaca, NY, 14853 USA (*correspondence: smk16@cornell.edu)
[2]Exxon Production Company, Houston, TX, U.S.A adam.r.goss@exxonmobil.com
[3]Antofagasta Minerals, Santiago, Chile

Glassy plagioclase phenocryst-free 8 to 2 Ma Andean andesitic lavas erupted at 27°-28.5°S can be argued to contain continental crust incorporated in the sub-arc mantle by forearc erosion as well as by melting in the overlaying ~65-70 km thick crust. These distinctive ~7.7 Ma pyx-bearing Dos Hermanos and 7-2 Ma amp-bearing Pircas Negras lavas (54-64% SiO_2) erupted as the frontal arc was being displaced ~50 km eastward over a developing bend in the Wadati-Benioff zone that now marks the Chilean flat-slab northern margin [1]. These lavas can show the most HFSE depletion (La/Ta=40-100) and adakitic-like character (Sm/Yb=4-9; Sr=600-1400 ppm) among Neogene lavas in the region and have higher $^{87}Sr/^{86}Sr$ (0.7055-0.7065) than 26-13 Ma lavas (<0.7055). Some 5-3 Ma lavas have high Mg# (to 61), Cr (to 250 ppm) and Ni (to 65 ppm). Their chemistry fits with trace element and isotopic models [2, 3] that begin with > 2 GPa partial melts of ~85:15 mixtures of mafic Jurassic and silicic Paleozoic Chilean forearc rocks reacting with sub-arc mantle peridotite. Mineral thermometry and MELTS program models for the Pircas Negras lavas indicate pre-eruption temperatures near 1050°C showing these magmas can then mix with and melt the overlying eclogitic crust. Given a constant arc-trench gap over the last 8 Ma, ~124 km^3/m. y./km of forearc crust needs to be removed to account for frontal arc migration at 8 to 2 Ma and is readily available to contaminate the mantle wedge.

Cathodoluminescence characterization of He^+ ion implanted plagioclase

M. KAYAMA[1]*, H. NISHIDO[1], S. TOYODA[2], K. KOMURO[3] AND K. NINAGAWA[22]

[1]Research Institute of Natural Sciences, Okayama University of Science, Japan
(*correspondence: kayama@rins.ous.ac.jp)
[2]Department of Applied Physics, Okayama University of Science, Japan
[3]Earth Evolution Sciences, University of Tsukuba, Japan

Cathodoluminescence (CL) techniques have been often used as an effective tool to visualize radiation halos in quartz. No investigation of radiation effects on CL of feldspar has been performed to date, although the visible halos can easily be found in the feldspar directly attached to radioactive minerals. In this study, CL of plagioclase implanted by He^+ ion has been conducted to clarify radiation effect on CL of plagioclase.

Single crystals of albite (Or_1Ab_{99}) from Minas Gerais, Brazil, oligoclase ($Or_2Ab_{82}An_{16}$) from Inabu, Japan, andesine ($Or_1Ab_{53}An_{46}$) from Bekily, Madagascar; and anorthite (Ab_5An_{95}) from Yoichi, Japan were selected for CL measurements. He^+ ion implantation with 4.0 MeV (dose density: 2.18×10^{-6} to 6.33×10^{-4} C/cm^2) on the samples was conducted using a 3M-tandem ion accelerator at at Takasaki Research Center of the Japan Atomic Energy Research Institute.

CL spectra of unimplanted and implanted plagioclase show emission bands at 350, 420, 580 and 740 nm. Implanted albite and oligoclase exhibit characteristic red emissions at 700–750 nm, where the intensities increase with an increase in radiation dose. Spectral deconvolution of albite and oligoclase samples can successfully separate the red emission into three Gaussian components at 1.861, 1.644, and 1.557 eV. Integral intensity of the component at 1.86 eV linearly correlates with radiation dose. The CL spectra of andesine and anorthite show no component at 1.861 eV. The component at 1.861 eV might be attributed to oxygen vacancy between Al and Si tetrahedra associated with two Na atoms ($O^{1-}/^{27}Al \times 2^{23}Na$ center). The component intensity clearly correlates with radiation dose as a function of $O^{1-}/^{27}Al \times 2^{23}Na$ center, but does not depend on the concentration and distribution of other emission centers, degree of Si-Al order and presence of microstructures or texture. CL spectral deconvolution, therefore, may be applied to evaluate radiation dose of alpha particles from natural radionuclides on Na-rich feldspar.

Semi detail orientation survey in semi arid conditions and mineral influenced basin, case study in Southestern Iran

A. KAZEMI MEHRNIA* AND I. RASA

University of Shahid Beheshti- Tehran, Iran
(*correspondence: akmehrnia@yahoo.com)
(I.Rasa@sbu.ac.ir)

Semi Detail orientation survey

The aim of this research is to find the optimum size fraction of stream sediment sampling in semi detail geochemical sampling and mineral influenced basin. In this study 21 stream sediment samples collected from of streams that draining Cu-Mo porphyry deposits in southeast of Iran.

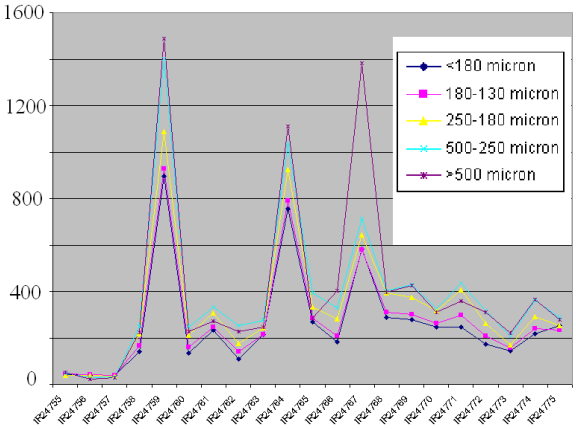

Figure 1: Sample Figure of Copper in stream sediments.

Discussion of Results

The charts (e.g. Fig. 1) suggest that >500 μm fractions give the strongest and most consistent anomalies for Cu, Mo and Au while 500-250 μm fractions give better Zn and Pb anomalies. The finer size fractions give a stronger anomaly response for gold [12]. By sampling the fine sediment fractions with high sampling density, uncertainty associated with the nuggety nature of gold can be reduced to a level [1]. In detail stream geochemistry the anomaly are not affected by Aeolian dust deposits respectively.

Testing the 'post-glacial weathering peak' hypothesis – A lacustrine record of $^{87}Sr/^{86}Sr$

ANDREW R. KEECH[1]*, DEREK VANCE[1], COREY ARCHER[1] AND STEVE LUND[2]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Queen's Road, Bristol, BS8 1RJ, UK
[3]Department of Earth Sciences, University of Southern California, Los Angeles, CA 90089-0740, USA
(*correspondence: andrew.keech@bristol.ac.uk)

Chemical weathering of the continents regulates levels of atmospheric CO_2, thereby acting as a primary control on Earth's climate [1]. The effect of continental ice sheets, as observed during the Pleistocene, on this regulation of global climate is not clear. It has been suggested that repeated transitions between glacial (high physical weathering) and interglacial (high chemical weathering) states may have enhanced CO_2 drawdown during the Quaternary [2].

[2] argue that present riverine inputs to the oceans are still distorted by the last glaciation and are above the long-term average. During the incipient stages of chemical weathering the Sr released is more radiogenic than the bulk rock [3, 4]. Therefore, associated with the landscape rejuvenation caused by each Pleistocene glaciation one might expect a peak in radiogenic Sr in continental runoff. Such a 'post-glacial weathering peak' is required to explain the modern marine Sr budget [2, 5].

We attempt to test the 'weathering peak' hypothesis by constructing a record of Sr isotope composition of waters draining the Sierra Nevada through the last glaciation using ostracods in previously studied sediment cores from Owens Lake, California (e.g. [6]). Preliminary data from ostracods in Holocene sediments show elevated $^{87}Sr/^{86}Sr$ relative to the modern flow-weighted mean $^{87}Sr/^{86}Sr$ of streams in the Owens Lake drainage (0.70911) [7]. Further analyses will complete a record of the Owens Lake Sr isotope composition from ~40ka to the present day and will allow for a comparision to the contemporaneous extent of glaciers in the Sierra Nevada [6] thus allowing us to test the 'post-glacial weathering peak' hypothesis.

As, Fe and S cycling during reductive biomineralisation of pedogenic jarosite

A.F. KEENE*, S.G. JOHNSTON, E.D. BURTON AND R.T. BUSH

Southern Cross GeoScience, Southern Cross University, Lismore NSW 2480, Australia
(*correspondence: annabelle.keene@scu.edu.au)

Jarosite (KFe_3 $(SO_4)^2$ $(OH)_6$) is an abundant Fe (III) mineral phase and important contaminant sorbent in coastal acid sulfate soils (ASS) [1]. Jarosite in these environments can be prone to reductive dissolution as a result of changes in local hydrology (e.g. sea-level rise and tidal seawater reflooding) [2]. However, very few studies have examined the reductive dissolution and transformation of K-jarosite, and the associated effects on contaminant mobility following seawater inundation of a jarosite-rich soil. Here we investigate the reductive biomineralisation of a natural As (V)-bearing pedogenic K-jarosite and explore the effects of a seawater gradient on the cycling of As, Fe and S. Solid and aqueous phase partitioning and speciation of As, Fe and S were determined using a wide variety of techniques including As- and S- K-edge XAS, TEM-SAED, SEM and XRD.

Whilst the rate and magnitude of fermentation processes were initially similar across the seawater gradient (100%, 10%, 1%), reductive dissolution of jarosite proceeded faster under 100% seawater conditions. Concentrations of $Fe^{2+}_{(aq)}$ were ~4-fold higher in 100% seawater and Fe^{2+}:K^+ ratios were initially congruent with respect to solid-phase jarosite. Evidence suggests both dissimiliatory reduction of jarosite-Fe (III) and abiotic reduction of Fe (III) by sulfide produced via sulfate-reducing bacteria. Residual jarosite became increasingly polycrystalline and developed hollow cores. Disordered nano-particulate mackinawite was a primary mineralisation product after 140 days in 100% seawater.

While As mobilisation was generally correlated with $Fe^{2+}_{(aq)}$ production, As displayed highly contrasting kinetics across the seawater gradient. Initial release of $As_{(aq)}$ was most rapid in low seawater treatments. Although As mobilisation in 100% seawater eventually exceeded the low seawater treatments, it was not substantially attentuated by the formation of mackinawite. The proportion of solid-phase As (III) increased over time and was greatest in 100% seawater. Findings provide important insights into the reductive dissolution of pedogenic jarosite following seawater inundation in coastal ASS environments.

On the significance of ultra-magnesian olivines in basaltic rocks

J.K. KEIDING[1]*, R.B. TRUMBULL[1], I.V. VEKSLER[1,2] AND D AND A. JERRAM[3]

[1]GFZ German Research Centre for Geosciences Potsdam Germany (*correspondence: jakob@gfz-potsdam.de)
[2]Technical University of Berlin, Germany
[3]Dept. of Earth Sciences, Durham University, United Kingdom

The temperature regime in the Earth's mantle is of prime importance for models of mantle convection and a key test of the mantle plume hypothesis. Olivine thermometry is commonly used to constrain mantle potential temperatures in basaltic magmatic provinces. Ultra-magnesian olivines, here defined as Fo > 92, are common in Archean komatiites and occasionally observed in Phanerozoic LIPs. The presence of ultra-magnesian olivines is generally interpreted as evidence for melts with extremely high MgO concentration and high eruption temperatures. Such melts are considered to be a hallmark of a hotter mantle in the early Earth and of thermal anomalies related to Phanerozoic mantle plumes. Estimating primary melt compositions and temperature based on mineral and rock data is a common approach but subject to large uncertainties. A better alternative is direct study of melt inclusions trapped with early-formed crystals and isolated from the rest of the magma. Here we present data of olivine-hosted melt inclusions and their host crystals from the Henties Bay-Outjo (HOD) dyke swarm in NW Namibia. These dykes are interpreted to have been feeders to the Etendeka volcanics and are characterized by the local presence of high MgO (picritic) compositions. The composition of melt inclusions trapped in ultra-magnesian olivine ($Fo_{93.3}$) from the HOD contradict the predicted 24 wt. % MgO for parental melts and 1680 °C mantle potential temperature based on olivine whole-rock models [1]. Instead, the trapped melts do not exceed 17.5 wt. % MgO and the maximum potential temperature indicated by these compositions is 1520 °C. Most olivines in the HOD rocks with Fo > 85 are too Mg-rich to be in equilibrium with the whole-rock composition, indicating that the grains are entrained xenocrysts from earlier, more magnesian melts. We show that ultra-magnesian olivines can be produced by protracted melt extraction from the mantle source and that this process also leaves a distinctive depletion in the incompatible trace elements.

A poor man's enzyme? Effects of reactive Mn(III)-oxalate complexes on structurally intact plant cell walls

MARCO KEILUWEIT[1,2], JEREMY BOUGOURE[2], PETER S. NICO[3]*, JENNIFER A. SUMMERING[1], MARKUS KLEBER[1] AND JENNIFER PETT-RIDGE[2]

[1]Department of Crop and Soil Science, Soils Division, Oregon State University, Corvallis, OR-97331
[2]Lawrence Livermore National Laboratory, Physical and Life Sciences Directorate, Livermore, CA-94550
[3]Lawrence Berkeley National Laboratory, Earth Sciences Division, Berkeley, CA-94720 (*correspondence: PSNico@lbl.gov)

Manganese (III)-ligand complexes such as Mn (III)-oxalate are potent and highly diffusible oxidizers for lignin model compounds [1, 2]. Although there is clear indication for their potential role in lignin decomposition processes in soils [3, 4], few reports exist on mechanistic aspects such as substrate specificity, reaction kinetics and oxidizing power of Mn (III)-oxalate complexes reacting with structurally intact plant materials. This is of particular importance in the context of soil organic matter decomposition since lignin cannot be viewed as a single substance [5], but has to be seen as an integral component of ligno-carbohydrate complexes (LCC) in fresh plant cell walls (e.g. in litter, root and wood).

Here we tested the hypothesis that Mn (III)-oxalate complexes may act as a 'pretreatment' for structurally intact LCC components in plant cell walls. The diffusible oxidizers are thought to be small enough to penetrate and react with composite LCC in cell walls, thereby increasing porosity which permits access to more efficient lignin- and cellulose-decomposing ezymes. This was investigated by reacting cell walls of single *Zinnia elegans* tracheary elements with Mn (III)-oxalate complexes in a continuous flow-through micro-reactor. The uniformity of these individual plant cells allowed us to examine Mn (III)-induced changes in cell wall chemistry and ultrastructure on the micro-scale using fluorescence and electron microscopy as well as IR and X-ray spectromicroscopy. This presentation will discuss the specificity of Mn (III)-complexes for certain cell wall functionalities, the impact of such reactions on cell integrity, and potential implications for soil C cycling.

The influence of co-contaminant complexing agents on radionuclide environmental behaviour

MIRANDA J. KEITH-ROACH[1,2]*, ESTELA REINOSO-MASET[1], COLIN C. MAY[1], LINDSAY YOUNG[1] AND PAUL J. WORSFOLD[1]

[1]Biogeochemistry Research Centre, University of Plymouth, Plymouth, PL4 8AA, UK
[2]Kemakta Konsult, S-11293 Stockholm, Sweden
(*correspondence: mkeith-roach@plymouth.ac.uk)

Organic complexing agents that are co-disposed in radioactive waste or formed *in situ* may enhance the migration of radionuclides at contaminated sites. However, the mechanisms of the interactions are poorly understood. We have therefore undertaken an extensive program of research to probe the speciation of radionuclide-organic co-contaminant complexes, competitive interactions with common metal ions and the mechanisms by which the complexing agents impact radionuclide sorption and transport. This work has utilised electrospray ionisation mass spectrometry for the characterisation of aqueous speciation, kinetic batch sorption experiments using a relevant, characterised terrestrial sand (Drigg sand) and dynamic column experiments coupled with the k1D transport code. Thorium (IV), U (VI), Sr (II) and Cs (I) were selected as model radionuclides of different oxidation states and EDTA, NTA, picolinic acid and isosaccharinic acid were included as key complexing agents.

The complexing agents generally influenced radionuclide behaviour in the expected order of Th>U (VI)>Sr, with no discernable effect on Cs, and EDTA generally exerted the greatest influence of the complexing agents. However, the results highlighted the complexity of these interactions. In several cases, the speciation of the complexes was more diverse than suggested by the existing speciation databases. Also, the kinetics of exchange between radionuclide complexes and common metal ions varied from occurring virtually instantaneously to over several months, and could involve precipitated metal phases.

Batch experiments demonstrated that the concentration of the radionuclide strongly influences the effect that a complexing agent can have, in terms of both the kinetics of sorption and the equilibrium position. Finally, transport experiments identified that the formation of ThEDTA complexes enhances Th transport, but that at higher Th concentrations, EDTA-mediated colloidal Th transport occurs. The key data from these studies will be presented and discussed in terms of the environmental importance of the complexing agents.

Geochemical study and U/Th dating of the Akköy fissure ridge travertine (SW-Turkey): Paleoclimatic and paleoseismic interpretations

S. KELE[1]*, M. ÖZKUL[2], A. GÖKGÖZ[2], C.-C. SHEN[3], I. FÓRIZS[1], M.O. BAYKARA[2] AND M.C. ALÇIÇEK[2]

[1]Hungarian Academy of Sci., Institute for Geochemical Research, Budaörsi út 45, H-1112 Budapest, Hungary (*correspondence: keles@geochem.hu)
[2]Pamukkale Univ., Dep. of Geol. Eng., TR-20070 Denizli, Turkey
[3]National Taiwan University, Taipei, Taiwan

Fissure ridge travertines are elongated, wedge-like nonmarine carbonate deposits formed due to CO_2 degassing from carbonate rich thermal spring waters. They are well-known indicators of past and present seismic activity, including Quaternary and prehistoric major earthquake events, as generally deposited from springs discharging in co-seismic extensional fissures along major active faults [1, 2]. The precipitation of travertines is strongly influenced by the water supply controlled mainly by climate, thus the question must be raised, whether the tectonic and/or climatic processes has the major role on their deposition.

To answer the question, we performed detailed U-series dating and stable isotope and trace elemental study of travertines collected along a vertical section, through the bedded layers of the Akköy, Karakaya Hill fissure ridge (Denizli Basin, SW-Turkey). The U-series age data range from 45±108 ka to 18±0.3 ka. The more or less continuous travertine deposition at the Akköy fissure ridge during cold-dry and warm-wet climatic events indicates that the travertine deposition was controlled strongly by tectonic processes, i.e. the area of the Denizli Basin was seismically active during the period mentioned above. The trace element concentrations of the bedded travertine deposits show temporal change in the geochemistry of the travertine depositing thermal water.

Mantle melting and melt transport beneath oceanic spreading ridges

PETER B. KELEMEN

LDEO, Columbia University (peterk@LDEO.columbia.edu)

Degree of melting & potential temperature

Reaction of cooling melt with shallow peridotite can reset indicators of degree of melting and potential temperature in both melt and residual peridotite. Yb concentration and spinel Cr# in peridotite are affected by (a) small scale variations in reactive melt transport, (b) variable extents of melt *extraction*, and (c) 'impregnation', i.e. partial crystallization of cooling melt in pore space. Also, many peridotites at ridges may have undergone several extensive partial melting events over Earth history, while others could be residues of extensive melt extraction from mafic heterogeneities in the mantle source.

Melt focusing to ridges

Modeled crystallization of cooling melt in the shallow mantle can create a permeability barrier guiding underlying melt diagonally toward the ridge, but field studies have not identified such barriers. Permeable 'shear bands' may guide melt to the ridge, but the nature of shear bands in open systems at natural grain size and strain rates is uncertain. 2D and 3D focused solid upwelling due to melt buoyancy and weakening as a function of permeability – especially increasing permeability with decreasing pyroxene content during melting – may warrant more attention.

Crustal thickness, spreading rate & melt productivity

The following three statements are inconsistent: (1) Modelled peridotite melt productivity beyond cpx exhaustion is ≥ 0.11%/GPa. (2) Crustal thickness is independent of spreading rate. (3) Thermal models predict, and observations confirm, thick thermal boundary layers beneath slow spreading ridges. Most sampled peridotites from ridges melted beyond cpx-out. Cpx in these rocks formed via impregnation and/or exsolution during cooling. The data can be understood if (a) melt productivity is << 0.1%/GPa beyond cpx-out, and (b) cpx-out occurs > 15 km below the seafloor beneath most ridges.

Conduit generation and geometry

Dunites, formed by pyroxene dissolution in olivine-saturated melt ascending by porous flow, are conduits for focused porous flow of melt, preserving disequilbrium between melt and pyroxene in surrounding peridotite at P < 1.5 GPa. Perturbations in permeability grow into dunite conduits because incongruent dissolution increases porosity and permeability. Perturbations may arise from 'shear bands' and/or heterogeneities in the mantle source. Conduits may also involve mechanical instabilities, if it is easier to open a pore than to close it. Most models and experiments do not produce the power law distribution of dunites at a given depth observed in peridotites, except for some shear band experiments.

Underplating of felsic rocks in arcs

PETER KELEMEN[1], BRADLEY HACKER[2] AND MARK BEHN[3]

[1]LDEO, Columbia University (peterk@LDEO.columbia.edu)
[2]UCSB (hacker@geol.ucsb.edu)
[3]WHOI (mbehn@whoi.edu)

Buoyant, felsic material may be subducted and then returned to the base of evolving crust via (a) relamination, (b) diapirs in the mantle wedge, and/or (c) imbrication (e.g. [1-5]). Subducting crust is carried to conditions (~700°C and P > 1 to 2 GPa) where garnet is stable, rendering some lithologies denser than mantle peridotite at the same PT, and where material is hot enough to flow viscously in response to buoyancy forces [6]. Whereas delamination and foundering can only remove dense lithologies from a narrow, high PT horizon at the base of typical crust, the *entire* subducting crustal section can undergo density sorting in subduction zones. Such efficient density sorting may explain why lower continental crustal compositions, including mafic estimates [7], are less dense than peridotite at the same PT [5, 6, 8].

Sediment subduction and 'subduction erosion' involve intermediate to felsic shale and greywacke. If they are in layers or blobs with dimensions > 100 m, they will rise buoyantly at > 700-800°C in times < 1 Myr [4]. Ascent in a 'subduction channel' involves isothermal decompression to a level of neutral buoyancy (a). Most UHP terrains record re-equilibration at 700°C and 0.5-1 GPa, in accord with this idea [5]. Diapric ascent through the hot mantle wedge (b) will induce extensive melting, producing the 'sediment component' in arc magmas [4]. Some trench sediments may be thrust directly into arc lower crust (c), producing andesitic paragneiss recording typical arc Moho PT (~ 800°C, 1 GPa [9]), as in the North Cascades. Indeed, the 35 km of crust beneath such exposures may itself have been added later, via continued underlplating of buoyant, felsic material. In general, arc magma flux estimates that assume subduction erosion always removes arc crust are overestimates.

Arc-arc or continental collision will also lead to efficient separation of dense, mafic rocks from bouyant, felsic metasediments and plutons that rise to neutral buoyancy [5].

As a result, much of the continental lower crust may be quite felsic, similar to typical granulite terrains. This is consistent with Vp and heat flow data provided that some U, Th and K are extracted via decompression melting [5].

Geochemical and ecological models of plant-driven chemical weathering: Insights into the sinks for atmospheric CO_2

C.K. KELLER[1]*, R. O'BRIEN[2], Z. BALOGH-BRUNSTAD[3] AND B.T. BORMANN[4]

[1]SEES, Washington State Univ., Pullman, WA 99164, USA (*correspondence: ckkeller@wsu.edu)
[2]Allegheny College, Meadville, PA 16335, USA
[3]Hartwick College, Oneonta, NY 13820, USA
[4]Forest Service PNW, Corvallis, OR 97331, USA

It is generally agreed that rhizospheric acidification of the shallow subsurface – the vascular-plant 'acid pump' – accelerates weathering and the loading of soil and drainage waters with base cations, thereby also promoting drainage losses of weathering products (chemical denudation) and lowering atmospheric CO_2 levels on geologic timescales [e.g. 1, 2]. Mass-balance tests of this model, in comparative studies of watersheds with different plant covers, report scattered results.

In our experimental mesocosm studies employing the same approach, a single ecosystem exhibits order-of-magnitude variations in chemical weathering and denudation rates over decadal timescales. Our results also show that the silicate-derived Ca+Mg denudation flux, i.e. the lithospheric CO_2 sink, is not equivalent to the alkalinity flux, i.e. the hydrospheric sink, because of disturbance-driven strong-acid generation. These results underline the idea that the efficacy of the plant-driven lithospheric CO_2 sink, and perhaps associated long-term climate control, may depend on the planet's geophysical, biological and ecological disturbance regime. It is true that the weathering power of vascular plant systems dwarfs that of nonvascular systems; but the vascular systems also have correspondingly great capacity to conserve the nutrients generated by weathering, by localizing water and nutrient cycles both during growth and following perturbations.

Our findings are consistent with an ecological model in which mechanisms of biologically mediated weathering are adaptive functions of ecosystem state. In this paradigm, which emphasizes the plant as chemical sink and builder of soil and ecosystem nutrient capital, vascular systems are likely to deploy varying portfolios of weathering and nutrient uptake strategies, involving a range of plant physiologies, rhizospheric symbioses, and mass transfer and transport mechanisms with a range of hydrochemical consequences.

Beyond the closure temperature concept: when does $^{40}Ar/^{39}Ar$ dating constrain exhumation?

S.P. KELLEY[1], C.J. WARREN[1] AND F. HANKE[2]

[1]CEPSAR, The Open University, Walton Hall, Milton Keynes, MK7 6AA, United Kingdom
[2]Surface Science Research Centre, Department of Chemistry, University of Liverpool, Liverpool, L69 3BX, United Kingdom

$^{40}Ar/^{39}Ar$ ages determined on metamorphic minerals are commonly assumed to reflect cooling and exhumation, but recently reported experimental results on muscovite suggest a significant pressure dependence of argon diffusion in muscovite, which acts to decrease argon diffusion rates at high pressure. Using numerical diffusion models, which include a pressure correction, we systematically interrogate the assumptions associated with $^{40}Ar/^{39}Ar$ dating of muscovite in such rocks. We show the pressure-temperature regions in which $^{40}Ar/^{39}Ar$ dating could constrain the timing of exhumation in an open system, and suggest a method for checking that the rock being dated has behaved as an open system during exhumation. The link between apparent $^{40}Ar/^{39}Ar$ age and traditional 'closure temperature' is shown to be valid only when muscovite crystallized under, or subsequently reached, high temperature and relatively low pressure conditions. Our modelling data suggest that HP and UHP rocks, particularly those that have experienced short orogenic cycles are unlikely to yield cooling and exhumation ages. The results and discussion presented here for muscovite are equally applicable to other metamorphic minerals commonly dated using the $^{40}Ar/^{39}Ar$ system.

Si isotope fractionation in high-temperature metal-silicate systems: Implications for core formation

J.KEMPL[1]*, P.Z. VROON[1], W.V. WESTRENEN[1], J.A. SMALL[2] AND H.G. JAK[3]

[1]FALW, VU University Amsterdam, The Netherlands (*correspondence: josepha.kempl@falw.vu.nl)
[2]CRC & [3]SPME, Tata Steel IJmuiden, The Netherlands

The observed difference in Si isotopic composition between CI chondrites and bulk silicate Earth has been explained by high P-T metal-silicate Si isotope fractionation accompanying Si incorporation into Earth's core [1, 2, 3].

We have measured Si isotopes in metal alloys and co-existing silicate slags that were produced at temperatures of ~1600°C in reducing atmospheric conditions in an industrial blast furnace at Tata Steel IJmuiden, the Netherlands.

Silicon isotopes were measured with a ThermoFinnigan Neptune MC-ICPMS [3] using a modified sample digestion procedure [3, 4]. Our results show an average mass difference of 0.75 ‰ for δ^{30}Si between metals and silicates (Fig.1).

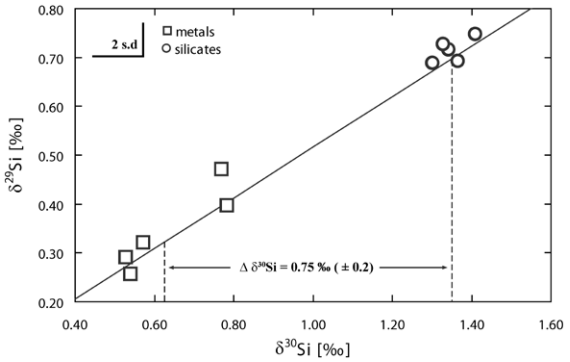

Figure 1: Three isotope plot showing Si isotope data of metals and silicates along the equilibrium fractionation line of Si.

Sign and magnitude of our results are in good agreement with results of high-pressure experiments [3] and theoretical predictions [1]. Si isotope fractionation clearly occurs in high-temperature metal-silicate systems under reducing atmospheric conditions, and high pressures are not required. Our data show that Si could have been incorporated into Earth's core during its early formation stages.

Increasing ocean oxygenation may have spurred the evolution of large multicellular metazoans during the Ediacaran Period (635-542 Myr ago). Fe speciation and other geochemical data from sedimentary rocks indicate that regional ventilation of the deep oceans commenced no later than 580 Myr ago but parts of the Ediacaran deep ocean remained anoxic. Reconstructing the timeline of ocean oxygenation is critical to understanding metazoan evolution, but the spatiotemporal distribuition of dissolved O_2 remains poorly understood. In contrast, the Mo isotope composition of euxinic (anoxic/sulphidic) black shales represents a proxy for global seawater and constrains global ocean redox conditions.

Here, we present Mo isotope evidence for the first known episode of widespread ocean oxygenation 551 Myr ago. High-resolution profiles through black shales at the top of the Doushantuo Formation (South China) reveal a transient excursion to heavy $\delta^{98/95}$Mo (from ~0‰ to 2‰) that approaches modern global seawater (2.3‰). The latter has heavy $\delta^{98/95}$Mo largely because isotopically light Mo is preferentially removed into oxic Fe-Mn crusts. We infer a similar extent of Mo burial in oxic sediments 551 Myr ago.

Older euxinic shales deposited between 1840 and 551 Myr ago are enriched in isotopically light Mo and indicate expanded deep ocean anoxia, including a prevalence of euxinic conditions at mid-depths along ocean margins. Between 551 and 400 Myr ago, the Mo isotope database points to an intermediate extent of oxygenation relative to older and younger oceans. We propose that there was a major increase in ocean oxygenation 551 Myr ago which sparked a major diversification of complex macroscopic metazoans.

Halogens (Cl, Br, I) in basalt glasses

MARK A. KENDRICK[1], VADIM S. KAMENETSKY[2], JON D. WOODHEAD[1], DAVID PHILLIPS[1] AND MASAHIKO HONDA[3]

[1]School of Earth Sciences, University of Melbourne, Australia (mark.kendrick@unimelb.edu.au)
[2]ARC Centre of Excellence in Ore Deposits, University of Tasmania, Australia
[3]Research School of Earth Sciences, ANU, Australia

Halogens have highly variable concentrations in basalt glass with part of the variation related to mantle abundance. Serpentinites (hydrated mantle lithosphere) are major reservoirs for halogens in subducting slabs and previous work has shown Br/Cl and I/Cl are strongly fractionated during serpentine breakdown. As a result, fractionated and characteristic low Br/Cl and I/Cl ratios could be useful for tracing the presence of subducted halogens (and other volatiles) in basalts from different tectonic settings.

The halogen partition coefficients were investigated using a suite of Enriched Mid-Ocean Ridge Basalt glasses from Macquarie Island (70-1400 ppm Cl; MgO of 5.5-9 wt %; La/Sm of 1.4-7.9; typical MORB $^3He/^4He$ of ~8 Ra). Log-log covariation diagrams demonstrate Cl, Br, K and U have statistically indistinguishable partition coefficients similar to that of I. Therefore, Br/Cl, I/Cl, K/Cl and U/Cl are not easily fractionated during mantle processing, confirming variations potentially track subducted volatile components. The Macquarie MORB mantle has Br/Cl and I/Cl weight ratios of $(3.7 \pm 0.5)\times10^{-3}$ and $(130 \pm 100)\times10^{-6}$, respectively. Together with the Cl/K/U data, these ratios suggest 19 ± 6 ppm Cl, 67 ± 31 ppb Br and 7 ± 5 ppb I (2σ) in the bulk silicate Earth.

Preliminary data for Back-Arc Basin Basalt glasses from Lau and Manus have up to 3000 ppm Cl and variable Br/Cl and I/Cl signatures, including some of the lowest Br/Cl ratios obtained in this study. These data could be partly explained by a Cl contribution from serpentine breakdown fluids, but data are now required to determine the subduction potential of Br and I in organic-rich meta-sediments.

Oceanic Island Basalts from the Society and Pitcairn seamounts ($^3He/^4He$ of 1-10 Ra ± solar Ne indicate mixed recycled and primitive components) are characterised by MORB-like I/Cl and Br/Cl ratios. In contrast, low Br/Cl values are expected in dehydrated serpentinites and high I/Cl values are expected in subducted sediments. Therefore, halogens in basalts with 'EM-type' signatures do not carry an obvious recycled signature, but could be explained by mixing recycled, 'primitive (?)' and MORB mantle components.

Possible Platinum Group Element (PGE) clusters in magmatic systems; Using synthetic sulphide melts

B. KENNEDY[1]*, M. TREDOUX[1], C. BALLHAUS[2], H.M. HELMY[2], H.C. SWART[3] AND L. COETSEE[3]

[1]Department of Geology, University of the Free State, South Africa (*correspondence: kennedybia@gmail.com)
[2]Steinmann Institute, Universität Bonn, Bonn, Germany
[3]Department of Physics, NNSCF, University of the Free State, South Africa

The aim of the study is to verify whether or not the primary binding mechanism of PGE, in a magmatic environment, is a pure chemical or physical/- mechanical process. The monosulphide (mss) phases of temperature controlled synthetic melts were investigated for the existence of small Pt clusters or nano-structures (10-100 atoms). If such entitites are found, they would point towards an initial physical mechanism as the dominant process during early magma differentiation.

Exeriments were run with variable concnetrations of Pt, As, Cu, S and Fe, chosen to mimic a natural Cu-Ni-S ± PGE system. Samples were cooled down rapidly (from 1050-25°C in a few seconds) and slowly (1050-400 °C over 48 hours).

Pt forms large heterogeneously distributed Pt-As_x and Pt-Fe_x phases (0.2-50 μm i.e. approximately 700-166666 atoms) within the melt phase of both slow and fast cooled samples. Results indicate that Pt needs a suitable anion like As, Fe or Cu to form a stable phase in a magmatic system. Pt-Cu_x phases (200-1000nm i.e. approximately 700-3333 atoms) in the mss phase of faster cooled samples confirm that some kind of clustering process is at work in Cu-Ni-S systems. Faster cooled samples show exsolution textures of Pt out of the mss phases into the melt phase (Cu_x-Fe_x-S_x).

While chemical behaviour may govern the secondary distribution of Pt-phases, clustering is potentially the primary (physical) mechanism. The clusters can easily be taken up into a immiscible sulphide, oxide or silicate phase. Clustering behaviour may explain the high enrichment of PGE in early cumulus phases (olivine and chromite) of the Bushveld complex.

Terrestrialization of the Earth and its influence on the advent of complex life

MARTIN KENNEDY

School of Earth and Enironmental Science, University of Adelaide, Adelaide SA,5005, Australia (martin.kennedy@adelaide.edu.au)

For the first 3 billion years of life's history on Earth single celled organisms were Earth's sole residents. In the Late Precambrian this record changed dramatically with the appearance of complex multicellular life (metazoans) that rapidly diversified and radiated. This radiation was likely triggered by planetary changes, though what those changes were, how they interacted with intrinsic (genetic) influence and which changes were causes and which effects constitute principal questions in geobiology with important implications for the conditions on other planets necessary to support complex life. Much of what we know of this transformation comes from the marine record because of a strong preservational bias relative to terrestrial sediments. It is evident from studies of the modern biosphere, however, that the terrestrial realm has a critical influence on the sustainability of complex life. While it is widely accepted that the early terrestrial surface of the Earth was inhospitable to life, and the timing of the greening of the Earth's surface remains poorly constrained, the infleunce of vascular land plants beginning in the Silurian is commonly believed to have been an important step in establishing the present Earth system. However an earlier more cryptic and simple biomass likely colonized and expanded across the Precambrain landscape, modifying physical and chemical weathering patterns, soil clay mineral production, marine and terrrestrial carbon burial, nutrient flux to marine systems and the hydrological cycle. It is reasonable to hypothesize that biogeochemcial systems, like clay mineral associated organic carbon preservation and burial, that play an important role in CO_2 sequestration and atmospheric oxygen production today, were intitated during this earlier transition. Secular changes in clay mineral composition of sediments through late Precambrain continental margin sediments show a distinct rise in phyllosilicates in support of this hypothesis. Alteration of the carbon isotopic composition of coastal carbonates by dissolved organic mater in meteoric waters also becomes a pronounced influence during this period of time, and finally new fossil discoveries also point to the terrestrial surface as being an important component in planetary transformation.

A continental amplifier for marine carbon sequestration in a greenhouse ocean

MARTIN KENNEDY[1] AND THOMAS WAGNER[2]

[1]School of Earth and Environmental Science, University of Adelaide, Adelaide SA, 5005 Australia (martin.kennedy@adelaide.edu.au)

[2]School of Civil and Engineering and Geosciences, Newcastle University, Newcastle upon Tyne, NE1, &RU, UK

Recent evidence has increased concern that future climate will be influenced by natural processes and feedbacks more common to a warm climate mode. It is well known from past greenhouse periods that anomalous concentrations of organic carbon were associated with disruption of marine ecosystems, widespread anoxia, and climate perturbations. While most models of black shale formation focus on oceanographic controls, findings on modern continental margin sediments also identify a strong landward influence on marine carbon burial that is also consistent with current understanding of hypoxic zone expansion. Here we show evidence for a direct land-sea mechanism that translates the effects of changing continental climate to carbon burial in deep marine sediments via the preservative effects of detrital clay mineral surfaces. We show a correlation (r^2=0.75) at cm resolution between mineral surface area (MSA) and abrupt (centennial or less) high magnitude shifts in TOC from 1% to 15% in pelagic sediments from the tropical Cretaceous Atlantic (ODP 959). Carbon burial was maximized by an enhanced flux of high MSA clay minerals formed in response to increased seasonality in tropical Africa that were exported to hypoxic shelf waters with high dissolved organic carbon concentration. Not only do these data identify a dominating terrestrial influence for back shale formation during one of the 'Cretaceous Oceanic Anoxic Events' ~ 85 ma (OAE3), but show that climate under greenhouse conditions can cross a threshold into a highly sensitive mode in which organic carbon burial efficiency is amplified, providing a negative feedback to pCO_2,

Geochemistry of fluids from the Bruce nuclear site: Evidence for a geologically ancient Ordovician porewater system

LAURA KENNELL[1], TOM AL[2], IAN CLARK[3] AND MARK JENSEN[1]

[1]Nuclear Waste Management Organization, 3rd Floor 22 St. Clair Avenue East, Toronto ON, M4T 2S3
[2]Department of Earth Sciences, University of New Brunswick, P.O. Box 4400, Fredricton, NB, E3B 5A3
[3]Department of Earth Sciences, University of Ottawa, 140 Louis Pasteur, Ottawa, ON, K1N 6N5

Groundwater and porewater geochemistry data were collected at the Bruce nuclear site near Tiverton, ON, located on the northeastern margin of the Michigan Basin, as part of multi-disciplinary site characterization activities for the proposed development of a deep geologic repository (DGR) for low- and intermediate-level radioactive waste (L&ILW).

The site-specific geochemical data is consistent with regional data collected in various locations within the Michigan Basin, suggesting that the origin and evolution of the brines at the regional- and site-scales have been controlled by the same, or similar, processes. The natural tracer data ($\delta^{18}O$, $\delta^{2}H$, Cl, Br) collected at the Bruce nuclear site support the long-standing hypothesis that the sedimentary brines originated from seawater, or evaporated seawater (e.g. [1, 2]), and have been modified over hundreds of millions of years by various mixing and *in situ* water-rock interaction processes (e.g. dilution, halite dissolution, dolomitization). In addition, enriched $^{87}Sr/^{86}Sr$ isotopic signatures throughout the entire Ordovician sedimentary sequence suggest that solute residence times within the Ordovician brines are long and these values are consistent with regional observations (e.g. [3]).

Horizontal hydraulic conductivities (K_H) and matrix permeabilities were measured in the Ordovician formations and range between 10^{-15} and 10^{-12} m/s, and 10^{-20} to 10^{-15} m^2, respectively. Vertical hydraulic conductivities are estimated to be less than K_H by a factor of at least ten in the Ordovician formations, and the presence of high isotopic gradients in the methane and helium compositions ($\delta^{13}C_{CH4}$, $\delta^{2}H_{CH4}$, and $^{3}He/^{4}He$) indicate that a barrier to vertical solute transport may exist at the base of the Cobourg Formation at the Bruce nuclear site. The geochemistry, when partnered with the physical data, suggests that the Ordovician porewater system is geologically ancient.

Characterising the Earth: Exploiting seismology and mineral physics

B.L.N. KENNETT

Research School of Earth Sciences, The Australian National University, Canberra ACT 0200, Australia (*correspondence: brian.kennett@anu.edu.au)

The dominant gradient in Earth properties is radial and this has enabled simple 1-D models to have considerable utility. Seismological reference models have been employed in ways that were not envisaged when they were created. In particular, the parameterizations were chosen for mathematical convenience rather than linked to any particular physical conditions. It should therefore come as no surprise that such seismological models do not conform to the properties expected for mineral physics predictions for reasonable mineral assemblage models and near adiabatic conditions. There will also be biases associated with lateral heterogeneity, e.g. the properties corresponding to the average temperature are not the same as the average of the same properties. Nevertheless seismology provides key tie points through well constrained discontinuities that can calibrate pressure scales, and mineral physics can investigate perfect aggregates and so explore a broad range of likely conditions. Rather than test a particular mineral physics configuration against a specific seismic reference model or a subset of seismological observations, we need to build new physical comparator models that recognise the limitations of both seismic and mineral physics models and provide explicit uncertainties on physical parameters. Such models should work with the standard seismological data sets and recognise the geodynamic state - non-adiabaticity is likely in a convecting system. We can examine the physical state implied by seismic tomography in terms of the predictions for different classes of parameter models and so gain insight into the controls we have on the Earth system.

Comparing the surface-promoted hydrolysis of phosphate mono- and diesters on goethite

JANICE P.L. KENNEY* AND PER PERSSON

Department of Chemistry, Umeå University, 901 87 Umeå Sweden (*correspondence: janice.kenney@chem.umu.se)

Phosphorus is an essential nutrient for both plants and microorganisms. However, in order for it to cross cell membranes, it must be in the form of orthophosphate or in some cases as small organophosphates. The majority of organic phosphates input into the biosphere are in the diester form, via pesticides, plasticizers, and hydraulic fluids. However, the P found in most soils is dominated by monoesters. Hydrolysis of phosphate esters in biological systems is important since it is a step that is required to make these large phosphate esters more bioavailable. While the hydrolysis of these phosphate esters is thermodynamically favourable, the reaction in water or a strong electrolyte solution is a slow process.

Phosphorus is a unique essential nutrient in its ability to strongly sorb to environmental particles. Therefore, reactions at the surfaces of these particles can control the fate and transport of phosphorus in the biosphere. Minerals, such as goethite, have been shown to increase the rate of hydrolysis of organophosphates by acting as a catalyst. In this study we have investigated the abiotic hydrolysis of a phosphate monoester and diester, p-nitrophenyl phosphate (pNPP) and Bis-[p-nitrophenyl] phosphate (BNPP), respectively. To determine the mechanisms and rate of the hydrolysis of pNPP and BNPP adsorbed on goethite surfaces we have used a combination of spectroscopic methods. The concentration of phosphate remaining in solution was determined by UV-vis spectroscopy, while the surface reactions were examined using infrared spectroscopy via the ATR sampling technique.

Spectroscopic results for the pNPP-goethite system show quick and complete adsorption of the ligand, followed by the subsequent hydrolysis, with the release of nitrophenol (NP) into solution. After 30 hours nearly 100% of the pNPP was hydrolyzed to NP and orthophosphate. Alternately, in the BNPP-goethite system, the ligand adsorbs much more slowly and to a lesser extent than the pNPP. Between pH 4 and 6, the maximum hydrolysis observed over 48 hours is less than 25%. Our results suggest that differences in surface affinity and surface-promoted hydrolysis between mono- and diesters are important factors to consider in order to explain differences in the overall biogeochmical behaviour of these two classes of phosphorus compounds.

Water in the mantle, melting, and the evolution of Earths atmosphere

HANS KEPPLER

(hans.keppler@uni-bayreuth.de)

Water and carbon are the most important volatiles in Earths´ interior, but they strongly differ in their behaviour. While carbon is mostly sequestered in accessory phases such as carbonates and elemental carbon, water mostly resides as OH point defects in the nominally anhydrous minerals of the mantle. In this presentation, I review (1) the observational constraints on water abundance in the mantle (2) the effect of water on mantle melting and the associated changes in electrical conductivity and (3) the coupling between the water abundance in Earth's mantle and the redox evolution of the atmosphere.

Water may be essential for inducing melting in the seismic low velocity zone of the upper mantle as well as above the 410 km discontinuity. Both effects are ultimately related to depth-dependent changes in the capability of mantle minerals to dissolve water as point defects. Major experimental advances in recent years have shown that both the solubility of water in olivine at the base of the upper mantle as well as the solubility of water in pyroxenes in the uppermost mantle are much higher than previously thought. Moreover, new *in situ* measurements show that water has a much stronger effect in enhancing the electrical conductivity of basaltic melts than anticipated and this effect increases with pressure. A consequence of these observations is that very likely, small fractions of hydrous melt can explain the electrical conductivity in the seismic low velocity zone of the upper mantle.

It has long been recognized that Earth's atmosphere became much more oxidized in the 'great oxidation event' 2.3 billion years ago. This event may be due to a change in oxidation state of volcanic gases or to photosynthesis by cyanobacteria. Changes in the oxidation state of volcanic gases 2.3 billion years ago have often been dismissed on the ground that there is no evidence for a corresponding change in mantle redox state at this time interval. However, the relevant gas equilibria between sulfur and nitrogen species do not only depend on oxygen fugacity, but also on water. I show that degassing of water from the mantle – at constant oxygen fugacity – may well induce the changes in the oxidation state of sulfur and nitrogen in volcanic gases required to oxidize the atmosphere.

Atomistic simulations of uranium in the environment: Diffusion, adsorption, and incorporation

S. KERISIT*, C. LIU, A.R. FELMY AND E.S. ILTON

Chemical and Materials Sciences Division, Pacific Northwest National Laboratory, Richland, WA 99352 USA (*correspondence: sebastien.kerisit@pnl.gov)

Uranium is the most common radionuclide contaminant in subsurface systems associated with the U.S. Department of Energy (DOE) sites where nuclear materials were processed and stored. We have used a suite of atomistic simulation techniques to provide an atomic-level characterization of U properties in model systems relevant to DOE sites.

U preferentially associates with intra-grain domains in U-contaminated sediments collected from the DOE Hanford site and diffusion is expected to control the future mobility of U in these sediments. Therefore, we present molecular dynamics simulations of the diffusion and adsorption of uranyl carbonate species in intra-grain micropores, using feldspar-water fractures as a model system. Uranyl carbonate species dominate U(VI) aqueous speciation in Hanford groundwater conditions. The simulations show the effects of confinment and of the presence of the mineral surface on the diffusion of water and several uranyl carbonate species [1-3].

Uranium sorption by Fe-(hydr)oxides, which are common minerals in soil systems, has been conceptualized as a surface process; however, sorption is not necessarily reversible. The potential for incorporation into the mineral structure is supported by EXAFS studies; however, the evidence for incorporation rests on distances that do not match distances claimed for simple adsorption. Therefore, independent data are needed to confirm the structural incorporation hypothesis.

In this paper, we present atomistic modeling performed to evaluate the coordination of U incorporation in three Fe-(hydr)oxides [4]. The simulations provided information on U-O and U-Fe distances, coordination numbers, and lattice distortion for U in different sites and oxidation states. Comparison of the simulations with available experimental data provides further evidence to support the structural incorporation hypothesis.

Probing mineral-water interfaces with computer simulation

S. KERISIT*, K.M. ROSSO AND A.R. FELMY

Chemical and Materials Sciences Division, Pacific Northwest National Laboratory, Richland, WA 99352 USA (*correspondence: sebastien.kerisit@pnl.gov)

The atomic-level structure of water at mineral sufaces is an important controlling factor in interfacial reactions. Therefore, differences in interfacial water structures could contribute to variations in surface reactivity between different surfaces of a single mineral. In this presentation, the water interfacial structure of three hematite surfaces, namely, the (012), (110), and (001) surfaces, will be contrasted [1]. An extensive comparison with X-ray scattering data provides further evidence that MD models can be used to reliably predict the structure of mineral-water interfaces. In addition, the MD trajectories were analyzed to gain insight into the surface structural controls on the interfacial water structure.

Mineral-water interactions also play an important role in carbonation reactions, which are one of the principal families of chemical interactions relevant to geological CO_2 capture and storage (CCS). Although carbonation of minerals in contact with a CO_2-containing aqueous phase has been extensively studied, carbonation reactions involving water-bearing supercritical CO_2 fluids (WBSF) have received comperatively little attention. However, the limited number of studies published to date all highlighted the dependence of the extent and rate of reaction on the water content of the WBSF. Therefore, a detailed understanding of the structure of the WBSF-mineral interface as a function of water content is critical to elucidating the mechanisms of carbonation reactions in conditions relevant to CCS.

MD simulations of a model forsterite surface in contact with WBSF of varying water content were performed to determine the partition of water between the WBSF and the mineral surface and the nature of CO_2 and H_2O bonding at the interface. The simulations show that water readily displaces CO_2 at the surface and that the formation of a water film at least three-monolayer thick can be exothermic even for water contents below saturation. The density, diffusion, and degree of hydration of CO_2 as well as the extent of CO_2/H_2O mixing at the interface were all predicted to depend strongly on the water content of the WBSF.

Advancing studies of the origin and role of hydrocarbons in ore-forming systems

MITCHELL J. KERR* AND JACOB J. HANLEY

Saint Mary's University, Dept. Geology, Halifax, Canada (*correspondence: mitchell.kerr@utoronto.ca)

We have advanced an in-line rock crushing, gas chromatographic (GC) technique that can detect and quantify hydrocarbons present within fluid inclusions to a lower limit of 1 ppm. This technique has been adapted from developments by Bray *et al*. [2] and Salvi and Williams-Jones [1] in order to comprehensively analyze a much wider range of hydrocarbons (C1-C9 olefins and paraffins). The system is comprised of four stainless steel rock crushers that crush rock fragments in a sealed and sterile environment, passing the released volatiles into the GC to be separated and analyzed.

Rock types associated with various ore-forming systems, as well as a number of others are being investigated. These include: mantle-derived xenoliths, hydrothermal veins from major ore deposit types including MVT, VMS and magmatic sulfide deposits, porphyry systems, IOCG deposits, and epithermal/geothermal deposits. With this work, we are: (1) constraining the importance of hydrocarbons in transporting ore metals via olefins, alcohols and/or carboxylic acids that may facilitate metal complexation and transportation; (2) determining hydrocarbon origin (e.g. mantle-derived, remobilized from associated hydrocarbon deposits, *in situ* formation by metal catalyzed Fischer-Tropsch reactions [3]).

We suspect that the presence of particular metals (i.e. group VIII elements [3]) may effectively catalyze the respeciation/polymerization of light hydrocarbons into higher order compounds via the interaction between oxidized and/or reduced carbonic fluids within hydrothermal systems with various ore metal-bearing systems. Tentative results collected from analyzing hydrothermal quartz veins associated with base metal sulfide deposits in the Canadian Shield illustrate a high level of hydrocarbon speciation, including compounds such as butane, pentane, hexane and various saturated and unsaturated isomers thereof. Trace quantities of higher order compounds within the C6-C8 region were also found (possibly toluene, xylene, octane, etc.).

Metallogenic provinces: Products of asthenosphere-thermal boundary layer-lithosphere interactions

R. KERRICH

Geological Sciences, University of Saskatchewan, Saskatoon, Canada S7N 5E2 (robert.kerrich@usask.ca)

Continental lithospheric mantle (CLM) was extensively modified by subduction-derived fluids especially at craton margins, and melts, from ~ 3 Ga as preserved in xenoliths of CLM. As well, melt-related metasomatism of CLM can be proxied by alkali basalts in ocean basins, by Dupal-type anomalies where a continental low-velocity zone is rafted into ocean basins as continents rift, and by continental alkali basalts all with high-LREE budgets.

Orogenic gold deposits, dominantly associated with accrertionary-type orogens, are generated at terrane boundaries where an accretionary wedge, and LVZ, are subcreted between the over-riding and subducting plates. Dehydration at low-water-rock ratios, during thermal rebound following cessation of subduction, generates low-salinity aqueous fluids enriched in Au, Ag, As, Sb, Hg and lithophile elements which advect along terrane boundaries where the deposits form. This element budget is a proxy for subduction-fluid induced metasomatism of the mantle wedge and sub-arc lithosphere during normall convergent margin magmatism.

During rifting of such metasomatised mantle in continental and oceanic settings, Au-rich fluids, and alkaline magmas, are generated as expressed in Au-porphyry deposits and epithermal systems. During plume impingement at craton margins ultramafic liquids interact with noritic melts generated from measomatised CLM raising Si- and H_2O-activities that trigger sulphide saturation for Ni-Cu-PGE deposits. At intracontinental rifts where plumes are focussed, the bimodal A-type granite and gabbro-anorthosite association is best expressed in the Proterozoic as controlled by the depth of the CLM. Fe-oxide, Cu, Au, REE deposits form by plume and decompressional melting and dehydration of metasomatised CLM with REE-contributed from entrained LVZ.

Glacial to Interglacial changes in the carbonate ion signature of deep and intermediate water masses in the Southern Ocean

F.KERSTEN* AND R. TIEDEMANN

Alfred Wegener Institute for Polar and Marine Research, 27570 Bremerhaven, Germany (*correspondence: Franziska.Kersten@awi.de)

The Southern Ocean (SO) currently acts as a sink for CO_2, which is transported to intermediate [1] and deep waters [2] and consequently alters the inorganic carbon chemistry there. With regard to the rise in atmospheric pCO_2 since the Last Glacial Maximum (LGM), we aim to reconstruct fluctuations in $[CO_3^{2-}]$ in the Circumpolar Deep Water (CPDW) and the Antarctic Intermediate Water (AAIW) in the Australian and Pacific Sector of the SO. For this purpose, B/Ca ratios in benthic foraminiferal shells (*C. wuellerstorfi, C. mundulus* and *Uvigerina spp.*) are obtained. Deep water samples from the South Tasman Rise show a clear decrease in average B/Ca ratios from the LGM (43 μmol/mol) towards the Holocene (29 μmol/mol), from which we reconstruct average LGM and Holocene carbonate ion contents of 130 μmol/kg and 81 μmol/kg, respectively. Holocene values are corroborated by data from nearby GLODAP sites and the observed drop in seawater- $[CO_3^{2-}]$ is consistent with an increase in atmospheric pCO_2 since the LGM. Reconstructed values from Challenger Plateau sediments (bathed by AAIW) follow the trend observed in deep water cores, showing a decrease in average $[CO_3^{2-}]$ from 93 μmol/kg (LGM) to 81 μmol/kg (Holocene). Results from the shallowest core (958 m water depth) however reveal rising $[CO_3^{2-}]$, which might reflect location- and depth-related differences in CO_2 uptake and release. To investigate this further, we are currently analysing sediments from the SE of New Zealand, which stem from AAIW and CPDW depths. Moreover, a continuous $[CO_3^{2-}]$- record for the last 20 ka will hopefully enable us to further constrain the temporal relationship between changes in SO carbonate chemistry and the step-wise release of CO_2 into the atmosphere.

Plutonium transport: Identifying the biogeochemical mechanisms controlling its behavior

ANNIE B. KERSTING

Glenn T. Seaborg Institute, Physical & Life Sciences, Lawrence Livermore National Laboratory, L-231, PO Box 808, Livermore, CA 94550

A major challenge in predicting the mobility and transport of actinides is determining the dominant biogeochemical processes that control its behavior in the subsurface. Plutonium (Pu) is of particular concern do to its large worldwide production inventory, high toxicity to human health and long half-life. There is more than 2200 metric tons of Pu throughout the world (ISIS website). The long half-life of Pu (^{239}Pu ~ 2.4 x 10^4 years) together with existing inventories guarantees that significant quantities will remain in our environment for a very long time. Effectively managing, controlling, and disposing of these materials in order to stop inadvertent release and transport through the geosphere is a serious scientific challenge. Currently, scientists cannot reliable predict how or how much Pu will move once deposited in the subsurface preventing accurate assessment of risk to human health. The behavior of Pu is complex because the reaction chemistry of Pu (i.e. aqueous speciation, solubility, sorptivity, redox chemistry, and affinity for colloidal particles, both abiotic and microbially-mediated) is particularly complicated. Its migration is known to be oxidation-state dependent and facilitated by transport on particulate matter (i.e. colloidal particles). Yet very little is known about how and under what geochemical conditions colloids facilitate the transport of Pu.

Despite the gaps in our understanding, recent field and laboratory experiments are helping to shape our conceptual understanding. I will summarize our current understanding of the biogeochemical processes controlling Pu transport by discussing recent field and laboratory studies. Field studies include weapons facilities where contamination of large quantities of Pu have been deposited and migrated in the subsurface. These studies demonstrate that colloids can and do play an important role in the transport of low-solubility radionuclides; yet, colloids are not always responsible for transport. It is becoming clear that the depositional history of the contamination, as well as the site-specific hydrogeology is critical to assessing the dominant biogeochemical processes controlling the migration of Pu. In addition, the dominant biogeochemical processes controlling migration of Pu can change along the flow path from the sourse to the far-field environment.

Magmatic evolution of the Eastern Anatolian High Plateau, E. Turkey

M. KESKIN[1]*, V. OYAN[2], V.A. LEBEDEV[3], A. CHUGAEV[3], S.C. GENC[4], E.V. SHARKOV[3], E. UNAL[2] AND N. AYSAL[1]

[1]İstanbul University, Faculty of Engineering, Dept. of Geol. Engineering, 34320 Avcilar, Istanbul, Turkey (*correspondence: keskin@istanbul.edu.tr)
[2]Van YYU, Faculty of Engineering and Architecture, Dept. of Geol. Engineering, Zeve Campus, Van, Turkey
[3]RAS, IGEM, Staromonetny per., 35, Moscow 119017, Russia
[4]Istanbul Technical University, Faculty of Mines, Dept. of Geol. Engineering, 34469 Maslak, Istanbul, Turkey

The Eastern Anatolia High Plateau is an actively-deforming continental collision zone with a long-lasting volcanism from the end of Middle Miocene to historical times. It hosts some of the largest volcanic centers and plateaus of the circum Mediterranean region (e.g. Mt. Ararat, Nemrut, Tendurek and Suphan). Eastern Anatolia is a unique place in the world where the continental crust, most of which is represented by an accretionary complex, directly overlies the asthenospheric mantle [1]. So, the region is devoid of a lithospheric mantle. This unusual setting has been proposed to be linked to a major slab-steepening & breakoff event [1, 2].

To better understand the magma genesis and the geodynamic setting, we have been conducting a series of projects in E Anatolia since 2007, carefully studying the stratigraphy of the volcanoes and conducting radiometric datings and geochemical analyses. Results from our new and rather comprehensive database have revealed that the volcanism initiated around the N of Lake Van in the south at ~15 Ma with the eruption of calc-alkaline lavas containing a distinct subduction signature. The geochemical character of the volcanism changed from calc-alkaline to alkaline both in time (from Mid. Miocene to Quaternary) and space (from N to S), while the subduction signature temporally diminished. Our melting models suggest a region-wide temporal change from garnet- to spinel-dominated mantle mineralogy and an increase in the degree of melting. Our AFC and EC-AFC models indicate a significant crustal involvement increasing to the south. These findings may imply that the steepening of the slab has been a much faster event than we previously anticipated and the magma generation might have been influenced by the reformation of a new lithospheric mantle.

[6]Department of Geology, Wayne State University, Detroit, MI, USA (baskaran@wayne.edu)

The Tinto and Odiel Rivers can be used as a natural laboratory to investigate how changes in the aqueous environment affect the mobility of U-series nuclides. These rivers have very low pH's of < 3 for most of their courses, as a result of acid mine drainage (AMD) processes. These AMD conditions generate preferential leaching of ^{234}U compared to ^{238}U from minerals in the background geological setting. Dissolved ^{238}U activities vary from 10 to 850 mBq/L, with the highest ^{238}U activities as well as the highest $^{234}U/^{238}U$ ratios (approaching 3.0) being present under the most acidic conditions. The acidic environment also promotes the dissolution of ^{230}Th, whose activities are up to several orders of magnitude higher than are commonplace in most natural waters. The mobilities of U and Th decrease as pH increases, resulting in precipitation of uranium-bearing minerals in the estuary. The high concentrations of sulfate appear to have an important role in complexation of dissolved Th. These results direct relevance to predicting the mobility behavior of other particle-reactive actinides under acidic conditions in the surface environment.

Liesegang banding and biochemically mediated geochemical self-organization

R.M. KETTLER[1]*, D.B. LOOPE[1] AND K.A. WEBER[1,2]

[1]Department of Earth and Atmospheric Sciences, University of Nebraska-Lincoln, Lincoln NE 68588-0340 USA(*correspondence: rkettler1@unl.edu, dloope1@unl.edu)

[2]School of Biological Sciences, University of Nebraska-Lincoln, Lincoln NE 68588-0118 USA (kweber2@unl.edu)

The Kanab Wonderstone is sandstone from the Shinarump member of the Chinle Formation that is variably cemented and stained with iron oxide. These sandstones contain approximately 5% Fe occurring as one to 5 mm thick, undulatory bands of iron oxide cement (IOC) that crosscut and obscure sedimentary structures. Between each pair of IOC bands are alternating bands of rock that are tinted with iron oxide stain (IOS) and unstained rock. The bands of IOS also crosscut and obscure sedimentary structures. The interior-most portion of the sandstone bed may contain a bleached sandstone core enclosed by a band of IOC. The IOC and IOS are related spatially to vertical joints that cut the sandstone at regular intervals. The IOC in the Shinarump comprises a mixture of acicular grains (goethite) and hexagonal plates with dendritic manganese oxide locally projecting from the cemented sandstone into more bleached rock. Although these features are unusual, they are not unique to the Shinarump member: similar features have been reported from other fluvial rocks worldwide. These features have been typically referred to as Liesegang bands, a type of geochemical self-organization.

The spacing of IOS is consistent with a Jablczynski coefficient [1] of 1.04 and the width of the IOS is a function of distance from the initial reaction front; characteristics that are typical of Liesegang bands [2]. Bands of IOC, on the other hand, exhibit more variable spacing and a relationship between IOC band thickness and distance between IOC. The Shinarump Wonderstone and similar rocks combine features of true Liesegang and biogenically mediated geochemical self-organization. Iron-oxidizing bacteria colonized the interface between siderite-cemented sand and porous sandstone, oxidizing iron and generating acid that caused dissolution of siderite. Aqueous ferrous iron diffused back to the biofilm where it was oxidized. Bands of IOS retain the morphology of reaction front fingers.

Origin and evolution of post-collisional volcanism: An example from Neoproterozoic Dokhan Volcanics at Gabal Nugara Area, Northeastern Desert, Egypt

EZZ EL DIN ABDEL HAKIM KHALAF

Geology Department, Faculty of Science, Cairo University (ezz_khalaf@hotmail.com)

Nugara volcanics are one of the northernmost outcrops of the Arabian-Nubian Shield (ANS). Two distinct volcanic successions are found in the Nugara basin: (1) old volcanic sequence composed of voluminous medium- to high-K calc-alkaline lavas, and minor alkali basalt; and (2) young volcanic sequence composed of subordinate tholeiitic mafic lavas. Their eruptions were punctuated by occasional volcaniclastic deposits that generated fall, flow or reworked suites compositionally identical to the lava flows. These volcanics are a part of a post-subduction and extensional-related magmatic event in Northeastern Desert of Egypt.

Volcanic rocks of the Nugara basin are characterized by strong enrichment in LILE relative to HESF, high LILE/HFSE ratios and depletions of Nb on MORB-normalized multi-element diagrams. Geochemical features of the volcanic rocks suggest that they experienced fractional crystallization, along with mixing processes. Crustal contributions to the magma sources may also have occurred during magmatic evolution. These processes have resulted in scattered major and trace element variations with respect to increasing silica contents. The model proposed for their origin involves contrasting ascent paths and differentiation histories through crustal columns with different thermal and density gradients.

Geochemical features of the most mafic samples suggest that the volcanic rocks in the region were derived from a mainly lithospheric mantle source that had been heterogeneously metasomatized by previous subduction events during convergence between the East and West Gondwanaland. The volcanic activity in the region is best explained by delamination of lithospheric mantle slices that were heterogeneously enriched by previous subduction-related processes.

Hydrogeochemistry and origin of cold high pCO_2 waters of Gonjinskoe spa (Priamurye, Russia)

N.A. KHARITONOVA, I.A. TARASENKO AND G.A. CHELNOKOV

690022, Russia, Primorsky region, Vladivostok, Prospect 100-letya 159, Far East Geological Institute Russian Academy of Science (tchenat@mail.ru)

Gonjinskoe is the most explored and popular spa with high pCO_2 groundwaters in the Priamurye. This spa is very actively used for treatments of gastrointestinal and heart diseases. In the last decade chemical composition of the spa was changed due to intensive exploitation so the main purpose of our study was to investigate the origin and evolution of the spa. Gonjinskoe spa is located in the Magdagachi area in the Valley of Bezimianniy River (Amur River basin) within the limits of the Mongolo-Okhotskaya geosynclinal area. Geologically, two rock formations were found of the study area. The oldest of these is Archeozoic metamorphic rocks of the Gonzhinsky horst. This formation essentially is composed of gneisses and marbles and often contents dykes of Early Cretaceous diorite and rhyolite. The tectonic structure of the spa is very complicated as two large regional faults northeast and sub-latitude directions are crossing here.

Groundwater mainly occurs in fractured Upper Cretaceous intrusive rocks of the area. Total area of the spa is 0, 9 Km^2 and three boreholes are actively utilized now. Water samples were collected over a ten-year period; additionally some published data were re-interpreted.

Two types of groundwater were distinguished here: fresh and high pCO_2 ones. Both types of water are very cold, the temperature is 0.5-1.0 ºC. Fresh water has very low TDS (up to 0.1 g/l) and belongs to Ca-Mg-Na-HCO_3 type. High pCO_2 groundwaters have TDS up to 3.5 g/l, CO_2dis. – 3.5 g/l and belongs to Ca-Mg-HCO_3 type. pH of waters very from 5.5 to 7.6.

Our bedrock and groundwater data indicates that both types of groundwater originate from meteoric water, and interactions between the water and these bedrocks have played a dominant role in the development of the chemical composition of the waters. Isotopic data indicates that CO_2 gas in the groundwater is mantle derived and its presence is critical for the development of the high pCO_2 groundwater. This type of groundwater evolves during gas-water-rock interactions only.

Flour content in the groundwater samples of Chahar-Farsakh area, South Khorasan, Iran

MARZIEH KHAZAII[1], AREZOO ABEDI[2] AND HANIYEH JALAYERY[3]

[1]Payamenour University, Nehbandan, Iran (mkhazaii@yahoo.com)

[2,3]Shahrood University of Technology,Shahrood,Iran (arezooabedi@shahroodut.ac.ir, hjalayeri@yahoo.com)

The study area is located about 24 km NW Nehbandan, South Khorasan province, Iran. Chahr -farsakh area was occurred at Iran's East Flysh belt junction with Lut block. This junction is a thin zone of crushed disruption, fault corrosion, extreme drift and metamorphism. Igneous, metamorphic and sedimentary rocks as granodiorite, quartz diorite, andesite, sandstone, shale, conglomerate, gneiss and schist with many other type of altered and crashed rocks from Jurassic to Neogen are the most rock formation in the area. In this study, the concentration of flour in 20 samples of groundwater sources as qanat and spring were determined. The results of analyses show that flour content were determined to range between 0.02-0.84 mg/l, lower than WHO 2008 limits. Temperature of waters distinguished between 19.4-30.6 C. The water PH were detected from 6.68 to 9.37. Flour show positive correlation with Na, Mg, Ca and HCO_3 in the water samples. Sandstone and shale seems to be the main aquifers in the study area. Mineralogical study by XRD shows that quartz is the main mineral in the aquifer and Illite, muscovite, shamosite, albite and calcite are subordinate minerals. Probably illite and muscovite are the main source of flour in the groundwater.

Boron contamination in the groundwater of Chahar-Farsakh area, South Khorasan, Iran

MARZIEH KHAZAII[1], AREZOO ABEDI[2] AND SOMAYEH TABASI[3]

[1]Payamenour University, Nehbandan, Iran (mkhazaii@yahoo.com)
[2,3]Shahrood University of Technology, Shahrood, Iran (arezooabedi@shahroodut.ac.ir, somayehtabasi@yahoo.com)

Groundwaters from 6 qanat and spring stations within the Chahar-Farsakh area, north-west of Nehbandan, South Khorasan province, Iran were sampled for metal contamination analysis. The data were used to calculate metal index (MI), all of the groundwater samples show metal index higher than 1. Among all analysis results, boron show high concentration in the groundwater samples. Concentrations of B in water samples from Chahar-Farsakh area were determined to range between 1.043-4.811 ppm, exceeding WHO (2009) limits (0.5 mg/L) for drinking waters. Naturally occurring boron is present in groundwater primarily as a result of leaching from rocks and soils containing borates and borosilicate. Geological surveying in the study area revealed some outcrops of pegmatite aplitic veins with tourmaline mineralization. Probably existence of tourmaline is the major natural source of boron in the water samples of Chahar-Farsakh area.

Petrography and mineralogy of Western Samen Metapelites

Z. KHODAIAN CHEGENI[1]*, A.A. BAHARIFA[2], M.H. EMAMI[3], M. MOHAJJEL[4] AND N. ASKARI[5]

[1]*Geological Survey of Iran, Research Institute for Earth Sciences, Tehran, Iran (khodaian@gsi.ir)

[3]Geological Survey of Iran, Research Institute for Earth Sciences, Tehran, Iran (hashememami@yahoo.com)
[4]Department of Earth Sciences, Tarbiat Modares University, Tehran, Iran (mohajjel@modares.ac.ir)
[5]Geological Survey of Iran, Research Institute for Earth Sciences, Tehran, Iran (askari@gsi.ir)

The study area is located in southern of Hamadan, Sanandaj-Sirjan zone. Metamorphic rocks involve philite and Schist with green schist facies, advanced to amphibolite facies. These rocks composed of various metamorphic minerals. EPMA analysis is applied on some mineral to recognition of chemical composition of rock forming minerals. Mineral chemistry shows Muscovites that formed in rim of andalusite, have higher grade than those are in matrix and resulted of progressive metamorphism of andalusite to Muscovite, Staurolite and Fibrolite. Also Biotites are ferric and garnet is almandine and belongs to Piralespite groupe. Zoning pattern in garnet imply two progressive metamorphism and a retrogressive metamorphism that preserved in some garnets. Analytical data only show the composition of Staurolite.

Natural cementitious analogues of Jordan

HANI N. KHOURY

University of Jordan, Amman, Jordan (khouryhn@ju.edu.jo)

The pyrometamorphic rocks in Jordan (Daba-Siwaqa, Suweileh and Maqarin) are unique and represent *natural analogues* of Portland cement for sealing of nuclear waste. The Natural occurrences are of great aerial exposure and offer good example to study the interaction of cementitious hyperalkaline leachates on repository host rock. Similarity to cement processes and products is much more obvious than in any of the occurrences reported before. The similarity extends beyond strong mineralogical equivalence. The source of energy for this extremely energy intensive process was the same as cement kilns (fossil fuel from oil shale).

Maqarin area represents an early stage in the evolution of cementitious repository.

Suweileh and Daba-Siwaqa areas represent a later stage. Results on natural analogues in Jordan indicate that secondary minerals as smectites, sulphates, and hydrated aluminium silicates act as a sink for hazardous elements. Highly alkaline (pH = 12.7) ground water dissolves from the combusted bituminous marl the radionuclides and heavy metals (Cr, Zn, V) and reprecipitate it farther down when reducing conditions are encountered [1].

Photochemical production of dissolved organic and inorganic nutrients from resuspended sediments

R.J. KIEBER*, M. SOUTHWELL, C.L. LAQUIRE, L. THOMPSON, S.A. SKRABAL, G.B. AVERY JR. AND R.N. MEAD

Department of Chemistry and Biochemistry, University of North carolina Wilmington, 601 South College Road, Wilmington, North Carolina 28403 (*correspondence: kieberr@uncw.edu)

A series of photolysis experiments were conducted in the presence and absence of tidal creek and continental shelf sediments to address the role of resuspension on nutrient fluxes in estuarine and coastal waters. There was a significant increase in TDN, phosphate and DOC when sediments were resuspended in overlying water and exposed to six hours of simulated sunlight. The majority of dissolved N was released as DON (87%) with relatively lesser amounts of ammonium (13%) and little or no nitrate. Results from autoclaved sediments suggest the mechanism of photolytic release was predominately abiotic. Results demonstrate that photoproduction from resuspended sediments is an episodically significant and previously unrecognized source of dissolved nutrients to coastal ecosystems receiving sediment plumes. This process may be especially important for continental margins where resuspension events occur as well as in regions experiencing high riverine sediment fluxes resulting from erosion associated with deforestation and desertification. The presentation also considers how photolytic fluxes of organics and nutrients may respond in the future during periods of salinity alteration as sea level rises.

Land vegetation contributes 90% of the global volatile organic compound (VOC) emissions [1]. Atmospheric oxidation of these VOCs contributes to new particle formation and atmospheric organic aerosol mass [2]. The formation of aerosols from biogenic VOC emissions constitutes a possible feedback element in biosphere-atmosphere-climate interactions due to the overall cooling effect of aerosols [3]. This is based on increasing VOC emission strengths with increasing temperature and emission patterns being invariant to temperature changes. Recently evidence emerges that temperature induced changes in VOC emission patterns may alter the picture. It has been shown that increased isoprene emissions may suppress atmospheric new particle formation [4] thus dampening the cooling effect of aerosols formed from biogenic VOCs.

In addition the use of direct emissions of VOCs from plants in experiments studying secondary organic aerosol (SOA) formation shows that, beyond the so far considered main compound classes isoprene and its derivatives monoterpenes and sesquiterpenes, other VOC classes significantly impact SOA formation. Many of these VOCs are emitted under plant stress conditions.

An overview of the state of the art knowledge of SOA formation from biogenic VOCs with respect to different VOC classes will be given. In particular we will focus on the importance of non-classical VOC classes emitted under stress conditions.

Factors affecting the stability of slags and metal release: The case study of historical Cu slags from Lower Silesia (SW Poland)

J. KIERCZAK*, A. PIETRANIK AND A. POTYSZ

University of Wroclaw, Cybulskiego 30, 50-205 Wroclaw, Poland
(*correspondence: jakub.kierczak@ing.uni.wroc.pl)

Historical slags originating from base metal smelting often contain considerable amounts of heavy metals and, when deposited, they may undergo potentially harmful interactions with surrounding soils, sediments and waters.

In this study we present mineralogical and chemical characteristics of historical slags from Rudawy Janowickie Mountains (Lower Silesia, SW Poland). We show that the studied slags are characterized by different cooling rates of the slag melt and we describe how these different rates affect slag properties (phase composition, metal distribution etc.). Furthermore, on the basis of leaching experiments, simulating various environmental conditions, we attempt to identify major factors controlling heavy metal release from slags.

Two types of slags produced during historical smelting of Cu ores occur in the studied area. The prevailing massive slag consists of silicate glass, olivine and hercynite. The second type is porous and comprises two types of silicate glass, olivine, ferrosilite, cristobalite and quartz. Both types contain important amounts of metals (up to 1.34 % of Cu).

The morphology of olivine crystals, phase assemblages, phase chemistry and distribution of trace elements in slag phases vary from sample to sample, which is consistent with different cooling rates. Careful investigation of cooling conditions is useful to predict susceptibility of slags to weathering. Leaching tests, performed on each type of slag show that the heavy metal release is more important for porous slags than for those having massive texture. Furthermore, larger proportions of heavy metals are released from slags formed under disequilibrium conditions than from those which cristallized under close to equilibrium conditions.

Mineralogical and geochemical analyses coupled with leaching experiments indicate that the most important factors controlling metal release from slags are: (1) textural characteristics and permeability of the material, (2) slag mineralogy and cooling rates, (3) environmental conditions (e.g. pH, organic matter content).

The work was financed by Polish Ministry of Science and Higher Education grant no. NN307051237.

Fluid microinclusions in octahedral diamonds

I. KIFLAWI[1], Y. WEISS[1]*, W.L. GRIFFIN[2] AND O. NAVON[1]

[1]The Institute of Earth Sciences, the Hebrew University of Jerusalem, Israel (*correspondence: yakov.weiss@mail.huji.ac.il)
[2]GEMOC, Macquarie University, NSW, Australia

Microinclusions carrying high-density fluids (HDFs) with silicic, carbonatitic and saline compositions are common in fibrous diamonds and represent the medium in which their host diamond grew. Such inclusions have not been documented previously in monocrystaline octahedral diamonds or in the octahedral cores of coated diamonds, allowing a debate on whether such fluids are responsible for the formation of octahedral diamonds as well. The other notable difference is that all nitrogen in microinclusion-bearing zones resides in A-centers, whereas most octahedral diamonds carry both A and B centers. We report the first finding of HDF microinclusion in an octahedral diamond from Finsch, South Africa and in the core of a coted diamond from Kankan, Guinea.

The microinclusions in the Finsch diamond are restricted to two thin layers (~10 μm), parallel to the (111) face, ~20 and 200 μm from the rim. Cathodoluminescence (CL) reveals concentric zoning and octahedral growth throughout the diamond. The inclusion-rich layers are easily recognized by their weak fluresence. The diamonds carry ~800-1200 ppm nitrogen. Absorbance of B centers is observed in the inner part (A/B=5) and between the inclusion rich layers and the rim (A/B=16). Forty-five inclusions of carbonatitic HDF were analyzed along the inner layer. Their major and trace element compositions and FTIR analyses are highly similar to the ones observed in HDFs from fibrous diamonds.

In the octahedral core of the Kankan diamond we found six microinclusions with saline composition. Unlike the case of the Finsch diamond, these inclusions are sporadically scattered, up to ~100 μm away from a sulfide mineral inclusion and were hard to find.

Supporting evidence for the involvement of HDF, similar to the ones capsulate in fibrous diamonds, in the formation of monocrystaline diamonds comes from LA-ICP-MS analyses of trace element patterns in monocrystalline diamonds (McNeill *et al*. 2009) and the sinosuidal REE patterns of garnet inclusions in diamonds (Stachel and Harris, 2008; Weiss *et al*. 2009).

Based on the above observation we have good reasons to believe that microinclusions and HDFs may be found in other octahedral diamonds, extending the role of HDFs to the formation of most natural diamonds.

Seasonal and temporal variations of uranium isotope ratio in atmospheric deposits in Japan

Y. KIKAWADA[1]*, R. YAMAUCHI[1], M. NOMURA[2], T. OI[1] AND K. HIROSE[1]

[1]Sophia University, Tokyo 102-8554, Japan (*correspondence: y-kikawa@sophia.ac.jp)
[2]Tokyo Institute of Technology, Tokyo 152-8550, Japan

The uranium isotope ratios, especially $^{235}U/^{238}U$, do not change substantially in the natural environment. The $^{235}U/^{238}U$ ratio in environmental samples differing from the natural ratio thus resulted from anthropogenic nuclear activities. The Japan Meteorological Agency (JMA) and the Meteorological Research Institute (MRI) have been monitoring the deposition amounts of anthropogenic radioisotopes, mainly ^{90}Sr and ^{137}Cs, using the atmospheric deposits collected with open surface samplers installed throughout the Japanese Islands since the 1950s. In our previous work, we had reported that the $^{235}U/^{238}U$ ratios in the deposits collected at Fukuoka, Kyushu, the most southwesterly one of the four Japanese main islands, were slightly but obviously higher than the natural ratio since the 1960s until today [1]. This time, we have measured the uranium isotope ratios in the atmospheric deposits collected at Akita, which is located at the northeastern region of Japan and faces to the Sea of Japan, in the months of March between 1964 and 2000 and every month in 1977 and 1978. The results revealed that the $^{235}U/^{238}U$ ratios in the atmospheric deposits had varied seasonally and temporally. The fluctuation pattern of the $^{235}U/^{238}U$ ratio in the Akita deposits through the 24 months in 1977 and 1978 is in good accordance with that of the deposition amounts of plutonium at Tokyo [2]. Contrary to this, the deposition amounts of ^{90}Sr and ^{137}Cs are not always connected with the uranium isotope ratio in the deposits. Our results suggest that a certain amount of depleted uranium (DU) had been transported to Japan in the 1970s with plutonium ejected into the atmosphere by the thermo nuclear tests then conducted in the test sites in the Central Asia. DU and plutonium had probably been transported by the mechanism different from that of radioactive strontium and cesium, although they all had come from the same source, neuclear test explosions.

Speciation of iron in natural and synthesized Bacteriogenic Iron Oxides (BIOS) using XAFS and μ-XRF-XAFS

S. KIKUCHI[1]*, H. MAKITA[2], S. MITSUNOBU[3], K. TAKAI[2] AND Y. TAKAHASHI[1]

[1]Hiroshima University, Hiroshima 739-8526 (*correspondence: m103384@hiroshima-u.ac.jp)
[2]Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Kanagawa 237-0061, Japan
[3]University of Shizuoka, Shizuoka 422-8526, Japan

Speciation of Fe in natural and synthesized bacteriogenic iron oxides (BIOS) was studied using XAFS, μ-XRF-XAFS, SEM and EPMA. Natural BIOS were collected at 2 sampling sites: seafloor at Mariana trough and from groundwater stream discharged at Sambe Hot Spring in Shimane Prefecture. BIOS was synthesized using a diffusion cell which consists of two cells that are separated by a membrane. Anoxic and oxic conditions were created in each cell to simulate the appropriate condition to BIOS precipitation in natural environment. Chemoautotrophic iron-oxidizing bacterium (*Mariprofundus ferrooxydans* [1]) or heterotrophic iron-oxidizing bacterium (*Leptothrix discophora* [2]) were cultured in the oxic cell.

SEM and EPMA analysis suggested similar precipitation morphology to all samples where iron oxides precipitated around bacterial-induced organic materials. Although each natural BIOS were precipitated in different environment, the XAFS spectra exhibited similar structures. Synthesized BIOS also showed spectra similar to natural samples regardless of the species of iron oxidizing bacteria and the medium employed in culture. In addition, μ-XAFS spectra collected at several Fe-precipitated area within few micro scale in the stalk were approximately identical, which is consistent with our bulk XAFS results of natural and synthesized BIOS. These results suggest that minerals presented in BIOS were homogeniously distributed in micrometer scale. The liniar combination fitting suggested that ferrihydrite is one of the Fe species in BIOS. It is also implied that Fe-carboxylate complex or Fe (III)-phosphate is a second Fe species of BIOS. These results will provide better insights into understanding the role of BIOS in the migration of trace elements in natural waters.

Serpentinites are rocks composed predominantly of the serpentine minerals, lizardite, chrysotile, or antigorite that form through hydrothermal alteration of peridotite. Substantial exposures of serpentinized peridotites are commonly found in fracture zones and in slow spreading mid-ocean ridge settings. Serpentinites from the Hero Fracture Zone, Drake Passage, Antarctica, contain serpentine, amphibole, talc, chlorite, and magnetite as well as relict olivine, pyroxene, and spinel from a spinel peridotite precursor. Two episodes of serpentinization are recognized. The initial serpentinization event resulted in material that contains relatively abundant relict minerals and small amount of lizardite and antigorite. This event resulted from seawater infiltration at about 178 - 283 °C seawater and a water/rock ratio less than 5. The second serpentinization event resulted in a material highly enriched in serpentine. This second event was caused by seawater infiltration at 170 - 298 °C and a water/rock ratio in excess of 5. The buoyant serpentinite ridge model is invoked to explain the ascent of serpentinite from the upper mantle to the surface. Increasing fracturing and seawater infiltration during the process resulted in increasing degrees of serpentinization and decreasing rock density. Buoyant uplift of serpentinite resulted from the contrast in density between serpentinite and surrounding mafic rocks. Some serpentinite rock fragments were detached from the serpentinite during ascent and embedded in oceanic sediment after exposure to the surface.

CO_2, CH_4, N_2O flux measurements from a constructed wetland

DEUG-SOO KIM* AND UN-SUNG NA

Dept. of Environ. Engineering, Kunsan National Univ., Kunsan, Jeonbuk 573-701, Korea
(*correspondence: dskim@kunsan.ac.kr)
(raja85@nate.com)

Implication

It is recently reported that microbial activity in freshwater wetland soils transforms considerable amounts of CO_2 into CH_4, which is then released into the atmosphere [1]. Consequently, this is likely to enhance greenhouse effect as CH_4 has a global warming potential greater than CO_2. The current study was focused on quantifying the source strenths of these greenhouse gases (GHG) from a wetland water surface and elucidating relationship between GHG emissions and physicochemical parameters.

Sampling and Experimental Methods

A closed chamber system was utilized to measure GHG emissions from water surface in a constructed wetland at Kunsan, Korea for six-month period (August~December, 2010 and March 2011). The measurements were made on 20 days during a day time (1400~1600LST) for experimental period only when weather was clear, and 50 ml of three consecutive gas samples for one GHG flux calculation were taken at each 10 min interval from a half spherical plastic chamber floating on the wetland water surface with plastic syringes. GHG fluxes were calculated based on the rate of change of GHG concentration [2]. Chemical characteristics in water (NO_3^--N, NH_3^+-N and pH) and water temperature also were monitored on measurement days. Concentrations of CO_2, CH_4 and N_2O were analyzed by using a Gas Chromatography (equipped with ECD/FID) at laboratory.

Results and Discussion

In order to examine the role of temperature on the gas flux, the changes of GHGs' emissions were investigated in terms of water temperature measured during sampling period (warm season: 18~31 ºC, cool season: 8~12 ºC). Results from current wetland experiment shows that water surface of the wetland absorbs CO_2 (sink) and emits CH_4 and N_2O (source) in average over the experimental period. Those levels were greater in warm season than in cool season. Futher results in correlations between physicochemical controlling parameters and those GHG emissions will be discussed in the conference.

The elemental and stable isotope geochemistry of Korean bottled waters: Characterization and identifying their origins

G. KIM[1], J.S. RYU[2], W.J. SHIN[2], M. CHOI[2] AND K.S. LEE*

[1]Graduate School of Analytical Science and Technology, Chungnam Nat'l Univ (goeun@kbsi.re.kr)
[2]Korea Basic Science Institute, Ochang Center, Chungbuk 363-883, Korea (*correspondence: kslee@kbsi.re.kr)

We investigated 54 Korean bottled waters to characterize their water types and to examine a good tool for identifying their origins using the elemental and isotopic geochemistry. The elemental and isotopic compositions of the bottled waters varied substantially in different types of bottled waters. Major ion chemistry and oxygen and hydrogen isotopes clearly discriminate marine waters from the other types of water. Fractionation of oxygen and hydrogen isotopes likely explains the altitude and latitude effects. Variations in dissolved inorganic carbon isotope values reflect artificial CO_2 addition in sparkling waters, and reveal fractionation during the desalination process of marine waters. Strontium isotope ratios ($^{87}Sr/^{86}Sr$) of bottled waters are clearly associated with those of basement rocks in which bottled waters were collected. The results suggest that combined elemental and stable isotope variations in bottled waters are useful for characterizing the bottled waters and identifying the origins. Furthermore, combined elemental and isotope geochemistry could be a powerful tool in the related research fields and forensic sciences.

Stabiliy of schwertmannite sorbed by oxyanions

JIYEON KIM, JONG-A CHOI, CHAN-YOUNG PARK, YEONGKYOO KIM* AND INCHANG RYU

Department of Geology, Kyungpook National University, Daegu, 702-701, Korea
(*correspondence: ygkim@knu.ac.kr)

Schwertmannite, commonly found iron-oxyhydroxysulfate in acid mine drainage has high sorption capacity and can play an important role in removing heavy metals in acid mine drainage. Heavy metals existing as oxyanions are known to have high affinity to schwertmannite compared with other heavy metals due to substitution for sulfate in the schwertmannite structure. However, schwertmannite is thermodynamically unstable and eventually transformed to goethite. The oxyanions such as AsO_4^{2-}, however, has been known to decrease the transformation rate. We made oxyanion-sorbed schwertmannite samples and studied their rates of transformation to geothite based on XRD patterns and pH values.

Schwertmannite was synthesized and oxyanion-sorbed schwertmannite was prepared by AsO_4^{2-}, SeO_3^{2-}, SeO_4^{2-}, MoO_4^{2-}, and CrO_4^{2-}. Because of the different sorption isotherms, the amount of sorbed oxyanions were fixed at 0.5 mmol/g for the samples. 0.1g of each samples were mixed with 40 ml distilled water and pH was adjusted at pH 9 at 30 ^oC to increase the transformation rate. The pH was measured every week pH values were adjusted to pH 9 again. The experiment was conducted for 3 months and during that period, 3 samples of each schwertmannite were analysed by XRD and compared.

Our results show that all the samples sorbed by oxyanions have slower transformation rate than pure schwertmannite, indicated by higher pH values. However, the transformation rates among oxyanions are different. Based on the pH value changes, the transformation rates to goethite are in the order of pure schwertmannite > SeO_4^{2-} > SeO_3^{2-} > CrO_4^{2-} > MO_4^{2-} > AsO_4^{2-}. XRD pattern of each sample shows that pure schwertmanite transformed to goethite after 1 month. After 3 months, the schwertmannite sorbed by SeO_4^{2-} almost transformed to goethite while other samples still have schwertmannite peaks. Therefore, the XRD patterns and pH values are quite closely matched. Our results show that sorption of oxyanions on schwertmannite decreases the transformation rate to goethite, and the rates of each samples are different.

Relations of arsenic concentrations among groundwater, soil, and bedrock in Geumsan, Korea: Implication for As mobilization according to changes in As-hosting minerals and land use

KANGJOO KIM[1]*, SEOK-HWI KIM[1], GI-YOUNG JEONG[2] AND PRAFULLA KUMAR SAHOO[1]

[1]Department of Environmental Engineering, Kunsan National University, Kunsan, Jeonbuk 573-701, Korea
(*correspondence: kangjoo@kunsan.ac.kr)
[2]Department of Earth and Environmental Sciences, Andong National University, Andong, Kyeongbuk 760-747, Korea

Arsenic concentrations and As-bearing minerals in bedrock, and soil, and their relations with groundwater concentrations were investigated in a small agricultural area of Korea to understand the changes in arsenic mobility by pedogenetic processes and changes in geochemical conditions. The arsenic concentration in bedrock shows a wide variation (<1 to 3990 mg/kg) and is well correlated with that in contacting groundwaters. Soils, the weathering product of bedrock, show much mitigated and dispersed, but still very high As concentrations (8.8 to 387 mg/kg). Furthermore, As concentrations in the shallow groundwaters were very low (<20 μg/L) and independent on the soil concentrations due to the differences in As hosts and geochemical conditions. Arsenopyrite is the major As-bearing mineral in bedrock and its oxidation controls the As levels in deep groundwater. In contrast, the As mostly resides in soil as Fe-(hydr)oxide bound forms. Due to low pH and oxidizing redox condition, the release of As from Fe (hydr)oxides are largely suppressed and the shallow groundwater show low As concentrations. However, it is suggested that the disturbance of geochemical conditions in soils by land use changes mobilize As and would cause serious As contamination in shallow groundwaters.

Hypoxia events in Cheonsu Bay, West coast of Korea, triggered by discharge of eutrophicated water from artificial lakes

KEE-HYUN KIM[1]* AND JAE-SUNG LEE[2]

[1]Chungnam National University, Daejeon 305-764, Korea (*correspondence: khkim@cnu.ac.kr)
[2]NFRDI, Busan 619-705, Korea, leejs728@nfrdi.go.kr

Frequent outbreaks of hypoxic water masses have been reported in Cheonsu Bay, west coast of Korea, due to the influx of eutrophicated waters heavily loaded with oxygen demanding material from artificial lakes formed by large-scale land reclamation and subsequent industrial development and rapid urbanization since early 1980s. The hypoxia events would give deteriorative impact on fisheries and aquaculture industry around the bay.

In summer 2010, we measured the concentration of dissolved oxygen (DO) and nutrients in bottom waters collected from 14 stations. We also measured the nutrient fluxes across the sediment-water interface in 3 stations by deploying a fully automated benthic lander, which collects time-series water samples inside a benthic chamber, on the seafloor for a couple of days.

We confirmed the on-going hypoxia in the northern parts of the bay into where the lakes discharged. DO content of the bottom water was below 2 mg/l, compared to that of 5 mg/l at the mouth of the bay. Organic carbon oxidation rate was estimated to be 55 mmol C m^{-2} d^{-1} and the oxygen consumption rates to be 50.4 mmol O_2 m^{-2} d^{-1}. These rates were about twice as fast as those at the bay mouth. Benthic fluxes of nutrients at the northern part of the bay were 4 to 6 times higher than those at the bay mouth.

Our results imply that it is necessary to keep keen eyes on hypoxia events since they would give severe damages to fisheries and aquaculture industry.

Oxygen isotope fractionation between calcium carbonate and water: Influence of ionic strength

SANG-TAE KIM

School of Geography and Earth Sciences, McMaster University, Hamilton, ON, L8S 4K1, Canada (sangtae@mcmaster.ca)

The conventional carbonate-water thermometer is one of the most successful paleotemperature proxies in the Earth sciences and it was developed on the theoretical basis of oxygen isotope fractionation between $CaCO_3$ and H_2O. As a result, numerous scientists have extensively studied the oxygen isotope systematics in the $CaCO_3$-H_2O system over the past several decades in order to establish a more reliable carbonate-water paleothermometer. Whereas the majority of natural calcium carbonate samples, such as corals and foraminifera, that are frequently used to reconstruct Earth's past climate changes on the basis of the conventional carbonate-water thermometer, are of oceanic origin, most of the experimental studies, that provide a baseline for the calibration of many of the species-specific carbonate-water paleotemperature proxies [1, 2], used calcium carbonates precipitated from parent solutions of low ionic strength (e.g. freshwater) rather than those precipitated from parent solutions of seawater salinity or ionic strength (e.g. ocean water).

In order to investigate the effect of a parent solution's ionic strength on the oxygen isotope fractionation between $CaCO_3$ and H_2O, calcium carbonates were synthesized in the laboratory from Na-Ca-(Mg)-Cl-HCO_3 solutions of seawater ionic strength (I = ~ 0.7). Subsequently, the oxygen isotope composition of the calcium carbonate precipitates and that of the parent solutions were determined. In particular, the passive CO_2 degassing and the constant addition methods, which are described in Kim *et al*. [3], were employed in this study. Our preliminary experimental results suggest that the oxygen isotope fractionation factors determined from calcium carbonates that were formed from high ionic strength solutions may not be always the same as those determined from low ionic strength solutions.

Extinction-to-backscatter ratio of Asian dust observed with a combined Raman elastic-backscatter lidar in Seoul, Korea

SANG-WOO KIM[1]*, MAN-HAE KIM[1], SOON-CHANG YOON[1] AND NOBUO SUGIMOTO[2]

[1]School of Earth and Environmental Sciences, Seoul National University, Seoul, Korea (*correspondence: kimsw@air.snu.ac.kr)

[2]Atmospheric Environment Division, National Institute for Environmental Studies, Tsukuba, Japan

The extinction-to-backscatter ratio (so called, lidar ratio), which is a key parameter in the issue of backscatter-lidar inversions, of Asian dust was observed with a combined Raman elastic-backscatter lidar in Seoul, Korea. The lidar ratio at 532 nm is calculated by the comparison of lidar-derived aerosol optical thickness (AOT) with sunphotometer-derived AOT for 4-year measurements (2006-2010). Here, the value of AOT 532 nm is calculated by the Ångström relationship using measurements at five wavelengths (400, 500, 675, 870, and 1020 nm). The annual mean lidar ratio (with standard deviation) is found to be 61.7±16.5 sr, and weak seasonal variations are noted with a maximum in summer (68.1±16.8 sr) and a minimum in winter (57.2±17.9 sr). The lidar ratios for clean, dust, and polluted conditions are estimated to be 45.0±9.5 sr, 51.7±13.7 sr, and 62.2±13.2 sr, respectively. While the lidar ratio for the polluted condition is appears to be consistent with previous studies (50-70 sr), clean and dust conditions tend to have larger values, compared to previous estimates (clean: 30-40 sr, dust: 40-50 sr). This discrepancy is thought to be mainly due to the anthropogenic aerosols existing in the atmospheric layer throughout the year around Seoul, which may cause increased S_a even for clean and dust conditions. For instance, the lower values of lidar ratio at 532 nm was directly estimated from Raman (inelastic) signals. The values of lidar ratio averaged for Asian dust layer was ranged from 25 and 40 sr on two Asian dust days (October 20, 2009 and March 15, 2010), with 10 ~ 20% of particle depolarization ratio.

Dependence of adiabaticity of stratiform clouds upon stability, and its relationship to aerosol-cloud interactions

Y.-J. KIM[1], B.-G. KIM[1]*, M. MILLER[2] AND C.-K. SONG[3]

[1]Department of Atmospheric Environmental Sciences, Gangneung-Wonju National Univ., Gangneung, 210-702, Korea (*correspondence: bgk@gwnu.ac.kr)

[2]Department of Environmental Sciences, Rutgers Univ., New Brunswick, NJ, 08901, United States

[3]Air Quality Research Department, National Institute of Environmental Research, Incheon, 404-708, Korea

The buffering mechanisms in the modifications of cloud microphysics and cloud albedo by cloud-active aerosol are only vaguely understood and are thought to include a myriad of processes that vary regionally and confound the application of simple physical models of cloud-aerosol sensitivity [1].

This study presents the relationship of aerosol-cloud interaction to cloud environment condition (adiabaticity and stability), using data from the Atmospheric Radiation Measurement (ARM) Southern Great Plain (SGP) site and the Pt. Reyes (PYE) deployment of the ARM Mobile Facility (AMF). Adiabaticity is defined as the ratio of the observed liquid water path (LWP) to corresponding adiabatic value in this study. The stability indicates the differences of potential temperature between 500 m above the mixed layer tops and the mixed layer tops. Strong inversions above the PYE cloud are shown to buffer marine stratocumulus from the effects of mixing with drier, warmer inversion air. This buffering reduces the variability of the cloud LWP and enables the clouds to remain nearly adiabatic. The critical comparison of cloud adiabaticity with static stability demonstrates the more adiabatic LWP in the condition of the stronger stability above the cloud. Weaker inversions above the SGP cloud promote variability in the LWP and sub-adiabatic LWPs. Aerosol-cloud interactions are probably more dominant in stratiform clouds that remain nearly addiabatic [2] and exhibit less variability in the LWP. This study implies static stability and adiabaticity are important controlling factors in the enhancement or attenuation of aerosol-cloud interactions.

This work was supported by the ‘National comprehensive measures against climate change’ by the ministry of environment, Korea (Grant no. 1600-1637-301-210-13).

Uranium minerals in black shale, South Korea

YOUNG JAE KIM[1], HYO EUN LEE[1], SUE-A KANG[1], JONG KI SHIN[2], SUNG YUN JUNG[2], YOUNG JAE LEE[1]*

[1]Department of Earth and Environmental Sciences, Korea University, Seoul 136-701, Korea (*correspondence: youngjlee@korea.ac.kr, jjbsnlove@korea.ac.kr, hyonim@korea.ac.kr, sue_a@korea.ac.kr)

[2]Coal & Uranium Exploration Team, Korea Resources Corporation, Seoul 156-406, Korea (jkshin1@kores.or.kr, jsy@kores.or.kr)

Uranium (U) in black shale, South Korea has been the subject of interest because of its potential roles in energy and mining industries. Previous reports found that balck shale in Korea is highly metalliferous with lead, uranium, and vanadium, but also that uranium content increases with increasing total carbon content in the black shale. Yet, identification and understanding of minerals for uranium and other elements in the black shale is still not clearly addressed. In the present study, U-containing minerals in the black shale is characterized by combination of geochemical compostion analysis and electron probe microanalyzer (EPMA) analysis.

Results show that uranium content is moderately proportional to the content of total organic carbon (TOC) in the black shale. XRF analysis shows that Al, Mg, Ba, and K are major elements with trace elements such as Zn, P, S, and Ti. Total uranium concentration is up to 0.13 wt. %, whereas total concentration of V and Ba are 0.17-1.6 wt. %, and 2.0-5.0 wt. %, respectively. Using EPMA, it is found that two different element series of U-P-Cu and U-V-Ba are found in U-containing minerals. Ratio of the series for U : V : Ba and U : P : Cu are 2 : 2 : 1 and 4 : 4 : 1, respectively. These results indicates that the U-containing minerals are francevillite ((Ba, Pb)$(UO_2)(V_2O_8)(H_2O)$) and torbernate (Cu $(UO_2)_2$ $(PO_4)_2$ $(H_2O)_8$) in the black shale. These findings are not consistent with previous reports showing that uraninite is a main mineral in U-containing minerals at a different area of the black shale, Korea. Upon our results, it is worthy to note that formation of uranium minerals are sensitively affected by geochemical environments and tectonic movements in the black shale, South Korea.

Uptake and retention of mercury by hydroxylapatite

YOUNG JAE KIM, HYO EUN LEE, SOO-OH PARK AND YOUNG JAE LEE*

Department of Earth and Environmental Sciences, Korea University, Seoul 136-701, Korea (*correspondence: youngjlee@korea.ac.kr, jjbsnlove@korea.ac.kr, hyonim@korea.ac.kr, orange261@korea.ac.kr)

Mercury (Hg) is well known as a toxic element for humans and ecosystems. Partitioning of the mercury to minerals and organics has been known to influence the fate and transport of mercury species in natural ecosystems. Despite the importance of mercury interaction with minerals, sorption mechanisms and modes are are not still clearly understood. Systematic characterization of mercury uptake by hydroxylapatite (HAP, $[Ca_5 (PO_4)_3OH]$) is little addressed over a wide range of physicochemical conditions.

Mercury sorption on HAP shows that the initial uptake of mercury by HAP sharply increases, levels off, and then followed by little changes as a function of concentration at pH 7.0 and 9.0, showing a typical pattern of Langmuir sorption. No obvious differences are found in the sorption pattern at the two pHs. Compared to that of the sorption at pH 7.0, however, the sorption of mercury on HAP decreases by a factor of 4 at pH 9.0. In addition, the mercury uptake by HAP decreases with increasing ionic strength of the solution. From $I = 0.01$ M to $I = 0.1$ M, total amount of the sorption decreases around by a factor of 2. During the duration of the kinetic experiments, the initial uptake and retension of mercury by HAP is rapid and ~85% of Hg is sorbed on the HAP within 30 mins, suggesting that adsorption plays an key role in the initial upatke of mercury at the HAP-water interface. Results reveals that different physicochemical conditions such as pH and I influence the mercury uptake by HAP sensitively.

Biogeochemical behaviour of Pu in a contaminated soil from Aldermaston, UK

R.L. KIMBER[1]*, P. PURDIE[2], C. BOOTHMAN[1], F.R. LIVENS[1] AND J.R. LLOYD[1]

[1]The University of Manchester, Oxford Road, Manchester, M13 9PL, United Kingdom (*correspondence: richard.kimber@postgrad.manchester.ac.uk)
[2]AWE Plc, Aldermaston, Reading, RG7 4PR, United Kingdom

Understanding the biogeochemical behaviour of actinides in the environment is essential for the long-term stewardship of radionuclide-contaminated land. Plutonium is of particular concern due its high radiotoxicity, long half-life and complex chemistry. Here, we investigate the biogeochemistry of Pu in a contaminated soil as microbial processes have the potential to mobilise Pu via the reduction of Pu (IV) to the potentially more mobile Pu (III). A series of microcosm experiments were designed to monitor changes in Pu solubility in an anaerobic environment stimulated via the addition of 10 mM glucose to Pu contaminated soils. A substantial shift in the 16S rRNA gene profile was observed between days 0 and 44 most notably with an increase in *Clostridia*, known glucose fermenters that have been reported to facilitate the reduction of Pu (IV) to Pu (III) [1]. A minor increase in Pu solubility was observed at day 44, decreasing to initial levels by day 118. The negligible change in Pu solubility, despite the onset of reducing conditions and formation of Fe (II), would suggest the Pu is highly refractory and unsusceptible to the influence of the surrounding geochemistry. To further examine the geochemistry of the Pu, a series of sequential extractions were performed. Around 75% of the Pu from the Aldermaston site was found to be associated with the highly refractory, residual fraction of the soils. This value greatly excedes the fraction of residual Pu at other nuclear sites reported in the literature after similar extraction protocols (34% at Sellafield and 8% at Dounreay [2]) and further suggests the Aldermaston Pu is highly resistant to changing geochemical conditions. Further work is currently being undertaken to investigate the impact of citric acid producing fungi on Pu solubility as citric acid has the potential to mobilize Pu. This information is important for understanding both the long-term mobility of Pu in the environment and for developing remediation options for Pu-contaminated soils.

We have developed the Arc Basalt Simulator (ABS), a quantitative forward model to calculate the mass balance of slab dehydration and melting, and slab fluid/melt-fluxed mantle melting, in order to quantitatively evaluate magma genesis beneath arcs. ABS models can reproduce magma compositions in many arcs.

The model suggests that the slab-derived component at volcanic fronts (VF) is mostly generated by dehydration, but successful models for most VF and all rear arc (RA) magmas also require the slab to melt. The compositions of slab fluids and melts are controlled primarily by the breakdown of amphibole and lawsonite beneath the VF and by the breakdown of phengite beneath the RA in addition to residual eclogite mineral phases including garnet, clinopyroxene, and quartz.

In the model, about 78-98% of relatively fluid-immobile elements including Nd and Hf in the arc lavas come from mantle peridotite. However, most liquid-mobile elements come from the slab. Modeled residual peridotite compositions are similar to those in some supra-subduction zone ophiolites and mantle xenoliths, providing constraints on reactions in the mantle wedge.

Altered oceanic crust (AOC) and sediment in the residual slab are modified by the subtraction of melt- and fluid-mobile elements. Unmodified AOC potentially becomes the EM I mantle component after 1 Ga, whereas melted AOC can have extremely fractionated U-Pb and become the HIMU source after 1-2 Ga. Element re-distribution beneath arcs can form the recycled materials that have been detected in ocean island basalts.

Interfacial reactions during olivine replacement

H.E. KING[1]*, H. SATOH[2], T. GEISLER[3] K. TSUKAMOTO[4] AND A. PUTNIS[1]

[1]Institut fuer Mineralogie, Westfaelische Wilhelms-Universitaet Muenster, Germany (*correspondence: hking_01@uni-muenster.de)
[2]Mitsubishi Materials Corporation, Japan
[3]Steinmann Institut, Universitaet Bonn, Germany
[4]Department of The Earth and Planetary Science, Tohoku University, Japan

Olivine-fluid interactions have a variety of applications in environmental remediation schemes, e.g. CO_2 sequestration and sulphate-rich acidic solution neutralization. We have conducted experiments to examine olivine reactivity within these systems, including mineral carbonation (200 °C, carbonated saline solution) and sulphuric acid neutralization (90 °C). Furthermore, we have used *in situ* phase-shift interferometry (PSI) to gain new insights into surface specific olivine dissolution.

The role of the interfacial solution composition was most pronounced in experiments with sulphuric acid, which produced an amorphous silica pseudomorph after olivine at high acid concentrations. Incorporation of ^{18}O into the silica layer in an isotope tracer experiment indicates that the replacement reaction occurred via an interface-coupled dissolution-reprecipitation mechanism. The formation of a pseudomorph in 3.6 M and 2 M solutions suggests that at these conditions olivine dissolution was the rate-limiting step. However, in 1 M solutions the formation of the amorphous silica layer controlled the rate, uncoupling the spatial relationship between dissolution and reprecipitation so that no pseudomorph was produced.

Dissolution of different olivine surfaces in saline solutions were studied with PSI, and showed that the fastest dissolving surface supersaturated the interfacial solution to precipitate a new phase at acidic conditions. This phase is predicted to be similar to the amorphous silica-enriched phase observed to form in the carbonation experiments indicating that the interfacial solution composition plays a critical role under a wide range of conditions.

Sulfur isotope studies in organic matter via SIMS using a statistical approach with heterogeneous standards

Solid bitumen, often found in rocks associated with a hydrocarbon phase, retains a paleo-signature reflecting the evolution of the hydrocarbon. For example, the $^{34}S/^{32}S$ ratio can provide information on the relative importance of thermal sulfate reduction over bacterial sulfate reduction during diagenesis. Such bitumen, distributed as small globules or grain coatings throughout the rock matrix, is a challenge to analyze. A technique with high-spatial resolution, Secondary Ion Mass Spectrometry (SIMS), is an excellent method, but there are challenges in applying this technique to such materials.

SIMS analysis of mineral phases is readily performed because standards allowing correction for instrument and matrix isotope fractionation have been developed. There are no comparable standards for sulfur isotopes in bitumen. Here we introduce the use of sulfur-bearing organic solids such as petroleum coke as such standards. They posses the required similarity in chemical bonding environment to that in bitumen. However to utilize these solids required that we develop a method to overcome their intrinsic chemical inhomogenity. For example, there are finely divided sulfate phases distributed in the organic matrix. Utilizing SIMS imaging to avoid secondary phases and a statistical analysis technique to mitigate the influence of unresolved secondary phases, we found that consistent correction factors for both instrument and matrix fractionation can be obtained. We have generated a Calibrated Matrix Correction that allows the systematic analysis of $\delta^{34}S$ values for bitumen, demonstrating those results by analyzing several bitumens from Brooks Range, Alaska and LaBarge, Wyoming.

Alpha-decaying nuclide ^{146}Sm, now extinct, was extant in the Early Solar System (ESS) [1] and was proposed as a cosmochronometer measuring the time between *p*-process nucleosynthesis and ESS condensation. Positive isotopic anomalies in the ^{142}Nd daughter have been measured in Earth rocks [2] and in Moon [3] and Martian meteorite [4] samples, relative to chondritic meteorites. This indicates that geochemical fractionation between Sm and Nd occurred while ^{146}Sm was still live, possibly during mantle differentiation. These issues stress the importance of ^{146}Sm half-life, determined as $(1.03\pm0.05)\times10^8$ yr [5, 6]. We have performed a new determination of the ^{146}Sm half-life by measuring both alpha-activity ratio and atom ratio of ^{146}Sm to ^{147}Sm ($t_{1/2}$= $(1.07\pm0.09)\times10^{11}$ yr [7]) in artificially activated ^{147}Sm. The new value of ^{146}Sm half-life, $(0.68\pm0.07)\times10^8$ yr, is significantly shorter than previously measured and will have interesting implications for the chronology of *p*-process and planetary differentiation. The experimental determination of ^{146}Sm half-life will be described and discussed.

Recycling of subducted sediments traced by HFSE and W systematics of K-rich mafic Aegean lavas

MARIA KIRCHENBAUR[1,2] AND CARSTEN MÜNKER[2]

[1]Steinmann-Institut, Universität Bonn, Germany (Kirchenbaur@uni-bonn.de)
[2]Institut für Geologie und Mineralogie, Universität zu Köln, Germany

Tungsten and other similar incompatible HFSE and LILE (Nb, Ta, Zr, Hf, Ba, Th, U) have been shown to be valuable monitors for assessing the flux of subducted sediments in arc systems [1]. In subduction-related tectonic settings, basalts of the K-rich series (medium-K, high-K and shoshonitic) are considered as the most incompatible element-rich endmembers, commonly being interpreted as tapping mantle sources that underwent a substantial flux of melts or fluids from subducted sediments. In order to constrain the behaviour of the extended HFSE group in the sources of K-rich lavas, we performed high-precision measurements of Nb- Ta-Zr-Hf and W concentrations by isotope dilution and MC-ICPMS on K-rich lavas from the Eo-Oligocene Eastern Rhodope province, Bulgaria and on mafic calc-alkaline lavas from the active Aegean Island arc (Santorini). Both suites share similar petrogenetic characteristics in that their sources were contaminated by subducted sediments from the African plate.

The concentrations of HFSE are enriched in all suites (e.g. 0.3 to 4.2 ppm W), similar to other incompatible elements such as K. The HFSE ratios of virtually all samples lie well within the MORB array (Nb/Ta = 12.8 – 15.1, Zr/Hf = 39.5 – 41.7). Only the absarokites exhibit elevated Nb/Ta (19.1 – 20.1) reflecting fractionation of phlogopite. The samples also exhibit lower Ta/W than MORB (0.19 to 0.68), similar as found for other arc suites [1].

The extended HFSE systematics for both Santorini and Bulgarian rocks can help to discriminate between different types of source overprint: lavas from Santorini, where source enrichment is controlled by melt-like components, exhibit consistently low W/Th (ca. 0.07), somewhat lower than MORB (ca. 0.15). In contrast, the HFSE and W budget in the Bulgarian K-rich rocks is dominated by both fluid- and melt-like components, and W/Th exhibit a large range from 0.07 to 0.3. Our data therefore confirm that W/Th in arc lavas can only be elevated in the presence of fluid-like subduction components. Conversely, in melt-controlled subduction regimes, W appears to behave slightly less mobile than Th.

Towards a numerical model to constrain the time scales for vertically moving axial magma chambers beneath fast-spreading ocean ridges

C. KIRCHNER, J. KOEPKE AND H. BEHRENS

Institut für Mineralogie, Leibniz Universität Hannover, Callinstr. 3, 30167 Hannover, Germany (c.kirchner@mineralogie.uni-hannover.de)

It is well accepted that AMCs ('axial magma chamber') under fast spreading ocean ridges are dynamic systems with the potential to oscillate vertically. Unfortunately, the time scales of these movements are poorly contrained by several multidisciplinary studies, varying between 10 and 100.000 years.

The IODP multi-cruise mission „Superfast Spreading Crust' (Site 1256, equatorial East Pacific Rise), offers the possibility to study natural samples from the lower sheeted dikes from the 1256D drillcore. Detailed petrographic work led to the conclusion, that the ascent of the AMC led to the formation of 'granoblastic dikes' due to an intense metamorphic overprint under granulite facies conditions [1].

In this study, we apply tools of diffusion profile modeling to relictic plagioclase phenocrysts occuring in the granoblastic dikes located above the AMC. Since the plagioclases were affected by the thermal imprint of the AMC (~1200°C), the detailed analysis and modeling of the concentration profiles allows us a quantification of the residence time of the heat source (AMC) in a high position and hence, temporal information about the vertical fluctuations of the AMC can be assessed.

First estimations on the basis of CaAl-NaSi interdiffusion profiles yield average time scales of 19000 years for the development of the profiles. Calculations based on Mg concentration profiles revealed different results: The durations extracted from the profiles are much shorter in the range of ~150-400 years. This discrepancy presumably reflects different processes contributing to the development of the element distribution patterns in these plagioclase phenocrysts and its meaning has to be evaluated in the near future.

[1] Koepke *et al*. (2008) Petrography of the dike-gabbro transition at IODP Site 1256 (equatorial Pacific) The evolution of the granoblastic dikes, *Geochem. Geophys. Geosyst.* **9**, Q07O09, doi, 10.1029/2008GC001939.

Sub-micromolar oxygen dynamics at redox boundaries of lakes

M. KIRF[1,2], C.J. SCHUBERT[1] AND B. WEHRLI[1,2]

[1]Eawag, Seestr. 79, 6047 Kastanienbaum, Switzerland (mathias.kirf@eawag.ch, carsten.schubert@eawag.ch)
[2]Inst. Biogeochem. Pollutant Dynamics, ETH, 8092 Zurich, Switzerland (bernhard.wehrli@env.ethz.ch)

The oxic-anoxic interface in stratified lakes is a habitat of intense microbial activity where a cascade of redox processes occurs at low O_2 concentration levels. Here we report well resolved profiles based on a two-sensor technique: The stable but slower signal from low-level optodes was verified independently with profiles from highly amplified amperometric sensors. Pre-exposure to anoxic waters reduced the drift of electrochemical sensors.

The sub-micromolar oxygen zone

An field survey of the permanently anoxic basin of Lake Zug (Switzerland) [1] revealed the spatial structure and temporal variability of the oxic-anoxic interface in the water column. The depth interval from 1 μM O_2 down to the detection limit had an extension of 0.5 to 5 meters. While most profiles showed a steady decrease, several observations revealed sharp excursions due to the effect of turbulent mixing in the weakly stratified water column with a stability frequency of $N^2 < 10^{-6}$ s^{-2}.

Fast fluctuations were also confirmed when sensors were depoyed at constant depth. Concentrations changed by about 1 μM O_2 within ~ 10 seconds and then remained quasi constant on time-scales of minutes.

The chemical gradients right at the oxic-anoxic interface were on the order of 1 mmol O_2 m^{-4}. Temperature profiles showed local maxima of >0.01°C over the sub-micromolar zone. These temperature changes were not compatible with short-term oxygen fluctuations. Therefore, the position of the oxic-anoxic interface seemed to oscillate over a limited depth range of meters. Microbial communities such as methanotrophs need to cope with oscillating conditions on the time-scale of minutes but will face a rather stable diurnal O_2 supply.

The new setup will facilitate the high-resolution sampling at the redoxcline, the measurements of the *in situ* concentrations for important microbial reactions, and boundary conditions for more detailed reaction-transport models.

Age of the Pueblo Viejo epithermal deposit, Dominican Republic: Re-Os isotope data for sulfides from the Moore and Monte Negro deposits

J.D. KIRK[1]*, S.E. KESLER[2] AND J. RUIZ[1]

[1]University of Arizona, Tucson, Arizona 85721, USA (*correspondence: jdkirk@email.arizona.edu)
[2]University of Michigan, Ann Arbor, Michigan 48109, USA

Knowledge of the age of the giant Pueblo Viejo high-sulfidation epithermal deposit (23.7 M oz Au) in the Dominican Republic is critical to our understanding of the geologic environment in which these deposits form. Two possibilities have been suggested: 1) 118-111 Ma, coeval with formation of Los Ranchos Formation island-arc tholeiites that host the deposit and represent the earliest stage of magmatism in the Greater Antilles arc, or 2) 77-62 Ma, coeval with calc-alkaline intrusions that formed during later stages of arc magmatism typical of many other deposits of this type in Cordilleran settings.

Gold is hosted directly by pyrite and to a lesser extent other sulfides, and is found in both sulfide-rich veins and layers of sulfide along bedding planes in carbonaceous shale. Analyses of six heavy mineral concentrates (largely pyrite), five vein pyrite or sphalerite and one layer pyrite from the Moore and Monte Negro ore bodies, form an isochron yielding an age of 115.1 ± 5.4 Ma with an $^{187}Os/^{188}Os$ initial value of 0.30 ± 0.14 (MSWD = 0.38). Taken separately, the concentrate analyses yield an isochron with an age of 116.4 ± 7.5 Ma and the vein analyses give an age of 116.9 ± 9.9 Ma. The combined isochron age and $^{187}Os/^{188}Os$ initial are consistent with synvolcanic derivation of metals from juvenile arc tholeiites at ca. 115 Ma.

These results confirm that high-sulfidation epithermal mineralization can form during early stages of island arc volcanism and is not confined to calc-alkaline magmatic associations, thereby considerably expanding geologic terranes that are favorable for mineral exploration.

Sea water circulation in coastal aquifers as inferred from radium isotopes: The Dead Sea case

Y. KIRO[1,2]*, Y. WEINSTEIN[3], Y. YECHIELI[2] AND A. STARINSKY[1]

[1]Institute of Earth Sciences, The Hebrew University, Edmond J. Safra campus, Givat Ram, Jeruslaem, 91904
[2]Geological Survey of Israel, 30 Malkhe Israel St., Jerusalem, 95501, Israel
[3]Department of Geography and Environment, Bar-Ilan University, Ramat-Gan 52900

Saline water circulation in coastal aquifers may be a major process that controls trace element mass balances in coastal areas. This study uses radium isotopes in order to quantify lake water circulation in the Dead Sea aquifer.

The Dead Sea is extremely enriched in radium, where both ^{226}Ra and ^{228}Ra (140 and 1-2 dpm/L, respectively) are 3 orders of magnitude higher than in ocean water, whereas the salinity of the Dead Sea is only 10 times higher. The main sources of ^{226}Ra and ^{228}Ra to the lake are fresh springs and brines discharging along the lake shoreline.

Circulated Dead Sea water in the aquifer contains decreased activities of ^{226}Ra (60 dpm/L). This coincides with the lower Ba concentrations in this water compared with the lake (1.5 and 5 mg/l, respectively). We suggest that the low ^{226}Ra and Ba concentrations are due to precipitation of barite from the supersaturated Dead Sea water on entering the aquifer. ^{228}Ra and the shorter-lived ^{224}Ra and ^{223}Ra, which have much lower activities in the Dead Sea, are enriched in the circulated Dead Sea water (20, 45 and 35 dpm/L, respectively) due to recoil and desorption. This implies that the circulation of Dead Sea water in the aquifer removes ^{226}Ra and contributes ^{228}Ra, ^{223}Ra and ^{224}Ra to the lake. This adds a major source with relatively high $^{228}Ra/^{226}Ra$ ratios to the Dead Sea mass balance.

In order to study the processes affecting radium isotopes in the Dead Sea aquifer, considering the dynamic conditions of the Dead Sea, we used a multi-species density-dependent groundwater flow model (SUTRA-MS). The results show that the adsorption distribution coefficient is very low, indicating that the large decrease of ^{226}Ra in the groundwater cannot be due to adsorption, which supports the proposition that ^{226}Ra decrease is due to precipitation of barite.

Based on ^{226}Ra and ^{228}Ra mass balances in the Dead Sea, the calculated amount of Dead Sea water circulation in the aquifer is 200-300 million m^3/yr, which is of the same order of magnitude as all other known Dead Sea water sources at present.

Plutonium redox reactions with iron oxides under anoxic conditions

R. KIRSCH[1,2]*, D. FELLHAUER[3], M. ALTMAIER[4], A. ROSSBERG[1], TH. FANGHÄNEL[3], L. CHARLET[2] AND A.C. SCHEINOST[1]*

[1]Inst. of Radiochemisty, HZDR, 013 14 Dresden, Germany AND ROBL (BM20) at ESRF, BP220, 38043 Grenoble (*correspondence: kirsch@esrf.fr, scheinost@esrf.fr)
[2]ISTerre, UJF/CNRS, BP 53, 38041 Grenoble, France
[3]EC-JRC-ITU, P.O. Box 2340, 76125 Karlsruhe, Germany
[4]KIT-INE, P.O. Box 3640, 76021 Karlsruhe, Germany

The environmental fate of plutonium, the major transuranium actinide in nuclear waste, is largely impacted by its sorption onto and redox reactions with iron oxide minerals [1, 2] that form as corrosion products of steel in the 'near field' and occur widely in sediments. To obtain information on oxid-ation state and local structure, we reacted ^{242}Pu as electro-lytically prepared Pu (V) or Pu (III) (1×10^{-5} M) under anoxic conditions in carbonate free 0.1 M NaCl with hematite, goethite, maghemite and magnetite. Pu-L_{III}-edge XAFS spectra were collected after 40 d and 6 months of reaction.

Results and Discussion

After reaction of either Pu (III) or Pu (V) with hematite (> 99.9 % of added Pu is sorbed on α-Fe_2O_3), Pu is mainly present as Pu (IV), with up to 30 % Pu (V). Also after reaction with goethite (γ-FeOOH) both Pu (IV) (55 %) and Pu (V) (45 %) are present. For both minerals, EXAFS spectra show no strong Fe-backscattering from the substrate and also give no evidence for the formation of a solid PuO_2 phase. In contrast, EXAFS spectra of Pu reacted with maghemite (γ-Fe_2O_3) and magnetite (Fe_3O_4) are characterized by strong iron backscattering, indicating the formation of inner-sphere surface complexes. With maghemite, oxidation state mixtures of Pu (III) and Pu (IV) or Pu (IV) and Pu (V) were found while with magnetite, Pu (III) was the predominant oxidation state [3]. However, in one case and probably due to an increased Pu / magnetite surface area ratio, formation of PuO_2 after reaction of Pu (V) with magnetite was observed. These results highlight the importance of plutonium surface complexation, in addition to solid PuO_2 precipitation, in controlling envi-ronmental Pu concentrations. Further, under reducing con-ditions where Fe (II)-bearing oxides such as magnetite exist, it is necessary to consider trivalent in addition to tetravalent plutonium species and PuO_2 (am, hyd) for risk assessment.

Monitoring CO_2-H_2O interactions using $\delta^{13}C$ & $\delta^{18}O$ at the CO2CRC Otway Project CO_2 storage pilot

D. KIRSTE[1,2], C. BOREHAM[1,3], L. STALKER[1,4] AND J. UNDERSCHULTZ[1,4]

[1]Cooperative Research Centre for Greenhouse Gas Technologies,
[2]Dept. of Earth Sciences, Simon Fraser University, Burnaby, BC V5A 1S6, Canada (dkirste@sfu.ca)

[4]Division of Petroleum Resources, CSIRO, Kensington, WA 6151, Australia (linda.stalker@csiro.au, james.underschultz@csiro.au)

The CO2CRC Otway Project is an extensively monitored demonstration site for the storage of CO_2 in a depleted gas field. Geochemical monitoring was carried out through the collection of high quality aqueous and supercritical fluid samples via a novel U-tube bottom hole sampling assembly. Several sampling zones within the depleted field were accessed using 3 separate U-tube lines, one completed in the methane-rich gas zone (U1) and two in the water leg at ~2 m (U2) and ~7 m (U3) below the initial gas-water contact. This configuration allowed for monitoring of the filling of the gas field by the injected CO_2. Injection of CO_2 began in late March, 2008 with breakthrough occurring between 101 and 121 days later and the transition to full self-lifting of U3 by day 303 Reservoir fluids were sampled for stable isotopic composition measurements of the $\delta^{13}C$ and $\delta^{18}O$ of the dissolved and immiscible phase CO_2 and the $\delta^{18}O$ and $\delta^{2}H$ of water. The U-tube assembly enabled sampling of fluids at reservoir pressure but cooling during sample lift meant that the subsurface temperatures were not maintained. The $\delta^{13}C$ of the pre-breakthough exsolved CO_2 and the gas phase CO_2 showed a fractionation consistent with that expected between $CO_{2\,(g)}$ and $CO_{2\,(aq)}$. As the injected CO_2 concentration increased the $\delta^{13}C$ shifted from that of the indigenous CO_2 to that of the injected. However, the $\delta^{13}C$ of the HCO_3^- showed a fractionation typical of a Rayleigh-type distillation and the fractionation factor reflected surface temperature conditions. The $\delta^{18}O$ of the water remained constant throughout the period for U2 and U3 until just prior to self-lift when there was an decrease. U3 showed considerable variability in the produced fluid immiscible/aqueous phase ratio near the transition and this is reflected in the oxygen isotopic of the aqueous and gas phase. Interestingly the $\delta^{18}O$ values showed no surface temperature fractionation like that seen for the $\delta^{13}C$.

Different coloured vitreous phases in obsidian

J. KIRSTE*, G. WAGNER, N. SCHULZE AND G. KLOESS

Institute for Mineralogy, Crystallography und Materials Science, Leipzig University, Scharnhorststrasse 20, 04275, Leipzig, Germany
(*correspondence: kirste@uni-leipzig.de)

Different coloured glass matrices obsidian are the object of the study. Their compositions and phase analyses of implemented nanocrystals were determined by Transmission Electron Microscopy (TEM). The analyses were carried out with an STEM Philips CM 200.

The Büyük Yayla obsidian (Eastern Pontides, Turkey) shows various bands, coloured black, red, and partially colourless. Moreover, a sharp black displacement (up to 1 cm) passes through the obsidian due to a still unknown shear process, displacing the several layers. Note, the different bands do not show a macroscopic 'schlieren-like' texture close to the displacement front.

The results of TEM-EDX analyses are given in the following table.

Oxide [wt-%]	red glass matrix	colour-less glass matrix	black glass matrix	glass close to the displacement trace
Na_2O	4.5	1.6	5.2	5.8
MgO	0.1	0.2	0.2	0
Al_2O_3	13.4	13.1	12.9	13.1
SiO_2	76.0	74.9	74.4	75.0
K_2O	4.7	8.4	5.3	4.6
CaO	1	0.9	1	1.1
TiO_2	0	0	0.2	0
MnO	0	0	0.1	0
Fe_2O_3 (Fe-tot)	0.4	0.9	0.6	0.5

Table 1: Chemical composition of different coloured glass matrices of the Büyük Yayla obsidian

Suprisingly the highest Fe-amount was detected in the colourless vitreous matrix. Hence, the iron soluted in the glass is not responsible for the different colours of the glass. The detected 0.3 – 0.5 wt-% of hematite- and magnetite-nanocrystals colour the vitreous matrices.

Calcium and magnesium isotopes in biogenic calcite

B. KISAKÜREK[1]*, A. EISENHAUER[1], M.N. MÜLLER[1,2], I. TAUBNER[1], J. FIETZKE[1], F. BÖHM[1], D. BUHL[3] AND J. EREZ[4]

[1]Leibniz Institute of Marine Sciences, IFM-GEOMAR, Kiel, Germany (*correspondence: bkisakurek@ifm-geomar.de)
[2]IMAS Institute for Marine and Antarctic Studies, Hobart, Australia
[3]Faculty of Geosciences, Ruhr-Universität Bochum, Germany
[4]Institute of Earth Sciences, The Hebrew Univ. of Jerusalem, Israel

As shown recently [1], the isotopic fractionation of calcium is strongly correlated with the partitioning of Sr in inorganically precipitated calcite, wherein the main control on both proxies is the precipitation rate. In a follow up study [2], the inorganic correlation between $\Delta^{44/40}$Ca and D_{Sr} has been verified for planktic foraminifera. We extend this approach to coccolithophores, including *Emiliania huxleyi* and *Coccolithus braarudii*, grown under controlled laboratory conditions. The slope of the regression between $\Delta^{44/40}$Ca (‰) and log D_{Sr} in coccolithophores (-1.8±0.9, [3]) is within error of that in inorganically precipitated calcite (-1.9±0.3, [1]), whereas there is a large offset between the inorganic and coccolithophorid regressions due to the higher Sr content in the latter.

Comparing the fractionation of magnesium isotopes versus the Mg content in the calcitic skeletons of the Alcyonarian soft coral *Rhythisma fulvum*, benthic foraminifer *Amphistegina* sp., coccolithophores *Emiliania huxleyi* and *Coccolithus braarudii*, echinoid *Echinocyamus pusillus*, red algea *Corallina officinalis*, brachiopod *Terebratula* sp. and sponge *Acanthochaetetes wellsi* [4, 5, 6] we find that species with high Mg content (>10 mol% $MgCO_3$) have a higher degree of fractionation ($\Delta^{26/24}$Mg<-2 ‰) compared to low Mg species (<5 mol% $MgCO_3$; $\Delta^{26/24}$Mg>-2 ‰). Planktic foraminifera and the blue mussel *Mytilus edulis* [5, 6] are exceptions with low Mg content but a high degree of fractionation ($\Delta^{26/24}$Mg<-3.5 ‰).

These results will be discussed in a comparative manner in terms of our understanding of the pathways of biomineralization in different calcifiers.

Post-deposition diffusion of ^{137}Cs in lake sediments

J. KLAMINDER[1], P. APPLEBY[2] AND I. RENBERG[1]

[1]Department of Ecology and Environmental Science, Umeå University, SE-901 87 Umeå, Sweden
[2]Department of Mathematical Sciences, University of Liverpool, P. O. Box 147, Liverpool, L69 3BX, UK

Large episodic emissions of radiocesium ^{137}Cs into the atmosphere, such as those generated by nuclear weapon testing programs in the 1960s and the Chernobyl accident in 1986, have been frequently utilized when dating lake sediments. The ongoing disaster at the reactors at Fukushima, Japan, is likely to generate a new chronological marker in sediments deposited over a large part of the region that can be recognized as subsurface peak in ^{137}Cs activities by future sedimentologists. However, the generation of a new ^{137}Cs dating horizon in lake sediment can eliminate the use of others due to significant post-depositional mobility and catchment processes as shown in this presentation. Here we show using archived sediment samples how the ^{137}Cs record within an annually varved sediment, from a lake situated about 1600 km from Chernobyl, is successively altered between 1985 to 2007 due to Chernobyl fallout and subsequent post-depositional diffusion and catchment inputs. The record reveals how Chernobyl ^{137}Cs becomes incorporated into the summer sediment in 1986 and diffuses downward in the core at a decreasing rate over time, making the marker of 1964 originally present in the core sampled three weeks before the Chernobyl accident unrecognizable two years after the accident. It is, therefore, questionable whether ^{137}Cs peaks in deep sediment can be used to recognize sediment deposited in the 1960s in regions that has received significant fallout from the accidents in Chernobyl or Fukushima.

Atomic force microscopy study of the dissolution of a calcite surface in the presence of phosphate ions

J. KLASA[1,2]*, E. RUIZ-AGUDO[3], C.V. PUTNIS[2], A. PUTNIS[2], P.F. SCHOFIELD[1], E. VALSAMI-JONES[1]

[1]Natural History Museum, Cromwell Road SW7 5BD, London, UK (*correspondence: j.klasa@nhm.ac.uk)

The dissolution of calcite in the presence of phosphate solutions has been studied using Atomic Force Microscopy (AFM). The presence of phosphate in aqueous solutions is known to inhibit calcite growth [1] and has been successfully used to reduce limescale formation. In this study, solutions containing phosphate salts such as ammonium and sodium phosphate were studied in order to compare their influence on the dissolution of a calcite surface {10-14} during continuous flow in the fluid cell of an AFM.

In the presence of phosphate solutions at pH ~ 8, a significant decrease in the dissolution rate was observed. However, the etch pit density, increased for both ammonium and sodium phosphate salts, suggesting a kosmotrope hydration character of phosphate ions and therefore similar behaviour to that of fluorine ions on calcite dissolution [2]. It was also observed that the dissolving calcite surface can act as a structurally suitable substrate for calcium phosphate growth, which may prove to be an environmentally important mineral replacement reaction for remediation of phosphate rich systems.

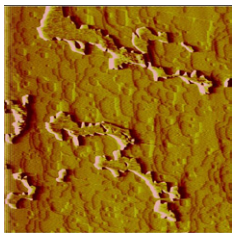

Figure 1: AFM image of calcium phosphate growth on a calcite cleavage surface. The process is limited by the release of Ca^{2+} from the dissolution of calcite.

Origin of the nodules in the 18.6 ka Sarno plinian eruption of Mt. Somma-Vesuvius (Italy) and their significance

R. KLÉBESZ[1,2]*, R.J. BODNAR[1] AND B. DE VIVO[2]

[1]Dept. of Geosciences, Virginia Polytechnic Institute and State University, Blacksburg, VA 24061, USA (*correspondence: krita@vt.edu)

[2]Dept. of Earth Sciences, University of Naples "Federico II", Naples 80134, Italy (bdevivo@unina.it)

Nodules (coarse-grain 'plutonic' rocks) were collected from the phreato-magmatic phase of the Sarno eruption in C. Traianello quarry, located on the NE slope of Mt. Somma. Based on the mineral composition the rocks can be classified as monzonite-monzogabbro. They consist of An-rich plagioclase, K-feldspar, clinopyroxene (ferro-diopside), mica (phlogopite-biotite) ± olivine and amphibole. Unlike most of the nodules from the other eruptions, these samples do not have typical cumulative texture, but rather display a porphyrogranular texture. The phenocrysts are large (up to few mm) with variable compositional zoning. The phenocrysts are often partially to completely enclosed by later poikilitic feldspars. Sometimes irregular intergrowths of alkali feldspar and plagioclase and smaller unidentified crystals can be observed. These features are interpreted as crystallyzed melt pockets. Based on their textures, the nodules may represent the *in situ* crystallizing melt on the walls of the magma chamber. The lack of the interstitial glass, which is common in nodules from similar environments, can be explained by the time difference between the plinian and the phreatomagmatic phase. The time difference might have provided sufficient time for the interstitial melt in Sarno samples to crystallize.

Minerals, especially clinopyroxenes, are abundant in crystallized silicate melt inclusions. The inclusions consist of mica, oxide minerals, clinopyroxene and possibly apatite, feldspar, interstitial glass, bubble. Unlike nodules from other eruptions, all fluid inclusions in Sarno samples are single phase and secondary in origin, and not associated with melt inclusions. The different textures and inclusion populations may indicate different pre-eruptive conditions and processes, compared to other eruptions. Melt inclusions in clinopyroxenes have been analyzed by LA-ICP-MS. The major and trace element compositions of MI are similar to the products erupted during the plinian phase, indicating that they may be co-genetic. Melt inclusions have been rehomogenized for further analyzes to determine the volatile content, in order to estimate a minimum crystallization depth.

Monte Carlo study of aggregation of alkyltrimethylammonium ions at the montmorillonite-water interface

B. KLEBOW[1]* AND A. MELESHYN[1,2]

[1]Institute of Radioecology and Radiation Protection, Leibniz Universität Hannover, Germany (*correspondence: klebow@irs.uni-hannover.de)

[2]Present address: Gesellschaft für Anlagen- und Reaktorsicherheit (GRS) mbH, Brunswick, Germany

Unlike naturally occurring bentonites, organically modified ones exhibit adsorption capabilities not only for cationic but also for anionic contaminants. This property renders them valuable for various environmental and industrial processes like sewage treatment, groundwater remediation, production of nanocomposites, and waste disposal. An additional essential advantage regarding the application of organoclays to the remediation of contaminated groundwater is their effective adsorption of non-polar organic contaminants such as the highly persistent, toxic and carciogenic polycyclic aromatic hydrocarbons.

The precise molecular structures of organically modified clays as well as the mechanisms determining their observed adsorption properties are still not well understood. To establish a relation between experimental observations and underlying molecular structures, we performed classical molecular simulations of the external montmorillonite surface modified by alkyltrimethylammonium (C_nTMA^+, with n being the number of methyl (ene) groups in the alkyl chain).

The adsorption of alkyltrimethylammonium ions at the montmorillonite-water interface and the formation of interfacial C_nTMA^+ aggregates at higher concentrations of adsorbed C_nTMA^+ were studied. The simulations were performed in NVT-ensemble at a temperature of 298 K applying the Metropolis and the configurational-bias Monte Carlo algorithms for increasing surface concentrations of C_8TMA^+, $C_{12}TMA^+$, and $C_{16}TMA^+$ ions. The discussion will comprise the arrangement of adsorbed organic and inorganic ions, structure and type of adsorption complexes, conformation of alkyl chains, and the water structure at the organically modified montmorillonite-water interface taking into account findings of previous experimental and simulation studies.

Dolomitization of serpentinized harzburgite from the Atlantis Massif

FRIEDER KLEIN

Woods Hole Oceanographic Institution, (fklein@whoi.edu)

Ophicarbonate breccias consisting of fragments of serpentinized peridotite and carbonate cement have been reported from outcrops at the Atlantis Massif, MAR[1]. While the carbonate cement precipitates due to mixing of high-pH, Ca-rich serpentinization fluids with seawater, the direct replacement of serpentinite by dolomite is more difficult to explain. Here, I report on observations made in a dolomite-altered, strongly serpentinized, partly steatitized harzburgite, from the IODP Leg 304, Hole 1309B at the Atlantis Massif. Dolomite appears in mesh and hourglass texture of completely serpentinized olivine adjacent to a talc-tremolite altered shear zone. The dolomite in these samples is surrounded by a zone of serpentine (Mg# 98), and magnetite, which traces the former (sub-) grain boundaries of olivine. Orthopyroxene is partly serpentinized to bastite, which subsequently underwent partial steatitization but not dolomitization. Both clinopyroxene and Cr-spinel are unaltered.

Dolomite in serpentinite can form by conductive heating of seawater[2]; however, in samples from Hole 1309B petrographic observations and microprobe analyses suggest a direct replacement of brucite and serpentine by dolomite. Phase relations in the system MgO-CaO-SiO_2-H_2O-CO_2 indicate that brucite is the first mineral being replaced by dolomite at relatively low CO_2, aq actvities, while dolomitization of serpentine and talc requires higher CO_2, aq activities. However, it remains to be resolved whether the CO_2 is of magmatic or of seawater origin. The Mg needed for the formation of dolomite is likely contributed by brucite and/or serpentine themselves, whereas Ca may have been transported from the adjacent talc-tremolite shear zone. Alternatively, the Ca may have been contributed by the dissolution of the Ca-Tschermaks component of partly serpentinized orthopyroxene.

This pilot study indicates that serpentine and brucite can act as a sink for CO_2 in the oceanic lithosphere, in particular where seawater and/or magmatic fluids interact with hybrid mafic/ultramafic lithologies.

Chromium mobility in hydrous fluids at upper mantle conditions

O. KLEIN-BENDAVID[1], T. PETTKE[2] AND R. KESSEL[1]

[1]The Fredy & Nadine Herrmann Institute of Earth Sciences, the Hebrew University of Jerusalem, Jerusalem, Israel, 91904 (*correspondence: ofrak1@gmail.com)
[2]Institute of Geological Sciences, University of Bern, CH-3012 Bern, Switzerland

Chromium is a minor component in the earth's mantle and is considered to be immobile in aqueous fluid under crustal and most mantle conditions. Exceptions to this are for example K-rich diamond forming fluids, shown to contain up to 1 wt% Cr_2O_3 (on a volatile free basis). A series of high-P experiments on the solubility of Cr_2O_3 in KCl bearing water were done using rocking multi anvil diamond trap techniques (1000 and 1200 °C; 4 and 6 GPa) combined with cryogenic LA-ICP-MS in order to determine Cr mobility in saline fluids (e.g. diamond forming fluids) under mantle conditions and its possible involvement in deep metasomatism. Chromium solubility in KCl-bearing water increases with salinity (KCl). At 250 μg/g KCl, Cr solubility in water is between 100 and 200 μg/g, independent of pressure. At 4 GPa, an order of magnitude increase in Cr-solubility is observed only for the 3 wt% KCl solution, while at 6 GPa such increase is observed already at 1.3 wt% KCl. No significant effect of temperature is observed. Metasomatic Cr-rich mineral assemblages are encountered in both subduction zone and deep lithospheric mantle environments, where alkali-rich hydrous fluids, similar to those examined in this research, are regarded as major metasomatic agents. In some cases, unique minerals found as micro- and macro- inclusions within diamonds (e.g. chromite and phlogopite) have significantly different compositions than common mantle minerals and are much richer in Cr. Thus, saline hydrous fluids can be considered an important metasomatic agent at deep lithospheric mantle conditions and appear to be efficient in transporting elements such as Cr during rock water interaction.

Evidence of K-Fe metasomatism in the SW Scottish Highlands

B.I. KLEINE*, A.D.L. SKELTON AND I.K. PITCAIRN

Department of Geological Sciences, Stockholm University, 10691 Stockholm, Sweden
(*correspondence: barbara.kleine@geo.su.se)

Metamorphosed basaltic lava flows, tuffs, sills and dykes are emplaced within metasedimentary rocks which are part of the Dalradian Supergroup (Argyll Group) in the SW Scottish Highlands [1]. These metabasaltic sills were affected by at least three fluid-rock interaction events during greenschist facies regional metamorphism: pre-metamorphic spilitisation, syn-metamorphic carbonation of metabasaltic sills and post-metamorphic quartz-carbonate-sulphide veins [2]. The infiltration of H_2O-CO_2 fluids during carbonation led to a mineral assemblage zonation within the metabasalt with carbonate-free interiors and carbonate-rich margins [3].

These three fluid events and an additional K-Fe metasomatic event of uncertain timing could be identified in alterated metabasalt on the island of Islay in the SW Scottish Highlands. At this locality, the alterated metabasaltic sills display a distinct change in mineral assemblage which seems to be coupled to brittle to ductile faulting. Only the areas close to the fault seems to be affected by the K-Fe metasomatism. The mineral assemblage pl+zoi+chl+qtz+cc changes into ep+chl+qtz+cc+ht+bt towards the fault system which cuts through the outcrop. These results were achieved by petrographic analysis, point counting of 1000 evenly spaced points in selected thin sections, XRF and SEM analyses.

The fact, that hematization took place and zoisite changes into the more Fe-bearing epidote, suggests that iron was added during the fluid event. The formation of biotite leads to the assumption that K-metasomatism is also coupled by this fluid-rock interaction.

Is it possible to constrain a sequence of fluid events in this area? The hematite phenocrysts are only slightly affected by the foliation of the metabasalt which suggests that the K-Fe metasomatism occured after peak metamorphism (400-530°C, 10 kbar) [3]. Also its spatial association with faulting suggests that K-Fe metasomatism was occured late during the fluid-infiltration history.

Hf-W chronometry of angrites: Implications for ^{26}Al heterogeneity and core formation in protoplanets

T. KLEINE[1]*, U. HANS[2], A.J. IRVING[3] AND B. BOURDON[2]

[1]Institute for Planetology, University of Muenster, Wilhelm-Klemm-Str. 10, 48149 Muenster, Germany (*correspondence: thorsten.kleine@uni-muenster.de)
[2]Institute for Geochemistry and Petrology, ETH Zurich, Clausiusstrasse 24, 8092 Zurich, Switzerland
[3]Department of Earth and Space Sciences, University of Washington, Seattle, WA 98195, USA

Angrites formed by some of the earliest igneous activity in the solar system and provide insights into the early stages of planetary melting and differentiation. Moreover, they are pivotal reference points for early solar system chronology [e.g. 1-3]. In order to study the processes and timescales of metal segregation in early protoplanets and to assess the distribution of short-lived radionuclides in the early solar system, the ^{182}Hf–^{182}W system was applied to a comprehensive suite of angrites. ^{182}Hf–^{182}W isochron ages for angrites are in excellent agreement with previously reported ^{207}Pb–^{206}Pb and ^{53}Mn–^{53}Cr results [e.g. 1] but are ~1 Myr older than ages obtained from ^{26}Al-^{26}Mg chronometry [e.g. 2]. These inconsistencies are best explained by a heterogeneous distribution of ^{26}Al in the early solar system, suggesting that at the time of CAI formation the angrite precursor material had an ^{26}Al/^{27}Al of ~1.8×10^{-5}, substantially lower than values commonly measured for CAI. Based on the Hf–W results four texturally and temporally resolved groups of angrites can be identified that were derived from at least two distinct mantle sources. These mantle sources are the result of separate events of core formation, both of which took place within ~2 Myr of CAI formation. Thus, core formation in the angrite parent body did not occur as a single event of metal segregation from a global magma ocean but rather took place under varying conditions by several more local events. Heterogeneities in the Hf-W systematics of the two distinct angrite source regions may result from inefficient core formation in some areas of the angrite parent body or may reflect variable redox conditions during metal segregation. The absence of global melting and homogenization in spite of an early accretion is consistent with a relatively low initial ^{26}Al/^{27}Al inferred here for the angrite precursor material.

Geodynamic implications of new U-Pb zircon ages for the Kamanjab Inlier (NW-Namibia)

I.C. KLEINHANNS[15], F. WILSKY[2], N. NOLTE[2], T. BECKER[3], B.T. HANSEN[2], R. KLEMD[4] AND D. FLIEGEL[5]

[1]Institute for Geoscience, University Tübingen, Germany, (kleinhanns@ifg.uni-tuebingen.de)
[2]GZG, University Göttingen, Germany
[3]BRGM, Orléans, France
[4]Geocentre Northern Bavaria, Erlangen, Germany
[5]Geoscience Institute, University Bergen, Norway

The Huab Metamorphic Complex (HMC) and Fransfontein Granitoid suite (FFG) are part of the Kamanjab Inlier (KI) in NW-Namibia. It is a poorly known pre-Pan African basement complex and, together with the Epupa complex (EC) further NW and the Grootfontein complex (GC) further E, marks the SW-margin of the Congo craton in N-Namibia. New LA-ICPMS U-Pb zircon ages frame FFG emplacement to 1.88-1.83Ga and protolith ages for HMC orthogneisses to 1.86-1.83Ga. These ages are roughly 100 m. y. older than protolith ages from the northern EC close to the Angolan border and roughly 100 m. y. younger than the GC. The southern EC in the Hoanib area is the only known Archean basement in Namibia, but shows eNd (1.83Ga) of -10.9 to -6.5 compared to those of the northern EC (-2 to 4.2), FFG (-5.9 to 1.2) and HMC (-2.3 to 2.3). Our study supports earlier speculations that the southern EC is an exotic terrane within the Namibian basement complexes. In contrast, the KI is comparable to the northern EC and GC and geochemical data indicate an active continental margin setting. This points to an event of Paleoproterozoic crustal growth at the SW border of the Congo Craton starting in the present E gradually moving towards the present NW.

The garnet-spinel transition in fertile and depleted mantle: Experimental data, thermodynamic calculations and implications for magmatic processes

S. KLEMME

Institut für Mineralogie, Universität Münster, Germany (stephan.klemme@uni-muenster.de)

With increasing depths in the Earth's mantle, the aluminous phase in the upper mantle changes from plagioclase to spinel to garnet. The transition from spinel lherzolite to garnet lherzolite could potentially influence the characteristics of some kinds of basalts, particularly mid-ocean ridge basalts (MORB), since this transition is thought to occur at about the same depths at which MORB may originate. Several studies have investigated the transition from garnet lherzolite to spinel lherzolite in simple systems (e.g. CaO-MgO-Al_2O_3-SiO_2) (e.g. [1-3]) but, due to experimental problems associated with slow reaction rates, few studies have tried to experimentally investigate the garnet-spinel transition in more complex and depleted composition (e.g. [4-5]). Here we set out to investigate phase relations from fertile to depleted mantle compositions using a new set of thermodynamic data and free energy minimization techniques [6]. We show that the stability fields of garnet and spinel in upper mantle lithosphere critically depend on the bulk composition of the peridotite. In fertile bulk compositions, the transition from spinel to garnet-bearing rocks is relatively sharp but in depleted bulk compositions there is a large pressure-temperature field where garnet and spinel coexist. We will show that the garnet-in reaction in depleted peridotite occurs in much greater depths than in fertile lherzolite. Furthermore, the results in depleted compositions may also be of relevance for the diamond exploration industry as the calculated Cr-rich spinel and garnet compositions may be used to quantitativly estimate pressures of origin and therefore evaluate the so-called diamond potential of mineral concentrates [7].

Secondary minerals in mine wastes at Sb deposits in Slovakia

T. KLIMKO[1]*, J. MAJZLAN[2], B. LALINSKÁ[1], M. CHOVAN[1], J. GÖTTLICHER[3] AND R. STEININGER[3]

[1]Department of Mineralogy and Petrology, Comenius University, Bratislava, Slovakia (*correspondence: klimko@fns.uniba.sk)
[2]Institute of Geosciences, Friedrich-Schiller University, Jena, Germany
[3]Institute for Synchrotron Radiation, Karlsruhe Institute of Technology, Germany

In this work, we have summarized results from a detailed mineralogical study of the weathering products formed in the environment of tailing ponds and soils from five Sb deposits in Slovakia, based on 250 samples of flotation tailing materials and soils, 2500 electron microprobe analyses and 500 micro-X-ray diffraction (μ-XRD) analyses. All studied bulk samples are rich in Fe (24.2–181 g/kg), As (0.1–13.5 g/kg), and Sb (1.2–15.7 g/kg). The most frequent sulphides in the flotation wastes are pyrite (FeS_2) and arsenopyrite (FeAsS); stibnite (Sb_2S_3) is rare owing to its rapid oxidation.

The most common Sb-bearing secondary oxide is tripuhyite ($FeSbO_4$) with variable Sb (15.94-50.83 wt. %) and Fe content (4.13-41.52 wt. %). Unit cell volume is in the range from 64.70 Å^3 to 75.83 Å^3 and depends mostly on the Fe/(Fe+Sb) ratio of the tripuhyite grains. In the tailings and soils rich in Ca, secondary minerals with the pyrochlore structure have been identified. These phases are rich in Sb (up to 52.90 wt. %), Fe (up to 21.22 wt. %) and Ca (up to 7.40 wt. %) and the μ-XRD patterns fit well with the structural models of stibiconite ($Sb^{3+}Sb^{5+}{}_2O_6$ (OH)) and lewisite (Ca, Fe^{2+}, Na)$_2$ (Sb, Ti)$_2O_7$). The most frequent secondary mineral at all studied sites is goethite (α-FeOOH), with high content of Sb (up to 14.49 wt. %) and As (up to 6.49 wt. %). Cell parameters depend on incorporation of foreign elements, in agreement with earlier studies. Frequent are also X-ray amorphous Fe oxides with variable amounts of adsorbed elements (up to 6.66 wt. % of Mg, 13.91 wt. % of Sb and 10.64 wt. % of As). Simple secondary Sb oxides such as cervantite (α-Sb_2O_4) and senarmontite (Sb_2O_3) were observed each just in one soil sample. The most common product of arsenopyrite oxidation - scorodite ($FeAsO_4 \cdot 2H_2O$) occurs rarely. Beudantite ($PbFe_3$ (AsO_4)(SO_4)($OH)_6$) was identified in a few samples with increased content of Pb. In one sample, a porous secondary oxide rich in Pb and As was identified by μ-XRD as clinomimetite (Pb_5 ($AsO_4)_3Cl$).

Experimental constraints on the composition of slab liquids below arc volcanoes

KEVIN KLIMM[1], FABIAN SCHRÖDER[1] AND JON D. BLUNDY[2]

[1]Institut für Geowissenschaften, Universität Frankfurt, D
[2]Department of Earth Sciences, University of Bristol, UK

The flux of elements from the slab into the mantle wedge is governed by the composition of the different subducted lithologies, the partitioning behaviour of trace elements and the subduction geotherm. Recently it has been shown that the concentration of key elements such as K, Zr, Ti, Nb and REE depends primarily on T and is controlled by the solubility of accessory phases, such as phengite, zircon, rutile and allanite, in the melt [1, 2]. This T-concentration relationship can be used as a geothermometer to determine the top slab T in subduction zones and suggests values that vary from 750 to 950 °C for different subduction zones [3]. Crucial questions that remain open are the effect of pressure and the presence of additional volatiles such as S, Cl and F on the stability of accessory phases and the composition of slab liquids.

Here we report preliminary results on crystallisation experiments on a H_2O-saturated and trace element-doped MORB composition at 5 GPa and 750-1000 °C. Together with previous results at 2.5 GPa and 750-900°C [2] the experimental dataset now covers the full range of P-T conditions predicted for the slab below volcanic arcs. The dataset will be augmented with a few runs containing additional S and F.

First results show that at 5 GPa the wet solidus of basalt is <900 °C. Experimental melts at 5 GPa are granitic compared to trondhjemitic melts at 2.5 GPa. With increasing P, D_{Na} in cpx increases and hence Na/K in the melt decreases. All runs contain gt, cpx and rutile. Allanite is present up to 950 °C. No effect of P on allanite composition has been recognised so far. Coesite is found to be stable at P >5 GPa. The trace element contents of the glasses are currently investigated by LA-ICPMS. One run at 950 °C and 5 GPa, containing small quantaties of F, crystallised REE-bearing CaF_2 and allanite. From these preliminary results we anticipate that a) increasing P (increasing depth of the slab) can explain the change from Na-rich to more K-rich signal in arc magmas and thus K is not only controlled by phengite stability and b) addition of F in the fluid stabilises REE-bearing CaF_2 in the solid residue.

Translocation of synthetic inorganic nanoparticles in a water-saturated sediment column

SONDRA KLITZKE[1]*, SUSANN APELT[2] AND LARS DÜSTER[3]

[1,2]Federal Environment Agency, Schichauweg 58, 12307 Berlin, Germany (*corrspondence: sondra.klitzke@uba.de, susann.apelt@uba.de)

[3]Federal Institute of Hydrology, Am Mainzer Tor, 156068 Koblenz, Germany (duester@bafg.de)

Breakthrough of synthetic, inorganic nanoparticles (NP) in porous media observed in laboratory experiments [1] raises the assumption of NP posing a risk to drinking water treatment methods [2] such as riverbank filtration. Hence, the aim of this experiment was (i) to gain first hints on the fate of NP under near-natural conditions and (ii) to understand the processes of NP interactions taking place in the water phase and the sediment.

Four types of NP (TiO_2, Ag(0), CeO_2, Sb_2O_5) were suspended in the supernatant of a water-saturated sediment column (1 m length) implemented into a slow sand filtration pond. The column was filled with coarse-grained medium sand and was fed with surface water (pH 7, 8, I = 19 mM, turbidity = 3 FNU) from the surrounding pond. The column was sampled in various depths (20 cm, 40 cm, 60 cm, 80 cm) and at the outflow. The NP were fractionated by filtration (0.45 μm and 0.1 μm) and the respective analytes (Ti, Ag, Ce, Sb) were determined using ICP-MS.

In the water phase, NP concentrations were reduced by a factor of 1000 due to particle aggregation, which was predominantly caused by an increase in ionic strength in relation to the original NP suspension. This resulted in a shift of the particle size distribution towards larger sizes and NP were found to form hetero-aggregates with suspended particulate matter. Our observations demonstrate that hydrochemical conditions substantially affect size distribution and aggregation of the investigated NP.

In the sediment, Sb_2O_5, the NP with the most negative zeta potential, was the only NP showing breakthrough (up to a depth of 40 cm). This result confirms that the zeta potential is a key factor in NP suspension stability. The various conditions led to a change in particle size distribution during sediment passage, too. The processes which play a key role in NP translocation remain to be elucidated.

The role of mineral surface chemistry in the prebiotic selection of pentose sugars

K. KLOCHKO[1], D.A. SVERJENSKY[1,2], R.M. HAZEN[1] AND H.J. CLEAVES II[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington, 5251 Broad Branch road, Washington DC 20015 (kklochko@ciw.edu)

[2]Department of Earth and Planetary Sciences, Johns Hopkins University, Baltimore, MD 21218.

Pentose sugars are major biochemical building blocks. Prebiotic syntheses have been proposed leading to complex mixtures including 4-, 5-, and 6-carbon sugars [1, 2]. However, the pentose sugar D-ribose has the greatest biological importance because it is the sugar found within modern nucleic acids. We are investigating whether this is due to some exceptional characteristic of ribose associated with its interaction with mineral surfaces.

Recent study of the adsorption of nucleosides and nucleotides on rutile [3] indicates that adjacent OH-groups on the ribose part of these molecules play a critical role in the attachment to mineral surfaces. The four pentose sugars ribose, xylose, lyxose and arabinose differ only in the arrangement of the OH-groups and their stereochemistry in solution. This suggests that the different structures of these sugars might lead to selective adsorption on mineral surfaces.

The present study is focused on interactions of D-ribose and D-xylose on rutile (α-TiO_2, pH_{PZC} = 5.4, BET = 18.1 m^2/g) in 10 and 100 mM NaCl solutions over a wide range of pH conditions (3-10). The rutile powder is the same as previously used for amino acid adsorption studies [4]. Batch adsorption experiments of the two sugars individually and in mixtures indicate that adsorption of both sugars increases with increasing pH of the solution. The pH dependancy of adsorption is more pronounced for ribose leading to a difference of ~20% adsorbed at pH > 8.5. Our preliminary results indicate a significant difference in the adsorption behavior of the two sugars.

Controls on lignin degradation in a temperate deciduous forest

THIMO KLOTZBÜCHER[1]* KLAUS KAISER[2] AND KARSTEN KALBITZ[1]

[1]Earth Surface Science, University of Amsterdam, Amsterdam, The Netherlands (*correspondence: thimo.klotzbuecher@gmail.com, k.kalbitz@uva.nl)

[2]Soil Sciences, Martin Luther University Halle-Wittenberg, Halle, Germany (klaus.kaiser@landw.uni-halle.de)

Degradation of lignin might play a critical role for carbon (C) storage in soils. Changes in climate or land-use affect inputs of nitrogen (N) and dissolved organic matter (DOM) to topsoils. We studied possible consequences for lignin degradation at a beech–oak site in Southern Germany. We hypothesized that degradation of lignin and other recalcitrant organic matter (OM) decreases with N inputs, but increases with input of easily degradable OM. The study also addressed effects of DOM composition on lignin degradation.

A column experiment using A horizon samples was conducted. Solutions differing in N and of different concentrations of DOM of various composition (i.e. glucose, DOM extracts of fresh or humified litter material) were added every 2-4 weeks for 11 months. Total N additions ranged from 0-32 mg N g^{-1} soil-N, organic C additons were 0 or 11 mg C g^{-1} soil-C (i.e. maximum C and N added equaled 2-3 times the annual input of dissolved organic C and total N from forest floors). Lignin degradation was assessed after 5 and 11 months using the CuO oxidation method.

In controls (no N or DOM added), the cummulated CO_2-C evolution (during 11 months of incubation) amounted to 13% of initial soil-C, while CO_2-evolution diminished during incubation indicating decreased C availability. Yields of lignin phenols decreased by 19% (0-11 months). Even in the later period (5-11 months), lignin degradation proeceeded, suggesting it was not limited by easily degradable OM. In line, glucose addition increased CO_2 evolution from soil-OM, but lignin degradation was not affected. However, addition of DOM led to enhanced lignin oxidation after 11 inubation months but the composition of DOM had no effect. This suggests that lignin degraders were stimulated by input of a complex mixture of organic compounds, but against expectations the share of easily degradable compounds played no role. Also N input did not affect CO_2 evolution or lignin degradation. To conclude, altered N inputs to topsoils due to land-use or climate change will not affect lignin degradation, whereas altered DOM inputs presumably has an effect. However, altered C availability seems not to be the reason. Other possible mechanisms will be discussed.

Basanite-phonolite mixing indicated by trace elements in green-core clinopyroxenes from La Palma

A. KLÜGEL

Geosciences Department, University of Bremen, Germany (akluegel@uni-bremen.de)

Green-core clinopyroxenes (Cpx) are ubiquitous in alkalic basalts worldwide. Commonly, anhedral and rounded green cores are enriched in Na, Fe and Mn compared to brownish rims and groundmass Cpx. Most are believed to have been formed by crystallization in evolved melts followed by magma mixing prior to eruption [1, 2].

This interpretation was tested by trace element analyses of Cpx phenocrysts in lavas from the active Cumbre Vieja volcano on La Palma (Canary Islands) where basanites and tephrites contain abundant green-core Cpx. Zoned and unzoned greenish Cpx in phonolites show a wide compositional range and characteristic S-shaped REE spectra with $(La/Nd)_N > 1$, $(La/Lu)_N > 1$ and $(Tm/Lu)_N \leq 1$. The spectra strongly differ from those of brownish Cpx rims and Cpx phenocrysts in basanites to tephrites, that have $(La/Nd)_N < 1$ and $(Tm/Lu)_N > 1$. The latter are also more restricted in composition and have higher compatible and lower incompatible trace element contents, and lower Zr/Hf and Nb/Ta, than phonolite-hosted Cpx. Calculated REE spectra of corresponding melts show strong enrichment of light relative to heavy REE, and are straight for basanites to tephrites but concave-upward for phonolites. All these differences are consistent with fractionation of observed phenocryst phases during the formation of phonolithic melts, with titanite being responsible for Nb/Ta fractionation.

Trace-element compositions of rounded cores from green-core Cpx overlap completely with green Cpx in phonolites, but differ systematically from brownish Cpx. This provides unequivocal evidence for formation of green-core Cpx in phonolitic melts, resorption after mixing with more primitive melt, and subsequent overgrowth by brownish Cpx. Mixing most likely occurs in the uppermost mantle at 430-780 MPa where La Palma magmes fractionate prior to eruption [3]. The commonness of green-core Cpx shows that mixing between basanitic and phonolitic melts periodically occurs beneath La Palma and is important to the evolution of magmas. The data also suggest that much more phonolite is produced at depth than inferred from erupted lavas.

Fluid evolution in the Byngi gold deposit, central Urals, Russia

YU.I. KLYUKIN[1]*, V.V. MURZIN[1] AND R.J. BODNAR[2]

[1]Institute of Geology and Geochemistry of the UB, RAS, Yekaterinburg, Russia klukin@igg.uran (*correspondence: klukin@igg.uran.ru)
[2]Fluids Research Laboratory, Virginia Tech (VT), Blacksburg, VA 24061, USA

The Byngi gold deposit, located in the central Urals, consists of multiple quartz veins that occur in and above the apical part of a buried plagiogranite stock that is part of a gabbro-granitic complex. The volcanogenic country rocks that host the quartz veins have undergone metasomatic alteration that is associated with gold mineralization. Stock has been dated at 345-318 Ma.

The studied sample is vein quartz containing pyrite and chalcopyrite. Gold is closely associated with chalcopyrite. The ore minerals fill cracks in quartz, suggesting mineralization is later than at least some of the quartz. Pyrite shows two (or more) generations – the earliest is growth of idiomorphic crystals that trapped chalopyrite and grains of quartz inside. The second generation represents metasomatic growth of pyrite over the earlier pyrite. A later event produced fractures between the two generations of pyrite, and these were later filled by quartz and chalcopyrite. The final stage is represented by deformation of ore minerals. The sample thus contains three generations of quartz: early recrystallized quartz formed before ore minerals, quartz (± chalcopyrite) in cavities within pyrite, and finally quartz precipitated in later brecciated pyrite.

Fluid inclusion assemblages (FIAs) were measured from the earliest and latest stage quartz using a Linkam THMS-600 heating/cooling stage, Raman spectroscopy and cathodo-lumenecense. All FIA contain inclusions that contain an aqueous liquid phase and liquid±vapor CO_2 and contain about 10-20 mole% CO_2. CO_2 melts in the range -57.1 to -58.9°C, suggesting the presence of other volatiles, but no other gases were detected by Raman analysis. Salinity calculated from the melting temperature of clathrate [1] ranged from 1 to 9 wt% NaCl equivalent. Homogenization of the CO2 phase ranged from 10.5-30.1°C. FI in early quartz homognize at 110-145°C, those in intermediate quartz at 130-145°C, and the latest quartz at 200-240°C.

Differences in coupling between AOM and SRR in marine sediments

NINA J. KNAB[1] AND BO B. JØRGENSEN[2]

[1]University of Southern California, 3616 Trousdale Parkway, AHF143, Los Angeles CA-90089, USA
[2]Max-Planck Institute for Marine Microbiology, Celsiusstr. 1, 28359 Bremen, Germany

Microbially mediated anaerobic oxidation of methane (AOM) is a major methane sink in the ocean, coupled to bacterial sulfate reduction (SRR) as electron accepting process. Yet, with increasing data of AOM and SRR measured in various sedimentary environments, ranging from cold seeps to diffusion dominated habitats, the regulation and linking of both processes remains controversial. In order to investigate if the regulation of AOM and the coupling between AOM and SRR is consistent in all environments, sediment from diffusion dominated sites on the continental shelf (Aarhus Bay and Kattegat/ Denmark) and a methane seep (Black Sea) were incubated under different combinations of methane and sulfate concentrations, and the response of both AOM and SRR evaluated. The experiments confirmed the strong dependence of AOM rates on methane concentrations at all sites but demonstrated differences in sulfate reduction rates with increasing concentrations of both, methane and sulfate. Whereas a close coupling of AOM and SRR, and respectively a strong dependence of rates on both substrates, was evident at the methane seep, the rate measurements from Aarhus Bay provide direct evidence for a decoupling of both processes. Furthermore, the ratio of both rates deviated from the even stoichiometry observed at the methane seep. The experiments demonstrate that there are significant differences in the regulation and coupling of AOM rates and SRR at different sites indicating that AOM might not be mediated in the same way at all sites.

Paleoenvironmental evolution of the Lower Miocene organic clays (the Sokolov Basin, Eger Graben, Czech Republic): Inorganic proxies

I. KNÉSL[1]*, B. KŘÍBEK[1], K. MARTÍNEK[2], P. ROJÍK[3] AND J. FRANCŮ[1]

[1]Czech Geological Survey, Klárov 3, 118 21 Prague 1, Czech Republic (*correspondence: ilja.knesl@geology.cz)
[2]Faculty of Science, Charles Univ. in Prague, Albertov 6, 128 43 Prague 2, Czech Republic
[3]Sokolovská uhelná JSC, Staré náměstí 69, 356 01 Sokolov, Czech Republic

Lacustrine sediments of the Cypris Formation cover in the Sokolov Basin approximately 20 km^2 of its area being represented chiefly by offshore organic matter and pyrite-rich clays of a thickness ranging from 130 m to 180 m, whereas near-shore facies are missing or preserved only rarely. Variations in Fe, Ca, K, Rb, S, Sr, Ti and Zr contents in lacustrine clays were studied in drill core (Dp 333-2009) using a portable XRF spectrometer Innov-X Alpha. The results of XRF measurements were verified by ICP-MS method after total digest of samples. The constant Ti/Zr ratio in the entire clay sequence indicates a uniform source of terrigeneous material brought into depositional area during the whole sedimentation period. Similarly, the Fe/Zr and Fe/Ti ratios are invariable thus indicating that most of the iron is confined to terrigenous material. Therefore, the correlation between Fe and S in clay is insignificant. The K/Zr and Rb/Zr ratios gradually increase from the bottom to the top of the studied sequence documenting an increase in the content of clay minerals in the sediments studied. Increase in Ca/Zr and Sr/Zr ratios upward in the section is attributed to the rising content of carbonates. The progressive increase in the content of clay minerals and carbonates towards the top of the sequence studied has been interpreted as indicating a gradual transition from the hydrologically open, relatively deep, freshwater lake environment, to the hydrologically closed, shallow water alkaline lake environment. This interpretation corresponds with the increasing content of anhydrite, montmorillonite and analcime upward in the clay sequence. Lacustrine clays of the Cypris Formation are usually laminated. The K/Zr and Rb/Zr ratios in organic matter-rich (10-18%TOC) and organic matter-poor (2-10% TOC) laminas are basically the same, but the Ca/Zr and Sr/Zr ratios are significantly higher in organic matter-poor laminas. Therefore, it is believed that the lamination reflects most likely seasonal variations in the organic matter and carbonate deposition.

This study was supported by the Grant Agency of the Czech Republic (GAČR 205/09/1162).

Modelling global trace gas emissions from biomass burning: Importance of emissions models vs. observed burned area

WOLFGAN KNORR, VEIKO LEHSTEN AND ALMUT ARNETH

Lund University, Sweden (almut.arneth@nateko.lu.se)

Biomass burning is one of the largest sources of atmospheric traces gases and aerosols globally. Emissions from biomass burning can be quantified by a combination of observed burned area, terrestrial ecosystem models to simulate fuel loads and the effect of fire on ecosystem dynamics, and emission factors that relate combusted biomass to the emission of various trace gases. However, different versions of global burned area data derived from satellite observations and emissions models still show major discrepancies. Studies on burned area products have so far focused on product inter-comparison, while the consequences of those discrepancies for fuel simulations and emissions modelling with ecosystem models are still unknown.

Here, we perform a sensitivity analysis of the influence of burned area products and emissions models using the ecosystem model LPJ-GUESS and modified version of the global fire model Spitfire. The emissions model follows two different strategies: a conventional one where fixed emission factors are multiplied by biomass combusted, and an alternative one where combustion efficiency depends on the ratio of grass to total combusted litter. Aerosol particle mass is also computed, following two different approaches derived.

Geochemical characterization of biosignatures in subseafloor basalts

E. KNOWLES[1]*, H. STAUDIGEL[2], N. MCLOUGHLIN[3] AND A. TEMPLETON[1]

[1]Deptartment of Geological Sciences, University of Colorado, Boulder, CO 80309 (*correspondence: knowlese@colorado.edu)

[2]Scripps Institution of Oceanography, University of California, La Jolla, CA 92093

[3]Centre for Geobiology & Department of Earth Science, University of Bergen, Bergen 5007, Norway

The discoveries of intriguing tubular and granular alteration features in subseafloor basalt glasses, ophiolites, and ancient greenstones [1, 2] has exciting implications for increasing our understanding of global geochemical cycling and the evolution of life on Earth, as well as for exploring other planets for signs of life. The suggestion that these features could represent some of the oldest signs of life on Earth [3] has sparked debate about their putative biogenicity. We have been working to constrain the physical and chemical conditions within the basalts at the time of alteration in order to put together a model of the mechanisms of alteration and preservation of the features.

Using a number of synchrotron-based X-ray microprobe and microspectroscopy techniques we have been able to geochemically characterize these alteration features at the sub-micron scale. We have mapped both major and trace element distributions in numerous tubular and granular alteration features, which shows intriguing patterns of mineral dissolution and authigenic precipitation. In addition, we have collected micro-diffraction patterns and analyzed the oxidation and coordination states of major and trace elements in potential biominerals, which may have formed as a result of microbial metabolic processes. We have been able to show that the mechanism of formation of the tubules clearly involves initial dissolution of the glass, followed by precipitation of authigenic minerals, with concomitant partial to complete oxidation of the reduced metals, such as Fe and sometimes Mn. XANES analyses have also revealed the coordination chemistries of these metals, leading to the identification of target phases that are potential biominerals.

The study on arsenic stabilization using recycled mine sludge

M.S. KO[1], J.Y. KIM[1], J.S. LEE[2], J.I. KO[2] AND K.W. KIM[1]*

[1]School of Environmental Science and Engineering, Gwangju Institute of Science and Technology (GIST), Gwangju 500-712,Republic of Korea

[2]Technology Research Center, Mine Reclamation Corporation(MIRECO), Seoul, 110-727, Republic of Korea

Materials and methods

The stabilization efficiencies of arsenic (As) in contaminated soil were evaluated using mine sludge collected from an acid mine drainage (AMD) treatment system.. The soil samples were collected from the Chungyang area, where abandoned Au-Ag mines are located in South Korea. As (V) and As (III) sorption properties were investigate to eveluate the As sorption capacity of mine sludge. The stabilization experiments of As in soil carried out various ratio of mine sludge.

Results and discussion

The pH of the soil samples was 5.07, and the soil texture was silt loam (sand 33%, silt 63%, clay 4%). The CEC value and LOI were 19.8 meq/100 g and 25.6%, respectively. From the results of the SPLP and TCLP tests, the arsenic concentrations in the studied soil were 0.23 and 1.14 mg/kg, respectively. These results show a lower value for the TCLP than that proposed by the USEPA (5 mg/kg). The total arsenic concentration via aqua regia digestion of the soil was 145 mg/kg.

In the kinetic experiments, 99% of As (V) was removed within 3 min and 20% of As (III) was removed from the solution after 20 min and 98% within 12 hours. As (V) and As (III) adsorption process is not pH dependent, and the adsorption isotherm of As (V) and As (III) followed Langmuir isotherm model.

The pH variation depends on the mine sludge ratio (0, 0.5, 3 and 5 wt%) to total soil weight in As stabilization experiments. The extracted arsenic concentrations increased in the control experimental set. The average As concentration was 2.8 μg/L at the 0.5 wt% mine sludge mixed set, and 1.3 μg/L of As was extracted from both 3 and 5 wt% experimental sets. These results suggested that mine sludge influenced on As stabilization and 3 wt% of mine sludge suitable for stabilization of As in soil.

Predicting spatial and temporal concentrations of arsenic within the Mekong Delta

B.D. KOCAR[1], S.G. BENNER[2] AND S. FENDORF[1]

[1]Dept of EESS, Stanford University, Stanford CA, 94305 USA
[2]Department of Geosciences, Boise State University, Boise ID, 83725, USA

It is generally accepted that arsenic release from sediments within the vast deltaic plains of South and Southeast Asia transpires under reducing conditions, and microbially-mediated reductive dissolution of arsenic-bearing iron (hydr)oxides is the dominant reaction liberating arsenic to the aqueous phase. Further, strong links have been established between groundwater contamination and arsenic release within near and sub-surface environments, and it has become clear that hydrogeologic conditions impart a domineering effect on As distribution during and following liberation. The hydrologic systems of the deltaic aquifers throughout South and Southeast Asia, however, have drastically changed due to extensive groundwater extraction, and from massive anthropogenic alteration of the soil-sediment profile for numerous small and large-scale (excavation) projects. We here present a unifying biogeochemical-hydrogeologic analysis of processes governing arsenic using field-calibrated one- and two-dimensional reactive transport simulations, and utilize three-dimensional simulations to examine the possible effects of excavation and irrigation pumping—processes prevalent in other countries in South and Southeast Asia. The ability to project arsenic levels in space provides the critical capacity to assess optimal locations and depths for groundwater extraction—provided they exist—while projecting temporal changes allows us to determine long- and short-term threats to low-arsenic wells, particularly those arising from land use changes.

Arsenic mobility in a waste rock pile at Dlouhá Ves, Czech Republic

E. KOCOURKOVÁ[1]*, O. SRACEK[2,3], S. HOUZAR[1], J. CEMPÍREK[1], Z. LOSOS[4], J. FILIP[2] AND P. HRŠELOVÁ[2]

[4]Masaryk University, Brno, Czech Republic
(*correspondence: ekocourkova@mzm.cz)

Products of fifty-years long alteration of a waste rock pile from a Pb, Zn-deposit at Dlouhá Ves, Vysočina region, Czech Republic, were studied in the pile centre (profile I) and on its slope (profile II). The pile material had initially high sulphide (10-20 wt. %) and very low carbonate content (1-2 wt. %); the only primary mineral of As was arsenopyrite.

Significant oxidation of sulphides (pyrite, pyrrhotite, arsenopyrite, sphalerite, galenite) took place in both profiles. The principal As-bearing phase at the top of the profile I is goethite, while down to its base most of As is present in the jarosite group minerals. Melanterite and anglesite were found in a sulfide-rich, lower part of the profile I. At the profile II, minerals of the jarosite-beudantite group, scorodite and kaňkite prevail and no Fe (II)-minerals were found. The paste pH was lower at the profile I (≥1.9) than at the profile II (≥2.8). Processes in the pile are affected by the ratio pyrite to arsenopyrite, where high pyrite content decreases the As/S ratio and results in the formation of jarosite group minerals and low pH conditions. Where arsenopyrite predominates, sulphides are coated by scorodite and other Fe-As phases like schwertmannite, which limit their further oxidation.

Arsenic concentrations released during the leaching experiments were generally low; maximum amounts (up to 0.56 ppm) were released from horizons with jarosite and arsenopyrite. In contrast, minimum amounts of arsenic were released from horizons with beudantite and scorodite. Differences between both profiles are caused mainly by limited water flow through the pile material and also limited penetration of oxygen into the deep parts of the excavation profile. It seems that beudantite and scorodite could represent a long-term option for immobilization of arsenic, but arsenic stored in jarosite can be mobilized relatively easily [1, 2]. However, potential mineralogical transformations and stability of arsenic in beudantite group minerals have yet to be evaluated, because the long-term stability of secondary arsenic minerals remains a serious problem [3].

Analysis of nanoscale Zero Valent Iron particles upon arrival at a monitoring well

C.M. KOCUR[1]*, A.I. CHOWDHURY[1], H. BOPARAI[1], N. SAKULCHIACHAROEN[1], M. KROL[1], B.E. SLEEP[2], L. AUSTRINS[3] AND D.M. O'CARROLL[1],

[2]University of Toronto, Toronto,ON, Canada
[3]CH2M HILL Canada Ltd. Kitchener, ON, Canada

Nanoscale Zero Valent Iron (nZVI) has received significant attention in recent years due to its ability to rapidly destroy numerous priority source zone contaminants in controlled laboratory studies. This has led to great optimism surrounding nZVI particle injection for insitu remediation. However, rapid nanometal settling and poor mobility has been encountered, reportedly due to the ferromagnetic attractive forces between particles leading to agglomeration [1]. Studies have proposed different methods to screen attractive forces between nZVI particles [2, 3, 4], thus protecting them from agglomeration and preventing rapid settling. Although analytical techniques used to characterize particles confirm that these methods yield high quality particles that are stable and readily reactive for extended periods of time in the lab, several important questions remain.

How well can nZVI particles travel through the subsurface?
What is their state when they reach target contamination?
Do current methods used to detect nZVI particles in the lab lend themselves to field application?

In this field study existing synthesis techniques [2] were scaled up and 800L of nZVI was injected into a contaminated utility corridor containing various chlorinated solvents. nZVI particles intercepted by monitoring wells were analyzed using transmission electron microscopy and dynamic light scattering that characterize their size. The zero valent iron content of the particles was also compared to nZVI immediately after synthesis to gain insight into the characteristics of nZVI being delivered to the contamination.

Seismological constraints on an evolution of the Izu-Bonin intra-oceanic arc

SHUICHI KODAIRA, NARUMI TAKAHASHI AND TAKESHI SATO

IFREE JAMSTEC, Showa-machi 3175-25, Kanazawa-ku, Yokohama 236-0001 JAPAN (kodaira@jamstec.go.jp, narumi@jamstec.go.jp, tsato@jamstec.go.jp)

JAMSTEC has been conducting intensive active-source seismic surveys to cover the entire Izu-Bonin arc. New seismological constraints on formation and evolution processes of the arc crust are revealed from those data. For examples, a large volume of felsic-to-intermediate component crust having Vp of 6.0 - 6.8 km/s is predominantly observed beneath basaltic volcanic centers along the current volcanic front. We also discovered a similar along arc variation of the felsic-to-intermediate component crust in the rear-arc, which is proposed to be separated from the volcanic front after Oligocene. These findings suggest that the main part of the arc crust consisting of the felsic-to-intermediate component was created before the rear-arc has been separated from the volcanic front probably in Oligocene age. From recently obtained seismic data in the fore-arc, on the other hand, we found that the structure of the fore-arc region represents significantly different characters from that of the volcanic front. Petrological studies in the fore-arc region proposed a formation of oceanic crust associated with boninitic volcanism during an initial stage of subduction. The newly obtained seismic structures in the fore-arc strongly support this idea; i.e. the crust beneath the Bonin ridge in the fore-arc is remarkably thin (less than 10 km), and velocity-depth profiles in the fore-arc is almost identical to that of typical oceanic crust.

Magnesium isotope composition of presolar silicate grains

JÁNOS KODOLÁNYI* AND PETER HOPPE

Max Planck Institute for Chemistry, Mainz, 55128 Germany (*correspondence: j.kodolanyi@mpic.de)

We have measured the Mg isotope compositions of presolar silicate grains, to gain insights into the stellar nucleosynthesis and Galactic chemical evolution (GCE) of Mg isotopes.

More than half of the Mg in the interstellar medium (ISM) is hosted by oxide and silicate dust produced by evolved stars [1]. The Mg isotope composition of dust grains predating our Solar System could provide information about the Mg isotope 'inventory' of the local ISM at the time of Solar System formation. This is of particular interest, as the $^{25}Mg/^{24}Mg$ and $^{26}Mg/^{24}Mg$ ratios of the Sun (and the Solar System) appear to be substantially lower than that predicted by GCE models for stars of solar metallicity (Z_{solar};[2]). Presolar silicate grains represent the silicate fraction of the interstellar dust at the time of Solar System formation. They are 200-300 nm crystalline or amorphous grains, which escaped Solar System processing, thereby retaining their pristine isotope compositions [e.g. 3, 4].

Presolar silicate grains of the present study were found in the matrix of Acfer 094 (an ungrouped carbonaceous chondrite), based on their O isotope compositions and Si-Al-O systematics. These were determined by the NanoSIMS, as were the grains' Mg isotope compositions (for analytical conditions see [5]). Based on their O isotope composition, the identified 26 grains were produced in the stellar winds of AGB stars, with initial masses (M) of 1.15-2.2 × M_{solar} and Z ~ Z_{solar} [6], similar to the majority (~80 %) of presolar silicates reported in the literature previously [e.g. 4]. Two of the 3 grains analysed for Mg isotopes so far have solar $^{25}Mg/^{24}Mg$ ratios within analytical uncertainty (1 σ) whereas a third grain shows a slight enrichment in ^{25}Mg relative to solar ($\delta^{25}Mg$ = 32 ± 20 ‰). The ^{25}Mg-enriched grain also has elevated $^{26}Mg/^{24}Mg$ ($\delta^{26}Mg$ = 39 ± 20 ‰), as do one of the other two grains ($\delta^{26}Mg$ = 35 ± 16 ‰). Interestingly, in a $\delta^{25}Mg$ vs. $\delta^{26}Mg$ plot our silicate grains fall along a line with slope ~1 as predicted by the GCE model of [2] for stars with ~solar Z; however, at much lower $^{25}Mg/^{24}Mg$ and $^{26}Mg/^{24}Mg$ ratios than predicted, similar to presolar oxide grains from akin stellar sources [7].

Fe acquisition from natural organic matter by an aerobic *Pseudomonad*: Siderophores and cellular Fe status

K. KOEHN[1], C. DEHNER[2], J. DUBOIS[2] AND P. MAURICE[1]*

[1]University of Notre Dame, 156 Fitzpatrick Hall, Notre Dame, IN 46556, USA (kkoehn@nd.edu, *correspondence: pmaurice@nd.edu)

[2]University of Notre Dame, 251 Nieuwland Hall, Notre Dame, IN 46556, USA (cdehner@nd.edu, jdubois@nd.edu)

Aerobic microorganisms have evolved various strategies to acquire nutrient Fe (often limiting in circumneutral environments), including the release of Fe-chelating siderophores. The potential importance of siderophores in Fe acquisition from natural organic matter (NOM) in the form of reverse osmosis (RO) and aquatic XAD-8-isolated humic samples (both with naturally associated Fe) was investigated using a wild type strain (WT) of aerobic *Pseudomonas mendocina* that produces siderophore (s) and an engineered mutant that cannot. Microbial growth under Fe-limited batch conditions was monitored via optical density, and a biosensor assay was used to report on transcriptional output as a measure of cellular Fe status. Both WT and mutant strains acquired Fe from NOM. Bacterially sensed Fe deficiency in the presence of the RO sample decreased with increasing [Fe] and was less for the WT than for the mutant. However, for both WT and mutant, maximum growth in the presence of the RO sample increased as: 1 mgC/L (0.2μM Fe) < 100 mgC/L (20μM Fe) < 10 mgC/L (2μM Fe); the highest concentration of NOM appeared to diminish numbers of free-swimming/planktonic bacteria, perhaps by inducing biofilm formation and/or as a result of associated Al. Growth was slightly more robust on the XAD-8 compared to the RO sample at 2 μM Fe, although there were no apparent differences in internal Fe status. Chelex® treatment to partially remove metals associated with the RO sample increased Fe stress but did not substantially affect growth. It was concluded that: (1) siderophores are useful but not necessary for Fe acquisition from NOM by *P. mendocina* and (2) NOM may have complex effects on microbial growth, related not just to Fe content but potentially to the presence of other (trace)metals such as Al and/or to effects on biofilm development.

No differences in Sr isotope ratios between ectomycorrhizal and arbuscular mycorrhizal ecosystems across a wide range of geological substrates

NINA KOELE[1]*, IAN DICKIE[1], JOEL BLUM[2], JAMES GLEASON[2], GARY LOVETT[3] AND MATT MCGLONE[1]

[1]Landcare Research - PO Box 40, 7640 Lincoln, New Zealand (*correspondence: koelen@landcareresearch.co.nz)
[2]University of Michigan, Dept. of Geological Sciences, Ann Arbor, MI 48109,USA
[3]Cary Institute of Ecosystem Studies, Box AB, Millbrook, New York 12545, USA

In highly weathered soils, where phosphorus (P) in particular may be a limiting nutrient, theory dictates that ectomycorrhizal (ECM) ecosystems are most efficient at uptake from mineral P through weathering of Ca-phosphate minerals and recycling of organic P. The ecological significance of mineral weathering by ECM fungi however remains unclear. We studied 10 pairs of pure arbuscular (AM) and pure ECM forests on different geological substrates on the South Island of New Zealand. Sr isotope ratios of dominant canopy tree foliage (AM *Dacrydium cupressinum* and ECM *Nothofagus menziesii*) were determined and in thin sections we analysed structural interactions between mycorrhizal hyphae and mineral and/or organic soil particles. Both AM and ECM forests had similar Sr isotope ratios that varied with geological substrates, indicating both forest types obtain Sr (and Ca-phosphate) from the same sources. Fungal weathering tunnels in feldspar grains were present in thin sections from both forest types. These preliminary data suggest there are no major differences in base cation nutrient uptake between AM and ECM ecosystems. This might challenge our understanding of the respective roles of ECM and AM fungi in ecosystem nutrient cycles.

Oceanic plagiogranites as products of hydrothermal activity at slow-spreading ridges

J. KOEPKE[1], P.E. WOLFF[1] AND S.T. FEIG[2]

[1]Institute for Mineralogy, Leibniz University of Hannover, Callinstr. 3, 30167 Hannover, Germany (Koepke@mineralogie.uni–hannover.de)
[2]CODES, University of Tasmania, Private Bag 126, Hobart, TAS 7001, Australia

We studied more than 100 oceanic gabbros from Mid-Atlantic Ridge and Southwest Indian Ridge by scanning electron microscopy and found in 90% of the samples microstructures suggesting that hydrous partial melting reactions proceeded. The best proxy for the underlying reaction is plagioclase strongly enriched in anorthite which is arranged in zones along grain boundaries implying that the partial melting process was triggered by fluids percolating on grain boundaries in a ductile regime. The composition of the new An-rich plagioclase is strongly impoverished in incompatible trace element excluding a model that these An-rich zones were precipitated by late, hydrous evolved melts. In some cases it is evidenced that the water-rich fluids are seawater-derived, suggesting a model that hydrothermal activity/circulation within the deep oceanic crust may trigger hydrous partial melting resulting in the production of oceanic plagiogranites, at temperatures exceeding 850° without any crack system, a prerequisite in current models for enabling hydrothermal circulation. This is in contrast with new findings of [1] stating that zircons of many plagiogranites from slow-spreading ridges show oxygen isotopes typically for equilibrium with mantle. However, new experimental work show that water activities prevailing during the melting reaction can be regarded as extremely low implying that a potential sea water source cannot be easily detected by stable isotopes.

Lithium-boron isotope fractionation during degassing of rhyolitic magma

K.T. KOGA[1]*, E.F. ROSE-KOGA[1], D. LAPORTE[1], N. CLUZEL[1], N. SHIMIZU[2] AND E. DELOULE[3]

[1]Laboratoire Magmas et Volcans, Clermont Université, BP 10448, Université Blaise Pascal, CNRS UMR 6524, IRD M163, Clermont-Ferrand, France (*correspondence: k.koga@opgc.univ-bpclermont.fr)
[2]Woods Hole Oceanographic Institute, Woods Hole, MA 02543, USA
[3]Centre de Recherches Pétrographiques et Géochimiques, CNRS UPR 2300, Vandoeuvre-lés-Nancy, France

It has been considered that some volatile trace elements partition into a gas phase and leave the host magma during degassing events. For example, lithium and boron are light elements, which show strong affinity to fluid phase. Then, it is certainly possible to partition these elements into degassing fluid bubbles under pressure. Furthermore, during such element redistribution via diffusion transport, isotopes of lithium and boron may fractionate.

We have analyzed experimentally degassed natural rhyolitic obsidian, which was pre-saturated in H_2O at 210 MPa, 800 °C giving approximately 6 wt%. These samples were isothermally decompressed at the rate of 1000 and 27.8 kPa/s. The final pressure before quench was approximately 70 MPa. Here, a rhyolitic composition was chosen for their ability to retain bubbles within the melt matrix. A maximum element exchange is expected between gas phase and melt, while element diffusivities are slower in rhyolite than basalt. The result shows that significant lithium and boron depletion in the host lava can take place within 12 min of isothermal decompression at 800 °C. The duration of bubble growth was 20 sec and 12 min depending on the decompression rate.

The fast and slow decompression resulted in heterogeneous lithium and boron abundance in the charge. The areas further away from bubbles have lithium and boron abundance indistinguishable from the starting glass, and the areas close to bubbles show 43 and 18 % depletion of lithium and boron, respectively, while H_2O depletion is 50%. When significant abundance depletions were observed in the glass, in close vicinities, ^{7}Li is enriched by as much as 20.2 ± 1.5 permil, and ^{11}B is enriched by 8.8 ± 2.6 permil. The association of abundance depletion and heavy isotope enrichment strongly indicates isotope fractionation governed by diffusion transport.

Loparite composition in stratified Lovozero alkaline intrusion

L.N. KOGARKO[1], Y. LAHAYE[2] AND T.C. WILLIAMS[3]

[1]Vernadsky Institute, Moscow, Russia (kogarko@geokhi.ru)
[2]Institut für Geowissenschaften, University Frankfurt, Germany
[3]Natural History Museum, London, England

Lovozero massif, the largest of the Globe layered peralkaline intrusion, comprises super-large rare-metal (Nb, Ta, REE) deposit. The main ore mineral is loparite (Na, Ce, $Ca)_2$ (Ti, $Nb)_2O_6$ which was mined during many years. Compositional evolution of loparite has been investigated through a 2.35 km section of the Lovozero massif using LA-ICP-MS Institut für Geowissenschaften, University Frankfurt and CAMECA SX50 British Museum of Natural History (London) (Kogarko *et al*. 2002). The composition of cumulus loparite changed systematically upward through the intrusion with an increase in Na, Sr, Nb, Th, Nb/Ta, U/Th and decrease in REE, Zr, V, Zn, Ba and Ti. Our investigation indicates that the formation of loparite ore was the result of several factors including the chemical evolution of high alkaline magmatic system and mechanical accumulation of loparite at the base of convecting unit.

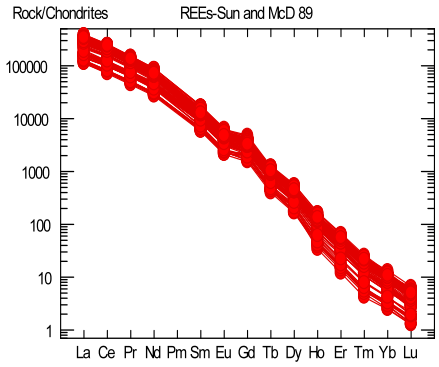

Figure 1: Range of REE contents in loparites.

Two- and three-dimensional imaging of platinum-group minerals at submicrometer scale with synchrotron X-ray

T. KOGISO[1]*, K. SUZUKI[2], T. SUZUKI[2] AND K. UESUGI[3]

[1]Graduate School of Human and Environmental Studies, Kyoto University, Kyoto 606-8501, Japan (*correspondence: kogiso@gaia.h.kyoto-u.ac.jp)
[2]IFREE, JAMSTEC, Yokosuka, Kanagawa 237-0061, Japan
[3]JASRI/SPring-8, Sayo, Hyogo 679-5198, Japan

Platinum-group elements (PGE) in the Earth's mantle are key tracers for understanding the differentiation history of the Earth. PGE in mantle peridotite are strongly concentrated in Fe-Ni-Cu sulfides [1], whereas platinum-group minerals (PGM) are also potential phases that host significant amounts of PGE in the mantle [2, 3]. PGM are too small to be detected with conventional analytical methods, and therefore it is difficult to know how abundantly and where PGM exist in the mantle. PGM ever found in peridotite samples are mostly associated with Fe-Ni-Cu sulfides [3, 4], implying that those PGM had exsolved from the Fe-Ni-Cu sulfides [1]. On the other hand, discrete PGM grains have been found from a sulfide-free harzburgite [5], but these PGM are interpreted to be residues formed in response to the complete consumption of Fe-Ni-Cu sulfides during partial melting of peridotite. Textural and morphological investigation of PGM in peridotites at submicrometer scale could be a powerful method to know whether PGM found in peridotites had originally existed as discrete grains in the mantle.

We did two- and three-dimensional imaging of PGM in peridotite samples using synchrotron X-ray at SPring-8 to reveal morphology of PGM and their textural relationship with surrounding minerals. Tho-dimensional mapping of PGM-bearing Fe-Ni-Cu sulfides with micro-XRF [4] demonstrated that PGM distributed near the rims of the slufide grains. Three-dimensional imaging of them with X-ray computed tomography and laminography revealed that some PGM grains are included within the sulfide grain. These observation suggests that not all of the PGM are exolusion products from the Fe-Ni-Cu slufides.

Trends in buffer capacity, pH and Al at the Swedish integrated monitoring sites

S.J. KÖHLER[1]*, T. ZETTERBERG[2], M.N. FUTTER[1], J. FÖLSTER[1] AND S. LÖFGREN[1],

[1]Swedish University of Agricultural Sciences, SE750 07 Uppsala, SE (*correspondence: Stephan.Kohler@slu.se)
[2]IVL Svenska Miljöinstitutet AB, SE10031 Stockhom, SE

The lumped parameter model MAGIC [1] was applied to four Swedish long-term integrated monitoring sites. The largest part of the uncertainty in the model outcome was driven by the underlying deposition scenario, assumptions about sulphate (SO_4^{2-}) adsorption and soil mass. Estimated weathering rates varied in a relatively narrow range between 47-62 or (42-47) meq m^{-2} $year^{-1}$ depending on the choice of available soil cation exchange capacity (CEC). Varying Aluminium (Al) solubility or introducing a dynamic weathering feedback that allowed BC release to increase at more acidic pH had a systematic effect on predicted changes in acid neutralizing capacity (ANC; ca. 10-41 ueq L^{-1}) and pH (ca. 0.1 -0.6 pH units) at all sites. Uncertainties about weathering and modelled temporal changes in pools and respective fluxes of Al between compartments may lead to systematic differences for projected changes in pH and ANC and warrant further systematic study [2].

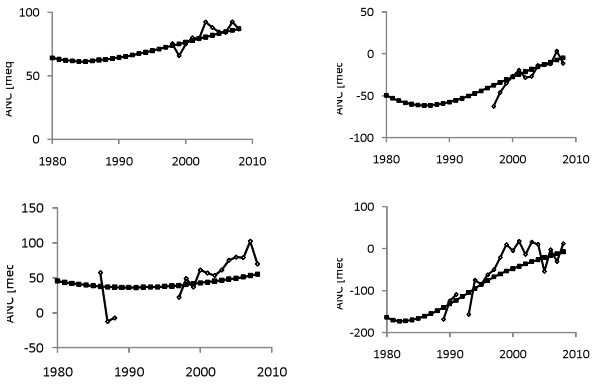

Figure 1: Time series of modelled and measured time series of ANC at each of the four sites.

Low-temperature thermochronology of the Mesozoic uplift history in the Hardangerfjord area, SW Norway

F. KOHLMANN*, A.K. KSIENZYK, J. JACOBS AND H. FOSSEN

Department of Earth Science, University of Bergen, PB 7803, 5020, Bergen, Norway
(*correspondence: fabian.kohlmann@geo.uib.no)

The geology of the Hardangerfjord area is dominated by the Hardangerfjord Shear Zone (HSZ), a major crustal-scale structure that formed during Devonian extension shortly following the Caledonian orogeny. The HSZ might be part of an even larger zone of crustal deformation stretching across the North Sea into the Highland Boundary Fault in Scotland. The Hardangerfjord itself follows the trend of the shear zone and acted as one of the largest sediment pathways in the area. The amount of inland erosion and the corresponding depositional patterns are strongly affected by onshore tectonics.

The present project aims to constrain the amount and timing of post-Caledonian uplift in this area by fission track, (U-Th)/He and K/Ar dating. In particular the apparent absence of Mesozoic brittle reactivation of the HSZ in this area is targeted by sampling of detailed profiles parallel and across the HSZ. Furthermore, vertical profiles on steep flanks of the Hardangerfjord are analysed in order to obtain more precise uplift and erosion rates. This study will improve our understanding of onshore tectonic processes and their effect on offshore sedimentation cycles in the North Sea.

Subducted oceanic crust exhumed from the lower mantle

S.C. KOHN[1]*, M.J. WALTER[1], D. ARAUJO[2], G.P. BULANOVA[1] AND C.B. SMITH[1]

[1]School of Earth Sciences, University of Bristol, BS8 1RJ, UK (*correspondence: simon.kohn@bristol.ac.uk)
[2]Instituto de Geociências, Universidade de Brasília, Brasília-DF, 70910-900, Brazil

Over the last 25 years diamonds from several continents have yielded inclusions that have been interpreted as sub-lithospheric in origin. The mineralogy and compositions of the inclusions have been interpreted in terms of both peridotitic and basaltic protoliths and a range of pressures. There is now an abundance of samples of basaltic inclusions that record transition zone and lower asthenospheric pressures [1], but until now there has been no convincing evidence for diamonds that crystallised in the lower mantle from a basaltic protolith.

In this study we report on a suite of mineral inclusions in diamonds from Juina, Brazil, which have exactly the mineralogy and chemistry expected for a basaltic composition at depths of 700-1200 km. Syngenetic, composite mineral inclusions in diamonds from a single kimberlite pipe (Juina 5) are found to have the bulk chemistries of the 'calcium ferrite' phase (CF-phase), 'New Aluminium Silicate' phase (NAL-phase), Al- and Fe-rich Mg-perovskite, and Ti-rich Ca perovskite. CF- and NAL-phases have previously been observed only in high pressure and temperature experiments on basaltic bulk compositions. The inclusions therefore indicate an origin of the diamonds and inclusions in oceanic crust subducted into the lower mantle.

The relatively high density of subducted basalt, especially if it is cooler than the surrounding peridotitic mantle, means that the mechanism for exhumation of basaltic crust from the lower mantle is puzzling. Available time constraints from other sub-lithospheric diamonds from the Juina region [2] indicate uplift rates of buoyant plumes of subducted material of ~ 1 – 50 cm/yr. Various subduction-exhumation cycles that can explain all the data will be discussed.

Mineralogical residence of Platinum Group Elements (PGE) in the Fe-Ni-Cu sulfide deposits of the Ivrea Verbano Zone (Italy)

P. KOLLEGGER*, F. ZACCARINI, G. GARUTI AND O.A.R. THALHAMMER

University of Leoben, Dept. Appl. Geol. Sci. Geophysics, Leoben, Austria
(*correspondence: peter.kollegger@unileoben.ac.at)

We present a residence-study of platinum group elements (PGE) in base metals sulfides (BMS) as well as in specific platinum group minerals (PGM). The PGE, Te and Re contents were analyzed by electron microprobe. The investigated Fe-Ni-Cu deposits of the Ivrea Verbano zone occur: 1) within layers of the igneous complex, 2) within an ultramafic sill intruding metasediments and 3) within ultramafic pipes intruding gabbros and metasediments.

PGE hosted by base metals sulfides (BMS)

Pyrrhotite (Po), pentlandite (Pn) and chalcopyrite (Ccp) were analyzed. Nearly two thirds of the analysis (n=349) contain Ir, Rh, Pt and Pd above detection limits (d. l.) (100, 32, 93 and 30ppm). BMS from all the three types of deposits contain PGE. Generally Te is above d. l. (100ppm); enriched in Pn. Different analyses of one specific mineral showed that the PGE are distributed dishomogeneously and that the quantities do not correlate with Te. Pt and Ir are mainly hosted by Po and Pn but not by Ccp. Pd is carried by each of the mentioned minerals. Rh occurs mainly in Po and only rare in Ccp and Pn. Re is only hosted by Po. Ir is enriched in Po and Pn and Ccp contains no Ir above d. l. Re was only detected in Po. Os data was neglect due to an interference with Cu. Ru was always below the d. l. of 35ppm.

PGE hosted by platinum group minerals

We investigated several PGM included within the base metals sulfides (sizes <10μm). The following species were found: Pd-rich melonite, merenskyite, moncheite, sperrylite and irarsite in decreasing order of abundance. According to the mineral chemistry, Te was partly substituted by Bi.

Our mineralogical observations suggest that the PGE, together with other chalcogens, were initially dissolved and collected by an immiscible sulfide liquid probably as small clusters. Subsequently, they were exsolved together with Te, Bi and As and crystallized as discrete PGM which are described for our investigated samples.

REE patterns in the ore-bearing of the Chortovo Koryto gold deposit (Eastern Siberia)

YU.V. KOLMAKOV* AND P.A. TISHIN

Tomsk State University, Lenin avenu 36, 634050 Tomsk, Russia (*correspondence: kolmakovyv@tpu.ru)

REE are usually considered as inert components at the metamorphic and metasomatic processes. But in recent years more and more papers indicating their mobility in the hydrothermal systems are published. The REE distribution in the rock associations of the orogenic gold deposit Chortovo Koryto was studied by ICP-MS method.

This deposit is located on the boundary between Baical-Patom fold-thrust belt and Siberian Craton. The gold ore are represented by system of quartz vein in the metaterrigenous slice of the Early Paleozoic formation Mikhailovskaya. The rock metamorphism corresponds to the greenschist facies. The composition of ore beds includes metaaleurolite - Qtz + Ab + Mus + Chl ± Bt (SiO_2 60-80%; Al_2O_3 8-19%; CaO 0.1-0.6%; K_2O 1.7-3.5%), carbonaceous slates - Qtz + Ab + Mus + Chl + C (SiO_2 41-64%; Al_2O_3 13-29%; CaO 0.05-2.1%; K_2O 1.9-6.8%), and altered rocks - Anc + Cal + Mus + Ab + Chl (SiO_2 29-68%; Al_2O_3 9-16%; CaO 6-12%; K_2O 1.4-7.6%).

The morphology of Chondrite normalized REE patterns of metaaleurolite is similar to the main sedimentary standards (La/Yb 7.3-11.4; Eu/Eu* 0.62-0.81), but differs in lower accumulation level of lanthanides (37-88 ppm). In the carbonaceous slates Σ REE increases up to 186 ppm mostly due to light REE (La/Yb 18, 5-31, 2), at the same time an evident negative Eu anomaly is shown (Eu/Eu* 0.41-0.66). In the altered rocks a maximum enrichment (Σ TR 251-875 ppm), lanthanides differentiation (La/Yb 41, 3-50, 1) and absence of Eu anomaly (Eu/Eu* 0.89-1.02) are observed; from axil zone in direction of contacts Σ REE decreases from 413 to 251 ppm.

LILE and HFSE distribution in studied rocks indicates that the ore system was formed with presence of two source matters. Metaaleurolites and carbonaceous slates are compared with upper crust (Zr/Hf 31.4-39.1; Ta/Nb 12.02-17.01); altered rocks are similar to the rock basalt-andesite-rhyolite volcanic series of greenstone belts and they supplement with OIB.

The study was funded by Russian Ministry of Education and Science.

Phase relations of an Fe-Ni alloy determined in an internally-heated diamond anvil cell

TETSUYA KOMABAYASHI[1], KEI HIROSE[2] AND YASUO OHISHI[3]

[1]Tokyo Institute of Technology, 2-12-1 Ookayama, Meguro, Tokyo 152-8551, (komabayashi.t.aa@m.titech.ac.jp)
[2]Tokyo Institute of Technology, 2-12-1 Ookayama, Meguro, Tokyo 152-8551, (kei@geo.titech.ac.jp)
[3]Japan Synchrotron Radiation Research Institute, 1-1-1 Kouto, Sayo, Hyogo 679-5198, (ohishi@spring8.or.jp)

The Earth's core is believed to contain several amounts of nickel while its major component is iron. In order to understand the nature of the Earth's core, we conducted *in situ* X-ray diffraction study of an iron-nickel alloy in an internally-resistive heated diamond anvil cell (DAC) up to pressures (P) and temperatures (T) of 110 GPa and 2500 K. High-P-T experiments with the angle-dispersive X-ray diffraction system were conducted at the SPring-8. The improved internally heated DAC configuration provides stable heating with reliable temperature and pressure determination and phase identification [1]. Due to this configuration, we are able to put tight constraints on the P-T location and the width of the two phase loop of the γ (face-centered cubic structure) and ε (hexagonal close-packed structure) phase transition boundary.

Results show that γ and ε transition boundary in $Fe_{0.9}Ni_{0.1}$ is located at lower temperatures than that of pure iron, consistent with the previous works which used the laser-heated DAC [2, 3]. However, the width of the two-phase loop is narrower than those of previous works. We also evaluated the equation of state for the ε phase in $Fe_{0.9}Ni_{0.1}$ from the compression data to P =100 GPa.

We will present the P-T phase diagram and the density of ε phase in $Fe_{0.9}Ni_{0.1}$, and discuss possible roles of the addition of nickel to iron in the Earth's core.

Environmental geochemistry of Cu in agricultural soils treated with Cu-based fungicides

M. KOMÁREK* AND E. ČADKOVÁ

Czech University of Life Sciences Prague, Czech Republic (*correspondence: komarek@af.czu.cz)

Introduction

Copper-based fungicides (such as the Bordeaux mixture - $CuSO_4$+Ca $(OH)_2$, Cu-oxychloride etc.) have been extensively used in Europe since the end of the 19th century to control fungal diseases on vine, such as downy mildew caused by *Plasmopara viticola*. Their long-term application and subsequent wash-off from the treated plants have resulted into extensive Cu accumulation in agricultural soils [1]. The aim of this paper is to provide information about the distribution, chemical fractionation and mobility of Cu in agricultural soils (vineyards, hop fields), including sorption processes and interactions with other commonly used organic fungicides (e.g. tebuconazole).

Results and Discussion

As in other contaminated soils, Cu in fungicide-impacted soils is mainly associated with the oxidizable and, to a lesser extent, with the reducible soil fraction, according to the soil organic matter and (hydr)oxide contents. The retention of Cu differs with the fungicide used (higher retention was observed for Cu originating from the Bordeaux mixture compared to Cu-oxychloride), which indicates that different retention processes occurs. The suggested mechanisms include: specific and non-specific adsorption (especially on soil organic matter) and precipitation of newly formed phases, such as CuO, Cu $(OH)_2$, various Cu-hydroxysulfates etc. The retention of fungicide-derived Cu in the studied soil types can be well described by the Freundlich isotherm and is directly controlled by its chemical form [2]. The presence of other organic-based fungicides, e.g. tebuconazole, can alter the adsorption behavior of Cu due to speciation changes (e.g. formation of Cu-tebuconazole complexes) [3].

Observing the diurnal variability of Aerosol Optical Depth (AOD) from a geostationary satellite: Implications for air quality and climate monitoring

S. KONDRAGUNTA[1]*, P. CIREN[2], C. XU[2], I. LASLZO[1] AND H. ZHANG[3,4]

[1]NOAA/NESDIS, 5200 Auth Road, Camp Springs, MD 20746.
(*correspondence: Shobha.Kondragunta@noaa.gov)
[2]IMSG at NOAA/NESDIS, 5200 Auth Road, Camp Springs, MD 20746.
[3]University of Maryland, Baltimore County, 1000 Hilltop Circle, Baltimore, MD 21250.

NOAA has been providing AOD product from the GOES series of Imagers to users for a decade now. GOES AODs are derived from the single visible channel using a look-up-table approach; cloud screening is done using IR channels. GOES AODs, available at 30-minute temporal resolution and 4-km spatial resolution, have a root mean square error of 0.12; retrieval errors, however, are large when solar angles and/or view angles are large. Other sources of errors include cloud contamination, calibration errors, and errors in surface reflectance characterization. Analysis of GOES AODs over the United States indicates that spatial and temporal variability during pollution events is well captured; sub-urban/rural regions show good grid-to-grid correlation and the urban regions dominated by local pollution sources show less correlation with sub-urban regions. Analysis also shows that diurnal sampling improves the accuracy of monthly/seasonal mean AODs that has relevance to monitoring the impact of climate change. In addition to these results, we will show analysis of some case studies of pollution events that highlight the strengths of diurnal sampling with respect to policy implications as well as the capabilities of the future satellite instruments (e.g. GEO-CAPE) that will have better product accuracy and precision.

Gold-ore resources of Uzbekistan: Systematization and regularities of deposits' location

R.I. KONEEV

National University of Uzbekistan, VUZ-gorodok, Tashkent, 100174, Uzbekistan (rkoneev@yahoo.com)

The principles of the classification of gold-ore deposits

While classifying a geology-industrial approach with emphasis on main mineras of ores (quartz, sericite, adularia, alunite, pyrite, arsenopyrite), high-, lowsulphidized types is used. It was found [1] that on all hydrothermal gold ore deposits of the world, independently from host environment, a standard row of mineral, correspondingly, geochemical types is shown: scheelite-molybdenite (Au-W), pyrite-arsenopyrite (Au-As), telluride-polymetallic (Au-Te), sulphosalt-silver (Au-Ag), antimonite-sulphoantimonite (Au-Sb), realgar-cinnabar (Au-Hg). A porphiritic (Au-Cu, Mo) type is marked separately. An industrial resource of the deposit is determined by1-4 types.

Regularities of location and mineral-geochemical style

Uzbekistan is one of the leading countries in the world on reserves of gold. All deposits are located within the Kyzylkum-Kurama metallogenic belt and they form ore districts in the places of intersection of the Beltau-Kurama volcanino-plutonic belt (BKVB) with deep faults. Each ore district is characterized by its mineral-geochemical style that is explained by different depth of the formation, hypo-, meso-, epithermal conditions. From the West to the East of the BKVB the role of later types from Au-W to Au-Sb-Hg types increases. Elements' concentration coefficients in ores relatively to their clarks form following rows and mineral forms [2]: Muruntau – Bi-As-Te-Au-Se-Pd-W-Ag-Sb-Mo; tellurides of Bi, maldonite, arsenopyrite, scheelite, pyrite, Co-Ni minerals. Charmitan – As-Te-Bi-Au-Sb-Ag-Se-Pb-W-Mo; Bi tellurides, maldonite, aurostibite, Pb-Ag-Se sulphoantimonites, arsenopyrite, pyrite. Kochbulak – Te-Au-Bi-Sb-Ag-Se-As-Cu-Pb-Sn; tellurides of Au, Ag, Bi, Sb, Pb, Cu, Hg; pyrite, goldfieldite, tetrahedrite. Kalmakyr – Te-Re-Bi-Mo-Au-Se-Cu-Ag-As-Sb; tellurides of Bi, Au, Ag; Re-molybdenite, chalcopyrite, pyrite.

According to the statistics [3] 5-6 medium size deposits (15-20 tonnes) and 25-28 small deposits (<15 tonnes) usually form around one big deposit (>100 tonnes).

The resources of gold in Uzbekistan are highly evaluated.

Chromium enrichment in iron formations record Earth's first acid rock drainage during the Great Oxidation Event

K. KONHAUSER[1], S. LALONDE, N. PLANAVSKY, E. PECOITS, T. LYONS, S. MOJZSIS, O. ROUXEL, M. BARLEY, C. ROSIERE, P. FRALICK, L. KUMP AND A. BEKKER[2]

[2](bekker@cc.umanitoba.ca)

Iron formations (IF) are iron rich (~20-40% Fe) and siliceous (~40-50% SiO_2) sedimentary deposits that precipitated throughout much of the Precambrian. Their trace element composition have been used as a proxy for ancient seawater chemistry, with the view of better understanding nutrient availability for the ancient marine biosphere [1, 2]. Recently, their composition have also provided new insights into the chemical weathering processes on land and the transfer of solutes to the ocean. For instance, a recent compilation of Cr enrichment in IF shows a profound enrichment at 2.48 Gyr, coincident with the advent of the Great Oxidation Event. Given the insolubility of Cr minerals, its mobilization and incorporation into IF indicates enhanced chemical weathering at that time, most likely associated with continental pyrite oxidation. Today, aerobic chemo-lithoautotrophic bacteria are essential to this process, catalysing the continued oxidation of Fe (II) as pH values drop below the threshold for inorganic Fe (II) oxidation. We suggest that the Cr pulse beginning 2.48 Gyr ago indicates that such bacteria began utilising O_2 for the first time to oxidise a previously stable and abundant crustal pyrite reservoir. Sulphuric acid generated by this metabolism ultimately leached Cr from ultramafic source rocks and residual soils. This profound shift in weathering regimes constitutes Earth's first acid rock drainage and accounts for independent evidence for increased supply of sulphate and sulphide-hosted trace elements to the oceans at that time.

Deep versus shallow slab melt signatures recorded by Nb/Ta in modern island arc lavas

STEPHAN KÖNIG[1,2] AND STEPHAN SCHUTH[3]

[1]Universität Bonn, Germany (stephan.koenig@uni.bonn.de)
[2]Universität zu Köln, Germany
[3]Universität Hannover, Germany

The Solomon Islands cover over 1000 km of the SW Pacific plate border and constitute a modern intra-oceanic arc system devoid of subducted sediments and continental crust. Due to a change of subduction polarity, an Eocene deeply-subducted Pacific slab and a shallower, recently subducting Indian–Australian slab remain in the subarc mantle at depths of >100 km and 35-80 km, respectively [1]. Slab melt-related lavas from the Solomons therefore provide unique insights into the residual mineralogy of two slabs at different depths and their influence on the geochemical signatures of shallow and relatively deep slab melts.

Mafic to intermediate slab melt-related lavas from the southwestern volcanic chain of the Solomon Islands show the largest range of Nb/Ta ever reported in a single modern subduction environment. They range from low, subchondritic Nb/Ta (min. ~10) to superchondritic values (max. ~27) that correlate with slab melt signatures (e.g. Gd_N/Yb_N) [2]. Isotope dilution MC-ICP-MS data confirm this large range of Nb/Ta observed in Q-ICP-MS data. One minor slab melt component characterised by a low Nb/Ta is derived from the shallow and recently subducting Indian–Australian plate where amphibole is still a significant residual phase. In contrast, the high Nb/Ta signatures can only be explained by enrichment of the sub-arc mantle source by partial melts from subducted oceanic crust in the presence of residual rutile-bearing eclogite, where amphibole is either a minor phase or entirely absent. Only the old subducted Jurassic Pacific slab is located at depths required for such mineral assemblages. The slab melts that enriched the sub-arc mantle with an unusually high Nb/Ta signature are derived from an initially intact Pacific plate that was probably subject to a slab break-off event and subsequent melting at depths >100 km. Pb isotope data support a Pacific origin of these slab melts [3]. Altogether these geochemical constraints support recent geophysical studies in that partial slab melting may also affect initially intact oceanic plates older than 50 Ma [e.g. 4].

Groundwater depletion: A U.S. national assessment and global perspective

LEONARD F. KONIKOW

U.S. Geological Survey, Reston, VA 20192 USA (lkonikow@usgs.gov)

Development of groundwater resources for agricultural, industrial, and municipal purposes greatly expanded during the 20th century, and economic gains from groundwater use have been dramatic. In many places, however, groundwater reserves have been depleted to the extent that well yields have decreased, pumping costs have increased, water quality has deteriorated, aquatic ecosystems have been damaged by reduced groundwater discharge, and land has subsided irreversibly. Some causes and effects of groundwater depletion are neither obvious nor easy to assess. If cumulative long-term global depletion is large, it will represent a substantial net transfer of mass from land to the oceans, thereby contributing to sea-level rise. Much groundwater pumped from confined aquifers is derived from storage losses in adjacent confining layers. Nevertheless, depletion in low-permeability layers is difficult to estimate, rarely monitored, and too often overlooked. A new simplified method for estimating depletion from confining layers was developed, tested, and applied. Results indicate that depletion in confining layers can greatly exceed the depletion from the confined aquifer itself. (For example, in the confined Dakota Aquifer, about 98 percent of the water removed from storage was derived from depletion in adjacent confining units.) A U.S. national groundwater depletion census indicates that about 800 km^3 of water was depleted from groundwater systems in the U.S. during the 20th century—equivalent to a sea-level rise of approximately 2.2 mm. Long-term global groundwater depletion since 1900 totalled about 3,400 km^3 through 2000 and 4,500 km^3 through 2008, equivalent to a sea-level rise of approximately 9.3 and 12.6 mm, respectively. The rate of annual depletion has increased markedly since about 1950, with maximum rates occurring during the most recent period (2000-2008), when it averaged about 145 km^3/yr (equivalent to 0.23 mm/yr of sea-level rise). This recent average rate would explain about 13 percent of the reported long-term rate of sea-level rise of 1.8 mm/yr. Worldwide, the magnitude of groundwater depletion is a small but nontrivial contribution to sea-level rise during the 20th century.

Discovery of new hydrothermal active fields in the South-West Pacific. Organic geochemistry of the fluids

C. KONN[1]*, J.L. CHARLOU[1], J.P. DONVAL[1], D. BIROT[1], V. GUYADER[1], F. PEREZ[2], P. JEAN-BAPTISTE[2], E. FOURRÉ[2], Y. FOUQUET[1] AND THE SCIENTIFIC PARTIES

[1]Ifremer c/Brest, Laboratoire de Géochimie et Métallogénie, BP70, 29280, Plouzané, France (*correspondence: cecile.konn@ifremer.fr)

[2]CEA-CNRS, LSCE, CEA-Saclay, 91191 Gif-sur-Yvette, France

Back-arc basins in the South-West Pacific have been investigated for hydrothermal activity in the last 20 years. Several hydrothermal fields have been discovered in the Lau basin, Manus basin and North Fiji basin. A new area off-shore the Futuna island was surveyed in fall 2010 during a French cruise conducted by Ifremer and two new hydrothermal active fields (Amanaki and Kulo Lasi) were discovered. The plumes were first evidenced by the use of physical and geochemical tracers. At Kulo Lasi, nephelometry, Mn, CH_4 He profiles strongly correlated and consistently showed a maximal anomaly in the water column at about 1200 m depth. Concentrations of CH_4 up to 1200 $nL.L^{-1}$ and up to 30 nM for Mn were detected. High-resolution bathymetry supported the tracers indications, showing a caldeira in the vicinity culminating at 1200 m. Numerous small black smokers were then discovered on the seafloor during our first submersible dive. CTD profiles were recorded around and on the field during 9 CTD operations and 6 Nautile dives. Alongside, water column samples and hydrothermal fluids samples were collected. On the one hand, physics and geochemistry of the Kulo Lasi plume will be discussed here. On the other hand, relatively elevated concentrations of H_2 and CO_2 have been measured in the fluids from Kulo Lasi (gas and inorganic geochemistry of the fluids will be the focus of another presentation by J.L. Charlou). In the presence of H_2 and CO_2, catalytic abiogenic reactions (e.g. Sabatier, Fischer Tropsch) may occur and generate hydrocarbons [1, 2]. Supercritical seawater (Pc = 298 bar, Tc = 407 °C) is a favourable media for cleavages, condensations, cyclisations, hydrolysis, oxydation, hydrogenation and hydroformylation. A great variety of organic compounds (heavier hydrocarbons, prebiotic molecules [3, 4]) may thus be produced at the Kulo Lasi hydrothermal field. The preliminary results on the organic geochemistry of the hot fluids will be presented here.

Thermodynamic and trace element modeling to quantify fluid fluxes and fluid-rock interaction in high pressure rocks from the Sesia Zone (Western Alps)

MATTHIAS KONRAD-SCHMOLKE[1], THOMAS ZACK[2], PATRICK J. O'BRIEN[1] AND MATTHIAS BARTH[2]

[1]Institut für Erd- und Umweltwissenschaften, Universität Potsdam, Karl-Liebknecht-Straße 24-25, 14476 Potsdam, Germany

[2]Universität Mainz, Fachbereich Geowissenschaften, Becherweg 14, 55128 Mainz, Germany

The amount and composition of fluids percolating through high pressure rocks and the effect of resulting fluid-rock interaction on fluid and wall rock composition has been constrained by thermodynamic and trace element modeling of partially overprinted blueschist-facies rocks from the Sesia Zone (Western Alps). Deformation-induced differences in fluid flux led to a partial preservation of pristine mineral cores in weakly deformed phengite and sodic amphibole grains that were used to quantify Li, B, Sr and Pb distribution during mineral growth, -breakdown and -modification induced by fluid-rock interaction. Our results show that Li and B budgets are strongly fluid-controlled, thus acting as excellent tracers for fluid-rock interaction processes, whereas Sr and Pb budgets in our samples are mainly controlled by the fluid-induced formation of epidote. Our calculations show that fluid-rock interaction caused significant Li and B depletion in the affected rocks due to leaching effects, which in turn leads to an up to five-fold enrichment of these elements in the percolating fluid. Depending on available fluid-mineral trace element distribution coefficients modeled fluid rock ratios necessesary to produce the observed trace element patterns in the affected minerals were up to 1 in weakly deformed samples and at least 1 – 4 in shear zone mylonites. These values can be used to determine time integrated fluid fluxes that were up to 4. 10^2 m^3m^{-2} in the weakly deformed rocks and at least 2 – 8. 10^3 m^3m^{-2} in the mylonites. Combined thermodynamic and trace element models help to quantify metamorphic fluid fluxes and the associated element transfer in complex, reacting rock systems and to better understand commonly observed fluid-induced trace element trends in metamorphic and magmatic rocks and minerals from different geodynamic environments.

Evidence for a Hawaii-Emperor bend in the Rurutu hotspot track

J.G. KONTER[1]*, M.G. JACKSON[2] AND A.A.P. KOPPERS[3]

[1]Dept. Geological Sciences, University of Texas at El Paso, El Paso, TX 79968 (*correspondence: jgkonter@utep.edu)

[2]Dept. Earth Sciences, Boston University, Boston MA 02215

[3]Coll. Oceanic and Atmospheric Sciences, Oregon State University, Corvallis, OR 97331

Hotspots have long been used as an absolute and fixed reference frame for modeling plate motions. However, the paths of hotspot tracks may be complicated by factors related to mantle flow and/or plume motion. The two longest, continuous hotspot tracks recognized on the Pacific Plate, the Hawaiian-Emperor and Louisville chains, exhibit different behavior prior to ~50 Ma, where the Hawaiian-Emperor chain shows a pronounced 'kink', while the Louisville chain is gently curved [1]. Furthermore, the Hawaiian hotspot might have incurred a ~15° southern shift between 80 and 50 Ma, while the Louisville hotspot seems to have behaved more stationary (or moving west to east) over the same time period. The causes of these differences are not well understood, and they have some important ramifications for absolute plate motion models and our understanding of mantle dynamics. Despite suggestions to retire the plume hypothesis, a more conciliary view explains the variety of observations with three different types of hotspots. This would imply the major hotspots may still reflect plate motion with respect to the mantle, although a component of plume motion could also be recorded by the orientation of a volcanic chain.

Recent geochemical evidence and radiometric ages suggest that the Rurutu hotspot is long-lived (100 Ma) [2, 3] and follows a track midway between Hawaii and Louisville. Like Hawaii, the Rurutu hotspot exhibits a sharp bend in the Tuvalu region between Samoa and the Gilberts Ridge, around 35-55 Ma following the latest absolute plate motion models. The hotspot volcanoes are characterized by HIMU-type isotopic compositions [3], distinguishing them from other hotspots such as Samoa [4]. Therefore, the Rurutu hotspot may provide a third, long-lived Pacific hotspot track that can help to deconvolve the effects of plate motion from plume motion in determining the paths of hotspot tracks.

Trace element systematics in HT metamorphic rutile: The robustness of the Zr geothermometer

E. KOOIJMAN[1]*, M.A. SMIT[1], K. MEZGER[2] AND J. BERNDT[1]

[1]Institut für Mineralogie, Westfälische Wilhelms-Universität, Corrensstraße 24, D-48149 Münster, Germany (*correspondence: e.kooijman@uni-muenster.de)
[2]Institut für Geologie, Universität Bern, Baltzerstraße 1-3, 3012 Bern, Switzerland

The Zr-in-rutile thermometer [1] has been successfully applied to a wide range of high-grade metamorphic rocks. However, experimental data indicate that rutile may be only moderately retentive to Zr [2]. Some field-based studies reported a large range of Zr concentrations from granulite facies metamorphic rocks suggesting post-peak diffusional resetting during slow cooling [3]. Further investigation into the Zr systematics in rutile is needed to improve the interpretation of Zr-in-rutile temperature estimates.

For this purpose, we analyzed rutile grains from zircon-bearing granulite-facies metapelites of the Archaean Pikwitonei granulite domain, Canada. The Zr concentrations were evaluated by acquiring compositional profiles and maps by electron probe micro-analysis. Profiles of Nb, Cr and V, which diffuse faster in rutile than Zr [4], were analyzed simultaneously. The variation in the concentrations of all elements is small within individual rutile grains (120-280 μm) from 3 different samples, but large differences are observed between grains only millimeters apart in the same sample.

The lack of diffusion profiles for all analyzed elements indicates that Zr concentrations are pristine. Zoning of high-Zr rutile (3000-4600 ppm) demonstrates Zr undersaturation during growth under dry UHT conditions in spite of the presence of zircon. Therefore, several rutile grains should be analyzed in a sample to obtain a useful minimum peak temperature estimate. The highest Zr-in-rutile temperatures for the samples from the Pikwitonei granulite domain are ca. 900 °C and thus exceed previous estimates of 820 °C based on two-feldspar thermometry [5], demonstrating the advantage of Zr-in-rutile thermometry for constraining peak temperatures of UHT rocks.

In situ analysis of U-Th disequilibria in titanite by fs-LA-MC-ICPMS

J.M. KOORNNEEF[1,2]*, B. BOURDON[1,3], G. FONTAINE[4], L. DORTA[4], B. HATTENDORF[4], D. GÜNTHER[4], P. ULMER[1] AND A. STRACKE[5]

[1]Institute of Geochemistry and Petrology, ETH Zürich, Switzerland,
[2]Department of Petrology, VU Amsterdam, the Netherlands (*correspondence: janne.koornneef@falw.vu.nl)
[3]Ecole Normale Supérieure de Lyon, Lyon, France (CNRS)
[4]Laboratory of Inorganic chemistry, ETH Zürich, Switzerland
[5]Institut für Mineralogie, Westfälische Wilhelms Universität, Münster, Germany

A new technique for *in situ* analysis of U-Th disequilibria in titanite by fs-LA-MC-ICPMS is presented. An in-house titanite glass ([U] = 215 ppm), determined to be in secular equilibrium by solution mode MC-ICPMS, is used to correct for U-Th elemental fractionation by sample standard bracketing. SEM-Faraday gain and abundance sensitivity are determined on solution standards interspersed every 15 laser ablation analysis.

The effect of instrument settings to the accuracy and precision of (^{230}Th/^{238}U) ratios was investigated by multiple analyses of secondary titanite standards. The laser analysis mode (scanning or spot), laser energy and wavelength, and titanite material properties were all found to variably influence the U-Th elemental fractionation and compromise the accuracy of the data to different extents.

During spot analyses using near infra-red (NIR) wavelength and high laser energy, time-dependent elemental fractionation is observed, resulting in relatively large standard errors on the (^{230}Th/^{238}U). Decreasing the laser energy significantly reduces the time-dependent elemental fractionation but does not eliminate it completely, e.g. 2RSE on (^{230}Th/^{238}U) are 5.2% instead of 19%. NIR scanning mode analyses are not compromised by time-dependent elemental fractionation (2RSE on (^{230}Th/^{238}U) are 3.2%), but the absolute amount of fractionation between analyses of different materials (e.g. glass versus minerals) is variable.

Ultra violet (UV) mode LA analyses are significantly less affected by time-dependent elemental fractionation compared to NIR analyses, but are limited by counting statistics due to lower signal intensities. Furthermore, differences in fractionation behaviour between various titanite materials are still observed. The effect of adjusting plasma conditions, with the aim to reduce the elemental fractionation, is currently investigated.

Preliminary results from Integrated Ocean Drilling Program Expedition 330 to the Louisville Seamount Trail

A.A.P. KOPPERS[1]*, T. YAMAZAKI[2], J. GELDMACHER[3] AND IODP EXPEDITION 330 SCIENTIFIC PARTY

[1]College of Oceanic & Atmospheric Sciences, Oregon State University, Corvallis, OR, USA (*correspondence: akoppers@coas.oregonstate.edu)
[2]Geological Survey of Japan, AIST, 1-1-1 Higashi, Tsukuba 305-8567, Japan
[3]Integrated Ocean Drilling Program, Texas A/M University, 1000 Discovery Drive, College Station, TX 77845, USA

Integrated Ocean Drilling Program (IODP) Expedition 330 drilled five different guyots in the Louisville Seamount Trail ranging in age between 80 and 50 Ma. The primary goals of this expedition were to drill a sufficiently large number of *in situ* lava flows at each seamount for high-quality estimates of their paleolatitudes using paleomagnetic measurements, for improving the overall age progression using high-precision $^{40}Ar/^{39}Ar$ geochronology, and for detailed geochemical studies of the volcanic evolution of these seamounts. With these data we can provide the unique record of the paleolatitude shift (or lack thereof) of the Louisville mantle plume and compare it with the ~15° paleolatitude shift observed for seamounts in the Hawaiian-Emperor Seamount Trail over the same time period. It also allows us to directly compare the geochemical evolution of a typical Louisville seamount with seamounts in Hawaii and to test the apparent long-lived homogeneous geochemical character of the Louisville mantle source. These comparisons are of fundamental importance to determine whether these two primary hotspots have moved coherently or not, and to understand the nature of hotspots and convection in the Earth's mantle. Finally, the paleolatitude, age and geochemical data together will provide a more advanced test of whether the Louisville seamounts were formed from the same mantle source that also formed the Ontong Java Plateau. If this is found to be the case, it is possible that the plume head of the Louisville mantle upwelling caused the massive LIP volcanism that formed the Ontong Java Plateau around 120 Ma and at an average 24±2°S paleolatitude.

Diamondiferous conglomerate preserves evidence for kimberlite and the deep cratonic root of the Mesoarchean Southern Superior craton

M.G. KOPYLOVA[1], V.P. AFANASIEV[2], L. BRUCE[1] AND J. RYDER[3]

[1]University of British Columbia, Vancouver, Canada (mkopylov@eos.ubc.ca)
[2]Sobolev Institute of Geology and Mineralogy, Russian Academy of Sciences, Novosibirsk, Russia
[3]Dianor Resources, Inc, 649, 3rd avenue, 2nd floor Val-d'Or (Quebec) J9P 1S7, Canada

Current models of the Superior craton growth invoke formation of the cold diamondiferous root soon after the 2.7 Ga orogeny that consolidated the craton. We show that the Superior craton included an older cratonic nucleus that had developed the deep diamondiferous root prior to 2.7 Ga, and also provide evidence for a Mesoarchean Superoir kimberlite. This evidence contradicts current views that Archean diamondiferous volcanics differed from kimberlites, which became a major diamond–bearing primary rock only in the Proterozoic.

The evidence is found in 2.697-2.701 Ga diamondiferous conglomerates of the Michipicoten Greenstone Belt (MGB) of the Wawa subprovince. The conglomerate metamorphosed in the greenschist facies contains mainly lithic igneous mafic to felsic clasts of local provenance. The conglomerate matrix includes diamonds and paragenetic diamond indicator minerals with subtle signs of mechanical abrasion and varying degrees of chemical resorption. The diamonds are predominantly white single octahedral crystals. Comparison of the size distribution, resorbtion and N aggregation of diamonds in Wawa lamprophyres and the conglomerate diamonds confirms that the latter did not derive from the proximal lamprophyric source. Heavy minerals panned from the conglomerate and extracted in commercial labs include Cr-diopside, olivine, corundum, chromite, anorthite, magnetite, pyrope with kelyphitic rims and picroilmenite. Low abundances of heavy minerals (several grains per 4-70 tonnes of the conglomerate) are, in part, explained by their complete or partial replacement by the greenschist assemblage. Cr-diopside, olivine, chromite and anorthite were derived from mafic-ultramafic anorthosite- and chromitite-bearing layered complexes mapped in the MGB. Corundum may have come from kimberlites or other mafic rocks as the majority of corundum is the Cr-bearing ruby. The presence of pyrope with more than 6 wt% Cr_2O_3 suggests derivation from the cratonic root, as such high-Cr pyropes are never found in the off-cratonic continental or oceanic mantle. Picroilmenite has compositions typical of kimberlite and unlike that of ultramafic lamprophyres and other volcanics transitional to kimberlites. The Wawa conglomerate, therefore, should be considered analogous to the Witwatersrand conglomerate in recording indirect evidence for the Mesoarchean kimberlites.

Monitoring of plagiogranite of the Yeşilova Ophiolite: Geochemistry and confocal Raman spectroscopy, Southwest Anatolia, Turkey

TAMER KORALAY[1] AND YUSUF KAGAN KADIOGLU[2]

[1]Pamukkale Univ., Geol.Eng. Dept., 20017 Denizli Turkey
[2]Ankara Univ., Geol. Eng. Dept., 06100, Ankara-Turkey

In most ophiolitic suites observed around the world, there are small bodies of intrusive leucocratic rocks, usually called plagiogranites. It has clear differences from other subunits of the ophiolite in colour, texture and geochemical character. Yeşilova ophiolite exhibits an incomplete oceanic crust stratigraphy with missing sheeted dykes and epioceanic sediments. It is composed of tectonites, ultramafic-mafic cumulates, isotrope gabbros, plagiogranites and pillow basalts from the bottom to the top. Diabase and microgabbro usually cross-cut the peridotites. Plagiogranites crop out as veins, dikes and small intrusive bodies intruded into the isotrope gabbro having a sharp contact. They have light green, white in color and fine to medium-grain size, consisting predominantly of quartz, plagioclase, uralitized pyroxene, opaque minerals and supported by the Confocal Raman spectrometry. Plagiogranites have hypidiomorphic granular texture and mainly characterized by the micrographic and myrmekitic groundmass texture under the microscope.

Whole rock geochemical of plagiogranites are characterized by high SiO_2 (73.44±2.81) with remarkably low K_2O (0.62±0.48), and generally higher MgO (1.66±1.30), CaO (3.89±1.82) than the continental granite. Moreover; they have slightly high amount of Fe_2O_3/MgO ratio and similar Rb, Sr and Zr values to oceanic plagiogranite composition. On variation diagrams, CaO, Fe_2O_3, Sr, V, Co and Ta display clear negative correlations, whereas Na_2O, P_2O_5, Y, Zr, Hf, La, Ce show positive correlation with increasing of SiO_2 ratio. These can be explained by fractional crystallization processes in the late stage of magma generation. Plagiogranite samples display enrichment in LILE relative to HFSE in MORB and ORG normalized multi-element diagrams. In these diagrams, they exhibit depletions in Rb, Ba, Nb, P and Ti as characteristics of subduction-related magmas. Rare earth element (REE) patterns for plagiogranite show REE enrichment with respect to chondrite values. They exhibit slightly depletion in LREE ($(La/Sm)_N$ = 1.43-2.83) relative to HREE ($(Sm/Lu)_N$ = 0.43-0.92). Furthermore, all the samples of the plagiogranites have small positive Eu anomalies ($(Eu/Eu^*)_N$ = 1.14-1.35), indicating the significant role of plagioclase in the fractional crystallization.

As a result, despite the lack of isotopic data, the petrographic and geochemical results suggest that plagiogranites of the Yeşilova ophiolite are the most probably related to crystal-liquid differentiation process of the oceanic crust of the Alpine belt.

Urban dead seas: Natural and anthropogenic influences on redox-stratified lakes and wetlands

C. KORETSKY

Department of Geosciences, Western Michigan University, Kalamazoo, MI 49008, USA (carla.koretsky@wmich.edu)

Redox-stratification is a pervasive feature of dynamic near-surface earth systems, occurring on scales of micrometers to kilometers. Examples can be found in systems as diverse as microbial mats, soils and sediment pore waters, groundwaters, lakes and seas. Physical processes, such as advective flow through pores or wind mixing of surface waters, interact with chemical factors, for instance the availability of electron acceptors and donors, and biological processes, including organic matter fixation, macrophyte root exudation, bioirrigation, bioturbation and microbially-mediated reactions, to produce spatially and temporally heterogeneous systems.

Anthropogenic activities can also have an enormous influence on redox-stratified systems. For example, the addition of limiting nutrients and labile organic matter to surface and groundwaters leads to substantial, widespread problems such as eutrophication and the creation of dead zones. There is increasing recognition that the introduction of other contaminants, such as road salt deicers, may also have important biogeochemical consequences, albeit often through subtle or indirect effects. Deciers, typically NaCl or $CaCl_2$, are applied in enormous and growing quantities in urbanized settings throughout the world. In the U.S. alone, >15, 000, 000 tons of decier are applied to roads each year. It is well-known that application of these salts can have a profound impact on macro- and micro- biological communities, yet remarkably few studies have examined the effects on biogeochemical processes.

Recent work suggests that such effects could be quite significant. For example, mesocosm data show that addition of NaCl, and especially $CaCl_2$, can stimulate anaerobic respiration in wetland soils. Furthermore, an increasing body of literature demonstrates that road salt deicers may suppress physical mixing in lakes, potentially resulting in transition from dimictic to monomictic or even meromicitic conditions, and in pronounced redox-stratification of lake column waters. Particularly in eutrophic urban lakes, this is expected to have enormous consequences for biogeochemical cycling, and could lead to saline, persistently anoxic lake bottomwaters: ‘urban dead seas’. This emerging environmental problem deserves greater attention and further study.

Cr(VI) adsorption on γ-alumina

C.M. KORETSKY* AND T.J. REICH

Department of Geosciences, Western Michigan University, Kalamazoo, MI 49008, USA
(*correspondence: carla.koretsky@wmich.edu)

Cr (VI) is a toxic contaminant that has been introduced into numerous surface and subsurface systems through industrial activities such as electroplating, leather tanning and steel manufacturing. In solution, it forms anionic complexes (CrO_4^{-2}, $HCrO_4^-$), and as such, may bind to the surfaces of positively charged solids. High surface area, synthetic γ-alumina is often used as an analog for aluminum oxides found in soils and sediments. It has a high point of zero charge (~5.5-8.9), and thus may bind Cr (VI) even at relatively high pH. However, few studies have investigated Cr (VI) sorption on γ-alumina.

In this study, Cr (VI) sorption on γ-alumina (N_2 BET SA = 233 m^2/g) was measured as a function of pH (3-10), ionic strength (0.1 to 0.001 M $NaNO_3$), and pCO_2 (0, atmospheric, 2.5%). A large batch slurry of 2 g/L γ-alumina with 10^{-5} or 10^{-6} M Cr (VI) was titrated from pH 3 to 10, with aliquots removed at ~0.5 pH intervals. Individual aliquots were further equilibrated for 4 hrs, after which the supernantant was removed by centrifugation and syringe-filtration and analyzed for Cr (VI) by UV-vis spectrophotometry (diphenylcarbazide method) or for total Cr by ICP-OES using matrix-matched calibration standards.

Cr (VI) sorption is rapid, reaching equilibrium within 15 minutes, and is reversible, with 100% desorption occurring within 24 hrs. As expected, sorption decreases with increasing pH. For a given solution condition, more Cr (VI) uptake occurs in the 10^{-6} M compared to the 10^{-5} M Cr (VI) experiments. Adsorption edges show little dependence on ionic strength or pCO_2, except that Cr (VI) sorption is suppressed at low pH in experiments with high ionic strength and high pCO_2.

The measured adsorption edges were individually modeled using constant capacitance, diffuse double layer and triple layer surface complexation models. For each model, multiple site density, protonation/deprotonation stability constants, Cr (VI) reaction stoichiometries and capacitances were tested. In each case, good fits could be produced for individual edges. However, none of the models tested resulted in satisfactory fits over the complete range of measured pH, ionic strength, sorbate/sorbent, and pCO_2 conditions. The best fits were obtained using a constant capacitance model, because stability constants for this model are ionic-strength dependent.

Timing of denudation, erosion and surface uplift of the Hunza Karakoram – A case study of combined thermochronological and geomorphological approaches

D. KORINKOVA[1]*, M. SVOJTKA[1] AND J. KALVODA[2]

[1]Institute of Geology, Academy of Sciences CR v.v.i, Prague 6, 165 00, Czech Republic
(*correspondence: korinkova@gli.cas.cz)
[2]Charles University in Prague, Faculty of Science, Albertov 6, Prague 2, 128 43, Czech Republic
(kalvoda@natur.cuni.cz)

Geomorphological records of extreme surface uplifts of the Hunza Karakoram in the late Cenozoic are correlated with thermochronological history of relevant crystalline rocks during active collision orogeny. A set of studied samples dated by apatite fission-track (AFT) technique come from the SW-NE transect in the Hispar and Gharesa regions of the Hunza Karakoram. Variable lithological types of crystalline rocks were collected from 2 400 to 5 600 m a. s. l. and yielded ages between 3.9 ± 0.2 Ma to 9.7 ± 0.4 Ma. Our results confirmed effective denudation, erosion and transport of near-surface rock masses during the late Cenozoic.

Time-temperature modeling of AFT samples from the Hunza Karakoram shows a similar thermal history style, involving a period of total thermal annealing and a subsequent period of cooling corresponding to considerable denudation and erosion processes. Two dominant trends of cooling rate have been observed: (1) the Upper-Miocene to Pliocene period of a slow rate about 0.1 km/Ma followed by (2) the Quaternary period of a relatively rapid rate about 2.6 km/Ma. The later period of cooling can be associated with an approaching of (sampled) rock assemblages nearby late Cenozoic denudation and/or erosion surfaces.

Measured track-lengths vary from 10.3 ± 2.8 μm to 12.1 ± 2.2 μm with a negative skewness. The track-lengths-frequency histogram demonstrate a bimodal distribution with a short peak representing the higher temperature tracks and also with longer peaks derived from final cooling. These data give evidence of mixed ages as a result of (at least) two-stage cooling history of studied crystalline rocks.

Denudation and erosion of rock masses in the Hunza Karakoram estimated by a combination of current elevations of samples and depths of fossil apatite partial annealing zones reached up to 4 km from the Upper Miocene to the present.

Modern natural and technogenic iodine biogeochemical provinces: Spatial structure and health effects

E.M. KOROBOVA[1]*, S.L. ROMANOV[2], A.I. KUVYLIN[1], V.YU. BERIOZKIN[1] AND I.V. KURNOSOVA[3]

[1]Vernasky Institute of Geochemistry and Analytical Chemistry, Rus.Ac. of Sci., 119991 Moscow, Kosygin Str., 19, Russia (*correspondence: Korobova@geokhi.ru)
[2]Unitary Enterprise Geoinformation systems., Belarus National Ac. of Sciences, 220004 Minsk, Surganov Str., 6, Belarus (romanov_s_l@mail.ru)
[3]Bryansk Clinical and Diagnostic Center Bryansk, Bezhitskayay 2, Russia (irina_k@bkdc.ru)

The ubiquity of living matter proved its chemical coevolution with and adaptation to the Earth geochemical environment. However the existence of homeostatic concentration intervals providing normal functioning of biosystems has led to formation of endemic species and/or distribution of regional and local biogeochemical endemic diseases in cases of expansion of species to environments with concentrations outside thresholds or catastrophic releases of chemical elements and/or compounds. A failure of regulatory mechanisms in at least 20% of population may be a criterion for biogeochemical province with endemy [1].

The main goal of our study was to reveal and analyze the structures of natural and technogenic geofields of iodine in soil and food chain components and iodine-dependent medical effects.

The study of Bryansk oblast affected by the Cherbobyl fallout included: 1) estimation of the initial radioiodine contamination; 2) cartographic estimation of the soil iodine status; 3) determination of iodine in drinking water, milk, pasture plants, arable soil in private farms of 100 rural settlements provided with medical data on renal iodine excretion, endemic goiter and thyroid cancer.

Analysis of the obtained data organized as GIS data base allowed performing spatially adequate comparison of the geochemical and medical data and contouring of potential risk zones as a superposition of geofields of iodine.

The work has been supported by Russian foundation of basic research (grants #07-10-00912 [2] and 10-05-01148).

Raman spectroscopy of sodium silicates and germanates

O. KOROLEVA AND T. IVANOVA

Institute of mineralogy UrB RAS, Miass, Russia (koroleva@mineralogy.ru)

The approach to melt description we use here bases on idea of structural units make the basis of crystal chemistry of silicates and, when connected with one another via bridging bonds, form composite anions in melts or a disordered network in glass. The germanate system is of interest because of their analogy to silicates at high-pressure conditions. The local structure of silicate system can be presented as a set of silicon-oxygen tetrahedrons with various proportions of bridging and non-bridging oxigen atoms (Q^n-units, where n is the number of bridging oxygen atoms). The coordination number of germanium atoms in glasses has attracted much attention deu to a network forming cation can be in 4-coordinated and 6-coordinated states.

The concentrations of structural units Q^n can be determined experimentally by techniques of Raman spectroscopy, which has no principal limitations in terms of temperature, so that *in situ* structural studies can be carried on in melts. Sodium silicates and germanates of $x\%Na_2O\cdot(100-x)\%MO_2$ composition, where M - Si or Ge, x = 33, 40, 50, 55 и 60 were synthesized from sodium carbonate and SiO_2 (GeO_2). To study the quantity dependence of structural units presented in glass (melt) from modifier content and temperature spectra were deconvoluted on Gaussian components.

The work was supported by the Russian Foundation for Basic Research (grant № 10-05-96044) and grant of President of Russian Federation (MK-109.2011.5).

Early and Middle Jurassic $\delta^{13}C$ and $\delta^{18}O$ trends: A high resolution dataset from the UK

C. KORTE[1], S.P. HESSELBO[2] AND C.V. ULLMANN[1]

[1]Dept. of Geography and Geology & Nordic Center for Earth Evolution, University of Copenhagen, DK, (ck@geo.ku.dk)

[2]Dept. of Earth Sciences, University of Oxford, UK, (stephess@earth.ox.ac.uk)

Low-Mg-calcite fossils have been extensively utilized to obtain past seawater chemistry and to reveal major environmental changes in Earth history [1, 2]. The resolution of these first generation long-term studies is often at biozone levels only. Recent work on major Phanerozoic events showed that distinctly higher resolutions are possible, revealing short-term stable isotope fluctuations and helping to discover its causes. Here we present new carbon and oxygen isotope data from mollusks and brachiopods collected from marine Early to Middle Jurassic successions of the UK representing a new generation of data in terms of temporal resolution. Together with literature data for the T–J boundary [3] and the Toarcian OAE [4] a nearly complete high-resolution record is now available. The fossils have been screened by various techniques, such as scanning electron microscopy and chemical analysis, to check for post-depositional alteration. The carbon isotope fluctuations obtained from the analyzed samples are the following: (1) a positive excursion in the earliest Sinemurian *Conybeari* zone, (2) a negative shift in the Sinemurian *Bucklandi* zone, (3) a negative excursion at the Sinemurian–Pliensbachian boundary (upper *raricostatum* and lower *jamesoni* zones), and (4) a positive excursion in the Late Pliensbachian *margaritatus* zone. The new oxygen isotope fluctuations in general correspond to those of the carbon isotopes, but with the exception for the Sinemurian–Pliensbachian boundary event, which is characterized by a positive $\delta^{18}O$ trend during the negative $\delta^{13}C$ excursion. This positive trend represents most likely bottom water cooling as a result of the Early Pliensbachian transgression. In addition, an Aalenian–Bajocian positive $\delta^{18}O$ excursion is identified. The new high resolution dataset shows partly a strong similarity between the positions of the global warming and cooling events within transgressive and regressive phases of second-order depositional sequences though the Early Jurassic supporting the idea that second-order depositional sequences are a result of eustatic sea-level changes at that time.

Geo-bio interactions in hydrothermal fluids and their potential role for hydrothermal metal fluxes

A. KOSCHINSKY[1]*, S. SANDER[2], V. KLEVENZ[1] AND M. PERNER[3]

[1]Jacobs University Bremen, D-28725 Bremen, Germany (*correspondence: a.koschinsky@jacobs-university.de)

[2]Dept. of Chemistry, University of Otago, Dunedin 9054, New Zealand

[3]Microbiology and Biotechnology, University of Hamburg, D-22609 Hamburg, Germany

Hydrothermal vents emit fluids with high concentrations of many metals at the seafloor. Until recently it was assumed that the precipitation of most metals (e.g. Cu and Fe) during mixing with seawater reduces their net fluxes from the hydrothermal systems into the open ocean to negligible values. However, the recent discovery of significant organic complexation of Cu and Fe in the hydrothermal fluids and rising plumes, has urged a revision of trace metal fluxes from deep-sea hydrothermal vents. We demonstrated using field data and geochemical modeling [1] that the presence of organic ligands stabilizing dissolved trace metals strongly competes with metal precipitation and significantly increases the dissolved metal concentrations in hydrothermal fluids and plumes. According to our calculations, hydrothermal metal fluxes may be significantly larger than previously assumed, i.e. up to 20% of the deep-ocean dissolved Fe and Cu budget can be assigned to hydrothermal sources.

While the importance of organic ligands for hydrothermal metal fluxes seems to be acknowledged by now, the nature and origin of these organic molecules is still unclear. Amino acids, probably of biogenic origin, which have been found in significant concentrations in hydrothermal fluids [2], and other organic molecules containing thiol groups would be potential candidates for stable metal complexation. In lab experiments with hydrothermal microbial cultures along Cu concentration gradients the production of organic Cu-binding ligands by the microbial communities due to increasing Cu stress was studied. Ligand production increased significantly with increasing Cu concentrations, implying microbial influence on dissolved metal concentrations, speciation and mineral precipitation in the hydrothermal vent environment. Our work suggests a significant modification of hydrothermal fluid chemistry and hydrothermal metal fluxes by biological processes.

Fluid inclusion study of a sediment-hosted copper ore deposit in the Lubin area (Poland)

JOANNA KOSTYLEW[1,2]* AND CHRISTOPH A. HEINRICH[1]

[1]Institute of Geochemistry and Petrology, ETH Zürich, Clausiusstrasse 25, 8092 Zürich, Switzerland (*correspondence: joanna.kostylew@erdw.ethz.ch)
[2]Institute of Geological Sciences, University of Wrocław, ul. Cybulskiego 30, 50-205 Wrocław, Poland

The sediment-hosted copper ore deposit in the Fore-Sudetic Monocline (Lubin area, SW Poland) is one of the largest in the world. Copper mineralization (Cu and Cu-Fe sulphides) follows a redox front (*Rote Fäule*) and occurs close to the contact between the uppermost Lower Permian terrestrial sandstones (*Rotliegendes*), and Upper Permian (*Zechstein*) marine deposits (including siliciclastics, shales, dolomites, and evaporates). Mineralization is characteristically vertically zoned, and the sulphide type is unrelated to the host-rock lithology. This deposit is believed to be an equivalent to the German *Kupferschiefer* copper ore formation.

Processes leading to the ore formation in the Lubin region can be better understood with a modern fluid inclusion study, combining of classical microthermometry with LA-ICP-MS analysis. This provides valuable data on temperature, pressure and chemical composition (including concentrations of major and trace elements in individual fluid inclusions) of the hydrothermal fluids.

Samples collected from the three deep mines (Lubin, Rudna and Polkowice-Sieroszowiec) represent a variety of rock types (from both oxidized and reduced zones). Fluid inclusions were found in various rock types, but the most abundant are calcite veins and calcite infills of cavities in dolomites. Fluid inclusions are generally very small (<10μm), but diameters range up to 20-50 μm. Three main fluid inclusion types were identified: (1) aqueous two-phase primary fluid inclusions of irregular shapes, with small vapor bubble sizes (5-10 vol.%); (2) square single-phase aqueous fluid inclusions, distributed in the outer parts of the crystals; and, (3) very small secondary aqueous fluid inclusions with medium vapor bubble sizes (30 vol.%), present in late cracks.

Our combined microthermometry and LA-ICP-MS analysis provides the first data on the origin and geochemical evolution of low-temperature hydrothermal fluids in the Polish *Kupferschiefer* ore formation.

Extreme pressure dependence of sulphur solubility in silicate melts (experimental data)

A.V. KOSTYUK* AND N.S. GORBACHEV

Institute of Experimental Mineralogy, Academica Osipyana 4, Chernogolovka, Russia (*correspondence: nastya@iem.ac.ru, gor@iem.ac.ru)

Physicochemical conditions of sulphur concentration within fluid-bearing magmas in the upper mantle and the earth crust during sulphide-silicate immiscibility are very important for understanding of origin of magmatic sulphide deposits. Influence of pressure on solubility of sulphur is still controversial [1-3].

We studied influence of pressure on the SCSS (sulphur concentration at sulphide saturation) in H_2O and H_2O+CO_2-bearing silicate melts. We used Pt-peridotite ampoules filled with powder of olivine basalt and synthetic sulphide $Fe_{30}Ni_{30}Cu_{30}S_{10}$ as starting compositions. The highest concentrations of sulphur were 0.88-1.01 and 0.2 wt.% in H_2O-and H_2O+CO_2-bearing silicate melts respectively at 1.5-2.0 GPa (Fig. 1). The minimum concentrations were 0.1-0.2 wt.% both at low (0.1-0.8 GPa) and high (2.5-4.0 GPa) pressure.

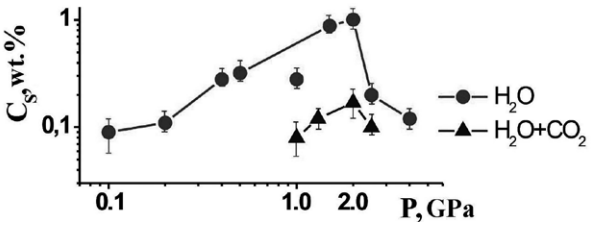

Figure 1: Relationships between pressure and SCSS in H_2O- and H_2O+CO_2-bearing silicate melts.

Inversion of relationships between pressure and SCSS in H_2O- and H_2O+CO_2-bearing silicate melts at P=1.5-2.0 GPa can be related to the inversion of volume effect of reactions and speciation of C, O, H and S in basalt melts at different pressure. Such inversion can play an important role in transport of sulphide sulphur and ore elements from the deep magmatic centres to the upper levels of the Earth crust where most of known sulphide ore deposits were discovered.

New geochronological U–Pb isotopic data of granitoids from the Kuznetsk Alatau Ridge, SW Siberia

A.D. KOTELNIKOV AND V.V. VRUBLEVSKII

Tomsk State University

The Kuznetsk Alatau is a part of the Central-Asian mobile belt (CAMB) and represents the ensemble of the Caledonian fold-thrust structures. The Early Paleozoic large granitoid intrusives are extensively distributed on its south-east slope. The recent U-Pb isotope-geochronological data (SHRIMP-II) obtained by us from sparse grains of the accessory zircon enable three time borders to be established for the manifestation of the granitoid magmatism.

We have studied two massifs of the derivatives of the earliest Martaiga complex of the Middle Cambrian which are composed by quartz diorites, tonalites, granodiorites and plagiogranites. By the quartz diorites from these massifs, the concordant age of their intrusion has been established corresponding to the time interval T = 510 ± 7 and 506 ± 4 Ma. Subsequently, at the Cambrian-Ordovician transition, the formation of the Tigertysh granite complex has been in progress. The dating of granitoids in its three satellites has demonstrated the similar concordant age of their formation – T = 495 ± 8; 495 ± 5; 493 ± 8 Ma. In the closing stage of the development of the Early Paleozoic granitoid magmatism, the numerous small intrusions of the mixed composition has been going on in the region: from quartz-monzonites and diorite-porphyrites to granites and granite-porphyries. The isotopic dates T = 432 ± 4; 431 ± 6; 429 ± 6; 425 ± 4 Ma have been obtained from four rock varieties. This suggests the comparatively narrow time interval (Llandovery – Wenlock) for the final magmatic events in the Early Paleozoic. We assume that granitoids from the SE slope of the Kuznetsk Alatau aged 510–493 Ma, along with ultrabasite-basite massifs, granite batholites, alkali basaltoids, complexes of alkali rocks and carbonatites of the Caledonian stage of development CAMB (~ 510–470 Ma) seem to form the Early Paleozoic Large Igneous Province in its limits [1–3].

This study was funded by the Ministry of Education and Science of Russian Federation (project 2.1.1/208, Federal program of ‘Scientific and Scientific-Educational Personnel of Innovative Russia 2009-2013).

Fluid equilibria in water–salt (sodium fluoride, sulfate, carbonate) – silicate systems

Z.A. KOTELNIKOVA[1]* AND A.R. KOTELNIKOV[2]

[1]Institute of Geology of ore deposits of RAS. Staromonetny 35, Moscow, 119017, Russia (*correspondence: kotelnik@igem.ru)

[2]Institute of Experimental Mineralogy of RAS, Chernogolovka, Moscow district, 142432. Russia

Heterogeneous fluid equilibria in the P–Q_type H_2O–salt (Na_2CO_3, NaF, Na_2SO_4) systems in the presence of SiO_2 or SiO_2 + $NaAlSi_3O_8$ were studied experimentally at 700–800°C and P=1–3 kb. The method of synthetic fluid inclusions used. The microthermomemtric study of the synthesized inclusions showed that under experimental conditions the fluid did not remain inert with respect to quartz and albite and was heterogeneous. Some inclusions contained a glasslike phase, and liquid released from this phase by heating. Having been heated, some inclusions entrapped in the upper heterogeneous region, revealed liquid immiscibility in the presence of vapor within a temperature range of 200 to 400°C. The solutions of various concentrations, including oversaturated solutions in the presence of solid phase, underwent recurrent heterogenization. Near 400°C, vapor is either dissolved in one of immiscible liquids or absorbs this liquid.

Re-immiscibility of the liquid, entrapped in higher heterogeneous area is the significant peculiarity of studied system. Then heterogenization may take place in two (or more for multicomponent systems) stages at large scale of *TP*-parameters. The immiscibility is very sufficient mode of the matter re-distribution between immiscible phases. Owing to the multistage of that is important at the enrich or deplete of the fluid phase by specific components.

Discovery of diamond and coesite in Bohemian granulites

J. KOTKOVÁ[1,2]*, P.J.O'BRIEN[3] AND M.A.ZIEMANN[3]

[1]Czech Geological Survey, Klárov 3, 118 21 Prague 1, Czech Republic (*correspondence: jana.kotkova@geology.cz)
[2]Inst. of Geosciences, Masaryk University, Brno, CR
[3]Institute für Erd- und Umweltwissenschaften, Universität Potsdam, Germany

Microdiamond and coesite have been discovered in high-pressure granulites of North Bohemia. The newly found, 5-30 μm sized microdiamonds, documented by micro-Raman, occur as inclusions in garnet, kyanite and zircon. They range from well-formed octahedra in kyanite to ragged sub-rounded crystals in places forming clusters in garnet. Within garnet microdiamond commonly occurs with graphite, which forms also diamond-free aggregates of up to 0.1 mm in diameter with associated phases apatite, rutile, quartz and carbonate minerals whereas in kyanite associated graphite is minor. Diamond occurrence below the surface of the polished section, variable size and morphology and breakdown to graphite confirm the *in situ* origin. Coesite, with a thin rim of quartz, has been identified as an inclusion in kyanite which is itself completely enclosed in garnet, in one of the samples containing polycrystalline quartz aggregates. Thus the north Bohemian crystalline basement is an UHP terrane and it represents a fifth accepted location where diamond has been confirmed *in situ* in continental crust rather than mantle rocks (along with Kokchetav Massif, Kazakstan; Saidenbachtal, German Erzgebirge; Rhodope Massif, Greece and Qinling Mts., China).

The microdiamonds have been found in both felsic quartzofeldspathic and intermediate garnet-pyroxene granulites from exposures in the Eger Crystalline Complex as well as drill cores in the crystalline basement c. 50 km to the ENE. The Saidenbachtal in Central Erzgebirge, belonging to the same Variscan unit, is located c. 50 km to NNE. Whereas the Saidenbachtal diamond-bearing gneiss is an unusual, rare rock [1], our granulites are macroscopically indistinguishable from those covering thousands of square kilometers of the Variscan crystalline core. Garnet peridotites are commonly associated with these granulites. Our discovery indicates that the continental crust was subducted deep into the mantle and captured slices of mantle thus finally yielding an explanation for the long known but still disputed granulite - garnet-peridotite association. Further, it suggests that the Variscan belt may be one of the largest UHP terranes worldwide.

[4]Institute for Geophysics and extraterrestrial Physics, University of Braunschweig, D
[5]Department of Chemical Engineering, Technical University Eindhoven, NL
[6]Geophysical Laboratory, Carnegie Institute of Washington, Washington, DC, USA

The *Miller-Urey Experiment in space* (MUE) will investigate the formation of prebiotic organic compounds in the early solar system environment when it is sent to, and later retrieved from, the International Space Station in 2012. The dynamic environment of the solar nebula with the simultaneous presence of gas, particles, and energetic processes, including shock waves, electrical discharges, and radiation may trigger a rich organic chemistry leading to organic molecules. Two gas mixture compositions (CH_4, NH_3, H_2 and N_2, H_2, CO) will be tested and subjected to continuous spark discharges for 48, 96, and 192 hours. Silicate particles will serve as surfaces on which thin water ice mantles can accrete. The experiment will be performed at low temperatures (-5 °C), slowing hydrolysis and improving chances of detection of initial products, intermediates and their abundances. Conducting the Miller-Urey experiment in the space environment (microgravity) allows us to simulate conditions that could have prevailed in the low gravity, energetic early solar nebula and provides insights into the chemical pathways that may occur as planetary systems form.

[3]School of GeoSciences, University of Edinburgh, Edinburgh EH8 9XP, Scotland, UK

The residence time of water in the subsurface is known to be an important control on chemical weathering rates because longer contact times allow for waters to dissolve more minerals. A second control on weathering rates is erosion, which accelerates mineral dissolution by supplying fresh mineral to the soil environment from the bedrock below. However, on hillslopes erosion can also dramatically impact the hydrologic conditions. The rate of erosion may influence the slope of the terrain, the hydraulic gradient, and the amount of weathering products (e.g. clays and Fe-oxides). These effects result in shorter contact times and potentially decreased solute fluxes from rapidly eroding landscapes.

One conceptual model for assessing the relative importance of hydrologic and erosional processes is to consider the fluid residence time required to reach chemical equilibrium (which would determine the maximum solute flux) relative to the actual average fluid residence time of water in the hillslope. Weathering systems where these thermodynamic and physical time scales are closely matched should have the maximum rates of chemical denudation.

To test this model, we have studied the chemical and physical compositions solids and waters from three soil-covered hillslope transects within a tributary basin of the Middle Fork Feather River, CA. One of the hillslopes is located above the knickpoint, while the others are adjacent to and below the knickpoint. Water contents and solute chemistry are fairly constant across each hillslope but variable between hillslopes. In general, the solute concentrations are lowest in the soils of the steeper hillslopes suggesting that water residence time is an important factor.

A new methodology to experimentally determine water incorporation into upper mantle olivine and pyroxene

I. KOVÁCS[1,2], D.H. GREEN[2,3], A. ROSENTHAL[1], J. HERMANN[1], H.ST.C. O'NEILL[1], W.O. HIBBERSON[2] AND B. UDVARDI[1,4]

[4]Lithosphere Fluid Research Lab, Eötvös University, Péter Pázmány sétány 1/C, 1117, Budapest, Hungray

This study explores experimentally the incorporation of water in olivine and pyroxene near the solidus of fertile lherzolite compositions at 2.5 and 4 GPa. A sensor-layer of olivine or pyroxenes was added to both sides of lherzolite material and their water contents were determined by Fourier-transform infrared spectroscopy. The IR absorption bands of the sensor crystals after the experiment are different from the bands present in the starting material, indicating that the sensor minerals equilibrated with the lherzolite material. The similarity of absorption characteristics in experimental runs to those from mantle derived rocks (summarised in the PULI spectral database) indicates that hydrogen defects in the sensor minerals can be successfully reproduced in chemically complex systems. Olivine, orthopyroxene and clinopyroxene contain 30-190, 290-320 and 910-980 ppm of water under the studied P-T conditions. The partition coefficients between orthopyroxene and clinopyroxene ($D^{cpx/opx}_{H_2O}$) are 2.7 and 3.5 at 2.5 and 4 GPa respectively, while values of $D^{opx/ol}_{H_2O}$ are ~7 and ~5, at 2.5 and 4 GPa respectively. Olivine and pyroxenes in our water-rich experiments display higher water concentrations than what is documented for most peridotites. They overlap only with the most water-rich natural samples from supra-subduction environments. Our experiments reproduce closely water-saturated conditions in the upper mantle in chemically analogue complex systems. Thus, our experimental strategy may be generally applied in the future for mapping out phase relations and maximum effective water storage capacity of the upper mantle.

[3]Dept. Geomorphology & Quaternary Research, HAS, H-1112 Budapest, Hungary (eoliandust@gmail.com)

Introduction

Red clays in Hungary (Tengelic Red Clay Formation: TRCF; Kerecsend Red Clay Formation: KRCF) is overlain by loess paleosol sequences. The red clay sediments in the Carpathian Basin are known from both exposures and boreholes. The age of these formations is ~3.5–0.5 Ma.

Nature of clay mineral assemblages is primarily a function of climate, essentially affected by the length of time of weathering, slope, water-rock ratio, and water chemistry. Therefore, clay mineralogy, and geochemistry are considered to be a powerful tool for interpreting weathering conditions and paleoclimate.

Elemental oxide analyses of red clays were determined by x-ray florescence (XRF), and x-ray powder diffraction (XRD) was used for mineral identification. In this study, we aim to determine the changes of clay minerals due to chemical weathering and age.

Results

The older type (Beremend Mb, age: 3.3–2.4 Ma) of the TRCF is red kaolinitic clay containing typically disordered kaolinite, mixed-layer smectite/kaolinite, smectite and little gibbsite. It was formed in the local subaerial weathering crust in warm, humid, subtropical or monsoon climate. The younger member of the TRCF (age: 2.5–1.0 Ma) contains red (or 'reddish') clay beds. It contains relatively fresh material (illite, chlorite), the weathering products are predominantly smectite and goethite formed under warm and dry climate in environmental conditions of savannah and steppe or forest steppe. The basal red clay layers of the Paks Loess Fm. and KRCF (age: 1.7–0.5 Ma) contain similar material as the underlying red clays belonging to the younger member of the TRCF. The slightly but significantly lesser degree of weathering (more illite and chlorite, less smectite) indicates cooling of the climate.

The epithermal deposits as a potential source of Critical High-Tech Metals (Ga, Ge, In, Sb)

V.A. KOVALENKER

IGEM RAS, Russia, Moscow, 119017, Staromonetny per. 35 (kva@igem.ru)

In the recent evidences arise that some so-called 'Critical High-Tech Metals' of epithermal deposits are not only of academic interest. It is primarily concerns Sb and In which minerals in a number of deposits are appreciably accumulated. The IS-type epithermal deposits of Au-Ag-base metal usually accumulated in large of ore clusters (e.g. deposits Mexico, Peru, Romania, Serbia, Slovakia) can be considered as the potential source of Sb, produced by tetrahedrite - one of the main ore minerals. Some other deposits of this type (e.g. Tayoha, Goka in Japan, Prasolovskoe in Kunashir Island, Russia, etc) are enriched with In that is presented both, in the minerals (roquesite, sakuraiite, petrukite, and unnamed Zn-Fe-Ag-Cu-Sn-In-sulfides), and of high concentrations in sphalerite as well. In gold epithermal deposits of HS-type (e.g. Chelopech, Radka in Bulgaria) presence of Indium is provided mainly by high (to 4.7 wt. %) concentration in a sphalerite, unlike to rare roquesite. These and other similar deposits contain minerals of Ge (renierite, germanite, briartite, unnamed Cu-Fe-As-Ge-minerals) and Ga (gallite), as well. It is note, that considerable (to the first wt. %) concentrations of Ga are related to sphalerite too.

Thus contrary to existing conceptions that epithermal deposits mainly produce Au, Ag, as well as in some cases also Cu, Pb, Zn, some of these deposits already should be considered as byproducts sources of scarce rare, so-called Critical High-Tech Metals, such as Sb, In, Ge and, possibly Ga. While Sb, Ge, and Ga are more characteristic for IS-type deposits, In can accumulated in both types of epithermal mineralization.

Computation of Li equilibrium isotope fractionation between minerals and aqueous solution

PIOTR M. KOWALSKI AND SANDRO JAHN

GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany (kowalski@gfz-potsdam.de)

We present an efficient *ab initio* based computational method for prediction of the equilibrium isotope fractionation factors in the high pressure and temperature materials, including fluids. The method originates in the Bigeleisen and Mayer [1] approximation and requires only the knowledge of the force constants acting on the fractionating element. An important aspect of the proposed method is the explicit modelling of materials as continuous media. This allows for investigation of the expansion and compression effects, which influence the fractionation process in high -T and -P materials. We have tested our method by computing the Li isotope fractionation factors between complex Li-bearing crystalline solids (staurolite, spodumene and micas) and aqueous solution, and by comparison of the results with the existing experimental data [2]. We show that we are able to reproduce correctly the experimental isotope fractionation sequence: staurolite-fluid-mica-spodumene and reproduce the measured values within 1 ‰.

We also have investigated the predictive power of the widely used cluster approach, in which a fluid or solid is represented by a cluster of atoms and treated as a large molecule for derivation of the vibrational spectrum - the input for the computation of the equilibrium isotope fractionation factors. We show that representation of the aqueous solution by Li $(H_2O)_n$ cluster results in the correct estimation of the isotope fractionation at low pressure (P<1GPa) but dramatically fails even on the qualitative level for higher pressures. This is because when computing materials under extreme conditions one has to account for the volume effects, such as compression or expansion, and structural changes in the fluid. These effects cannot be modelled unambiguously using the cluster approach. The proposed method accounts for these effects and predicts increase of isotope fractionation with pressure, which is more realistic and in agreement with the recent high pressure (P=8GPa) measurements for spodumene [3].

In situ $\delta^{18}O$ and Mg/Ca analyses of diagenetic and foraminiferal calcite: Implications for paleoceanographic proxy records

R. KOZDON*, D.C. KELLY, K. KITAJIMA, A. STRICKLAND AND J.W. VALLEY

WiscSIMS, Dept. of Geoscience, Univ. Wisconsin, Madison, WI 53706 USA (*correspondence: rkozdon@geology.wisc.edu)

The vast majority of planktic foraminiferal shells in deep-sea sediments are affected by various degrees of diagenesis; the effect on oxygen isotope ratios and minor/trace element abundances may be profound, but is debated. Previously, numerical models were applied to describe the oxygen isotope exchange during burial and recrystallization of deep-sea carbonate [1]. Furthermore, the partition coefficients for minor and trace element incorporation in diagenetic calcite are not clearly defined; in particular, the conversion of Mg/Ca ratios from diagenetically altered foraminiferal shells to water temperature is not straightforward.

We used an ion microprobe to analyze $\delta^{18}O$ and Mg/Ca in 200-500 μm sized diagenetic calcite crystallites cementing small aggregates of foraminiferal shells from the Early Paleogene section of ODP Site 865, Central Pacific. The $\delta^{18}O$ values of these diagenetic crystallites range from 0.1‰ to 2.2‰ [PDB] with an average of 1.2‰, and are in agreement with values predicted by numerical models [1]. The $\delta^{18}O$ of these diagenetic calcites are ~6‰ higher than that previously reported from *in situ* measurements of unaltered domains (basal areas of muricae) within planktic foraminiferal shells from the same core samples [2]. Thus, both the endmember biogenic and diagenetic $\delta^{18}O$ values are determined.

Mg/Ca of the diagenetic calcites range from ~25 to 100 mmol/mol with sharp gradients (variations of ~70 mmol/mol over 100 μm), implying complex, small-scale processes of dissolution and recrystallisation that are not reflected in the $\delta^{18}O$. The average Mg/Ca ratio of 60 mmol/mol confirms previous results from inorganic precipitation experiments [3] and is >10 times higher than the Mg/Ca of biogenic foraminiferal calcite. In contrast Mg/Ca ratios of diagenetically altered foraminiferal shells from the same core samples are not significantly elevated. Low Mg/Ca does not prove preservation of biogenetic values because the processes governing foraminiferal diagenesis differ from those that mediate the precipitation of interstitial cements.

Mineral surface charge development in mixed electrolytes

PH.A. KOZIN AND J.-F. BOILY*

Department of Chemistry, Umeå University Umeå, Sweden
(*correspondence: jean-francois.boily@chem.umu.se)

Electrolyte ions play a central role in electric double layer formation at mineral/water interfaces. The presence of these ions in aqueous solutions is in fact essential for neutralizing charges of potential-determining ions (H^+, OH^-) coordinated to mineral surfaces. The charge-neutralizing capacity of electrolyte ions is notably controlled by their size-to-charge ratio as well as their ability at forming or breaking water structures. Although much has been learned through the study of Hofmeister-type series of ions, understanding effects of co-existing ions at mineral/water interfaces is central to the elucidation of multicomponent systems representative of geochemical settings.

This study was devised to follow charge development on surfaces of α- and γ-FeOOH submicron-sized particles in mixtures of NaCl and $NaClO_4$ electrolytes. Surface charge and zeta potential data notably show that end-member NaCl and $NaClO_4$ properties, such as capacitance and shear plane position, cannot be used to predict mixed systems (Fig. 1). Experiments on FeOOH particles of varied aspect ratios moreover point to important surface structural controls on these results as well. Mixed electrolyte systems are therefore likely to develop distinct interfacial water structures and ionic distributions.

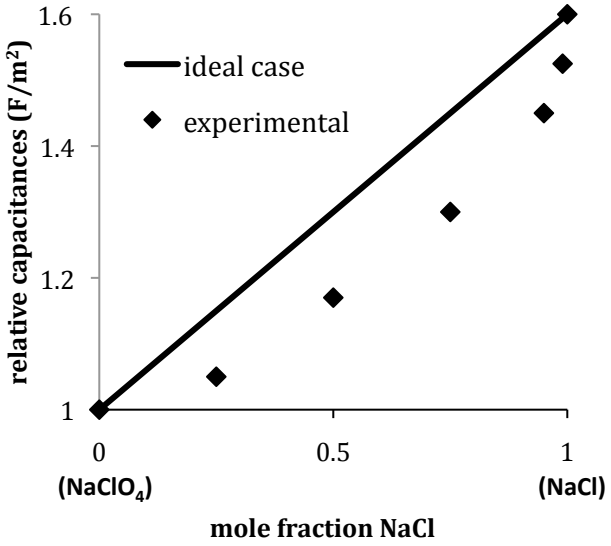

Figure 1: Relative capacitances of synthetic goethite (α-FeOOH) in mixed aqueous solutions of NaCl and $NaClO_4$. Total ionic strength 0.1M Na(Cl,ClO_4).

Comparative genome analysis of *Metallosphaera yellowstonensis* and a novel iron-oxidizing sulfolobales from Yellowstone National Park

M.A. KOZUBAL[1,*] AND W.P. INSKEEP[2]

[1]Department of Land Resources and Environmental Sciences and Thermal Biology Institute
(*correspondence: mark.kozubal@msu.montana.edu)
[2]Montana State University, Bozeman, MT 59717, USA
(binskeep@montana.edu)

Draft genomes have been completed for the iron and sulfur-oxidizing crenarchaea *Metallosphaera yellowstonensis* and Sulfolobales sp. strain MK5 (a novel member of the order Sulfolobales exhibiting only 89% 16S rRNA similarity to the closest *Sulfolobus* spp.). Both strains were obtained from a ferric iron mat within an acidic geothermal spring in YNP. This study compares the putative genes involved in iron and sulfur oxidation, heavy metal resistance, carbon fixation, and oxygen reduction between the two strains and with a diverse group of known iron-oxidizing acidophilic prokaryotes.

The draft genomes of each of these organisms contain sequences similar to putative iron-oxidizing open reading frames found in *M. sedula* and *S. tokodaii*, including a novel *fox* terminal oxidase gene cluster, a multicopper oxidase (*mco*), and the *cbs*AB-*sox*L2N operon. These genes differ considerably from the hypothesized cytochromes found in the genomes of *Acidithiobacillus ferrooxidans* and *Leptospirillum* sp. Group II. *M. yellowstonensis* and strain MK5 contain conserved heterodisulfide (*hdr*) gene clusters believed to be involved in the oxidation of elemental sulfur, as well as sequences that code for proteins involved in the oxidation of sulfide (*sqr*), sulfite (*som*), and thiosulfate oxidation (*tqo*). Multiple copies of the heme copper oxidase (HCO) subunit I were identified in both draft genomes. *M. yellowstonensis* also contains a *bd*-type terminal oxidase not found in other known members of the Sulfolobales.

M. yellowstonensis and strain MK5 are similar to other Sulfolobales in regards to genes involved in CO_2 fixation (i.e. 3-hydroxypropionate/ 4-hydroxybutyrate cycle) and heavy metal resistance; however, *M. yellowstonensis* is the only known archaeon to contain a methyl mercury lyase (*mer*B) gene. Analysis of gene sequence data suggest that, in addition to the diversity of HCO's, *M. yellowstonensis* and *Sulfolobales* strain MK5 exhibit novel mechanisms of iron oxidation, sulfur metabolism, autotrophy, and heavy metal resistance, all of which are consistent with the observed distribution of these organisms in high-temperature habitats of YNP.

Influence of different cleaning methods on seawater εNd extracted from planktonic foraminifera

STEFFANIE KRAFT[1]*, ED HATHORNE[1], MARTIN FRANK[1] AND SYEE WELDEAB[2]

[1]IFM-GEOMAR, Wischhofstr. 1-3, 24148 Kiel, Germany
[2]University of California, Santa Barbara, CA 93106-9630, USA

Seawater Nd isotope ratios extracted from foraminiferal calcite can be biased by contaminant phases, such as organic matter, ferromanganese coatings or secondary carbonates causing a shift towards bottom water signatures.

We compared two different cleaning methods to extract surface seawater neodymium isotope ratios from planktonic foraminiferal calcite. We used a modified version of the flow through method developed in [1] and a batch method following [2]. Single species samples (*G. menardii* and *G. ruber* pink) were obtained from core top sediments from the Gulf of Guinea to calibrate the method. Down core samples were investigated for paleoceanographic reconstruction of riverine input.

We tested the efficiency of two cleaning methods of the calcite by analysis of different element ratios (e.g. Al/Ca, Mn/Ca). The Al content was used as an indicator for successful clay removal whereas the Mn content reflects remaining early diagenetic coatings. Both elemental data and Nd isotope composition indicated indistinguishable levels of cleaning efficiency, whereby the batch method was less time consuming. For the different core top samples of our study clay particles had the strongest influence on the isotope and element ratios. To obtain a bottom water signature we analyzed mixed benthic foraminiferal carbonates from core top and down core samples. Additionally we compared these data with sediment leach data. The elemental ratios of the down core samples, both planktonic and benthic, showed elevated Mn/Ca ratios. To determine the origin of this contamination we analyzed the Fe/Ca and Mn/Fe ratios. The Mn/Fe ratios of planktonic and benthic samples presumably display different types of contamination.

In summary both planktonic and benthic foraminifera from the down core samples showed the same εNd values as the sediment leachates. Thus the Nd isotope compostition of the foraminiferal carbonate has most probably been overprinted by the bottom water isotope composition.

Use of sequential extractions to evaluate the mobility of heavy metals in the Huanuni basin (Bolivia)

M. KRALJ[1]*, M. MARCHESI[2], E.DINELLI[1], A. SOLER[2], S.LAFUENTE[3] AND F.CORONADO[3]

[1]CIRSA, University of Bologna, 48100 Ravenna, Italy (*correspondence: martina.kralj2@unibo.it)
[2]MAIMA, Universitat de Barcelona, Barcelona, 080028, Spain (massimo.marchesi@ub.edu)
[3]PQII, Universidad Tecnica de Oruro, Bolivia

Water and sediment quality in the Huanuni river basin is affected by acid mine drainage (AMD) from three main mines (mainly on cassiterite deposits). The area, with a population over 50.000 inhabitants approx., is located in the Oruro department, Bolivia. Concentrations of trace metals and REE were determined in stream waters, groundwater wells, suspended materials and bedload sediments. Moreover, a BCR sequential extraction (four-stage) were applied in bedload and suspended sediment in order to better constrain mobility and relative sources of trace metals and REE.

The main stream and tributaries waters are characterized by strongly acidic conditions (pH 2.9-4.5), elevated SO_4^{2-} concentrations (up to 2400 mg/L), and high metal contents (especially Fe, Zn, Cd, Ni, Pb). Hydrochemistry coupled to sequential extraction allow the characterization of the contribution of the three considered main mines.

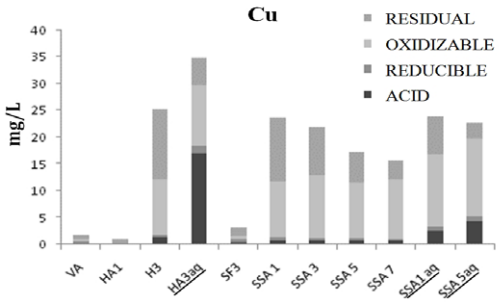

Figure 1: Cu concentration and fractionation pattern

The sequential extraction shows differences in partitioning and total concentration between suspended (in the figure indicated as codeaq, e. g HA3aq) and bedload sediment (e.g. HA3), with higher metal concentrations and exchangeable fraction in the suspended material. Cd, Zn and Cu (only Cu shown in Fig.1) seem related to the oxidizable fraction, whereas Cr and Ba with the reducible fraction.

Preliminary results suggest prioritizing remediation efforts on the suspended sediment.

Modeling of soil degradation in the Czech critical zone observatories

P. KRAM* AND J. HRUSKA

Czech Geological Survey, 11821 Prague 1, Czech Republic
(*correspondence: pavel.kram@geology.cz)

Three small catchments situated 5-7 km apart, with similar forest cover (Norway spruce), but underlain by contrasting bedrocks served as critical zone observatories (CZO). Sites are situated in the geochemically diverse Slavkov Forest [1] close to power plants with large S emissions in 1950s - mid 1990s. The MAGIC model [2] was used to simulate soil and water chemistry. Model parametrization at Lysina (LYS, area 27 ha, podzol on leucogranite) and Pluhuv Bor (PLB, 22 ha, stagnosol on serpentinite) was based on published data [3]. Parametrization at Na Zelenem (NAZ, 55 ha, cambisol on amphibolite) was based on recent sampling [4]. Simulated soil base saturation (BS) declined from 20% to 6% at LYS, from 56% to 31% at NAZ, and from 94% to 88% at PLB (Fig. 1). Contrasting soil and drainage water compositions were generated mainly by differences in chemical weathering rates of divalent base cations, Ca and Mg (0.4 keq/ha/a at LYS, 1.5 keq/ha/a at NAZ, and 2.4 keq/ha/a at PLB).

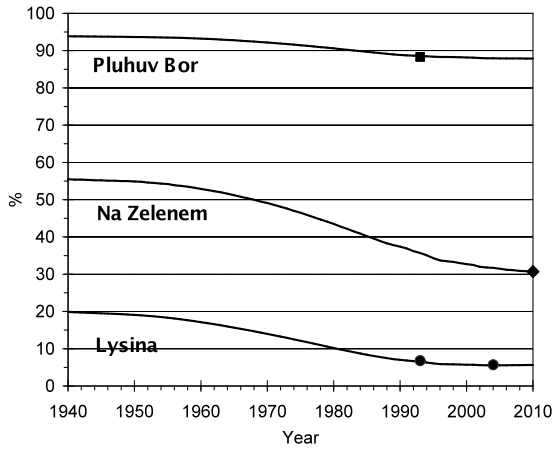

Figure 1: Simulated (lines) and measured (dots) soil base saturation at three Czech CZO in the Slavkov Forest.

Plant-microbe interactions in Cd-contaminated soils - Do Fe(III)-reducing bacteria influence the accumulation of Cd in the metal-hyperaccumulating plant *Arabidosis halleri*?

U. KRÄMER[1]*, E.M. MUEHE[2] AND A. KAPPLER[2]

[1]Plant Physiology, University of Bochum
(*correspondence: Ute.Kraemer@ruhr-uni-bochum.de)
[2]Geomicrobiology, University of Tuebingen

Soils worldwide have increasingly been contaminated with industrial waste metals, such as cadmium, which may subsequently enter the food chain through plants. These toxic metals can have dramatic effects on human and environmental health. Therefore, there is a need for the development and application of new techniques to efficiently remediate contaminated soils. In the present study, we combined phytoremediation and (microbially) enhanced natural attenuation to determine whether a more time- and cost-efficient removal of cadmium from contaminated sites can be achieved. In plant-microbe-soil microcosms, geochemical and microbial parameters are determined to trace the microbial release of cadmium from Cd-bearing Fe (III) minerals by the natural microbial community of the soil or by an isolated Cd-tolerant Fe (III)-reducing bacterium. Additionally, cadmium uptake and accumulation by the metallophyte Cd hyperaccumulator plant *Arabidopsis halleri* in the presence of these bacteria is quantified. Cadmium is made phytoavailable to the plant by the stimulation of naturally occurring Fe (III)-reducing bacteria which release cadmium from Fe (III) (hydr)oxides through reductive dissolution. Subsequently, the aqueous cadmium is actively taken up by the plant *A. halleri* and accumulated in the above ground tissue. By harvesting the plant regularly, an efficient removal of cadmium from contaminated sites may be achieved.

Calcium carbonate precipitation by the marine cyanobacterium *Trichodesmium*

SVEN A. KRANZ*, DIETER WOLF-GLADROW, GERNOT NEHRKE, GERALD LANGER AND BJÖRN ROST

Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany (*correspondence: Sven.kranz@awi.de, Dieter.Wolf-Gladrow@awi.de, Gernot.Nehrke@awi.de, Gerald.Langer@awi.de, Bjoern.Rost@awi.de)

Cyanobacteria are important primary producers of the contemporary oceans and have affected global biogeochemical cycles over geological timescales. The diazotrophic *Trichodesmium spp*. are known for their large-scale blooms and substantial input of 'reactive nitrogen' to the oligotrophic subtropical and tropical areas. In this laboratory study, we monitored the buildup of biomass and concomitant shift in seawater carbonate chemistry over the course of a *Trichodesmium* bloom under different phosphorus (P) availability. During exponential growth, dissolved inorganic carbon (DIC) decreased while pH increased until maximum cell densities were reached. Once P became depleted, DIC decreased even further and total alkalinity (TA) dropped, accompanied by precipitation of aragonite. Under P-replete conditions, DIC increased and TA remained constant in the post bloom phase while no aragonite was formed. A diffusion-reaction model was employed to estimate changes in carbonate chemistry of the diffusive boundary layer of an aggregate of *Trichodesmium*. This study demonstrates that *Trichodesmium* can induce precipitation of aragonite from seawater and further provides possible explanations about underlying mechanisms.

Parental melts of Avachinsky volcano (Kamchatka) recorded in melt inclusions

S. KRASHENINNIKOV[1]* AND M. PORTNYAGIN[1,2]

[1]V.I.Vernadsky Institute of Geochemistry and Analytical Chemistry, ul. Kosygina 19, Moscow 119991, Russia (*correspondence: spkrasheninnikov@mail.ru)

[2]Leibniz Institute of Marine Research, IFM-GEOMAR, Wischhofstrasse. 1-3, D-24148 Kiel, Germany

We studied ca. 700 melt inclusions (MIs) in 6 major minerals (Ol, Opx, Cpx, Pl, Amph and Mt) from 61 Holocene andesitic and basaltic andesites tephra of Avachinsky volcano erupted during the last 10 ^{14}C ky.

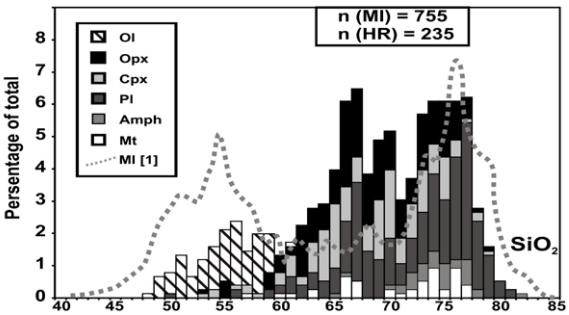

Figure 1: MIs compositions in Avachinsky tephra depending on host mineral phase. Dotted line – compilation of MIs from island-arc rocks after [1].

MIs have low-K to middle-K basaltic to rhyolitic compositions (fig. 1). The continuum of MIs can be well explained by fractional crystallization from parental basaltic melts. No apparent bimodality is observed in the dataset in comparison with [1, 2]. Melts of intermediate compositions are abundant and commonly found in minerals from basaltic andesites. In comparison with the host rocks, MIs have systematically more silicic compositions, and this difference increases with increasing SiO_2 content in the host rocks. Dacitic and rhyolitic MIs predominate in our dataset due to the prelevance of basaltic andesites and andesites on Avachinsky volcano.

These results show that the previously reported bimodality of MIs in island-arc rocks [1, 2] may result from unrepresentative sampling and does not reflect true volume proportions of melts with different SiO_2 content in island-arcs.

Mantle peridotites from the Stalemate F.Z. (NW Pacific)

E. KRASNOVA[1], M. PORTNYAGIN[1,2], S. SILANTYEV[1], R. WERNER[2] AND K. HOERNLE[2]

[1]V.I.Vernadsky Institute of Geochemistry and Analytical Chemistry, Kosygin St. 19, 119991 Moscow, Russia
[2]Leibniz Institute of Marine Sciences, IFM-GEOMAR, Wischhofstr. 1-3, 24114 Kiel, Germany

The Stalemate Fracture Zone (SFZ) is a 500 km long SE-NW trending transverse ridge between the northernmost Emperor Seamounts and the Aleutian Trench, which originated by flexural uplift of Cretaceous (?) oceanic lithosphere along a transform fault at the Kula-Pacific plate boundary [1].

The lithosphere cropping out along the NW flank of the SVZ was sampled by dredging during the R/V Sonne cruise SO201-KALMAR Leg 1b. Strongly altered mantle rocks ranging from pyroxene-rich lherzolites and pyroxene-poor dunites were obtained at the station DR37 at the northern SVZ bend. The compositions of primary minerals (*Cpx*, *Opx*, *Sp*) change systematically from lherzolites to dunites. *Sp* in lherzolites has higher Mg#, NiO, lower Cr#, Fe^{3+}# and TiO_2 (Mg#=0.65-0.68, NiO=0.26-0.34 wt%, Cr#=0.26-0.33, Fe^{3+}#=0.021-0.030, TiO_2=0.04-0.09 wt%) than spinel in dunites (Mg#=0.56-0.64, Cr#=0.38-0.43, TiO_2=0.19-0.28 wt%, NiO=0.19-0.26%, Fe^{3+}#=0.027-0.043). *Cpx* in lherzolites is moderately Mg- and Ni-rich, Ti- and Na-poor, has lower Cr# (Mg#=91.7-92.4, Cr#=0.12-0.16, TiO_2=0.06-0.15 wt%, Na_2O=0.19-0.41 wt%, NiO=0.06-0.09 wt%) and is extremely MREE- and Zr-depleted (C1-normalized Yb_n=4.0-5.6, Sm_n/Yb_n=0.05-0.14, Zr_n/Y_n=0.001-0.009) compared to clinopyroxenes analyzed in a sample of dunite DR37-3 (Mg#=93.7, Cr#=0.16, TiO_2=0.23wt%, Na_2O=0.85wt%, NiO=0.06wt%, Yb_n=5.7-7.4, Sm_n/Yb_n=0.22-0.27, Zr_n/Y_n=0.22). Some *Cpx* from lherzolites have flattened or strongly U-shaped patterns of REE (Sm_n/Yb_n=0.11-0.49, La_n/Sm_n=0.36-3.6) though their major element composition is indistinguishable from the more LREE depleted *Cpx*.

The variations of *Cpx* and *Sp* compositions can be explained by the two-stage process [2]: 1) near fractional melting of depleted mantle to 10-12%, 2) interaction of the residual lherzolite with N-MORB-like melts to form dunites. The protolith of lherzolites and dunites dredged from the SFZ can thus represent disintegrated parts of shallow oceanic mantle variably modified by melt percolation.

Unusual apatite crystals and pegmatites with Rare Earth Elements tetrad effect

STEPAN KREJSEK[1] AND JINRICH KYNICKY[2]

[1]Masaryk University, Faculty of science, 611 37 Brno (krejsek.stepan@seznam.cz)
[2]Mendel University in Brno, 613 00 Brno, Czech Republic (jindrich.kynicky@mendelu.cz)

Dolní Bory pegmatite deposit in the Czech Republic, display well developed zonality and different concentrations of rare earth elements with chondrite-normalized patterns that show a clear convex tetrad effect. Similar patterns and zonality exhibit also apatite crystals (Fig. 1). The Y/Ho and Sr/Eu ratios and very high Y and U content of the apatite samples correspond with evolved fractionation relative to the corresponding chondritic values. Based on the La/Lu, Sr/Eu and Y/Ho ratios of apatite, the apatite zones can be divided into two main groups which reflect two main stages of magma-fluid evolution, namely, a magmatic and a magmatic hydrothermal transition stage.

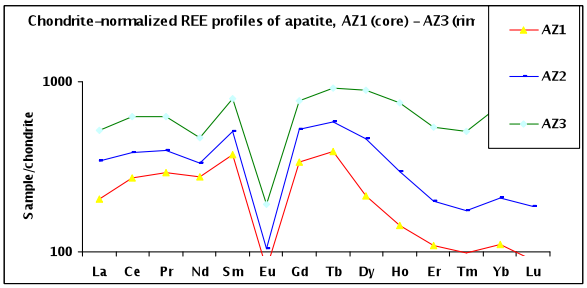

Figure 1: Chondrite-normalized REE profiles (apatite).

Interaction of a most evolved parental fluid with already formed pegmatite matrix and apatite probably produced the strongest REE tetrad effect in the youngest white zones of apatite rims (AZ3).

Deciphering the early fossil record of cyanobacterial mats based on their mode of mineralization

B. KREMER[1], J. KAZMIERCZAK[1] AND S. KEMPE[2]

[1]Institute of Paleobiology, Polish Academy of Sciences, Twarda 51/55, 00-818 Warsaw, Poland (kremer@twarda.pan.pl)
[2]Institut für Angewandte Geowissenschaften, Technische Universität Darmstadt, 64287 Darmstadt, Germany

Archean traces of life are vague and confusing due to poor preservation. Identifying traces of life in early geological record requires understanding the mode of fossil formation. Carbonaceous matter, although abundant in many Archean deposits, does not *per se* prove presence of life. Key to decipher earliest life forms could be their mode of mineralization. Etching of Neoarchean carbonates (Nauga Fm, South Africa) revealed coccoid cyanobacterial mats preserved as web-like structures composed of pits, mineralized with $CaCO_3$, and walls permineralized with Al-Fe-Mg-K silicates [1, 2].

Similarly permineralized web-like structures commonly occur in modern coccoid cyanobacterial mats. Studies on such mats from Lake Van (Turkey), Niuafo'ou Island (Tonga), and Satonda (Indonesia) showed that after death the mats undergo mineralization. The type of mineral phase(s) and the rate of mineralization depend chiefly on geochemical conditions within the degraded biomass. First to decompose is the cellular content and the thin mucilage sheaths surrounding individual cells and smaller groups of cells. Therefore cells are only exceptionally preserved. The most durable parts of the mat are the thicker outer web-like mucilagenous sheaths, which due to early permineralization with $CaCO_3$ and silicates, are fossilized.

Early diagenetic calcification and silicatization is associated with post mortem activity of heterotrophic bacteria. Bacteriolysis liberates cations complexed during cyanobacterial lifetime in their EPS. This process enhances mineral precipitation in the bacterially degraded mucilage sheaths and preserves their web-like texture. Morphology and mineral composition of Neoarchean web-like structures resemble those of modern mineralized cyanobacterial mats and can therefore be regarded as biosignatures of benthic coccoid cyanobacterial mats.

Density functional study of uranyl adsorption on solvated surfaces of clay minerals

ALENA KREMLEVA, SVEN KRÜGER AND NOTKER RÖSCH

Department Chemie & Catalysis Research Center, Technische Universität München, 85748 Garching, Germany (roesch@mytum.de)

Actinide adsorption on clay mineral surfaces represents an important retardation mechanism for these metal ions. With the topical issue of safe disposal of radioactive waste in mind, it is important to gain comprehensive knowledge of the environmental chemistry of radioactive elements and their compounds, where the interaction of actinides with mineral surfaces in general plays an important role. Various experimental techniques are being used to examine these issues, and these results are favorably complemented by computational chemistry studies.

We explored uranyl adsorption on solvated clay minerals with the plane-wave based projector augmented wave approach as implemented in the program VASP. Neutral 1:1 layered kaolinite was considered as a simple model clay mineral. We focused on (001) basal aluminol and (010) edge surfaces. Solvation plays a crucial role when modeling the latter type of surfaces. These effects were approximated by including a mono- or bi-layer of adsorbed water in the quantum mechanical models.

We mainly explored bidentate inner-sphere adsorption complexes on deprotonated sites representing neutral or slightly higher pH. Uranyl adsorption on kaolinite edge surfaces commonly leads to a deprotonation of aqua ligands of uranyl, resulting in monohydroxide as adsorbate. Aluminol adsorption sites are preferable for uranyl adsorption compared to mixed aluminol-silanol sites. The geometry of adsorption complexes is compared to available experimental results. Overall, complex formation energies suggest that several adsorbed species may simultaneously be present at kaolinite surfaces.

Speciation and micro-scale spatial distribution of As in a mining-affected river floodplain

R. KRETZSCHMAR[1]*, P. MANDALIEV[1], C. MIKUTTA[1], K. BARMETTLER[1] AND T. KOTSEV[2]

[1]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland
(*correspondence: kretzschmar@env.ethz.ch)
[2]Institute of Geography, Bulgarian Academy of Sciences, Sofia, Bulgaria

Many rivers worldwide are polluted with trace elements originating from past or present mining. Even after closure and remediation of the mines, highly contaminated floodplains often remain as a source of contaminant release into river and ground water. Arsenic (As) has a high potential for mobilization unter reducing conditions, e.g. during soil flooding, but this strongly depends on the speciation of As among other factors.

We studied the speciation and micro-scale distribution of As in alluvial soils and sediments along the river Ogosta in NW-Bulgaria. Ogosta, an important tributary to the lower Danube river, was strongly affected by mining of Au, Fe, and Pb/Ag between 1951 and 1999.

Soil samples were collected along transects ranging from the river bed through the lower and upper floodplains, taking special precautions to minimize oxidation. All samples were analyzed for soil pH, mineralogy, elemental composition, and oxalate-extractable As and Fe. Arsenic speciation was investigated by As K-edge X-ray absorption spectroscopy (XAS). Thin sections of undisturbed soil were prepared and examined by micro-X-ray fluorescence (μ-XRF) spectrometry and μ-XAS. Additionally, selected soils were size-fractionated to explore the elemental composition, mineralogy, and As speciation as a function of particle size.

Soil As concentrations in the floodplain ranged between 40 and 37, 400 mg kg^{-1}. Highly As-contaminated soils were also enriched in Fe, Mn, S, Pb, Sb, and other trace elements. Bulk and micro-XAS, combined with oxalate-extractions, revealed that most As was present as As (V) sorbed to poorly-crystalline Fe (III)-oxyhydroxides, with smaller amounts of As bound in arsenopyrite. The fine particle size fractions <5 and 5-20 μm were strongly enriched in As (up to 93, 000 mg kg^{-1}) as compared to the corresponding bulk soils. These size separates contained only traces of arsenopyrite and exhibited very high oxalate-extractable As and Fe contents, reaching molar Fe/As ratios of <5. Our results suggest that As and Fe in these soils should be readily bioavailable for microbial reduction upon soil flooding.

Groundwater Recharge in the Santo Tomás Valley, Baja California, México

T. KRETZSCHMAR* AND W. THOMAS

CICESE, Ensenada, Mexico
(*correspondence: tkretzsc@cicese.mx)

Overview

The purpose of this study is to better understand Mountain Front Rrecharge (MFR) and Mountain Block Recharge (MBR) in a mountainous watershed in Baja California by creating a detailed fracture-trace map of the Santo Tomas basin along with stable isotope (O, H) and chemical analyses of spring water (thermal and cold), groundwater, and stream runoff throughout the study area.

This study focused on the topography, geology, vegetation and hydrologic characteristics of the eastern section of the Santo Tomas valley, located approximately 50 km southeast of Ensenada. Each method used in study was completed with the intention to integrate all data to better understand MBR in the study area.

Methods

Models of elevation, slope, lithology, vegetation, and fractures within the 300 km^2 watershed were created to help characterize the basin. Images were generated in ArcMap, using DEM data, field observations, and LandSat satellite imagery. Each visual was examined individually as well as in conjunction with other physical and chemical parameters to better understand the dynamic of the watershed.

Results

The stable isotope ($\delta^{18}O$ and $\delta^{2}H$) data show two distinct types of spring water within the watershed representing local and regional flow paths. Thermal springs, display a -1.9‰ $\delta^{18}O$ depletion compared to the other spring water, indicativing a higher elevations recharge or older waters. This distinct isotopic signal was found 15 km downstream in the alluvial aquifer, showing that a significant amount of water is recharging the basin aquifer via the mountain block along this flow regime. The thermal system and most cold-water springs surface along active faults, which appear to transmit more water than the undifferentiated fractures. An isotopic distinction can be seen between the hot and cold springs within the watershed despite that all the spring samples are taken between 400 - 550 m elevation.

Heavy minerals in the Kafue River sediments, Copperbelt Mining District, Zambia: Indicators of industrial contamination

B. KŘÍBEK[1]*, F. VESELOVSKÝ[1], I. KNÉSL[1] O. SRACEK[2], M. MIHALJEVIČ[3] AND V. ETTLER[3]

[1]Czech Geol. Survey, Geologická 6, 152 00 Prague 5, Czech Republic (*correspondence: bohdan.kribek@geology.cz)
[2]University Palacky, 17. listopadu 12, 771 46 Olomouc, Czech Republic
[3]Charles University, Faculty of Science, Albertov 6, 128 43 Prague 2, Czech Republic

Sediments of the Kafue River that drains the whole of the Copperbelt region were found to contain up to 1 wt% Cu, 0.1 wt% Co, 1.3 wt.% Mn and a number of other toxic elements like Pb, As and Hg. The study of heavy minerals in both types of sediments was intended to identify the sources of contamination. Heavy minerals found in uncontaminated sediments of this river comprise mostly of ilmenite, limonite, rutile, amphibole and tourmaline, while apatite, clinochlore epidote and zircon are minor. On the other hand, the contaminated sediments contain, besides rock-rorming minerals, chalcopyrite, pyrite, bornite, malachite and azurite the concentrations of which vary considerably. Chalcopyrite and pyrite evidently come from leaks of tailings still in operation in which the sulfides were not yet oxidized. Washing out and erosion of old flotation tailings ponds are responsible for enhanced contents of malachite, azurite, bornite, copper metal and chrysocolla together with limonite with high contents of copper and other elements in the contaminated Kafue River sediments. Particles of slag rich in magnetite and also particles of intermediate solid solution of Cu-Fe-S (ISS) affected by various degree of oxidation were found in sediments close to the smelters. The identification of heavy metals and their relative proportions enabled to assess the extent of contamination of stream sediments and also the character of individual sources of contamination. No extensive dissolution of copper and cobalt minerals in stream sediments takes place due to the neutral or slightly alcaline character of surface water in the area. However, occassional accidents in chemical plants processing copper and cobalt concentrate (acid spikes) result in short term but sharp increase in acidification of surface water (pH 3-4) which consequently leads to sharp increase in copper contents in these water. The study originated within the UNESCO/IGCP 594 Project 'The impact of ore mining and processing on the environment and human health in Africa'.

Combining phase petrology, reaction balancing and partial pseudosections – Theory and examples

L.M. KRIEGSMAN[1]* AND A.M. ÁLVAREZ-VALERO[1,2]

[1]NCB Naturalis, Leiden, The Netherlands (*correspondence: Leo.Kriegsman@ncbnaturalis.nl)
[2]Dept. of Earth, Atmospheric and Planetary Sciences, MIT

Both classical phase petrology and phase diagram modelling by pseudosections have their strengths and weaknesses. Phase petrology is well suited for generic P-T grids and phase diagrams in relatively simple chemical systems or subsystems (e.g. KFASH in metapelites), but is hard to use in more complex systems, unless pure phases exist from which to project. Pseudosections [1, 2] are complementary to grids in portraying all reactions that may potentially operate in a given bulk composition as a function of P and T. Both petrological tools assume equilibrium conditions that may not always be appropriate. Reaction overstepping, re-entering of inclusions into a reacting assemblage during host breakdown, kinetic barriers, etc., all highlight the local absence of equilibrium or the operation of patchy equilibrium [3]. In addition, pseudosections assume constant bulk chemistry, which may be invalid during melt loss [2] and when certain phases (e.g. inclusions) or cores of zoned minerals do not participate in a reaction [3].

Hence, deriving P-T-t paths is a subtle process that requires a multi-faceted approach combining textural analysis, mineral chemistry, reaction balancing [4], qualitative pseudosections using model reactions [5], quantitative P–T pseudosections for selected microdomains, and thermobarometry on selected textures apparently close to equilibrium. In addition, P-T vectors may be constrained by modelling of reaction line slopes [6], a technique that merits far more attention and use. Examples are given from migmatites (Finland), granulites (Sri Lanka) and xenoliths (Spain) to highlight this approach.

Trace and REE geochemistry of the Angola Basin sediments

E. KRIKUN, M. RIMSKAYA-KORSAKOVA AND A. DUBININ

P.P. Shirshov Institute of Oceanology RAS, Moscow, Russia (evgenia.krikun@gmail.com)

We studied chemical composition of sediment core samples collected from the Angola Basin (23°30´S, 4°17´W, 4990 m depth). Oxidized pelagic foraminifera oozes (60-98 wt% carbonate) represent the recovered core (length 210 cm). Mn and reactive Fe concentrations range from 0.1 to 0.3 % and decrease with $CaCO_3$ increase. The contents of Co, Ni, Mo and U along the core correlate with Mn concentrations due to scavenging on Mn-oxyhydroxides. Concentrations of REE decrease with $CaCO_3$ content increase. The values of Ce-anomaly range from negative in carbonate- rich sediments to positive in the carbonate-depleted layers. The concentrations of REE and Th correlate with reactive Fe content ($r > 0.9$). REE pattern indicates its hydrogenous origin.

Using negative correlation of each rare earth and carbonate concentration ($r>-0.9$), we calculated REE compositions in 100% $CaCO_3$. The latter is consistent with REEs in Atlantic ocean foraminifera from Palmer [1]. REE pattern of red clay component was obtained by extrapolation to 0% $CaCO_3$, and coincide with mean composition of pelagic red clays from Brazil Basin located symmetrically across the MAR. The REE are originated from the two main sources: biogenic carbonate and red clay component, and could be defined with variable content of these constituents. Biogenic carbonate is characterized with Ce depletion and low concentrations of REE, red clay component has positive Ce-anomaly and higher concentrations of trivalent REE.

Volatiles in Siberian flood basalts: Melt inclusions study

N.A. KRIVOLUTSKAYA[1]*, A.V. SOBOLEV[1,2,3], N.M. SVIRSKAYA[1], I.K. NIKOGOSIAN[1], S.G. SIMAKIN[1] AND D.V. KUZMIN[3]

[1]Vernadsky Institute of Geochemistry, RAS, 119991 Moscow, Russia (*correspondence: nakriv@mail.ru)

[2]ISTerre, University J. Fourier BP 53, 38041 Grenoble Cedex 9, France (alexander.sobolev@ujf-grenoble.fr)

[3]Max Planck Institute for Chemistry, Postfach 3060, 55020 Mainz, Germany

We report major, trace and volatile elements (Cl, F, B, S, H_2O) contents in melt inclusions in clinopyroxene phenocrysts from the Southern Maslovsky intrusion (Norilsk region) studied by EPMA, SIMS and LA-ICPMS technics. Modelling by PETROLOG software [1, 2] suggests that melts were saturated by both olivine (Fo 76-68) and CPX (Mg#78-69) and crystallized at shallow depth (below 100 MPa pressure) in the temperature range 1130-1080ºC. Incompatible elements patterns of melts are similar to typical Siberian flood basalt (La/Sm_n=1.4, Nb/La_n=0.6, Gd/Yb_n=1.1).

Melts are undersaturated by sulphur and have S/Dy=200, (150-300), markedly lower than for MORBs and OIBs (250-300, [3]). Water contents are variable (H_2O=0.08-0.45wt%) suggesting low pressure degasing of melt. The highest concentrations yields H_2O/Ce over 160, close to the typical range of OIB and MORB [3]. Chlorine and boron show significant excesses yielding Cl/K= 0.29, (0.24-0.40); B/K= $0.9*10^{-3}$, ($0.6\text{-}1.2*10^{-3}$), which are few times higher than those for typical MORB and OIB [3]. Contents of fluorine F/Ti= 0.045 (0.021-0.056) and F/Nd= 29 (18-38) are also higher than commonly found in MORB and OIB [3].

The recovered accesses of Cl and B of SFB melt are very uncommon for intraplate mantle derived magmas. But they are similar to those of Gudchikhinskaya suit (one of the lower units of Norilsk volcanic section) parental melt, which was proposed as a pyroxenite-derived end-member component of SFB originated from recycled oceanic crust [4]. This may suggest that the recycled oceanic crust was one of the sources of excessive Cl and B in SFB in general. The other source could be the actual continental crust. Anyway, data suggest significant emission of Cl to atmosphere at the time close to P-T environmental crisis.

Murataite-pyrochlore complex oxide series for actinide immobilization: Nanoscale structure and complexity

SERGEY V. KRIVOVICHEV[1]*, VADIM S. URUSOV[2], SERGEY V. YUDINTSEV[3], ANNA S. PAKHOMOVA[1] AND SERGEY V. STEFANOVSKY[4]

[1]Dept. Crystallography, St. Petersburg State Univ., University Emb. 7/9, 199034 St. Petersburg, Russia

Synthetic murataite, an analogue of a rare titanate mineral, was identified in Synroc ceramic designed for immobilization of high-level nuclear waste [1, 2]. Five volume percent of this phase accumulated about 40% of the total uranium present in the sample. Laverov *et al*. [3] discovered different murataite varieties, *Mu*-3, 5, 7, and 8, where numbers correspond to the multiplicity of murataite *a* cubic unit cell parameter with respect to the same parameter of the fluorite unit cell. Experimental studies demonstrated that the crystallization sequence of phases in the U (Pu)-Zr-Mn-Fe-Ti-Al-O complex system can be expressed as: Pyrochlore - *Mu*-7 - *Mu*-5 - *Mu*-8 - *Mu*-3. In murataite ceramic, typical grains contain pyrochlore and *Mu*-5 at the core surrounded by *Mu*-8 and *Mu*-3 phases. Since the most actinide-bearing phases are encapsulated by low-actinide varieties, this creates an additional barrier for actinide leaching and increases chemical durability of murataite ceramics. Recently, we have been able to structurally characterize *Mu*-3, 5 and 8 varieties of synthetic murataite and to demonstrate their polysomatic nature, in agreement with the earlier proposal by Urusov *et al*. [4]. It turns out that members of the murataite-pyrochlore series are the result of nanoscale mixing of murataite and pyrochlore structures. For instance, the structure of Mu-5 [5] is a complex framework consisting of pyrochlore unit cells uniformly distributed in murataite-type recombined structure. The structure of Mu-8 contains alternating murataite and pyrochlore unit cell modules separated by transitional structure.

The lamprophyre problem: Return to the roots

LUKÁŠ KRMÍČEK

Institute of Geological Sciences, Masaryk University, Brno, CZ-61137, Czech Rep (l.krmicek@gmail.com)

The term ‘lamprophyre’ has been introduced in 1874 by Gümbel for Variscan mafic post-collisional dykes from the Bohemian Massif characterized by phenocrysts of mafic mica embedded in a feldspar groundmass (minette and kersantite type). In analogy to these, Rosenbusch in 1887 added the amphibole-bearing types such as vogesite and camptonite, from which spessartite was subsequently distinguished. Unfortunately, during the 20th century, petrologists enlarged this ill-understood group by incorporating different rocks containing mafic phenocrysts, such as kimberlites, lamproites, nepheline-, leucite- and melilite-bearing rocks. This resulted in a single large supergroup of polygenetic rocks termed the ‘lamprophyre clan’. In contrast, recent understanding of lamprophyres provides a sound basis for rejecting such a variable group of polygenetic origin [1, 2]. As true lamprophyres, we can now recognize five original types (end-members) among which there are continuous transitions: minette, kersantite, vogesite, spessartite and partly camptonite (in the original sense). It is important to note, that not every rock labelled as a true lamprophyre falls into this group. For example a ‘peralkaline minette’ is not a lamprophyre but very probably corresponds to a lamproite [c. f. 3, 4].

Since the term camptonite is usually used for an alkaline ‘lamprophyre’ variety (in fact volatile-rich basalt), I recommend not to use it in context with the true lamprophyres. Lamprophyre varieties containing kaersutitic amphibole can be easily described as titanospessartite or titanovogesite, respectively (Table 1). Moreover, the last proposed variety fills the gap in the current nomenclature.

Phlogopite/matrix, Cpx/matrix and Cpx/phlogopite trace element partitioning in true lamprophyres

M. KRMÍČKOVÁ[1]*, L. KRMÍČEK[2], V. KANICKÝ[3], T. VACULOVIČ[3] AND M. GALIOVÁ[3]

[1]Institute of Geotechnics, Brno University of Technology, Brno, CZ-602 00, Czech Rep (*correspondence: m.halavinova@gmail.com)
[2]Institute of Geological Sciences, Masaryk University, Brno, CZ-61137, Czech Rep
[3]Department of Chemistry, Masaryk University, Brno, CZ-61137, Czech Rep

Introduction

Partition coefficients for true lamprophyres (i.e. in their original sense [1]) are poorly known. Therefore, mineral/matrix and mineral/mineral partition coefficients were determined by LA-ICP-MS for clinopyroxene (Cpx) and phlogopite crystals from a Variscan calc-alkaline (agpaitic index = 0, 6) lamprophyre of minette-type from the Bohemian Massif (Křížanovice locality, Bohemicum). Quantification was performed using the glass reference material NIST SRM 612 as external standard, and microprobe analyses of Si as internal standard.

Results

Cpx/matrix partition coefficients (D) for 23 trace elements have values ~1 (0.9-1.1) for the HREE only. This suggest that HREE can be concentrated in clinopyroxene during crystallization from lamprophyre melts [2]. The coefficients differ significantly from published D-values for HREE (~0.3-0.4) in clinopyroxenes growing from 'lamprophyric' melt of alkaline composition [3].

In phlogopite, only 14 elements had concentrations above detection limit. Phlogopite/matrix partition coefficients have average values higher than 1 for Ba (D = 1.1), Rb (D = 1.7) and Ti (D = 1.5). On the other hand, D-values for LREE are extremely low (D < 0.02) and it was not possible to determine D-values for the majority of HREE.

During simultaneous crystallization of clinopyroxene and phlogopite phenocrysts, Th, Zr, Hf and REE are preferentially partitioned into clinopyroxene. The main reason for the behaviour of these elements may be found in the lack of a suitable crystallographic site in the phlogopite structure [5].

Chronology of climate archives – A never-ending story

BERND KROMER

Curt-Engelhorn Centre for Archaeometry, C 4,8, D-68159 Mannheim, (bernd.kromer@cez-archeometrie.de)

Accurate dating of climate archives is essential for the reconstruction of past climate and to infer rates of climate change. Of special interest is the time range of the last Glacial and the transition into the Holocene, during which strong climate fluctuations are evident. Chronology of these archives is based on a number of dating systems, such as radiocarbon, U/Th and layer counting. Each clock has its strengths and limitations, and in the past decade important progress has been achieved to resolve inconsistencies within a dating method and between the methods. This keynote lecture will focus on this fascinating venture and the current status of establishing firm and consistent chronologies in the past 50.000 years.

O-isotope compositions of ferroan olivine in Ngawi (LL3–6) breccia

A.N. KROT[1]*, K. NAGASHIMA[1] AND M.I.PETAEV[2]

[1]University of Hawai'i, USA (sasha@higp.hawaii.edu)
[2]Harvard University, USA (mpetaev@fas.harvard.edu)

Ferroan olivine (*fa*, Fa_{50-100}) is one of the major minerals in matrices of unequilibrated ordinary (H, L, LL) and metamorphosed carbonaceous (CV, CK, CO) chondrites. The origin of matrix *fa* is not understood: high-T (>1000°C) gas-solid condensation under highly oxidizing conditions in the protoplanetary disk [1–3] and low-T (<300°C) formation during fluid-assisted thermal metamorphism on the chondrite parent bodies [4, 5] are being discussed. Here we report on the mineralogy and O-isotope compositions of secondary *fa* (Fa_{50-99}) in LL3 clasts of the Ngawi LL3–6 breccia. The *fa* coexists with phyllosilicates, replaces magnetite+sulfide nodules in chondrules and matrix and forms veins crosscutting fine-grained rims around chondrules. On a three-isotope diagram, oxygen compositions of *fa* measured *in situ* using the UH Cameca ims-1280 plot along mass-dependent fractionation line with $\Delta^{17}O$ value of 4.2±1.4‰ (2σ), well above the compositions of phenocrysts in LL3 chondrules [7]. The similar $\Delta^{17}O$ values, 4.9±1.9‰ (2σ), were reported for magnetite grains in Ngawi and Semarkona (LL3.0) [1]. We conclude that Ngawi *fa* formed *in situ* in the presence of aqueous solutions.

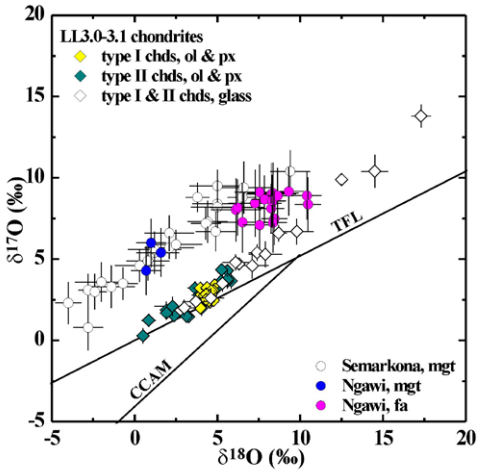

Figure 1: O-isotope compositions of the ferroan olivine [this study], magnetite [6], and phenocrysts and interstitial glass in chondrules [7] from LL3 chondrites.

Late Cretaceous alnöite from the Delitzsch (Germany) carbonatite – ultramafic complex

J.C. KRÜGER, R.L. ROMER AND H. KÄMPF

Deutsches GeoForschungsZentrum, 14473 Potsdam, Germany (jekruege@uni-potsdam.de, romer@gfz-potsdam.de kaempf@gfz-potsdam.de)

The Delitzsch complex consists of late Cretaceous ultramafic lamprophyres, alnöites and carbonatitic rocks, which are covered by up to 100 m thick sequences of Tertiary sedimentary rocks. Lamprophyre, alnöite and carbonatite dikes and diatrems are emplaced in Paleozoic to lower Permian volcanic and sedimentary rocks. The size and geometry of the Delitzsch complex is not well known, but exploration drilling has documented lamprophyres and carbonatites in an area of 150 km² [1]. The complex includes a diversity of magmatic and subvolcanic rocks, ranging from beforsites, rauhaugites, and alvikites for the carbonatitic rocks and aillikites, monchiquites, alkali picrites, and alnöites. Contact relations and distribution of xenolithic material indicates that phases of carbonatite and ultramafic lamprophyre magmatism overlapped.

The alnöite dike/diatrem at the northern flank of this complex is highly heterogenous with abundant wallrock xenoliths and reaction zones between alnöite and xenolithic material. The xenolithic material was incorperated during ascent and emplacement of the alnöite. Fresh alnöites have abundant melilithe, minor olivine, phlogopite, and pyroxene in a porphyritic texture. Acessory minerals are perovskite, apatite, chromian spinel, and magnetite. They are affected by post magmatic chloritization of olivine and especially pyroxene. The alnöites are relatively high in SiO_2 (~35%) and have high MgO, Cr, Ni, and Sr contents. The rocks have unradiogenic Sr and positive ε_{Nd} (T) values. Their Sr, Nd, and Pb isotopic compositions fall between HIMU and EM1 mantle components.

Xenolith-bearing alnöites show seperated areas with rounded quartz and K-feldspar. These texturally distinguished types are also geochemically and isotopically distinctive, with REE pattern similar to average crust and crustal Sr, Nd, and Pb isotope signatures. Xenolith-bearing alnöites show texturally and geochemically marked transition zones with selective enrichment of heavy REE, not attainable by simple assimilation of xenolithic material in the alnöite.

Microbial conversion of oil, coal and shales into methane – A future energy resource

M. KRÜGER[1]*, F. GRÜNDGER[1], M. SIEGERT[1], H.-M. SCHULZ[2] AND H.-H. RICHNOW[3]

[1]BGR, Hannover, Germany (*correspondence: Martin.Krueger@bgr.de)
[2]GFZ, Potsdam, Germany
[3]UFZ, Leipzig, Germany

Since decades it is known from stable isotope studies that large amounts of biogenic methane are formed in oil reservoirs. The investigation of this biodegradation process and of its biogeochemical controls are of great economical and social importance for: (1) The understanding of reservoir biodegradation may be of great use for the exploration industry, and (2) a biotechnological stimulation of methane formation in reservoirs could provide new economical perspectives for hydrocarbon recovery. Even under optimal conditions, today not more than 30-40 % of the total oil in a reservoir are actually recovered. The conversion of at least parts of the non-recoverable oil, coal or shales via an appropriate biotechnological treatment into easily recoverable methane would provide an extensive and ecologically sound energy resource. Laboratory mesocosms and high pressure autoclaves with samples from different geosystems showed high methane production rates after the addition of different oils, coals or shales. Stable isotope probing (SIP) combined with fingerprinting of the microbial enrichments showed a large bacterial but limited archaeal diversity involved in degradation. For the characterization of degradation pathways metabolite spectra will be analysed, combined with the use of SIP. The variability of carbon and hydrogen isotopes of produced methane falls in a relative narrow range. Further we have analysed the isotope composition of methane in reservoirs and oil-contaminated aquifer to test whether the isotope composition of methane can be used as an indicator for methanogenesis. The variability of carbon and hydrogen isotope composition *in situ* was almost identical with those obtained with the enrichment cultures. This implies a common methanogenic degradation mechanism resulting in consistent patterns of hydrocarbon alteration. This will provide an exploration tool to identify and assess these microbial processes in different reservoir geosystems. Mass balance calculations showed that significant fractions (2-10%) of added coals or oils were converted to methane. Current studies focus on the identification of stimulating or inhibiting factors for scale-up and field studies on MEOR.

Fluid inclusions in stalagmites used as a quantitative thermometer in paleoclimate research

Y. KRÜGER[1,3]*, D. MARTI[1], R. HIDALGO STAUB[1], D. FLEITMANN[2,3] AND M. FRENZ[1]

[1]Institute of Applied Physics, Univ. of Bern, Switzerland (*correspondence: yves.krueger@iap.unibe.ch)
[2]Institute of Geological Sciences, Univ. of Bern, Switzerland (fleitmann@geo.unibe.ch)
[3]Oeschger Centre for Climate Change Research, Univ. of Bern, Switzerland

We present a new approach to determine paleo-temperatures (mean annual surface temperatures) based on fluid inclusion liquid-vapour homogenisation temperatures (T_h) in stalagmites. A precondition for these measurements is to stimulate the nucleation of a vapour bubble in the initially monophase inclusions by means of single ultra-short laser pulses [1]. The aim of our study is to explore the potential and the limitations of this new paleothermometer and to develop a reliable methodology for routine applications in paleoclimate research. Therefore, we have investigated recent fluid inclusions from the top part of actively growing stalagmites from various caves to compare our results with the present-day cave air temperatures.

The method makes specific demands on the selection, handling and preparation of the stalagmites to avoid artificially induced modifications of the original fluid densities by leakage or stretching of the inclusions. Additionally, the measured homogenisation temperatures $T_{h\ (obs)}$ need to be corrected for the effect of surface tension to determine the nominal homogenisation temperature $T_{h\ (nom)}$ [2] that is expected to be equal to the stalagmite formation temperature and therefore closely corresponds to the mean annual surface temperature outside the cave. Based on our present results we may expect an accuracy in paleotemperature determinantions within ±0.3 °C. The application of this thermometer is, however, restricted to climate zones and periods with mean annual surface temperatures higher than 9–11 °C. Inclusions formed below this temperature limit do not feature a stable liquid-vapour state and thus T_h cannot be measured.

Hf-W evidence for rapid accretion and core formation in protoplanets

T. KRUIJER[1]*, P. SPRUNG[1], T. KLEINE[2], I. LEYA[3] AND R. WIELER[1]

[1]Inst. of Geochemistry and Petrology, ETH Zurich (*correspondence: thomas.kruijer@erdw.ethz.ch)
[2]Institute for Planetology, Universtity of Muenster
[3]Space Research and Planetary Sciences, University of Bern

Introduction

Several Hf-W studies [e.g. 1] showed that the parent bodies of magmatic iron meteorites formed very early, about contemporaneously to Ca-Al-rich inclusions (CAI). Cosmic-ray induced neutron capture reactions can, however, modify the W isotope budgets of iron meteorites [2] but no accurate method is yet available for correcting these effects [3, 4]. Consequently, the exact timing and duration of core formation in these bodies remain uncertain.

Approach

Cosmogenic noble gas abundances can help to select iron meteorite samples whose W isotope budgets likely remained unaffected by cosmic rays. Nevertheless, quantitative corrections of cosmic-ray induced shifts in W isotopes using a direct neutron dose monitor like ^{113}Cd [see e.g. 5] are desirable [2]. We here report results from a combined noble gas and W isotope study on different groups of magmatic irons. Complementing Cd isotope analyses on the same samples are currently on going.

Results

Cosmogenic noble gas concentrations in most of the analyzed samples are at the lowermost end of the range observed in iron meteorites [6]. Samples with the lowest cosmogenic noble gas abundances have ε^{182}W values (10^4 deviations from the terrestrial value) ranging from -3.3 to -3.2, indistinguishable from the CAI initial of -3.28±0.12 [7].

Implications

The (weighted) mean ε^{182}W of the weakly irradiated irons analyzed in this study is -3.25±0.05. Unlike in previous W isotope studies, this average value is higher than the CAI initial, not lower, demonstrating that ε^{182}W values lower than the CAI initial reflect cosmic-ray induced effects. Our W isotope data indicate that different iron meteorite parent bodies segregated their cores within a brief interval of less than 1 Myr. The average core formation age of the samples investigated here is $0.3^{+1.3}/_{-1.1}$ Myr after Solar System formation.

Sorption properties of supercritical carbon dioxide in nano-porous synthetic rocks

ELIZABETH G. KRUKOWSKI[1]*, GERNOT ROTHER[2†] AND ROBERT J.BODNAR[1]

[1]Department of Geosciences, Virginia Tech, 4044 Derring Hall, Blacksburg, VA 24061, USA (*correspondence: egk@vt.edu)
[2]Chemical Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-6110, USA ([†]rotherg@ornl.gov)

Carbon dioxide (CO_2) generated in fossil-fuel powered plants is a concern due to its potential contributions to global warming. Large-scale carbon capture and sequestration (CCS) can help to slow the rise of atmospheric CO_2 levels. In this process, CO_2 is stripped from the plant emissions, compressed and injected into subsurface reservoirs. Directly after injection, the dominant processes to contain the supercritical CO_2 in the reservoir are sorption and capillary trapping. Quantification and understanding of these processes is needed to estimate reservoir capacities and model long-term storage security. In this study, gravimetric sorption experiments were conducted from 0-200 bars and 35-50°C, using mesoporous silica, a synthetic proxy for quartz-rich rock. The CO_2 excess sorption isotherms were measured for samples with different pore sizes and morphologies. Strong adsorption of CO_2 to silica was found at low pressure, with the formation of a maximum in the excess sorption isotherm. The excess sorption is small or negative at high pressure. An inverse temperature dependence of the sorption strength was found in the adsorption region at low pressure, while the excess sorption showed little temperature dependence at high pressure. Our data suggest the existence of an optimum pressure, between 75–100 bars depending on temperature and pore size, for carbon storage in dry quartz-rich rocks.

We also studied the sorption of supercritical CO_2 to Na-montmorillonite clay, a proxy for cap rock materials. Limited amounts of CO_2 adsorbed to this clay mineral.

$\delta^{18}O$ and Cl/Nb evidence for fractional crystallization origin of silicic island arc magmas

S. KRUMM, K.M. HAASE, M. REGELOUS AND M.M. JOACHIMSKI

GeoZentrum Nordbayern, University of Erlangen-Nürnberg, Schlossgarten 5, D-91054 Erlangen, Germany (stefan.krumm@gzn.uni-erlangen.de)

Subduction-related silicic magmas may form either by extreme crystal fractionation or by partial melting of crustal rocks. Both mechanisms can be distinguished by their characteristic $\delta^{18}O$ and Cl signatures.

Laser-fluorination analysis of andesitic to rhyolitic volcanic glasses from the Kermadec island volcanoes and of basaltic to dacitic glasses from the Lau and Havre backarc rifts yielded very uniform $\delta^{18}O$ values of 5.4 to 6.5‰. This range is characteristic for mantle-derived magmas. The Cl concentrations show a positive correlation with the SiO_2 content while Cl/Nb ratios remain almost constant for the samples.

Magma generation by partial melting of sediments and/or low temperature hydrothermally altered oceanic crust, both typically having high $\delta^{18}O$, can be ruled out as these processes would cause much heavier isotopic values. A strong positive correlation between $\delta^{18}O$ and SiO_2 content would be expected but is not seen in our data.

Hydrothermal alteration of the oceanic crust leads to amphibolite with low $\delta^{18}O$, and melting of such rocks would lead to values much lower than observed. Assimilation of such materials also causes high and variable Cl concentrations and variable Cl/Nb ratios unlike the observed systematic trend.

The small variation of the $\delta^{18}O$ data as well as the very slight increase with SiO_2 content is best explained by fractional crystallization that modifies $\delta^{18}O$ values of the precursor mantle magma by 0.3 to 0.8‰ towards heavier values [1]. This is also consistent with a positive correlation between the incompatible Cl and SiO_2 content and with the constant Cl/Nb ratios in these samples. Both parameters prove monotonous enrichment of the magmas in Cl with increasing differentiation and indicate that degassing was insignificant at least for the submarine glasses.

Destruction of Paleoproterozoic crust: Deciphered from detrital zircon populations and geochemistry of quartzites (NE Poland)

E. KRZEMIŃSKA[1]*, L. KRZEMIŃSKI[1], I.S. WILLIAMS[2] AND J. WISZNIEWSKA[1]

[1]Polish Geological Institute-National Research Institute, Warsaw, Poland, (ewa.krzeminska@pgi.gov.pl)

[2]Research School of Earth Sciences, The Australian National University, Canberra, Australia

Among the many crystalline rocks sampled from the Precambrian basement of NE Poland, which is accessible only by drilling, there are local occurrences of quartzites and quartzitic schists. The quartzites were previously interpreted as Neoproterozoic quasi-platform cover which was formed during post-Gothian peneplanation after emplacement of Mezoproterozoic AMCG intrusions [1]. Correlation with Jotnian sediments exposed in Central Fennoscandia (Baltic Shield) was presumed. Here we present the first results of detrital zircon U-Pb and geochemical investigations of the provenance of quartzitic samples from two isolated drill holes (Mońki and Zabiele). Quartz meta-arenites and subarkoses in terms of Herron's chemical classification record a transition from an active continental margin towards a passive continental margin setting (Th–Sc–Zr/10, Th–La–Sc and Ti/Zr–La/Sc plots). A total of 70 detrital zircon grains from two drill core samples were analyzed by SHRIMP II. The U-Pb data demonstrate that the detritus was derived mainly from Paleoproterozoic crust (2.1–1.8 Ga). Archean grains are rare. No Mezoproterozoic component was detected. Three Paleoproterozic age populations were identified with a major peak at 1.95 Ga. The youngest concordant grains were dated at 1757 ± 24 Ma (Mońki depth 740 m) and 1745 ± 24 Ma (Zabiele depth 690 m) age. These data, however, do not support a Jotnian signature as deposition of Jotnian sediments in central Fennoscandia continued long after the 1.55 Ga anorogenic rapakivi magmatism up to 1.26 Ga A significant revision of the formerly assumed stratigraphic position of quartzitic rocks and correlation with uppermost mature Paleoproterozoic Västervik quartzites [2], S Sweden from the Fennoscandian continental margin, is proposed.

Geochemistry of tin in the southern part of the Silesian Upland

J. KUCHARZYK[1], W. BUREĆ-DREWNIAK[1], I. JAROŃ[1], W. NARKIEWICZ[1] AND A. PASIECZNA[2]

[1]Central Chemical Laboratory, Polish Geological Institute – National Research Institute, 4 Rakowiecka Street, 00-975 Warsaw, Poland (jkuc@pgi.gov.pl)

[2]Environmental Geology Department, Polish Geological Institute – National Research Institute, 4 Rakowiecka Street, 00-975 Warsaw, Poland

Introduction

Majority of soils from the southern part of the Silesian Upland are highly degraded and contain elevated levels of the toxic heavy metals [1]. Therefore, the purpose of presented studies was evaluation of tin pollution and determination of its mobility and bioavailability in soils from the investigated area.

In this work the soil samples were taken from industrial area. The soils samples were collected from two depths: topsoil (0, 0-0, 3 m) and subsoil (0, 8-1, 0 m). Comparison of elements concentration between topsoil and subsoil allows identification of the source of pollution (natural or anthropogenic).

Results

Considerably degree of chemical degradation was observed in both types of analyzed samples. The subsoil and topsoil samples were rich in tin (subsoil – 1265 mg/kg, topsoil – 37 mg/kg). Moreover, in both samples were noticed high concentration of copper, mercury, lead, arsenic and sulphur.

The sequential extraction experiments according to BCR method [2, 3] showed minimal tin mobility in the analyzed samples (almost 99% of tin was leached in the 4th step with aqua regia). The X-ray diffraction (XRD) analysis of selected samples showed the lack of tin minerals in the investigated soil. However, found the presence of quartz, clay minerals, calcite and gypsum.

Mesoarchean gabbroanorthosite magmatism of the Kola Region (Russia)

N.M. KUDRYASHOV AND A.V. MOKRUSHIN

Geological Institute of the Kola Science Centre of the Russian Academy of Sciences,14, Fersman str., Apatity, Russia (nik@geoksc.apatity.ru)

The Kola peninsula is the region marked with development of anorthosite magmatism in the NE Baltic Shield. The Archaean gabbroanorthosites intrusions - Tsaginsky, Achinsky and Medvezhe-Schucheozersky - have the age of 2.7-2.6 Ga. The Patchemvarek and Severny gabbroanorthosites intrusions are located in the junction zone of the Kolmozero-Voronja greenstone belt and the Murmansk domain. Age data for sedimentary-volcanogenic rocks of the Kolmozero-Voronja belt and Murmansk domain granitoids are 2.8-2.7 Ga.

The gabbroanorthosites intrusions have more calcic composition (70–85% An) of normative plagioclase, and low contents of TiO_2, FeO, and Fe_2O_3. U–Pb zircon dating established Mesoarchean ages of 2925±7 and 2935±8 Ma for the gabbroanorthosites of the Patchemvarek and Severny massifs, respectively. The gabbroanorthosites of the studied massifs have fairly low REE contents (Ce_n = 2.2–4.2, Yb_n = 1.6–2.6) and distinct positive Eu anomaly. Comagmatic ultrabasic differentiates have practically unfractionated REE pattern, low total REE contents (Ce_n = 1.2, Yb_n = 1.1, La/Yb_n = 1.32), and no Eu anomaly. The studied samples of the Archean gabbroanorthosites are characterized by positive εNd= +2.68 for the gabbroanorthosites of the Severny Massif and from +2.77 to +1.66 for the Patchemvarek Massif. The rocks of the Severny and Patchemvarek massifs has $^{87}Sr/^{86}Sr_i$ = 0.70204±8 and $^{87}Sr/^{86}Sr_i$ = 0.70258±8, respectively. The differences in the initial $^{143}Nd/^{144}Nd$ ratios between the Neoarchean and the Mesoarchean gabbroanorthosites suggest the existence of two mantle sources. One of them produced intrusions with an age of 2.67–2.66 Ga, while other was responsible for the formation of massifs with an age of 2.93-2.92 Ga.

The gabbroanorthosites of the Patchemvarek and Severny massifs were presumably derived from MORB-type basalts of oceanic settings, while the Tsaginsky, Achinsky, and other anorthosite massifs of the Neoarchean age were generated from subalkaline magma formed in within plate anorogenic setting. The Sm-Nd isotope data suggest the existence of several mantle sources in the Kola region, which produced melts for different-age gabbroanorthosite massifs since Mesoarchean to the middle Paleoproterozoic.

Chemical and mass changes of the vein type mineralizations in Çetilli area, (Ordu, Turkey)

KAMER KUDUN YOZGAT* AND NECATI TÜYSÜZ

Karadeniz Technical University, Department of Geological Engineering, 61080, Trabzon, Turkey (*correspondence: kameryozgat@gmail.com)

In this study, chemical and mass changes of Çetilli (Ordu) area vein type mineralization at the Eastern Black Sea region are investigated. The geology of the study area consists of volcanic, sedimentary and intrusive rock units. The study area is covered by Upper Cretaceous aged andesite, basalt and their pyroclastic equivalents, trachyandesite and its tuff, volcano-sedimentary sequence and limestone; Paleocene aged limestone, sandstone, claystone, marl, tuff and andesitic dyke; Eocene aged nummulites bearing limestone, andesite, basalt and their pyroclastics, monzonite; Upper Eocene aged basalt and Quvaterner aged travertine. Upper Cretaceous aged andesite, basalt and their pyroclastics are cut by E-W, NE-SW, NW-SE directed many fault systems. The Çetilli Orebody was formed by hydrothermal solutions arising throughout this fractured and cracked zones. Ore minerals are pyrite, sphalerite, chalcopyrite, galena and nabit gold.

Alteration of Çetilli Mineral Deposit display indistinct spatial zonation. Alteration zones are completely controlled by fault systems. Alteration types are observed silicification, calcification, zeolitization, clay, sericitization, limonization, hematization and pyritization. Chloritization and epidotization are observed cut distal part of veins. Alteration minerals are mainly quartz; lesser calcite, dickite, nacrite, ankerite, dolomite, kaolinite and a bit barite. The mass change calculations indicate a 19% volume increase in the ore zones, mainly due to addition of Si (24.45g/100g), Ca (1.06g/100g), K (0.61g/100g) and ore forming elements.

Iodide in kelp: An inorganic antioxidant in life impacting atmospheric chemistry

FRITHJOF C. KÜPPER

Scottish Association for Marine Science, Oban, Argyll PA37 1QA, Scotland, UK (*correspondence: fck@sams.ac.uk)

Brown algae of the Laminariales (kelps) are the strongest accumulators of iodine among living organisms. Not surprisingly, this element was discovered in kelp ashes 200 years ago. Kelps represent a major pump in the global biogeochemical cycle of iodine and in particular, the major source of iodocarbons in the coastal atmosphere. Nevertheless, the chemical state and biological significance of accumulated iodine have remained unknown to this date. Elucidation of these questions was the objective of this study. Using an interdisciplinary array of techniques, chiefly relying on synchrotron X-ray absorption spectroscopy, we show that the accumulated form is iodide, which readily scavenges a variety of reactive oxygen species (ROS). We propose here that its biological role is that of an inorganic antioxidant, the first ever to be described in a living system. Upon oxidative stress, a strong iodide efflux occurs. On the thallus surface and in the apoplast, iodide detoxifies both aqueous oxidants and ozone, the latter resulting in the release of high levels of molecular iodine and consequent formation of hygroscopic iodine oxides leading to particles, which are precursors to cloud condensation nuclei.

Comparison of internal and external metabolites produced by a diatom

ELIZABETH B. KUJAWINSKI*, MELISSA C. KIDO SOULE AND KRISTA LONGNECKER

Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA (*correspondence: ekujawinski@whoi.edu) (msoule@whoi.edu, klongnecker@whoi.edu)

Introduction

Marine photosynthetic microorganisms play a key role in the global carbon cycle because they fix inorganic carbon into organic compounds. Many of these compounds are exuded into the environment during growth and collectively, they constitute a large fraction of dissolved organic matter in the surface ocean. Despite the significance of this carbon production mechanism, we know little about the molecular-level composition of photosynthetically-derived dissolved organic matter and the environmental factors that govern its production.

Methods

We sampled laboratory cultures of a marine phytoplankton (*Thalassiosira pseudonana*) at different stages of its growth. At each sampling point, we compared the molecular-level composition of dissolved organic matter released into the environment with the dissolved organic compounds retained within the phytoplankton cells. All measurements were made with an HPLC coupled to an ultrahigh resolution mass spectrometer (FT-ICR MS) in positive ion mode. Resulting mass and fragmentation data were compared to metabolite databases such as KEGG and MassBank.

Results

Our data reveal distinct differences between the dissolved organic compounds retained inside the phytoplankton compared to those compounds released into the surrounding media as well as some similarities in these two metabolite pools. Tentative identifications based on database comparisons and fragmentation data suggest a dynamic metabolome for *T. pseudonana*. From these identifications, we will present possible biomarkers for future quantitative metabolic studies of this diatom and related organisms.

Evolution of Variscan orogenic Popiel peridotite (SW Poland)

A. KUKUŁA[1], J. PUZIEWICZ[1]*, M. MATUSIAK-MAŁEK[1] AND T. NTAFLOS[2]

[1]Univ. Wrocław, Poland (*correspondence: jacek.puziewicz@ing.uni.wroc.pl)
[2]Univ. Wien, Austria (theodoros.ntaflos@univie.ac.at)

Small (few hundred metres in diameter) outcrop of peridotite occurs in the western part of the Sudetes (SW Poland) at the Intra-Sudetic Fault Zone, close to the NE margin of the Karkonosze granite, which is one of the main tectonic lines in NE Bohemian Massif.

The rock consists of olivine (Fo_{84-88}, NiO 0.17 – 0.36 wt %), orthopyroxene (mg# 0.84 - 0.88, Al_2O_3 0, 71- 4, 69 wt %) and spinel (typically $Mg_{0,68}Fe_{0,31}Ni_{0,01}Al_{1,79}Fe_{0,13}Cr_{0,08}O_4$) + chromiferous magnetite ($Fe_{0,99}Mg_{0,02}Mn_{0,01}Ni_{0,01}Fe_{1,68}Cr_{0,19}Al_{0,06}Ti_{0,03}O_4$ + very scarce ilmenite. The composition of minerals vary from sample to sample. The primary mineral assemblage is overprinted by tremolite (Si = 7.95 atoms pfu), overgrown by magnesiohornblende (Si = 6.78 a pfu). The serpentine is texturally later than the amphibole.

The rock composition: SiO_2 39 - 43, Al_2O_3 4 – 7, CaO 3- 6 wt %, MgO 24 – 32 wt % and Fe_2O_3 11 -13 wt % is Fe, Al and Ca enriched. Whole rock trace-element and REE patterns are slightly (1 – 10 times) enriched relative to primitive mantle, flat, with weak Zr and Eu negative anomalies. The rocks was altered by low-grade metamorphism producing tremolite, followed by contact metamorphism in the Karkonosze granite aureole (hornblende crystallization). The rock has been affected by metasomatism and later metamorphism under oxidizing conditions. It is the unique in Sudetes (NW margin of the Bohemian Massif) example of small orogenic peridotite body affected by metasomatic and metamorphic conditions.

On the application of jarosite and hematite thermochronology to assess aqueous environments on Mars

J. KULA* AND S.L. BALDWIN

Department of Earth Sciences, Syracuse University, Syracuse, NY 13244, USA (*correspondence: jkula@syr.edu)

Hematite and jarosite, identified in the Burns Formation by the Opportunity Mars Exploration Rover (MER), have been interpreted as *in situ* evidence for past aqueous conditions on the Martian surface. Hematite has been demonstrated as a useful (U-Th)/He chronometer, although it is not a commonly analyzed mineral. Likewise, jarosite has been used as a $^{40}Ar/^{39}Ar$ chronometer, although prior to this study, argon diffusion kinetics in jarosite were unknown. Using long-duration, low-temperature, furnace step heating, jarosite argon diffusion parameters (E, log D_o/a^2) have been determined. Incremental fractional loss measurements from three size fractions (75-125, 125-150, 150-200 μm) yield an average activation energy (E) of 38.80 ± 1.58 kcal/mol and a log D_o/a^2 of 6.09 ± 0.67 s^{-1} corresponding to a closure temperature (cooling rate 100°C/Ma) of 146 ± 30°C. Using published morphologic constraints and He diffusion kinetics on hematite spherules, and newly determined argon diffusion parameters for jarosite, we use the forward modeling program DECOMP to assess if these minerals will retain original (U-Th)/He and $^{40}Ar/^{39}Ar$ ages during long residence times (4.0 Ga) at Martian surface conditions (22°, 0°C). Model results indicate that for hematite spherules (≥1.0 mm in diameter), (U-Th)/He ages will record the timing of formation within analytical certainty. Jarosite (75-200 μm in diameter) is also expected to retain radiogenic ^{40}Ar, with predicted ages falling within 0.5% of the true age. We infer that in the absence of post-crystallization diffusive He or $^{40}Ar^*$ loss, (U-Th)/He and $^{40}Ar/^{39}Ar$ ages measured from Martian hematite spherules and jarosite respectively, can be used to constrain the time since water was present on Mars. Application of model results to the 'wetting-upwards' Burns Formation at Meridiani Planum, indicates that post depositional hematite from the lower eolian dune subunit would provide a minimum age of deposition, while possibly syndepositional hematite from the upper interdune/playa unit may yield the age of the unit. Jarosite ages throughout the section should record a downward migrating aridification front as the water table retreated. A vertical profile of hematite and jarosite ages may constrain the timing and rates of the transition from wet to dry conditions at Meridiani Planum. Application of hematite and jarosite thermochronology to samples returned from Mars may be key to determining if water was available for sufficient durations required for the development of life.

Rhine River: First case of anthropogenic lanthanum as a dissolved microcontaminant in the hydrosphere

SERKAN KULAKSIZ* AND MICHAEL BAU

Jacobs University Bremen, Earth and Space Sciences, Campus Ring 8, 28759, Bremen
(*correspondence: s.kulaksiz@jacobs-university.de)

The rare earth elements (REE) are a group of elements that behave coherently in natural systems, usually plotted with concentrations normalized to a known reference (e.g. shale). This style of representation makes the presence of anomalies easier to distinguish.

The first report of anthropogenic contamination of the natural REE distribution in river water appeared in the mid-1990s (Bau & Dulski, 1996). Gadolinium (Gd) concentrations in the Havel River downstream of the city of Berlin were up to 3 orders of magnitude higher than natural background concentrations. This study also reported on the Rhine River showing a similar excess of Gd concentration. Gadolinium is used in magnetic resonance imaging as a contrast agent, causing positive anthropogenic Gd anomalies in sewage effluent, rivers, estuaries and groundwater via several pathways in its highly-stable form (e.g. Gd-DTPA).

More recently, excess lanthanum (La) was also measured in the River Rhine, up to an order of magnitude higher than background values. The anomaly is introduced into the Rhine River north of the city of Worms at Rhine river-km 447.4. Samples taken a few hundred meters upstream/downstream of an effluent at this location show strong differences in La and light REE concentrations. The effluent itself shows 49 mg/kg La, well-above levels that are ecotoxicologically effective. Excess La is present 400 km downstream at the German-Dutch border where >93% of total La and Gd are of anthropogenic origin.

Since River Rhine water is used for artificial groundwater recharge and bank infiltration, anthropogenic La (and Gd) are both to be expected in tap water of those cities that rely on the Rhine River as a drinking water source. Indeed, several cities along the Rhine River carry positive anthropogenic Gd anomalies (e.g. Leverkusen, Koblenz, Düsseldorf, Duisburg, and Essen) and positive anthropogenic La anomalies (e.g. Leverkusen, Worms, and Kleve).

While several adverse health effects of Lanthanum are known, information on the potential health risks to the ecosystem inhabiting the river is lacking. Further research and monitoring is essential in order to avoid potential negative environmental consequences.

Risk assessment analysis of Kadji-Sai uranium tailings site, Kyrgyzstan

ZH. KULENBEKOV* AND BRODER J. MERKEL

TU Bergakademie Freiberg, Gustav Zeuner Str. 12, 09596, Germany (*correspondence: kulenbekov@gmail.com)

Sediment samples and coal ashes from Kadji-Sai uranium tailing site, Kyrgyzstan (a former coal and uranium mine) taken at depth of 0.1-0.2, 1, and 2 meters were investigated with gamma spectrometry and electron microscopy coupled with Energy-Dispersive X-ray Fluorescence Spectroscopy (SEM/EDX). Gamma spectroscopy showed significant elevated activities for uranium, radium, and lead-210 (Table 1).

Sampling points	Depths (m)	^{238}U kBq kg^{-1}	^{226}Ra kBq kg^{-1}	^{210}Pb kBq kg^{-1}
Catchment pool	0.1-0.2	0.43 to 1.2	0.10 to 0.07	0.11 to 0.07
Uranium tailing dump	1.0	6.8	31.2	23.9
Uranium tailing dump	2.0	7.2	26.6	24.2

Table 1: Gamma activity at shallow depths of the Kadji-Sai uranium tailing site

These results reveals that the uranium extraction technique was rather inefficient leaving about between 20 and 30% of the uranium in the tailings and that no sufficient cover of the tailings is in place. SEM/EDX was used to study the chemical forms and morphology of the coal ash and sediments particles. The precise knowledge of the elemental composition of radioactive wastes occurring in the tailings is important for future remediation and migration of radioactive elements and stability of secondary minerals being formed in the dump piles.

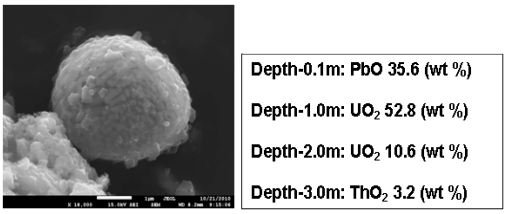

Figure 1: SEM image and EDX data of coal ash from different depths

Consistent treatment of entropy, enthalpy and volume effects of multi-dentate adsorption reactions

D.A. KULIK[1]* AND J. LÜTZENKIRCHEN[2]

[1]Paul Scherrer Institut, 5232 Villigen PSI, Switzerland (*correspondence: dmitrii.kulik@psi.ch)

[2]KIT INE, Postfach 3640, 76021 Karlsruhe, Germany (johannes.luetzenkirchen@kit.edu)

Evidence for aqueous ions binding to several oxygen atoms on mineral-water interfaces (MWI) has raised interest in multi-dentate surface complexation models [1, 2]. We investigated [3] how (fitted) intrinsic equilibrium constants [illegible] for a δ-dentate M adsorption reaction depend on the choice of concentration scale for ≡$_δ$M, e.g. molarity ($^{[]}$); relative surface fraction (^{o}); molecular surface density (^{r}, in mol·m^{-2}); or relative surface density Γ/Γ_o (^{o}, where $\Gamma_o = 2 \cdot 10^{-5}$ mol·m^{-2} [4]). We have shown that, for δ ≥ 2, only [illegible] and [illegible] are denticity-invariant, and only [illegible] is independent of the real site density Γ_C. This makes the (^{o}) scale the best choice for defining the standard state of a surface species.

In this contribution, our approach is extended to T and P corrections of [illegible] defined by the partial molal entropy $\Delta_r S$, enthalpy $\Delta_r H$, isobaric heat capacity ($\Delta_r Cp$), and volume $\Delta_r V$ effects (at T_r = 298 K) of the M adsorption reaction. These effects can be predicted, or fitted from [illegible] values known for several temperatures. For the same experimental data set, fitted $\Delta_r S$ values depend on the chosen concentration scale for [illegible]; the bias can reach 275 J·K^{-1}mol^{-1} for tetradentate cations on rutile surface. General conversions such as

$$\Delta_r^{[]} S^{\delta}_{M,298} - \Delta_r^{o} S_{M,298} = -R(\delta - 1)\ln[\equiv]_{TOT} \quad (1)$$

$$\Delta_r^{\Gamma} S^{\delta}_{M,298} - \Delta_r^{o} S_{M,298} = -R(\delta - 1)\ln \Gamma_o \quad (2)$$

($[\equiv]_{TOT}$ is the total molarity of sites ≡ at site density $\Gamma_{Co} = \Gamma_o$) depend on δ and on the chosen value of Γ_{Co} (1) or Γ_o (2).

Upon adsorption of aqueous M, several H_2O molecules must be liberated from its solvation shell and from the MWI. Thus, a standard-state density $\Gamma_◊$ should lead to 'standard' $\Delta_r^{o} S^{◊}_{M,298}$ and $\Delta_r^{o} V^{◊}_{M,298}$ effects consistent with known entropies and volumes of hydration of aqueous cations (cf. [5]). We find that $\Gamma_◊$ cannot be chosen arbitrarily; setting it close to the density of H_2O molecules in the surface monolayer ($2 \cdot 10^{-5} \pm 1 \cdot 10^{-5}$ mol·m^{-2} [6]) leads to entropy and volume effects related to $^{o}K^{◊}_{M}$ that are compatible with the available data on partial dehydration of aqueous ions and surfaces upon adsorption. In turn, this provides a constructive basis for future discussions aimed at reaching the ultimate thermodynamic convention on standard states of any-dentate surface complexes on MWIs.

Mantle volatiles in groundwaters near the San Andreas Fault

JUSTIN T. KULONGOSKI[1], DAVID R. HILTON[2] AND KENNETH BELITZ[3]

[1]U.S. Geological Survey, California Water Science Center, San Diego, CA 92101 (kulongos@usgs.gov)
[2]Scripps Institution of Oceanography, UCSD, La Jolla, CA 92024-0244 (drhilton@ucsd.edu)
[3]U.S. Geological Survey, California Water Science Center, San Diego, CA 92101 (kbelitz@usgs.gov)

Groundwater samples were collected from 19 wells along the San Andreas Fault (SAF) in the Cuyama, Cuddy, and Mil Potrero Valleys in southern California, USA. Previous work has shown leakage of mantle He via the SAF indicative of a focused mantle contribution to the surface. In this study, we assess the relation between He, a major volatile phase, and CO_2, the hypothesized carrier of the helium from the mantle.

The isotopic composition and concentrations of dissolved gases were determined. Measured $^3He/^4He$ ratios were compared to the $^3He/^4He$ ratio of air = 1.4 x 10^{-6} = Ra, to determine whether groundwaters were enriched in crustal (0.02Ra) or mantle (8Ra) helium. Concentrations of ^4He, corrected for air-bubble entrainment, varied from 3.0 to 58.1 x 10^{-8} $cm^3STP\ g^{-1}H_2O$. $^3He/^4He$ ratios varied from 0.46 to 3.58 Ra, consistent with mantle He in all samples (up to ~50%). A subset of 10 samples were analyzed for CO_2 and $\delta^{13}C$; concentrations of CO_2 varied from 0.059 to 0.223 $cm^3STP\ g^{-1}H_2O$, and the $\delta^{13}C$ of the CO_2 varied from -21.50 to -11.87‰. In groundwater, $\delta^{13}C$ ratios of ~-6‰, and elevated CO_2 concentrations may indicate the presence of mantle volatiles, particularly when they co-occur with high $^3He/^4He$ ratios. Measured $CO_2/^3He$ ratios varied from 64.1 to 1632 x 10^9 (mantle $CO_2/^3He$ = ~1.5 x 10^9).

Samples were collected from Quaternary alluvium filled valleys formed by motion along the northwest-trending, right-lateral strike-slip SAF. The flux of deep mantle fluids to the seismogenic zone at high hydrostatic pressure may cause fault rupture, and transfer volatiles into the shallow crust. $^3He/^4He$ and $\delta^{13}C$ ratios, and ^4He and CO_2 concentrations are highest in the wells located in the Cuddy and Mil Potrero valleys, which are closest to the SAF. Samples with the highest $^3He/^4He$ ratios also had the lowest $CO_2/^3He$ ratios. However, the eight wells sampled in the Cuddy and Mil Potrero valleys were located <1km from the SAF, yet their $^3He/^4He$ and $CO_2/^3He$ ratios varied by up to an order of magnitude suggesting heterogeneous fluxes of mantle volatiles along this 40 km section of the SAF.

Biological precipitation of calcite in stalagmites

A. KUMAR[1], J. ROUTH[1] *, A. MANGINI[2], J. PATTANAIK[1] AND S. BASKAR[3]

[1]Dept of Earth Sciences, IISER-K, Kolkata741252, India (*correspondence: joyanto.routh@iiserkol.ac.in)
[2]Institut für Umweltphysik der Universität Heidelberg, Heidelberg, Germany
[3]Dept. of Environmental Science and Engineering, GJUST, Hisar, India

In recent years, spleothems have become an important archive for paleoclimate studies. To deduce paleoclimatic information from carbonate deposits, which is precipitated under non-equilibrium-conditions, it is important to improve the understanding of biological calcite precipitation.

In this study, laboratory experiments were conducted with calcium carbonate precipitating bacteria isolated from stalagmite deposits collected from Krem Syndai in Meghalaya, India. The medium used to culture these bacteria was designed in accordance to the drip water composition. We have isolated a new strain S4 that has been partially identified by 16S rDNA sequencing. The strain shows less than 95% similarity with any of the existing *Bacillus* stains involved in bio calcification. SEM and AFM studies are being carried out to understand the tomography of S4 strain.

Biocalcification rate of this strain was studied at regular intervals by studying the change in optical density, pH and calcite (wt%) precipitated in the medium. There is a positive correlation (r =0.925) between optical density and pH implying increased precipitation over the 40 day period. XRD was done to identify the minerals in the microbial precipitate. In addition the precipitate was analyzed for the isotopic composition of $\delta^{13}C$ and $\delta^{18}O$.

Dry deposition: A major pathway of atmospheric dust particle deposition

RANJIT KUMAR[1] AND K. MAHARAJ KUMARI[2]

[1]Department of Applied Chemistry, Technical College
[2]Department of Chemistry, Faculty of Science, Dayalbagh Educational Institute (Deemed University), Dayalbagh, Agra -282005. Ph: 0562-2801545, Fax: 0562-2801226 (rkschem@rediffmail.com)

Acidic deposition is of major concern due to their detrimental effects including wide spread acidification of soil, ponds, lakes, corrosion of building materials, injury to vegetation etc. The major mechanisms of removal of pollutants from the atmosphere to earth surface are dry deposition, wet deposition and occult deposition. Dry deposition is an important process for Indian climatic conditions as dry conditions prevail for most part of the year while rains are confined to short monsoon period. Direct measurements of dry deposition on natural surfaces are significant because measurements made so far are on surrogate surfaces that do not simulate the natural surfaces. Dry deposition flux was higher on rougher surface of Cassia leaf comparison to leaf of Ashok because it prevented the re-entrainment of deposited particles and therefore has higher deposition flux. Contribution of alkaline components is higher towards total dry deposition and hence dry deposition is basic in nature, which is dominated by the soil-derived elements Ca^{2+} and Mg^{2+}. NH_4^+ also plays important role in neutralization. Three major sources responsible for dry deposition of major ions are combustions for F^-, Cl^-, NO_3^-, SO_4^{2-} and K^+, road dust/soil for Ca^{2+}, Mg^{2+} and NH_4^+ and brick-kiln industries for Na^+ and F^+. The deposition velocities are relatively larger for cationic species than anionic species probably because the soil-derived aerosols (Na^+, K^+, Ca^{2+}, and Mg^{2+}) have higher MMDs.

Integrated GIS approach for characterisation of hydrogeochemical processes governing the groundwater quality in Sabarmati basin, Gujarat, India

RINA KUMARI, CHANDER KUMAR SINGH AND SAUMITRA MUKHERJEE

School of Environmental Sciences, Jawaharlal Nehru University, New Delhi-110067

Factors influencing the groundwater hydrochemistry in pre and post monsoon season were evaluated for a part of Sabarmati river basin of Gujarat, a hub of intense growth of agricultural and industrial activities. Samples were collected on the basis of spectral signature of vegetation and soil as observed on satellite image. 14 water quality parameters were analysed which formed the attribute database for spatial variation of respective parameter using GIS. Graphical plots were used to decipher the hydrogeochemical process occurring in the study area. Gibbs plot, USSL diagram, % sodium and SAR were used to verify the suitability of groundwater for irrigation. It was observed that leaching of wastes disposed from anthropogenic activities and agrichemicals is the major factor along with the natural processes such as weathering, dissolution and ion-exchange. Control of indiscriminate and unplanned exploitation of groundwater, application of fertilizers and disposal of industrial wastes in the affected areas can possibly ensure groundwater protection from further pollution and depletion.

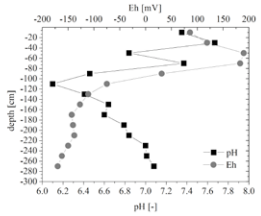
Porewater composition of cores from Palinuro sea mountain, Italy

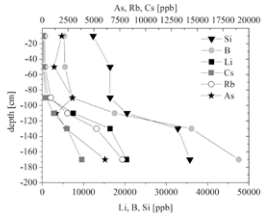
N. KUMMER[1]*, B. MERKEL[1], B. PLANER-FRIEDRICH[2] AND M. SCHIPEK[1]

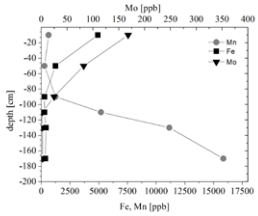
[1]TU Bergakademie Freiberg, Freiberg, Germany (*correspondence: kummer1@geo.tu-freiberg.de)
[2]University of Bayreuth, Bayreuth, Germany

During RV Meteor cruise M73/2 (14-30 August 2007), cores were sampled from a submarine hydrothermal vent site at the Palinuro volcanic complex in the southeastern Tyrrhenian sea, Italy. Pore water samples were taken from the sediment cores using rhizon-samplers. Results from one of the cores are presented showing a distinct pattern for certain elements.

The redox potential changes from 100-200 mV in the upper one meter to strongly reducing conditions (-170 mV) at a depth of 280 cm. The pH has a minimum of 6.1 at a depth of 110 cm. While Fe and Mo show their highest concentrations in the upper parts of the profile, Mn increases with increasingly reducing conditions.







Si, B, Li, Cs, Rb, and As show the same behavior as Mn. While this is expected for As, it is quite surprising for all the other elements which are not redox-sensitive. Major cations and anions as well as electrical conductivity do not change significantly over depth. Arsenic speciation showed a predominance of arsenate and arsenite to a depth of 80 cm. At 90 and 110 cm, mono- (10%), di- (18%), and trithioarsenate (25%) were detected besides arsenate (34%) and arsenite (14%). At 110 cm, trithioarsenate was the predominant species with 64% of total As, followed by 28% dithioarsenate. The geochemical pattern is an indication for upwelling geothermal water and mixing with ocean water in the upper part where Fe and Mo is released from sediment under slightly oxidizing conditions.

Time-resolved emission of iodine from seaweed measured with a new on-line mass spectrometric technique

M. KUNDEL[1], U.R. THORENZ[1], J. BOSLE[1], R.J. HUANG[1,2] AND T. HOFFMANN[1]

[1]Johannes Gutenberg-University, Institute for Inorganic and Analytical Chemistry, Duesbergweg 10-14, 55128 Mainz
[2]School of Physics, Centre for Climate and Air Pollution Studies, National University of Ireland, Galway

Molecular iodine and iodocarbons are released by macroalgae and phytoplankton into the atmosphere. These volatile iodine-containing compounds are involved in the tropospheric ozone depletion and the marine new particle formation. Recent studies suggest that biogenic emissions of molecular iodine rather than iodocarbons are the dominant source of reactive iodine atoms in the marine boundaray layer [1]. Especially during low tide, when the seaweed is exposed to atmospheric air, increased levels of I_2 were detected at different measurement sites [2],[3]. In this work we present a new application of the time-of-flight aerosol mass spectrometer for the determination of I_2 in real-time. ToF-AMS were developed for the measurement of non-refractory atmospheric aerosols with high sensitivity [4]. In order to use the high sensitivity of the ToF-AMS for I_2 measurements, I_2 has to be converted from the gas phase into the particle phase by α-CD/NH_4Br particles inside a 0.5 L flow tube before entering the ToF-AMS. LOD of 300 ppt was achieved for 1 min time resolution and could be improved to 60 ppt for 30 min time resolution. Additionally this method was compared to a recent developed method that combines denuder sampling of I_2 and GC-MS analysis. The newly developed ToF-AMS method was used to explore the time-resolved emission of I_2 by various seaweed species from the eulittoral und sublittoral zone of Helgoland (North Sea, Germany). For our measurements entire seaweed species were removed from sea water, shaken free of excess water and introduced into a 4 L chamber made of glass to simulate low tide conditions. Additional stress was applied to the seaweed by flushing a continous flow of ozonated (20-150 ppb) synthetic air through the chamber to investigate the influence of ozone on the emission of I_2. Furthermore, volatile iodocarbons were quantified by TD-GC-MS and compared to I_2 measurements.

Dynamical correlations in transition metal compounds

JAN KUNES

Institute of Physics, AS CR, Cukrovanicka 10, Praha 162 53, Czech Republic (kunes@fzu.cz)

The standard methods of density functional theory describe the eletronic structure of materials in terms of Slater determinants. While such description proved useful in many cases, in transition metal compounds it is often not sufficient. We use the dynamical mean-field theory (DMFT) [1] to study such systems and phenomena related to electronic correlations. The exmples include the spin state transitions in MnO [2] and Fe_2O_3 [3], driven by pressure, and in $LaCoO_3$ [4], driven by temperature. We discuss the relationship of the spin transition to the metal-insulator transition and tendencies towards long-range ordering.

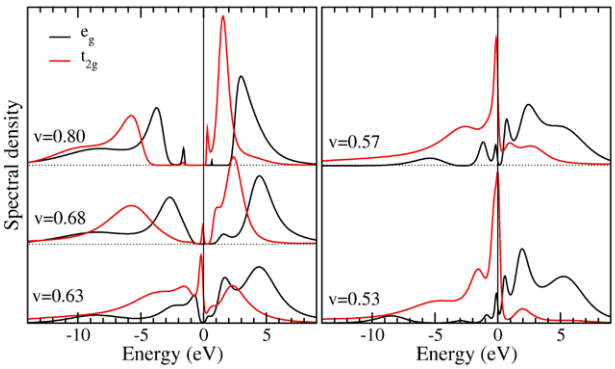

Figure 1: The orbital resolved Mn-*d* spectral density in MnO for various specific volumes. The results correspond to the temperature of 1160 K.

We will show how the local electronic correlation leads to emergence of non-fermionic degrees of freedom, such as the local magnetic moments, and how their fluctuations influence the material properties. The talk will focus on the qualitative differences between the DMFT description and static mean-field theories such as LDA or LDA+U.

Phyllosilicate dissolution kinetics: experimental observations and Kinetic Monte Carlo modeling

INNA KURGANSKAYA*, ROLF. S. ARVIDSON AND ANDREAS LUTTGE

Dept. of Earth Science, Rice University, Houston 77005, USA (*correspondence: iak2@rice.edu)

We present our recent results in the study of phyllosilicate dissolution kinetics. The major problem in this field is the influence of the layered structure on dissolution mechanism and the difference in reactivity between edge and basal faces. We use an integrated approach including experiments and modelling to understand real crystallographic control of dissolution kinetics. Vertical Scanning Interferometry allows us to observe mineral surface topography during the dissolution process, measure dissolution rates and access their spatial and temporal variability. Detailed information about surface structure has also been obtained from AFM work. We simulate the dissolution of phyllosilicates using Kinetic Monte Carlo (KMC) approach. This stochastic method links elementary reactions taking place on the mineral surface with the topographic outcome of these processes. The KMC model has been parameterised using activation energies of elementary bond-hydrolysis reactions obtained from quantum mechanical calculations. As a result, we have reproduced experimentally-observed dissolution patterns in our KMC simulations (Fig.1). The combination of these techniques will help us to understand complex behaviour of crystalline systems in the dissolution process.

The influence of biofilms on fluid flow and contaminant transport in porous media

HANNA KURLANDA*, SUYIN YANG, BRYNE T. NGWENYA, IAN B. BULTER AND STEPHEN C. ELPHICK

School of GeoSciences, University of Edinburgh, Grant Institute, West Mains Rd, King's Buildings, EH9 3JW, Edinburgh, United Kingdom (*correspondence: hkurland@staffmail.ed.ac.uk)

Subsurface biofilm growth is a relatively novel and cost-effective method of bioremediation. Multiple injections of nutrients into the subsurface stimulate biofilm growth, forming a biobarrier. Biobarriers are known to reduce hydraulic conductivity, as well as immobilise metals in the matrix of the exopolymeric saccharides (EPS), produced by bacterial cells.

This research focuses on observing the influence of biofilm growth on transport in homogenous and heterogeneous column experiments under various nutrient conditions, as well as visualising and quantifying biomass of these biofilms *in situ* using x-ray micro computed tomography (μCT). This study will provide insight into materials and processes pertaining to groundwater vulnerability and assess the viability of biofilms to reduce the transport of aqueous metal contaminants. Biofilms were grown under continuous flow conditions in glass columns. A *Pseudomonas putida* culture was injected into the columns for biofilm growth. A decrease in hydraulic conductivity, column outflow and fluid velocity through the duration of the flow experiments was observed, which signifies bioclogging took place in the columns. Biomass distribution was examined using extraction methods and protein/ carbohydrate analysis. Additionally, syringe column experiments were carried out in order to observe and quantify microbially mediated mineral precipitation using μCT. In separate experiments *Sporosarcina pasteurii*, a ureolytic strain, was injected into the syringes to enable biofilm development and also $CaCO_3$ precipitation. The distribution of biomass, mineral precipitates and fluid flow paths in these experiments were visualised using x-ray μCT. Preliminary μCT imaging illustrates that for microbial processes in porous media, both biofilm growth and $CaCO_3$ precipitation as a result of ureolysis, can be visualised and quantified using CT techniques and software.

High-pressure single-crystal elasticity of $MgSiO_3$ and $(Mg,Fe)SiO_3$ perovskites at pressures of the Earth's lower mantle

A. KURNOSOV, D.M. TROTS, T. BOFFA BALLARAN, D. HARRIES[1] AND D.J. FROST

Bayerisches Geoinstitut, Universität Bayreuth, 95447 Bayreuth, Germany

Sound wave velocities obtained in seismology are at the moment the only direct measure of the properties of the Earth's lower mantle. In order to use such measurements to constrain the chemical and thermal state of the Earth's interior, however, knowledge of the pressure dependence of acoustic wave velocities of model minerals are essential. $MgSiO_3$ perovskite-type structures, with the end-member composition or containing some amount of Fe or Al, have been the subject of several studies, since are likely the primary lower mantle constituent. Experiments, however, are limited either to room pressure conditions [1, 2] or to aggregate materials [3, 4] due to the challenge of synthesizing and recovering high-quality single-crystals of this high-pressure mineral. Therefore the best knowledge so of the full elastic constant tensor of orthorhombic (Mg, Fe)SiO_3 perovskites results from first principle calculations [5, 6].

We succeeded to synthesize and select good quality single crystals of MgSiO3 perovskite (Mg - end member) and (Mg, Fe)SiO3 perovskite containing up to 4% of Fe. The crystals are prepared for high-pressure brillouin measurements using FIB (focused ion beam) technology providing double side parallel cutting of the surfaces with required dimensions and quality.

We present the data of simultaneous measurements of sound velocities (by brillouin spectroscopy) and density (by single crystal x-ray diffraction) vs. pressure of the perovskite single crystals loaded in diamond anvil cell with He pressure medium. Behavior of elastic constants calculated from these data and effect of Fe will be discussed in the presentation.

High magnitude MIF-S due to increased atmospheric $p(O_2)$

F. KURZWEIL[1]*, M. HANNINGTON[2] AND H. STRAUSS[1]

[1]Institut für Geologie und Paläontologie, WWU Münster, D-48149 Münster, Germany (*correspondence: f_kurz01@uni-muenster.de)
[2]University of Ottawa, Ottawa ON, Canada

Earth's atmosphere experienced several profound changes in the geological past. Among these was the Great Oxidation Event (GOE) at ~2.4 Ga as indicated by the subsequent absence of mass independently fractionated sulphur isotopes (MIF-S). The temporal evolution in MIF-S from low towards high magnitude was recently suggested to reflect changes in the total atmospheric composition and not exclusively resulting from variations in $p(O_2)$. [1] proposed that a rise in the atmospheric SO_2/H_2S ratio enlarged the magnitude of MIF-S.

Black shales from the Superior craton (2.71 Ga) record a high magnitude MIF-S signal ($\Delta^{33}S$ up to 4‰) following a period with greatly attenuated MIF-S between 3.2 and 2.7 Ga. Their $\Delta^{33}S$ vs. $\Delta^{36}S$ relationship shows a slope of -1, which appears to be a typical signature of rocks younger than 2.7 Ga. We interpret this shift towards high magnitude MIF-S and the concomitant change in the slope of $\Delta^{33}S$ vs. $\Delta^{36}S$ at 2.71 Ga as a consequence of a rise in atmospheric SO_2/H_2S. However, we suggest that a rise in atmospheric O_2 ultimately caused this increase, not variations in volcanic outgassing [1]. An increase in atmospheric $p(O_2)$ would have strengthened the conversion of H_2S to SO_2 resulting in a higher SO_2/H_2S ratio. Such a scenario would be consistent with a proposed onset of oxidative weathering already at 2.7 Ga [2]. Still, a generally reducing atmosphere kept oxygen levels below 10^{-5} PAL, low enough to allow for MIF-S until the GOE at ~2.4 Ga.

Internal structure of icy satellites of Jupiter and Saturn and subsurface oceans

O.L. KUSKOV*, V.A. KRONROD AND A.P. ZHIDIKOVA

Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, 119991 Moscow, Russia (ol_kuskov@mail.ru)

Models of the internal structure of icy satellites have been constructed on the basis of the mass and moment of inertia constraints, geochemical constraints on composition of silicate fractions of ordinary and carbonaceous chondrites, and thermodynamic data on the equations of state of minerals and high-pressure ices [1, 2]. The mass and moment of inertia values are used as input data for determination of the thickness of an outer water-ice shell, the density distribution with depth, and the core sizes and masses. The equilibrium phase assemblages in the system Na_2O-TiO_2-CaO-FeO-MgO-Al_2O_3-SiO_2 were calculated using the technique of free energy minimization combined with the Mie-Grüneisen equation of state. The density variations in the mantle and Fe-S core radii are found by the Monte-Carlo method. The allowed thickness of Europa's H_2O layer (whether liquid or ice) ranges from 115 to 135 km (6-8% of total mass) for a L/LL-type chondritic mantle [2]. Two alternative models of Ganymede's outer shell composed of the high-pressure ice phases or of water and ice are considered. The thickness of the shell is in the range 800-900 km. The content of H_2O in Ganymede's outer shell is 46-48% [1]. We show that Callisto must only be partially differentiated into an outer ice-I layer, a water ocean, a rock-ice mantle, and a rock-iron core. The maximum thickness of the outer water-ice shell is up to ~300 km and that of the internal ocean is about 150 km. The total amount of H_2O in Callisto is found to be 48-55 wt%. The results of modelling support the hypothesis that Callisto may have an internal liquid-water ocean [2, 3]. The correspondence between the density and moment of inertia values for the Galilean satellites shows that their bulk compositions may be, in general, similar and may be described by the composition close to a material of the L/LL type chondrites [1-3]. Planetesimals composed of these types of ordinary chondrites could be considered as analogues of building material for the rock-iron cores of the Galilean satellites. A comparison of the internal structure of Ganymede and Callisto with that of Titan has been made.

[2]TITECH, Tokyo 152-8550
[3]Geol. Surv. Japan, AIST
[4]Kochi Inst. Core Sample Res., JAMSTEC

The main aim of this study is to contribute to better understanding of fluid processes occurring in subduction zones with a comprehensive framework involving slab-derived fluids to near-surface fluids such as seawater, meteoric water and hot spring waters.

Our previous geochemical research on the Arima-type brine, anomalous non-volcanogenic hot springs with extreme high $^3He/^4He$ (e.g. [1, 2, 3]), identified and characterized the concentrated 'source' brine in a robust multi-elemental/isotopic space, and so far, supports the idea that NaCl-CO_2-rich aqueous fluids, which are possibly slab-derived fluids originated from subducting oceanic crusts, might have uprisen from a deep part of the forearc region and might supply solutes, gases and water itself to the brine.

While several other studies estimated the contribution of slab-derived fluids to island-arc magmatism (e.g. [4]), in non-volcanic or forearc regions, their involvements have been hardly found.

Therefore we extended our research area from the Kinki district in southwest Japan to forearc regions in central Japan, where two different slabs have been subducting, which might imply that one could expect involment of two different slab-derived fluids. Along the Median Tectonic Line, which divides the adjacent forearc region in two, there are several non-volcanogenic hot springs, some of which are thought to be classified as the Arima-type brine. Here we present the results of our geochemical and isotopic analyses of these hot springs in forearc regions in central Japan.

[4]Vernadsky Institute of Geochemistry, RAS, 119991 Moscow, Russia

We intend to perform high precision absolute dating of lower unites of Norilsk volcanic section in order to understand evolution of Siberian flood basalts and their relation to P-T mass extinction [1]. For that purpose we picked up zircon grains from lower unites of Norilsk volcanic suit: Ivakinskaya (Iv), Severminskaya (Sv), Gudchikhinskaya (Gd) and Tuklonskaya (Tk) units. Here we report the first data on the structure and composition of 275 zircons grains obtained by CL, EPMA and LA ICP-MS techniques.
