Qarhan salt lake is located in Qaidam Basin, Qinghai Province, China. There are about 3 million tons of solid potassium resources in Qarhan salt lake[1]. About half of the solid resources are of low grade. We can't exploit the low grade resource directly.

The solid potassium can be dissolved and transferred to liquid state by mixed with solution in low potassium concentration. We use water from Seniehu lake as the solution to carry on the research.The experiment area is 1 km^2. 35 monitoring wells are set up in order to obtain data of the saline water level and composition. There is a recharge trench on one side of the experiment area and a drainage thench on the other side. The low potassium solution comes into the experiment area from the recharge trench. During the flowing process, the concentration of potassium resolution becomes high. In the end, the high potassium solution flows out of the experiment area through the drainage trench.

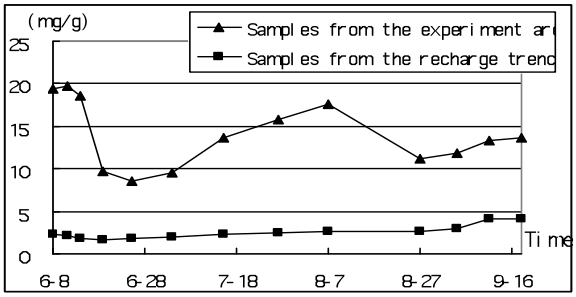

Figure 1: Potassium concentration duration curve

The result shows that solution with low potassium concentration can essily dissolve the solid potassium. However, the concentration of sodium must not be too high.[2]

U–Pb zircon, geochemical and isotopic constraints on age and origin of Cretaceous granites from the North Qinling, central China and implications for interaction between crust and mantle

XIAOXIA WANG[1]*, TAO WANG[2], QIUJU QI[3] AND SHAN LI[2]

[1]Institute of Mineral and Resource, Chinese Academy of Geological Science, Beijing 100037, China (*xiaoxiawang@hotmail.com)
[2]Institute of Geology, Chinese Academy of Geological Science, Beijing 100037, China
[3]China University of Geosciences, Beijing 100083, China

Zircon U-Pb dating, geochemical and isotopic (Nd, Sr, Hf) analyses for two granitoid plutons have been carried out in the different blocks of the North Qinling. Zircon dating by LA-ICP-MS for the Lantian granite in the southern margin of the North China Block and Muhuguan granite in the North Qinling orogen yields ages of 133±1 Ma and 150±1Ma, respectively. The samples studied from the Lantian granite contain zircons mostly having xenocrystic cores. The inherited zircons have Paleoproterozic ages. Both granites exhibit similar mineralogical, chemical and isotopic characteristics. They have metaluminous to peraluminous compositions (A/CNK ratios 0.9 to 1.05) and display K_2O/Na_2O ratios of 0.9 to 1.5. In terms of trace elements, they show an enrichment of LREE and medium fractionation between LREE and HREE (La_N/Yb_N ratios 16 to 33). Compared with the primordial mantle, distinct negative anomalies of P and Ti, and slight negative anomalies of Ba and Nb are observed in both granite plutons. They are further characterized by low $\varepsilon_{Nd}(t)$ of −11.8 to −18.3 and $\varepsilon_{Hf}(t)$ of −23.4 to −5.7 for the Liantian granite and low $\varepsilon_{Nd}(t)$ of −7.6 to −11.4 and $\varepsilon_{Hf}(t)$ of −17.4 to −7.3 for the Muhuguan granite. We interpret these Cretaceous granites as partial melting of old crust, mixed with juvenile mantle component and suggest the basement of the North Qinling with more juvenile composition from the southern margin of North China block to Shangdan suture.

Particle size effects in bioleaching of uranium waste ore

WANG XUEGANG[1,2,3]*, SUN ZHANXUE[3] AND LIU JINHUI[3]

[1]State Key Laboratory Breeding Base of Nuclear Resources and Environment, East China Institute of Technology, Nanchang, JX 330013, P. R. China (*correspondence:xuegangwang@yahoo.com.cn)
[2]Key Laboratory of Radioactive Geology and Exploration Technology Fundamental Science for National Defense, East China Institute of Technology, Fuzhou, JX 344000, P. R. China
[3]Department of Civil and Environmental Engineering, East China Institute of Technology, Fuzhou, JX 344000, P. R. China (zhxsun@ecit.cn, liujh@ecit.cn)

The effect of mineral paricle size on the bioleaching of uranium from the 721 Uranium Mine Shan-nan deposit waste ore, located in the Jiangxi Province, south of China, was investigated. A mixed bacteria, which isolated from the uranium mine ores and the predominant bacteria were *Acidithiobacillus ferrooxidans* and *Leptospirillium ferriphilum,* was applied into the column bioleaching test. The uranium leaching effect in different particle size uranium ore were shown in table 1.

particle size (mm)	U content (%)	Slag U content (%)	Leaching rate(%)
>25	0.0289	0.00258	10.73
20-25	0.0141	0.00098	30.49
15-20	0.0161	0.00089	44.72
10-15	0.0330	0.00093	71.81
5-10	0.0332	0.00069	79.21
2-5	0.0403	0.00068	83.13
1-2	0.0434	0.00058	86.63
<1	0.0479	0.00057	88.10

Table 1: The leaching rate of different particle size

As can be seen from table 1, with the waste uranium ore particle size decreasing, the leaching rate was increasing. Decreasing the particle size from 25mm to 1mm the uranium leaching rate enhanced from 10.73% to 88.1%. While the particle size less than 15mm fraction leaching rate was over 71.81%, also the particle size greater than 15mm fraction leaching rate less than 44.72% , which adverse to uranium bioleaching. Consider the actual process, recommended crushed ore to -15mm can be obtained better effect.

From solids to liquids: A coordinated approach for studying dynamic processes in the deep Earth using large-volume apparatus and synchrotron radiation

YANBIN WANG

Center for Advanced Radiation Sources, The University of Chicago, 5640 S. Ellis Ave., Chicago, IL 60637, USA (wang@cars.uchicago.edu)

For the past fifteen years, we have been developing synchrotron-based large-volume high pressure (LVP) techniques at the GeoSoilEnviroCARS (GSECARS) sector of the Advanced Photon Source (APS) for a better understanding of the thermodynamic state, the dynamic processes, and the evolution of the Earth and other planets. The technical and scientific developments have enabled us to conduct coordinated studies on materials in both the solid and liquid states under simultaneously high pressure and high temperature conditions. In this presentation I will discuss the following dynamic aspects of recent scientific studies: (1) rheological properties of earth materials at high pressure and temperature, using the deformation DIA (D-DIA) – recent results on olivine deformation will be used as an example, (2) textural evolution in multi-phased materials under large shear deformation using the high-pressure x-ray tomographic microscope (HPXTM) – applications of such studies on mantle dynamics will be discussed, (3) in-situ high-pressure tomographic studies on Fe-S melt segregation from silicate using HPXTM and new constraints on the timing of formation of the Earth's core, and (4) new development for melt studies, including fusion curve, structure, density, and elasticity, aiming at a "complete suite" of physical properties for a better understanding of melt physics. A brief discussion on future prospect will also be presented.

Quantitative ^{2}H NMR as site-specific $^{2}H/^{1}H$ probe to study organic matter

Y. WANG[1], G.D. CODY[1], C.M.O'D. ALEXANDER[2] AND M.L. FOGEL[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington (ywang1@ciw.edu, gcody@ciw.edu, mfogel@ciw.edu)

[2]Department of Terrestrial Magnetism, Carnegie Institution of Washington (alexander@dtm.ciw.edu)

Recent studies show that the biosynthetic fractionation between fatty acids and water can vary by up to 500‰, depending on biological and environmental factors that include: species, metabolic pathways, aridity, and salinity. These variations are poorly understood, which has restricted the specificity of biomarker $\delta^{2}H$ records and thus their use as paleoenvironmental and geobiological proxies. Direct detection of the site-specific ^{2}H distribution via ^{2}H NMR provides a powerful means for investigating these variations and the underlying mechanisms. Unlike approaches that employ chemical/thermal fragmentation and IRMS measurements, ^{2}H NMR is non-destructive, applicable to almost all types of organic molecules, and free of isotopic fractionation. Similar to the advent of compound-specific isotope analyses, it has the potential to open a new door to the study of organic materials that will benefit a broad range of biogeochemical and low-temperature geochemical studies.

Historically, ^{2}H NMR experiments on natural samples have been difficult due to the scarcity of the ^{2}H nucleus and its low receptivity to radio frequency radiation which together lower the sensitivity by ~$7x10^{5}$ times compared to ^{1}H NMR. Furthermore, the ^{2}H NMR spectra is complicated by the quadrupolar interaction of the ^{2}H nuclei. We have successfully developed a solid state ^{2}H NMR experimental protocol to significantly amplify the signal-to-noise ratio and yield simplified, purely isotropic spectra.

With this method, we studied the site-specific ^{2}H distribution in residual organic matter from two carbonaceous chondrite meteorites and a bituminous coal. Combined with ^{1}H NMR spectra and bulk $^{2}H/^{1}H$ analyses, we derived the $\delta^{2}H$ values for aliphatic and aromatic sites and the $^{2}H/^{1}H$ fractionation factor between these groups, which provide a unique basis for coupling the $^{2}H/^{1}H$ distribution to the chemical history of chondrites. In an on-going study, we investigated H isotope exchange rates by incubating pristane, cumene, and anthracene, separately, with clay minerals soaked in ^{2}H-enriched water. Liquid state ^{2}H NMR was used to study the efficiency of ^{2}H substitution at methyl, methylene, methine, and aromatic sites. The results will improve our understanding of the influences on H isotopic composition of sedimentary organic matter and petroleum.

Nd-Sr-Pb isotopic and elemental geochemistry of silicalites from the sulphide ore deposit in the Guangdong region, China

WANG YINXI[1], LI HUIMING [1] ,WANG YUANYUAN [2], CHEN YIJUN[1], ZHANG MENGQUN[1] AND WANG HENIAN [2]

[1]Center of Modern Analysis, Nanjing University, Nanjing 210093, China
[2]Nanjing Institute of Geology and Paleontology, Academy of Sciences, Nanjing 210008, China.
[3]Dept.of Earth Science, Nanjing University, 210093, China

Silicalite is well developed and is present as layers, thin layer or siliceous band in the banded ores. The Dajiangping pyrite deposits lie on the Yunfu County of Guangdong .region, China. is a super-large pyrte ore deposite.

The silicalite is mainly coposed of microlitic and cryptocrystalline quartz. SiO_2 is the essential chemical composed of the silicalite, ranging from 81.50% to 94.32%, together with Al2O3 content between 0.45% and 9.44%, CaO< 0.12% and MgO<0.36%. The contents of FeO, MnO, K_2O and Na_2O are commonly low. The isotopic characters of the Dajiang pyrite orebody are: εNd(t) =-12 ~ -13, $(^{87}Sr/^{86}Sr)I$ = 0.73085 ~ 0.73104, $(^{206}Pb/^{204}Pb)I$ =18.467 ~ 18.485, $(^{207}Pb/^{204}Pb)I$ =16.239 ~ 16.384 and $(^{208}Pb/^{204}Pb)I$ =39.805 ~ 39.873. Because of the isotopic characteristic of Sr-Nd-Pb in the whole rock, these evidences reflect the character of crust source but not that of magmatic source region.

The dertermination of Dajiangping pyrite deposit indicates that the Precambrian continental rift massive sulphide ore deposit is also an important kind of deposit in South China basides. Evidently, the above-mentioned Sr-Nd-Pb isotopic geochemistry reflecte the crust source r of the Dajiang pyrite deposits.

Rb-Sr and Sm-Nd isotopic ages of Sulphide deposits in the Guangdong region, China

WANG YINXI[1], LI HUIMING [1], WANG YUANYUAN [2], HU XIN[1], LIU DI[1], TAO XIANCONG[1] AND WANG HENIAN [3]

[1]Center of Modern Analysis, Nanjing University, Nanjing 210093, China (*correspondence: yxwang@nju.edu.cn)
[2]Nanjing Institute of Geology and Paleontology, Academy of Sciences, Nanjing 210008, China.
[3]Dept.of Earth Science, Nanjing University, 210093, China

The Dajiangping pyrite deposits lie on the Yunfu County of Guangdong .region, China. is a super-large pyrte ore deposite.

Rb-Sr and Sm-Nd isotope ages were measured by using VG354 mass spectrometer at Modern Analysis Centre, Nanjing University and the analytical procedures were discussed and given in detailed by Wang(1)

The Rb-Sr and Sm-Nd dating of the orebody give the ages of 630.1±7.3Ma and 637.5±6.9Ma,respectively. The ages slightly approximate the age in ferred from the occurrence of the later Proterozoic algae. This may be related to the subsequent geological effect on the Rb-Sr and Sm-Nd isotope system of the Dajiangping pyrite orebody. Because of the good linearity of Rb-Sr and Sm-Nd internal isochron between the whole rock, these evidences reflect the character of well-ditributed source. Evidently, the above-mentioned Rb-Sr and Sm-Nd isotopic ages reflecte the ages of the Dajiang pyrite deposits.

The silicalites ages of deposits in this are 630.1±7.3Ma and 637.5±6.9Ma, belonging to the later Proterozoic epoch. The dertermination of Dajiangping pyrite deposit indicates that thePrecambrian continental rift massive sulphide ore deposit is also an important kind of deposit in South China basides . The Dajiangping pyrite deposit is similar to the famous Proterozoic super-large depostis in the world. The ages determination of Dajiangping pyrite deposit bed plays an important role in confirming the agesof the Yunkai Group.

Nd-Sr isotopic geochemistry of fossils from the bottom of Cambrian in the Yunnan, Sichuan and Xinjiang region, China

YINXI WANG*,[1], YUANYUAN WANG , JIEDONG YANG[1] AND HUIMING LI[1]

[1]Center of Modern Analysis, Nanjing University, Nanjing 210093, China (*correspondence: yxwang@nju.edu.cn)
[2]Nanjing Institute of Geology and Paleontology, Academy of Sciences, Nanjing 210008, China.

This paper the results of Rb-Sr and Smi-Nd isotopic date fromphosphatic fossils and collophanites collected from three important Precambrian-Cambrian boundary section in China.The samples under study were collected from three important sections in China, namely, the Meishucun section at Yunnan Province, the Maidiping section at Sichuan province and the Wushi section at Xinjiang Uygur Autonomous Region.

$\varepsilon_{Nd(}$(T) and $^{87}Sr/^{86}Sr$ values of small shelly fossils from maidiping section are -6.5 to -7.1 and 0.709624 to 0.709812, respectively. $\varepsilon_{Nd(}$(T) and $^{87}Sr/^{86}Sr$ values of small shelly fossils from Meishucun section are -6.1 to -7.1 and 0.709310 to 0.709700, respectively. $\varepsilon_{Nd(}$(T) and $^{87}Sr/^{86}Sr$ values of small shelly fossils from Kalpin section are -6.1 to -6.5 and 0.709436 to 0.709576, respectively. $\varepsilon_{Nd(}$(T) and $^{87}Sr/^{86}Sr$ values of small shelly fossils from three section are very similar.

The palaeoseawater in the three areas of China was co-oceanic during the Precambrian-Cambrian transitional period, with an average $\varepsilon_{Nd(}$(T) value of -6.6 ± 0.5. The Nd model age of the tested samples is about 1.8Ga, which represents the mean age of the continental source sres surrounding China's seawater.

This work is granted by the National Natural Science Foundation of China (No. 40872028) and by the Analysis Testing Foundation of Nanjing University

Surfacial geochemical features of elements in Qinghai-Tibet Plateau

WANG YONGHUA[1] AND WANG MINGQI[2]

[1]Chengdu center, China Geological Survey, Sichuan, China 610082
[2]China University of Geosciences, Beijing, China

Qinghai-Tibet Plateau in China covers the area about 2,400,000km^2. Different landscapes including high-cold mountain, high-cold lake and swamp plateau, desert, deep velley are developed in the area. National geochemical mapping results show that there are typical distribution patterns of elements in different terrains.

High-cold mountain landscape, which is about 900,000km^2, over 4,000m hight and less than 0°C annual temperature, is situated in the heart of the plateau. Most elements including Ag, Au, Ba, Be, Bi, Cd, Co, Cr, Cu, F, Hg, La, Li, Mn, Mo, Nb, Ni, P, Pb, Sn, Sr, Th, U, V, Y, Zn, Zr, SiO_2, Al_2O_3, TFe_2O_3, MgO and Na_2O in the stream sediments are quite close to the average value of the whole area and only As, B, Sb, W and K_2O are slightly enriched .

High-cold lake terrain is over 800,000km^2, 4500m hight, 100-400mm rainfall and 0°C-4°C annual tempreture. Most elements including Cr, La, Li, Nb, P, Sn, Sr, V, Zr, Al_2O_3, TFe_2O_3, Ag, B, Ba, Be, Bi, Cd, Co, F, Hg, Li, Mn, Mo, Ni, Pb, Th, U, W, Y, Zn, K_2O, MgO, Na_2O in the terrain are decreased and only CaO is strongly enriched and As, Sb, Sr are slightly encreased.

Desert is widespread in west part of China and over 800,000km^2 in the plateau, in which annual rainfall is less than 400mm and the annual temperature is about 0 °C. The many elements like As, B, Cd, Hg, Li, Ni, Sb, Ti, U, V, W, Zn, Ag, Be, Bi, Co, Cr, Cu, F, La, Mn, Mo, Nb, P, Pb, Sn, Th, Y, Zr, TFe_2O_3 in the terrain are low than the average value of whole plateau; but Ba, Sr, CaO, MgO, Na_2O and K_2O are increased.

Deep valley landscape, which is 640,000 km^2 and over 1500m relief, is distributed around the plateau. The average contents of most elements including Ag, Au,Be, Cd, Co, Cr, Cu, F, Hg, Mn, Mo, La, Li, Mn, Mo, Nb, Ni, P, Pb, Sn, Th, Ti, U, V, W, Y, Zn, Zr, Al_2O_3, Tfe_2O_3 and K_2O in the terrain are much higher than that in whole plateau.

n-Alkan-2-ones of lacustrine sediments and its climate significance in Linxia Basin, NE Tibetan Plateau, NW China

YONGLI WANG[1,2], XIAOMING FANG[2], YUANMAO LI[1], DAXIANG HE[1], YINGQIN WU[1], HUI YANG[1] AND YOUXIAO WANG[1]

[1]Key Laboratory of Petroleum Resources Research, Institute of Geology and Geophysics, Chinese Academy of Sciences, Lanzhou 730000, China

[2]Center of Basin-Mountain System and Environ-ment, Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing 100085, China (correspondence:Fangxm@itpcas.ac.cn)

Abundant n-alkan-2-ones were detected in all samples and the distribution ranging was from C17 to C31 in the lacustrine sediments of Maogou section in the Linxia Basin, NE Tibetan Plateau, NW China. The maxima peaks of C27, C29 and C31 were especially obvious and the odd carbon number predominance was remarkable from C25 to C31. The different maxima peaks of n-alkan-2-one from relative higher to lower carbon-numbered compounds were changed obviously and six climate stages could be identified in entire depositional section. Abundant isoprene-ketones (i.e., isomeric C18 ketones, iKC18) were detected in all samples. The relative abundance of isoprene-ketones for MG5 and MG8 to MG11 were higher, while that for MG1 to MG4 and MG6 to MG7 were lower. The isoprene-ketone can be regarded as recorder of temperature changes of the sedimentary environment. The higher abundance of isoprene-ketones indicates the low temperature of the sedimentary environment. The greatest change showed for MG7 to MG8 when the relative abundance of isoprene-ketones increased sharply, indicating the climate turned to cold condition at ~8Ma suddenly. Another obvious change in the relative abundance of isoprene-ketones was higher in MG5 indicating a cold condition at ~13Ma.

Based on the distribution characteristics of these biomarkers, we suggest that they record information related to climate change.

Water hydrogen and oxygen isotope composition characterization in the tea ditch of Anxian, China

WANG YONGLI, NI SHIJUN AND ZHANG CHENGJIANG

[1]Department of Geochemistry, Chengdu University of Technology, Sichuan Province, (wangyl@cdut.edu.cn, nsjl@cdut.edu.cn, zcj@cdut.edu.cn)

This paper studies isotopic composition in the Chayuan Gou of Anxian area. The results showed that the water body δD is between -68 ‰ ~ -54 ‰, $\delta^{18}O$ in between -11 ‰ ~ -8 ‰; Sample put above global rainfall line and distribute in two different area(ChuBa Gou water area, Chayuan Gou water area). these show the groundwater and surface water originated in the meteoric waters of supply; according to $\delta^{18}O$ isotopic composition water Supplies elevation are about 1400 ~ 1500m.

ChuBa Gou water system and Chayuan Gou water system has different hydrogen and oxygen isotopic composition, the front is enrich lighter isotopes and the later is enrich heavy isotopes. S15 isotopic composition of spring water showed that the groundwater come from different two type groundwater mixing, the mixing ratio of 3:2.

Mechanism of uranium accumulation in a mining-impacted acidic peatbog

Y. WANG[1]*, M. FRUTSCHI[1], V. PHROMMAVANH[2], M. DESCOSTES[2] AND R. BERNIER-LATMANI[1]

[1]Ecole Polytechnique Fédérale de Lausanne (EPFL), Environmental Microbiology Laboratory (EML), Station 6, CH-1015 Lausanne, Switzerland (*correspondence: yuheng.wang@epfl.ch)

[2]AREVA NC - Business Group Mines, Direction R&D, BAL 3720C, Tour AREVA, 1, place Jean Millier, 92084 Paris La Défense Cedex, France

Uranium can accumulate in peatbogs from both natural and anthropogenic sources [1, 2]. An acidic peatbog located in central France was affected by historical uranium mining activities as well as by continued uranium leaching from granite rocks. As a result, this site displays areas, referred to as hotspots, in which uranium concentration can reach up to 4,000 mg/kg [3]. The first-order question for this site is the mechanism leading to this remarkable accumulation. Microbially-driven reductive immobilization is a possible route but so is the complexation of U(VI) by solid phase organic matter that is abundant in the peat soil.

In order to unravel this mechanism and to evaluate the impact of proposed remediation strategies, extensive depth-resolved sampling of soil and porewater have been carried out at hotspots as well as at U-free background areas. Core samples were analyzed for chemical composition, mineralogy and uranium speciation using a combination of x-ray diffraction, gamma spectrometry, sequential chemical extractions, electron microscopy of petrographic sections, cryo electron microscopy of plunge-frozen samples and bulk and micro-scale X-ray absorption spectroscopy. Moreover, the microbial community present in the soil was characterized phylogenetically and probed for its metabolic potential for U(VI) reduction. Additionally, porewater physico-chemical parameters (e.g., pH, Eh, DO, Fe(II), SO_4^{2-}, sulfide, U, Mn(II), major inorganic cations and anions, TOC, TIC) were obtained from the same spots to allow correlation of the water and soil characteristics as a fucntion of depth. This approach is the basis for a delineation of the redox transition from oxic to anoxic and the corresponding microbial activity in each redox zone and provides the information needed to understand the mechanism of accumulation of U in this site.

Modeling hydrogen and carbon isotopes of thermogenic gases from different kerogens in closed system

YUNPENG WANG[1], CHANGYI ZHAO[2] ,HONGJUN WANG[2] AND JINZHONG LIU[1]

[1]SKLOG, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China

[2]RIPED of PetroChina, Beijing 100083, China

For better characterizing the hydrogen and carbon isotopes of thermogenic gases, we studied three selected lacustrine, marine and terrigenous kerogen (coal) samples using gold-tube closed system. We found the obvious fractionation mutation of hydrogen isotope at higher conversion rate for lacustrine and marine kerogen. How to model the isotopic variation is a key issue. Here, we take Rayleigh's method proposed by Rooney (1995) [1], and the isotopic variation was modeled by using two Rayleigh's functions and the results are showing in Fig. 1. In Rayleigh's function, we fitted the experimental results through adjusting the initial isotope compositions of the gas precursors (δ_0) and fractionation factors (ε=1000(α-1), α is the ratio of reaction rates of isotopes). It is clear that there exist variations for evolution trend of lacustrine and marine kerogen while conversion rate (F) reaches around 0.6, but the variation is not obvious for coal in comparison. Figure 1 suggests that the initial isotope and fractionation factor changed for type I/II kerogen. Inspecting the generation and cracking record, we found these variations are corresponding to the onset temperature of massive secondary cracking of heavy hydrocarbons to methane. This study implies that the secondary cracking of oil in closed system will chang the hydrogen and carbon isotopes of thermogenic gases.

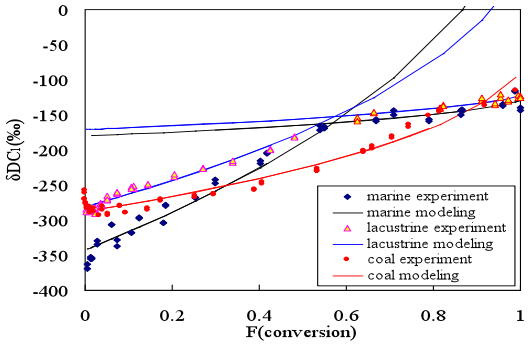

Figure 1: The experimental and modeling results

Fractionation of highly siderophile elements, selenium and tellurium in peridotites from the Baldissero and Balmuccia peridotite massifs, Ivrea Zone (Northern Italy)

Z. WANG*, H. BECKER AND T. GAWRONSKI

Freie Universität Berlin, Institut für Geologische Wissenschaften, Malteserstrasse 74-100, D-12249 Berlin, Germany (*correspondence: zaicongwang@gmail.com)

Peridotites from the Ivrea Zone (Northern Italy) are known for their excellent preservation and absence of low temperature alteration features. We have determined abundances of highly siderophile elements (HSE), Se and Te, and $^{187}Os/^{188}Os$ in depleted and fertile spinel lherzolites and a harzburgite (loss on ignition <1 %) from the Balmuccia and Baldissero massifs in order to study the behaviour of elements such as Au, Re, Se and Te that are otherwise easily affected by alteration processes. The lherzolites (Al_2O_3=2.0-3.1 %) have absolute and relative abundances of Os, Ir and Ru (Os/Ir=1.13±0.04, Ru/Ir = 2.02±0.08, n=10), consistent with typical mantle lherzolites. Incompatible HSE are relatively depleted (e.g., Re/Ir = 0.04±0.02, Au/Ir= 0.30±0.10, Pd/Ir=1.90±0.40). Balmuccia peridotites show limited variation and Baldissero peridotites larger scatter, with a harzburgite showing the lowest abundances of incompatible HSE and chalcophiles. All samples show a systematic depletion pattern in CI chondrite normalized diagrams with Pd > Au > Re, but no systematic variation with lithophile tracers exist. Se concentrations of lherzolites range between 54 and 89 ng/g and Te contents from 12 to 18 ng/g, resulting in Se/Te (4.2-7.3) below CI chondrite values. Initial $\gamma Os_{(300Ma)}$ (-2.3 to +2.0) are consistent with the notion that the last partial melting event occurred during the Phanerozoic. The data on lherzolites can be explained by moderate degrees of partial melting and control of partitioning by sulphide-silicate equilibrium with $D_{Re}<D_{Au}<D_{Pd}$ and $D_{Se}<D_{Te}$.

In situ stable isotopic detection of anaerobic oxidation of methane in Monterey Bay cold seeps via integrated cavity ouput spectroscopy

SCOTT D. WANKEL[1]*, MANISH GUPTA[2], J. BRIAN LEEN[2], ROBERT PROVENCAL[2], VIMAL PARSOTAM[2] AND PETER R. GIRGUIS[3]

[3]Department of Organismic and Evolutionary Biology, Harvard University, Cambridge, MA 02138

Anaerobic methane oxidation (AOM) plays an important role in the global methane cycle by governing the release of CH_4 from anoxic sediments into the global ocean and ultimately the atmosphere. Thus, gaining an accurate understanding of both the distribution of CH_4 sources and the occurrence of AOM as well as the spatial and temporal variability of cycling pathways is critical. Environmental analyses of methane stable isotopic composition ($\delta^{13}C_{CH4}$) provide just such an indicator of CH_4 source, whether biogenic or thermogenic, as well as a spatial and temporal integrator of microbial cycling pathways, such as AOM. Here we present results from several deployments of a newly developed *in situ* methane stable isotope analyzer (Off-Axis ICOS) capable of measuring $\delta^{13}C_{CH4}$ to full ocean depths. Deployments to cold seep environments (960m) in Monterey Canyon (California) revealed a distinct separation between $\delta^{13}C_{CH4}$ in advecting fluids relative to sediment pore fluids. Multiple visits to two sites revealed $\delta^{13}C_{CH4}$ in advecting fluids ranging from -70.2 to -63.8‰, while fluids sampled from adjacent pushcore holes exhibited higher $\delta^{13}C_{CH4}$ (-64.2 to -50.2‰). While advective flux of CH_4 from the central seep orifice is substantial, these data implicate the importance of AOM in consuming a minimum of 57 to 70% of the diffusive flux of CH_4 in the surrounding sediments.

Crustal accretion on mid-ocean ridges revealed through volatile concentrations in olivine-hosted melt inclusions

V.D. WANLESS*, A. SHAW AND M. BEHN

Department of Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA (*correspondence: dwanless@whoi.edu)

We present volatile (H_2O, CO_2, Cl, S, and F) and major element data from melt inclusions in olivines found in crustal xenoliths and crystal clots from the fast-spreading East Pacific Rise to determine the depths of crystallization on mid-ocean ridges (MOR). The melt inclusions are generally, more primitive compared to the host glasses, with MgO concentrations ranging from 7.5 to 11.5 wt% and 6.6 to 8.4 wt%, respectively. Vapor saturation pressures calculated from equilibrium CO_2-H_2O concentrations suggest crystallization depths ranging from the crust-mantle transition (~6 km bsf) to above the seismically imaged, shallow melt lens (~600 m bsf). Minimum pressures estimates indicate that most of the melt inclusions (~70%) cluster between 1 and 2.5 km, consistent with crystallization in the shallow melt lens. However, the remaining melt inclusions show minimum equilibration pressures deeper than 2.5 km, implying that olivine crystallization beneath fast-spreading centers is not limited to the shallow melt lens.

Vapor-saturation pressures are also used to determine how volatile and major element concentrations vary with depth in the ocean crust. In general, volatile concentrations are much more variable in the upper 4 km of crust compared to the lower crust. For instance, Cl concentrations in melt inclusions formed in the upper crust range from 10 to 66 ppm, compared to only 42 to 51 ppm in melt inclusions formed deeper in the crust. This may result from higher degrees of fractional crystallization and/or increased fluid-rock interaction in the shallow crust. Major elements show no systematic variations with depth; however, more evolved olivines (Fo <86) are restricted to pressures within the shallow crust.

Several models have been proposed for crustal accretion beneath MORs (e.g., gabbro glacier or stacked sills), however there is no consensus on how the lower crust is formed at MORs or the depths over which crystallization occurs. Our volatile data imply that crystallization on fast-spreading ridges occurs throughout the crust, favoring models of in-situ crystallization or stacked sills and is inconsistent with a purely top-down, gabbro glacier model for lower crustal accretion on fast-spreading MORs.

A role of plant biomass-derived black carbon in electron transfer processes?

T. WANZEK[1], M. KEILUWEIT[1,2], D.PIERSON,[1] J. BAHAM[1] AND M. KLEBER[1]*

[1]Oregon State University, Department of Crop and Soil Science, Corvallis, OR 97331 (*correspondence: Markus.Kleber@oregonstate.edu)

[2]Lawrence Livermore National Laboratory, Physical and Life Sciences Directorate, Livermore, CA 94550

Recent work by Roden *et al*. [1] has provided strong evidence for a role of aromatic compounds in providing solid-state electron shuttles for electron transfer between bacteria and metal oxide surfaces. Historically, such materials are considered to be part of operationally defined "humic" substances [2] and are thought to result from "humification", i.e., from processes of secondary synthesis in the course of organic matter decomposition. However, there is increasing evidence that soils and sediments are subject to large imports of aromatic carbon on a global scale [3,4] through vegetation fires and additions of industrial black carbon. Future additions of aromatic carbon to soils are expected to rise in the wake of the evolving "Biochar" movement [5].

Up to one fifth of oxygen-containing functional groups on industrial black carbon can have quinonic functionality [6], and a number of studies suggest that quinone functionalities within natural organic matter can be a suitable electron transfer mediator for iron bioreduction and contaminant degradation [7]. It has been determined that the efficiency of quinone redox mediators is controlled by their reduction potential, stability towards side reactions and kinetic reactivity in electron transfer reactions [7].

Here we take a first step towards identifying a potential role of plant biomass-derived black carbon in generating aromatic compounds with the ability to serve as electron transfer media. Titrations and spectroscopic information were used to test the hypothesis that redox potentials of chars vary as a function of quinone group abundance. Grass and wood chars generated across a range of heat treatment temperatures [8] allowed us to represent the varying amounts of oxygenated surface groups known to occur in natural chars.

Modelling phase behaviour in the geological storage of carbon dioxide

O. WARR[1]*, C.J. BALLENTINE[1] AND A. MASTERS[2]

[1]SEAES, University of Manchester, M13 9PL, UK (*correspondence: oliver.warr@postgrad.manchester.ac.uk)
[2]CEAS, University of Manchester, M13 9PL, UK

Global warming is currently accepted as a key issue facing man. One potentially viable solution is carbon dioxide sequestration in shallow aquifers [1] where carbon dioxide is expected to exist as a supercritical phase above an underlying water phase [2]. It is essential therefore that this binary phase system is fully understood. One technique is to use trace inert proxies (i.e. noble gases) which can coexist as solute particles within both phases, the partitioning of which is affected by the extent of phase interactions (groundwater contact) and the magnitude/rate of carbon dioxide dissolution. These proxies can therefore be used to yield essential information on these processes [3].

It is however imperative that noble gas partitioning between the two phases is well constrained. We are constructing a Gibbs-Ensemble Monte Carlo simulation to model this binary phase system which will include noble gas tracers to generate the partitioning coefficients for all noble gases for the wide range of conditions expected in storage sites. This simulation simultaneously samples the molecular configurations in both water-rich and carbon dioxide-rich phases. Particles are exchanged between the two systems. At steady state the two phases are at thermodynamic equilibrium and the corresponding compositions and overall densities can be calculated. Models selected for water [4] and carbon dioxide [5] have already been extensively tested across the temperatures and pressure ranges of interest (40-150 Bar, 320-360 K) with average simulated densities being within 1.1% and 5% respectively of experimental values and thus are considered sufficiently accurate thermodynamically for incorporation into the model. Further ground-truthing for the model is being provided by lab experiments under simulated shallow aquifer conditions. We present the current progress in creating this model and discussion of the challenges which have arisen as a result of modelling such a complex system.

Mantle heterogeneity constraints from abyssal peridotite sulfide Pb and Os isotopic compositions

JESSICA M. WARREN[1]* AND STEVEN B. SHIREY[2]

[1]Geological and Environmental Sciences, Stanford University (*correspondence: warrenj@stanford.edu)
[2]Department of Terrestrial Magnetism, Carnegie Institution of Washington

Convection over the history of the Earth has led to multiple cycles of mantle depletion and enrichment, which are preserved as ancient chemical compositional anomalies in the oceanic mantle. Studies of long-lived radiogenic isotopes in basalts, such as Pb, have indicated signficant mantle heterogeneity in both the depleted upper mantle and the mantle source of ocean island basalts. The basalt data array defines a ~2 Ga age that has been interpreted as recording mixing of ancient subducted slabs with depleted mantle.

In contrast to basalts, abyssal peridotites from oceanic ridges have the potential to constrain the sub-kilometer lengthscale of mantle variability. Analysis of Pb isotopes in peridotites has been limited by the very low concentration of Pb in these residues of mantle melting. We have employed a technique for the determination of Pb and Re-Os isotopes and concentrations in peridotite sulfides using a modified version of the Re-Os technique for sulfide inclusions in diamonds.

The Pb and Re-Os isotopic composition of 21 sulfide grains were determined for abyssal peridotites from the Gakkel and Southwest Indian Ridges. Concentrations of Pb and Os in sulfides are correlated, with a correlation coefficient of ~0.8. The relatively lower mantle normalized concentrations of Pb (27, for an average of 4 ppm) with respect to Os (470, for an average of 1.6 ppm) indicates that Pb is much less compatible in sulfide during mantle melting than previously thought. Sulfide Pb concentrations are so low that sulfides cannot be the main reservoir of mantle Pb, storing only ~2%, with the remainder hosted in silicates.

Sulfide Pb isotopic compositions extend to unradiogenic values that plot to the left of the geochron and cover a wider range than associated basalts. Pb and Os isotopic compositons are correlated, also with a coefficient of ~0.8. The Re-Os data in sulfides fall along a 2 Ga model age, similar to the age given by the Pb-Pb system for the same sulfides. Multiple grains from the same peridotite have different isotopic compositions and elemental concentrations. Taken together, these results indicate that the mantle is heterogeneous down to the sub-sample lengthscale, with the Pb-Os correlation requiring that these heterogeneities were created by prior ridge melting events at ~2 Ga.

Suspended floc: Links between microbial ecology, FeOOH and trace element dynamics

L.A.WARREN*, A.V.C. ELLIOTT AND J.M. PLACH

SGES, McMaster University, 1280 Main St West, Hamilton ON L8S4K1 Canada
(*correspondence: warrenl@mcmaster.ca)

The linkages between microorganisms and geochemical processes in environmental systems hinge on ecological relationships associated with the microbial consortia involved. These ecological relationships are often highly cooperative and macroscopically structured to enable microscale redox cycling not favourable under bulk system conditions. Suspended floc, highly microbially active, trace element (TE) rich and interactive with bulk aqueous solution, are poorly studied with respect to microbial-mineral-TE biogeochemistry. Characterization of suspended floc TE abundance and partitioning for Ag, As, Cu, Ni and Co across six variably impacted aquatic ecosystems identify floc to be a key TE sequestration sedimentary compartment, concentrating TE ~55x above that of surficial bed sediments. Further, floc TE-geochemical partitioning patterns were conserved across systems, with amorphous Fe oxyhydroxides (FeOOH) consistently as the most important sorbent phase for TE retention, irrespective of physcio-chemical conditions or TE involved. Results indicate that floc TE uptake is biologically linked to floc microbial components. Floc organic concentration directly predicts floc FeOOH concentration while imaging analysis shows bacterial exopolymeric substances (EPS) fibrils, a major floc constituent, to be heavily mineralized. Thus while floc FeOOH are the dominant floc TE sequestration phase, EPS and microbial constituents are the critical foundation underpinning floc TE behaviour through their structural role in floc FeOOH occurrence, ultimately creating a distinctly different solid than bed sediments with differing controls on TE uptake. Further, the enrichment of both iron reducing and iron oxidizing microorganisms from all flocs collected across a spectrum of systems widely variant in [O_2] and pH indicate previously unconstrained Fe cycling occurs at the floc scale that is controlled by floc ecology, not by system geochemistry. These results add to the growing evidence that ecological partnership enables consortial microbes to "sidestep" geochemical constraints predicted to occur at the bulk scale.

Carbonation of artificial silicate minerals: Passive removal of atmospheric CO_2

C-L. WASHBOURNE[1]*, P. RENFORTH[2] AND D.A.C. MANNING[1]

[1]School of Civil Engineering and Geosciences, Newcastle University, NE1 7RU, United Kingdom (*correspondence: carla-leanne.washbourne@ncl.ac.uk)
[2]Department of Earth Sciences, University of Oxford, Oxford, OX1 3AN, United Kingdom

Artificial silicate minerals present an accessible source of material for enhanced weathering. Silicate 'wastes' may perform carbon sequestration through *in situ* carbonation of calcium (Ca) and magnesium (Mg) phases. Maximum carbon (C) capture potential using artificial silicates is 190-332Mt C a^{-1} [1]. Soil engineering, promoting CO_2 sequestration by inclusion of these reactive mineral substrates, has the potential to capture a portion of the C turnover of the global pedologic system; 75 Gt C a^{-1} [2][3][4].

Stable isotope data ($\delta^{13}C$, $\delta^{18}O$) confirm that >50-90% of C in pedogenic carbonates, formed on artificial silicates, is atmospherically derived. Field observations and laboratory data demonstrate that anthropogenic soils accumulate 20-30 kg C m^2 as carbonates (≥organic carbon content in natural soils). Flow-through experiments (25°C, 1 atm.) using fresh basic steel slag show pH buffered at ~11.6 as Ca leaches at a rate of $\log_{10}$-8.9 – $\log_{10}$-9.3$mol^{-1}sec^{-1}cm^{-2}$, several orders of magnitude faster than 'natural' silicates. Once portlandite ($Ca(OH)_2$) has been consumed pH is reduced to ~9.1 and calcium carbonate precipitation continues.

Effective, low-energy field-scale implementation of mineral carbonation through soil engineering could assuage current constraints on economic performance [5][6][7]. Proof of principle for carbonation of artificial silicates in engineered soils has been demonstrated [4]; proof of field scale feasibility will be demonstrated though continued empirical and experimental observation including extensive analysis of carbon in urban soils at the Science Central development site, Newcastle upon Tyne, UK.

Pathways of dissolved organic matter in the subterranean estuary: Evaluation of organic geochemical tracers

HANNELORE WASKA[1]*, MICHAEL SEIDEL[1], THORSTEN DITTMAR[1] AND GUEBUEM KIM[2]

[1]Max Planck Research Group for Marine Geochemistry, ICBM, University of Oldenburg, Germany (*correspondence: hwaska@mpi-bremen.de, mseidel@mpi-bremen.de, tdittmar@mpi-bremen.de)
[2]Environmental and Marine Biogeochemistry Laboratory, School of Earth and Environmental Sciences, Seoul National University, South Korea (gkim@snu.ac.kr)

The mixing zone of fresh terrestrial groundwater and recirculating seawater in a coastal permeable aquifer, the so-called "subterranean estuary", is a powerful bioreactor which determines the fate of dissolved compounds as they are transported into the ocean via submarine groundwater discharge (SGD). Dissolved organic matter (DOM) plays a crucial role in driving microbial remineralization processes, and through its breakdown contributes to the groundwater nutrient pool. Until recently, DOM in the subterranean estuary was mostly determined as bulk dissolved organic carbon, providing limited information on sources and degradation states. Studies of chromophoric DOM (CDOM) and biomarkers such as lignin provide information on DOM origin. Other traditional parameters, such as amino acid D/L ratios and degradation indices, and stable isotopic composition (e.g. $\delta^{13}C$), can be used to track the processing of DOM. Emerging analytical techniques, e.g. ultra-high resolution Fourier-transform ion cyclotron resonance mass spectrometry (FT-ICR-MS), improve our understanding of the chemical composition of DOM by providing molecular fingerprints. We investigated two intertidal subterranean estuaries, in Hampyeong Bay along the Yellow Sea coast of South Korea and on Spiekeroog Island, a barrier island in the German Wadden Sea. The major objective was to characterize pathways of DOM as it travels through the aquifer. In Hampyeong Bay, amino acid and CDOM data pointed to a mostly marine DOM source, whereas on Spiekeroog, $\delta^{13}C$ values indicated both a marine and a terrestrial DOM source. Molecular fingerprinting showed that a large amount of DOM was processed in the aquifer of Spiekeroog Island, whereas several components were passing the subterranean estuary unaltered, possibly forming a source of refractory DOM.

Is your clean lab full of zinc?

L.E. WASYLENKI[1]*, E.B. WILKES[2] AND A.D. ANBAR[3]

[1]Dept. of Geological Sciences, Indiana University, 1001 East Tenth Street, Bloomington, IN 47405-1405 USA (*correspondence: lauraw@indiana.edu)
[2]Dartmouth College, Hanover, NH 03755 USA
[3]School of Earth and Space Exploration and Dept. of Chemistry and Biochemistry, Arizona State University, Tempe, AZ 85287 USA

Contamination of samples with extraneous zinc is likely much more common and severe than many metal isotope geochemists expect. Bottles, tubes, pipette tips, and especially disposable gloves are often produced with Zn stearate as the mold release agent. By far the largest amount of zinc is introduced by gloves. Dilute HCl will effectively rid other items of Zn, but gloves cannot be cleaned easily, and their use can lead to surface contamination throughout the lab.

We recently conducted experiments in which dissolved Zn was partly adsorbed onto Mn-oxide particles. The dissolved and adsorbed pools were separated by filtration, and isotope ratios were analyzed by MC-ICP-MS. A commercial ICP solution was both our standard ($\delta^{66/64}Zn = 0$) and the source of Zn in the experiments. When gloves were worn for sample handling, blanks contained as much as 150 ng Zn, and both the dissolved and adsorbed pools came out enriched in heavy isotopes relative to the starting pool, in apparent violation of mass balance. Without gloves, blanks were lower, but still variable, and mass balance was more closely satisfied. Zinc leached from two brands of allegedly low-zinc vinyl gloves was +10‰ relative to our standard ($\delta^{66/64}Zn$). We conclude that glove Zn in our lab contaminated our samples, even when gloves were not worn for sample processing.

We were only able to see clear evidence of contamination because (1) we had an expectation of mass balance, and (2) we happened to use a standard strongly enriched in light isotopes relative to our gloves. We caution others who measure unknown, natural samples that most natural samples are similar in isotopic composition to the gloves we measured and to JMC-Lyon Zn, which is becoming an accepted Zn isotope standard. Knowing whether variable amounts of glove zinc are contaminating samples is therefore a challenge. We recommend very careful monitoring of blanks and column chemistry yields, and we plan to designate and clean a glove-free workspace within the clean lab for further zinc isotope work.

Raman spectroscopic insight into structural changes in berlinite with high pressure and temperature

ANKE WATENPHUL[1]* AND CHRISTIAN SCHMIDT[2]

[1]Deutsches Elektronen-Synchrotron DESY, Notkestr. 86, 22603 Hamburg, Germany (anke.watenphul@desy.de) (* correspondence: anke.watenphul@desy.de)
[2]Deutsches GeoForschungsZentrum (GFZ), Telegrafenberg, 14473 Potsdam, Germany (hokie@gfz-potsdam.de)

Berlinite ($AlPO_4$) and α-quartz are structural isotypes, which are related to each other by the coupled substitution 2 Si = Al + P. The SiO_4 tetrahedra along the *c*-axis in α-quartz are replaced in berlinite by alternating AlO_4 and PO_4 tetrahedra. This preferred ordering results in a doubled *c* unit-cell parameter. The frequencies of Raman modes of berlinite and α-quartz are very similar because the atomic masses of Al + P are almost the same as that of two Si atoms [1]. However, detailed inspection reveals a greater complexity in the Raman spectrum of berlinite [2]. To obtain more information on the relationships to the berlinite structure, we studied the strong A_1-Raman lines at 462 and the 1111 cm^{-1} at temperatures up to 800 °C and pressures up to 10 GPa.

The positions of both bands shift in the opposite direction with pressure (*P*) and, likewise, with temperature (*T*). The 1111 cm^{-1} Raman line is accompanied by a less intense band at 1104 cm^{-1}. With increasing *P*, the 1111 cm^{-1} band shifts towards lower wavenumbers and that at 1104 cm^{-1} to higher wavenumbers. Both lines thus display the same frequency at about 1.4 GPa at 23 °C. With further increase in *P*, they become fully separated above 5 GPa. Both Raman lines originate from stretching vibrations of the PO_4 tetrahedra. The opposed behavior with pressure is tentatively interpreted as being caused by the alternate succession of the AlO_4 and PO_4 tetrahedra along the *c*-axis, which permits a different compression/extension of the P-O1 and P-O2 distances.

The results also indicate the great potential of berlinite as a pressure sensor for diamond-anvil cell experiments, including studies at elevated *T*. A relative shift, defined by the difference of the shifts in the wavenumber between the 462 and the 1111 cm^{-1} lines with *P* and *T*, can be used as pressure gauge. Moreover, this sensor may be applicable at higher pressures than α-quartz [3] because no high-pressure polymorph isomorphic to coesite or stishovite is known.

Effect of ionic strength on Ca isotope and Sr incorporation into calcite

J. WATKINS[1]*, D.J. DEPAOLO[1,2], F.J. RYERSON[3] AND M. GONZALES[4]

[1]Univ. of California-Berkeley, Berkeley, CA 94720, USA (*correspondence: jwatkins@berkeley.edu)
[2]Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA
[3]Lawrence Livermore National Laboratory, Livermore, CA 94550, USA
[4]The Pennsylvania State, University Park, PA 16802, USA

Chemical reactions in nature lead to stable isotope variations in part because diffusivities and reaction rates are mass-dependent. For crystals grown from aqueous solution, there is no general theory that relates reaction rate to mass, but the contribution of isotope-specific reaction rates to the net isotope composition of a mineral must be related to processes occurring at the mineral-fluid interface.

Laboratory experiments have shown that the Ca isotope composition ($\delta^{44}Ca$) of calcite precipitated from aqueous solution varies considerably (up to 1.5‰) and correlates with the crystal growth rate (*R*). Generally, inorganic calcite precipitation experiments yield calcite crystals that are enriched in the light isotope of Ca relative to the parent solution. The degree of light isotope enrichment correlates with Sr/Ca in calcite. These observations indicate that variations in $\delta^{44}Ca$ in calcite reflect a mass dependence on reaction rate coefficients (*k*) and that the physical process responsible for mass discrimination is also responsible for trace element discrimination. We postulate that dehydration/rehydration kinetics of Ca^{2+} and Sr^{2+} and/or the presence of impurities on the mineral surface are controlling the kinetic isotope and trace element effects. If true, the presence of other ions (e.g. NH_4^+) in solution should perturb the stability of the hydration shell of Ca^{2+} and Sr^{2+} and also interfere with their incorporation into the mineral lattice.

We present results from inorganic calcite precipitation experiments using two solutions that differ in ionic strength (*I*=0.095 vs. *I*=0.485 mol/l). In low ionic strength experiments, we observe correlations between $\delta^{44}Ca$, Sr/Ca and *R* that are in excellent agreement with results from a previous study that used a similar parent solution composition (Tang *et al.*, *GCA*, 2008). In our initial experiments at high ionic strength, values of $\delta^{44}Ca$ vs. *R* and Sr/Ca vs. *R* lie off the previous trends, but $\delta^{44}Ca$ and Sr/Ca co-vary such that $\delta^{44}Ca$ vs. Sr/Ca is relatively independent of solution composition. Additional experiments are underway and results will be discussed in the context of molecular-scale processes - and their liquid composition-dependence – controlling isotopic and trace element incorporation into minerals.

Sum Frequency Vibrational Spectroscopy (SFVS) of water and hydroxyls on the corundum ($1\bar{1}02$) surface: Acid-base properties from direct observation of protonation states

G. A. WAYCHUNAS[1]*, J. SUNG[2] AND Y. R. SHEN[2]

[1]Earth Sciences Division, LBNL, Berkeley, CA 94720, USA (*correspondence: gawaychunas@lbl.gov

[2]Physics Department, UC Berkeley, Berkeley, CA 94720 USA

SFVS is a powerful tool for quantitative measurement of protonated functional groups on mineral surfaces, especially when used in a phase-sensitive mode [1]. This is demonstrated for the corundum ($1\bar{1}02$) interface where the orientation and nature of surface hydroxyls on the dry protonated surface can be obtained and compared with models for the surface termination derived from crystal truncation rod (CTR), X-ray reflectivity (XRR) measurements, and with the most likely functional group assignments [2]. Hydroxyl orientations are determined from pole-figure type measurements of the magnitude of the non-linear optical susceptibility for each band, and the polar orientation (up-down with respect to the z-direction) is determined from measurements of the imaginary part of the susceptibility. A scheme for describing the hydrogen bonding among these protonated groups is found to be consistent with surface symmetry and the particular vibrational frequencies observed. The addition of water to the interface alters the hydrogen bonding of the hydroxyls and introduces water-functional group hydrogen bonding [3]. Direct measurement of the SFVS hydroxyl and water band amplitudes as a function of pH can be used to test the expected pKa values for the functional groups, and hence link interfacial acid-base properties to precise molecular surface entities and their protonation states.

Evolution of the lower crust from S. Mexico: Constraints from Lu-Hf isotopes and U-Pb ages in zircon

B. WEBER[1]*, E. SCHERER[2], K. MEZGER[3] AND J. RUIZ[4]

[1]CICESE, 22860 Ensenada B.C., México (*correspondence: bweber@cicese.mx)

[2]Mineralogie, WWU, D-48149 Münster, Germany

[3]Geologie, Uni Bern, CH-3012 Bern, Switzerland

[4]Geosciences, Univ. Arizona, Tucson AZ, 85721 USA

Unraveling the origin and tectonic evolution of lower continental crust is often complicated by granulite facies metamorphism that obscures petrogenetic features and resets isotopic systems. In order to reconstruct the assemblage of ancient supercontinents (like Rodinia), it is crucial to understand the evolution of individual crustal blocks, its relations, and its position with respect to the cratons. Four isolated lower crustal complexes of mid-Proterozoic (Grenville) age also referred to as "Oaxaquia" [1] are exposed in E and SE Mexico. Oaxaquia was interpreted in terms of arc magmatism, followed by backarc rifting, and migmatization, predating AMCG (anorthosite-mangerite-charnockite-granite) intrusions and granulite facies metamorphism [2].

U-Pb zircon dating by laser ablation MC-ICPMS and single-grain Lu-Hf analysis by solution MC-ICPMS was applied to elucidate crustal growth and igneous history of Oaxaquia. Typical Oaxaquia rocks include AMCG suite rocks as well as arc-type migmatites and orthogneisses, all of which having zircon cores at ~1.2 Ga, additional igneous growth zones migmatite zircons, and granulite facies rims at ~1.0 Ga. Hafnium isotopes of typical Oaxaquia rocks display little variations yielding $T_{DM(Hf)}$ model ages from 1.50 to 1.65 Ga [3]. Significant differences could be observed in zircons from E Mexico orthogneiss (Huiznopala) with $T_{DM(Hf)}$ at ~1.8 Ga [3]. New detailed laser dating of such zircons revealed mostly ~1.4 Ga and older zircon cores, surrounded by ~1.2 Ga igneous zones, indicating melting of crustal precursors different from typical Oaxaquia.

The results lead to a new model in which typical Oaxaquia evolved as juvenile arc in the early mid-Proterozoic. Continental crustal slices, probably from the continental arc of Amazonia, were thrusted over or attached to the Oaxaquia oceanic arc, which was then buried and partially melted to produce AMCG rocks prior to the collision with Baltica during the final stage of Rodinia assemblage.

Airborne measurements of volcanic particles and gases with small aircrafts — Examples of measurements in the Eyjafjallajökull ash plume over Germany and Iceland

K. WEBER[1]*, J. ELIASSON[2], A. VOGEL[1], C. FISCHER[1], M.F. MEIER[3], B. GROBÉTY[3] AND D. DAHMANN[4]

[1]University of Applied Science, 40474 Düsseldorf, Germany (*correspondence: konradin.weber@fh-duesseldorf.de)
[2]University of Iceland, 107 Reykjavik, Iceland
[3]University of Fribourg, 1700 Fribourg, Switzerland,
[4]IGF, 44789 Bochum, Germany

During the 2010 eruption period of the Eyjafjallajökull the University of Applied Sciences of Duesseldorf and the University of Reykjavik performed several measurement flights with small aircraft in the volcanic plume. Whereas the University of Applied Sciences mapped the distal plume over Germany, the University of Iceland explored the airspace over western Iceland and near the Eyjafjallajökull, partly entering the volcanic plume boundary directly.

The use of the small piston-motor driven research aircraft in the special situation of volcanic plumes has several advantages over jet engine driven research aircrafts:

The piston-motor driven aircraft are robust enough to operate even at elevated ash concentration levels.

The small aircrafts allow a low cruising speed during the measurements and have thus the advantage of delivering results with a high spatial resolution.

The low possible aircraft cruising speed during the measurements simplifies the intake of even bigger ash particles into the measurement systems.

Small aircraft allow a very cost effective operation.

The aircraft were equipped with optical particle counters (OPCs) for on-line in-situ results. Moreover, the German aircraft was equipped with a DOAS system for SO_2 and a NDIR analyzer for CO_2 measurements.

The measurement flights revealed that the ash plume over Germany had a very inhomogeneous structure. Sub-plumes and different vertical plume layers could be identified. Regional elevated SO_2 concentrations could be detected. Peak ash particle concentrations of more than 330 μg/m3 could be found during the measurement flights over northern Germany, whereas the flights over Iceland showed low concentrations outside the plume, but values of about 2000 μg/m3 within the boundary of the plume.

A "cradle to grave" analysis of geothermal arsenic in a lowland river system

J.G. WEBSTER-BROWN[1]*, N.J. WILSON[2], A.F. HEGAN[3], H.K. CHRISTENSON[1] AND P.J. SWEDLUND[4]

[1]Waterways Centre for Freshwater Management, University of Canterbury, Christchurch, New Zealand (*jenny.webster-brown@canterbury.ac.nz, hannah.christenson@pg.canterbury.ac.nz)
[2]University of Bayreuth, Bayreuth, Germany (nathaniel.wilson@uni-bayreuth.de)

[4]Department of Chemistry, University of Auckland, New Zealand (p.swedlund@auckland.ac.nz)

In the central North Island of New Zealand, arsenic is released from geothermal hotsprings into the large lowland Waikato River, and thereafter into the Tasman Sea. Aspects of arsenic geochemistry in the geothermal fluids, and in the river and its lake waters, have been previously studied but a catchment-scale analysis of factors affecting geothermal arsenic on its journey to the sea has highlighted the importance of biological as well as geochemical processes.

Evidence for biological interactions with arsenic occurs on a different timescale to that typically used to identify geochemical interactions. For example, when arsenic is released into the surface environment via the Champagne Pool hot spring at Waiotapu, it occurs predominantly as arsenite ion. In the outflow arsenic is immediately exposed to a regime of decreasing temperature, attended by increasing oxygen and periodic influxes of H_2S from small fumeroles, favouring oxidation to arsenate ion or removal as orpiment (As_2S_3) respectively. However, diurnal variations in arsenic concentrations in the outflow confirm the influence of photosensitive microorganisms, evidently through their intervention in dissolved sulphide-sulphate equilibria. Similarly, after discharging into the Waikato River, geothermal arsenic appears to be most immediately controlled by adsorption to the iron oxide component of SPM. However, long term adsorption experiments under light/dark conditions, and a more detailed assessment of the competitive adsorption of important diatom nutrients; silica and phosphate, indicate that arsenic concentration is not regulated simply by the availability of iron oxide adsorption sites. In a river such as the Waikato, enriched in both geothermal silica and agricultural phosphate, diatom growth and decay also influences arsenic speciation and mobility.

Thermophilic anaerobic oxidation of methane performed by novel microbial consortia

G. WEGENER[1,2], K. KNITTEL[1], T. HOLLER[1], V. KRUKENBERG[1], F. WIDDEL[1] AND A. BOETIUS[1,2,3]

[3]Alfred Wegener Insitute for Polar and Marine Research, Bremerhaven, Germany

The anaerobic oxidation of methane with sulfate (AOM) controls the emission of the greenhouse gas methane from the ocean floor and is performed by microbial consortia of archaea (ANME) associated with bacterial partners [1]. So far, *in vitro* propagation of AOM was documented for temperatures up to approx. 25°C, but the presence of molecular ANME markers in hydrothermal sediments suggests higher temperature ranges for this process [2, 3]. In natural enrichments from Guaymas Basin hydrothermal sediments we show *in vitro* propagation of AOM up to 70°C with a growth optimum of 50°C and doubling times of around 60 days. We performed microbiological experiments and genetic, microscopic and mass spectrometric analyses to characterize the key agents in thermophilic AOM. The hot Guaymas enrichments are dominated by filamentous ANME-1 archaeal cells, which form individual sheaths around their bacterial partners. These belong to the deep-branching HotSeep-1 cluster which closest relatives are thermophilic sulfur reducers, e.g. *Desulfurella*. So far the interaction between these novel ANME-1 types and their bacterial partners is not resolved, but the highly structured consortia support previous hypotheses of an obligate syntrophic partnership. Furthermore, our results indicate that AOM might be more widespread than previously assumed including hot subsurface sediments and gas reservoirs [4,5] .

Spinels under elevated pressures and temperatures – A synchrotron study

M. WEHBER[1]*, C. LATHE[2] AND F. SCHILLING[3]

[1]DESY/HASYLAB, Notkestrasse 85, 22607 Hamburg, Germany (*correspondence: michael.wehber@desy.de)
[2]Helmholtz-Centre Potsdam, GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany (christian.lathe@desy.de)
[3]KIT Karlsruhe Institute for Technology, Institute for Applied Geosciences, Kaiserstrasse 12, 76131 Karlsruhe, Germany (frank.schilling@kit.edu)

Spinels have the general formula AB_2O_4 and crystallize in the cubic spacegroup Fd-3m. They play important roles in geosciences and technical applications. The aim of this study was to make simultaneous high-pressure/high-temperature (HP/HT) measurements to find out how the thermal expansion behave under high pressure.

In this study, the three different spinels magnetite ($FeFe_2O_4$), franklinite ($ZnFe_2O_4$) and gahnite ($ZnAl_2O_4$) were investigated with energy-dispersive powder XRD using two different multi-anvil-presses at HASYLAB. Isothermal experiments were performed up to 15 GPa using MAX200x, thermal experiments up to 5 GPa and 1100 K using MAX80. Diffraction data were evaluated with the Rietveld-method to obtain the cell parameter of the sample and the pressure medium. Pressure-volume-data were fitted to second and third order Birch-Murnaghan equation of state to obtain the bulk moduli of each sample. In addition, the thermal expansion coefficient were calculated at different pressures.

Evaluation of the HP measurements yielded the following bulk moduli. For magnetite: $K_{T2nd} = 187(6)$ GPa, $K_{T3rd} = 184(7)$ GPa with $K' = 4.5(2)$, for franklinite $K_{T2nd} = 180(5)$ GPa, $K_{T3rd} = 178(6)$ GPa with $K' = 4.6$ and for gahnite $K_{T2nd} = 207(7)$ GPa, $K_{T3rd} = 204(9)$ GPa with $K' = 4.9$. HP/HT experiments showed a linear pressure dependence of the thermal expansion at least up to 5 GPa ($-1.3*10^{-6}$ $(KGPa)^{-1}$ for magnetite, $-1.7*10^{-6}(KGPa)^{-1}$ for franklinite and $-3.0*10^{-6}(KGPa)^{-6}$ for gahnite). There seems to be an additional connection to the iron content of the spinels whereat the increase of the iron content decreases the slope of the pressure dependence.

On the fluid-mobility of molybdenum, tungsten, and antimony in subduction systems

H. WEHRMANN*[1], R. HALAMA[2], D. GARBE-SCHÖNBERG[2], K. HOERNLE[1,3], G. JACQUES[1], K. HEYDOLPH[1,3], J. MAHLKE[1,3] AND K. SCHUMANN[1,3]

[3]IFM-GEOMAR, Kiel, Germany

Molybdenum (Mo) and tungsten (W) have long been regarded as being more or less immobile during slab fluid-induced arc magma generation. Here we characterize about 180 samples of young, predominantly mafic to intermediate tephras and lavas for their Mo, W, and antimony (Sb) concentrations, to examine the fluid-mobility of these elements in subduction systems. Samples were taken along the active arcs of the Chilean Southern Volcanic Zone (SVZ) and the Central American Volcanic Arc (CAVA). When relating Mo, W, and Sb to trace element ratios typically used to constrain the involvement of subduction fluids in magma formation, such as Ba/La or U/Th, Mo, W, and Sb are enriched in the most fluid-influenced, highest-degree melts. W/Mo ratios correlate positively with Pb/Ce, which is established to reflect a recent subduction signal or assimilation of crustal material with an ancient subduction signature, suggesting that subduction processes promote enrichment of W over Mo. This is well expressed at the SVZ and most of the CAVA; while few OIB-type rocks from Central Costa Rica form an opposite trend. Moreover, Mo/W ratios co-vary with Cl contents derived from melt inclusions, indicating that the relative degree of mobilization responds to the composition of the subduction fluid. To evaluate the mobility of Mo, W, and Sb during metamorphism in the slab, eclogites with no or minor metasomatic overprint and a fluid-induced overprint in an eclogite-blueschist sequence were investigated. None of the three elements shows a systematic variability related to metasomatism and the minor variations are interpreted to reflect protolith heterogeneity. This suggests that Mo, W and Sb remain relatively immobile up to depths of 70 km in the subduction zone.

Long-term development of diagenetic signals of past sulfate-methane transition zones in subseafloor sediments

L. M. WEHRMANN[1]*, C. MÄRZ[2], P. MEISTER[1], C. OCKERT[3], B. BRUNNER[1], N. GUSSONE[3], B.M.A. TEICHERT[3] AND T.G. FERDELMAN[1]

[3]University Münster, Germany (charlotte.ockert@uni-muenster.de, Nikolaus.Gussone@uni-muenster.de, barbara.teichert@uni-muenster.de)

Anaerobic oxidation of methane (AOM) coupled to sulfate reduction in the sulfate-methane transition zone (SMTZ) leaves prominent diagenetic carbon and sulfur signatures in pore-water and solid-phase chemistry that are preserved over geological time scales. We report on the evolution of these signals in the sediments of Site U1341 drilled during Integrated Ocean Drilling Program (IODP) to the Bering Sea to a depth of 600 meters below seafloor (mbsf). At this site, present-day microbial activity associated with organic carbon mineralization is comparably low as evidenced in low dissolved inorganic carbon (DIC) concentrations, and a minor decrease in sulfate concentrations in the top 50 mbsf. Strong decrease of sulfate concentrations below 140 mbsf mirrored by pronounced ^{34}S-sulfate enrichment at the depth of minimum sulfate concentrations suggest that the extent of microbial sulfate reduction was high in this sediment interval deposited during a period of elevated primary productivity in the water column between 2.48 and 2.56 Ma. Elevated sulfate reduction rates drove sulfate to depletion and facilitated the onset of methanogenesis, AOM and the installation of a SMTZ. Rates of these processes apparently declined as a consequence of decreased availability of organic carbon during later time periods. This interpretation is consistent with ^{34}S-enriched pyrite, ^{13}C-depleted dolomite phases and barium depletion to detrital background in distinct sediment intervals. Close examination of the diagenetic pore-water and solid-phase signals, however, revealed that their relative positions in the sedimentary sequence considerably diverge. Also, pore-water DIC, sulfate, Ca and Mg concentrations and isotope profiles do not covary systematically. Our results suggest variable responses of diagenetic signals produced by past SMTZs in the pore-water and sediment over prolonged time scales.

Seawater pH records from a fringe coral reef in southern Hainan Island, the Northern South China Sea: Implications for ocean acidification

GANGJIAN WEI[1], LUHUA XIE[1], WEIZHONG WU[1], WENFENG DENG[1] AND MALCOLM T. MCCULLOCH[2]

[1]State Key Laboratory of Isotope Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China

[2]School of Earth Environment, The University of the Western Australia, WA 6009, Perth, Australia

The observations for seawater pH time-series have been conducted since 2008 in Luhuitou coral reef, fringed to Sanya in the southern Hianan Island, the northern South China Sea (SCS). Diurnally cycles are the most significant variations for seawater pH on coral reef, with amplitudes up to 0.3~0.6 in general. High pH generally occur at noon (12 am ~ 2 pm), while low pH generally occur at mid-night (0 am ~ 2 am). The pH variations are highly correlated to those of dissolved inorganic carbon (DIC) and dissolved oxygen (DO) concentrations in seawater, as well as $\delta^{13}C$ of DIC and sea surface temperature (SST). This suggests that such seawater pH changes are mainly controlled by photosynthesis and respirations of the bio-mass on coral reef. Seasonal seawater pH variations on this coral reef are of ~0.3, and an ~0.1 pH decrease trend from 2008 to 2010 can be figured out. Such variation patterns apparently correlate to changes in atmospheric CO_2 concentration, but the variation amplitudes are significantly larger than that contributed from the increaseing pCO_2. Ecosystem decline on this coral reef possibly resulted from rapid urbanization in this region may account such seawater pH decrease.

A seasonal-resolution seawater pH record from 1980 to1996 has also been recontructed by the $\delta^{11}B$ of a *Porites* coral rom this reef. No decline trend of seawater pH has been observed during this period. Periodical variation with an apparent 10-yr period is clearly presented in this record, which is similar to that from the Great Barrier Reefs of Australia [2]. This indicates that natural variations for seawater pH with large annual amplitude (0.1~0.3) are generally observed on coral reefs in the west Pacific. Such variations are comparable to the predicted ocean acidification trend in the following centary (0.3~0.4 for global ocean: [1]).

Deltaic landforms and stratigraphic controls on groundwater arsenic

B. WEINMAN[1]*, S.L. GOODBRED[2], A. VAN GEEN[3] AND A.K. SINGHVI[4]

[1]Univ of Minnesota, St. Paul, MN 55108, USA (*correspondence: bweinman@umn.edu)

[3]Lamont Doherty Earth Observatory, Pallisades, NY 10964, USA

[4]Physical Research Laboratory, Ahmedabad 380-009, India

Sediment deposits can have physical (hydraulic conductivity and anisotropy) and chemical (diagenetic) effects on biogeochemical cyclings. In Asian deltas, our sedimentological work shows that groundwater arsenic heterogeneity can be explained by an aquifer's depositional history. In Bangladesh, variable thicknesses of the floodplain's mud-capping (0-13m) allows for differential flushing in the shallow aquifer [1]. In turn, this allows for differential groundwater arsenic concentrations over 10's of meter distances, supporting more of a physical (flushing) control on arsenic by the sediments. In Vietnam, there is a more "chemical" type of sedimentary control, with higher groundwater arsenic sourced in Holocene sands, while lower arsenic is seen in water from Pleistocene units. This is different than the more "physical" sedimentary control observed in Bangladesh, indicating more of a reactive-transport or chemical (weathering) control by the sediments [2, 3].

Despite these differing chemical and physical effects on groundwater arsenic by their host sediments, one commonality between these and other arsenic-prone regions is that abandoned-channel facies consistently serve as local depocenters for muds and/or Holocene sand units, which both correlate to higher groundwater arsenic. This raises an ancillary concern about hydroelectric and other river-diverting projects, which can leave downstream areas starved for both sediments and water [4,5]. In the case of groundwater arsenic, we see these types of diversions as potentially mimicking the natural waning associated with the abandonment by a river, leaving a potential for new landforming events favoring higher arsenic concentrations in the groundwater.

Isotopic fractionation of Cu in plants

CHARLOTTE WEINSTEIN*[1], FREDERIC MOYNIER[1], KUN WANG[1], RANDAL PANIELLO[1], JULIEN FORIEL[1] AND SYLVAIN PICHAT[2]

[1]Department of Earth and Planetary Sciences, Washington University in St. Louis, 1 Brookings Dr., St. Louis, MO 63130, USA (*correspondence: cbweinstein@wustl.edu)
[2]Laboratoire de Sciences de la Terre, Ecole nomale superieure de Lyon, 46 allee d'Italie, 69007 Lyon, France

Knowledge of the copper cycle in the plant-soil-water system is needed in order to better constrain proper plant micronutrient nutrition, control pollution, and determine sustainable soil management practices. Here, we will report the Cu isotopic compositions of different components (seeds, germinated seeds, leaves, and stems) of the dicot, lentil (*Lens culinaris*), and of two monocots, Virginia wild rye (*Elymus virginicus*) and hairy-leaved sedge (*Carex hirsutella)*. The isotopic measurmeents were done by multi-collection inductively coupled plasma-mass spectrometry at Washington University following the procedure described in [1,2,3]. Our data are reported in permil deviation (δ^{65}Cu) from the standard, NIST 976. The isotopic compositions of these plants (δ^{65}Cu≈ -0.43,-0.41) are systematically enriched in the lighter isotope of Cu (^{63}Cu) in comparison to the soil in which they grow (δ^{65}Cu≈ +0.19), suggesting a preferential uptake of ^{63}Cu into the plant. Furthermore, different components within the plants themselves are isotopically fractionated. The shoots (stems, leaves and seeds) are systematically lighter than the underground parts of the plants and the Cu isotopic compositions of individual leaves become lighter in correlation with their heights on the plant. These results are similar to what has been observed for Zn isotopes, which are assumed to be transported through plants by means of diffusion and kinetic fractionation across cell membranes [4]. Because of this similarity, we suggest that the same transport mechanisms (diffusion and transport through cell membranes) are also responsible for the observed isotopic fractionation of Cu. Furthermore, the Cu isotopic variations measured in plants are similar in magnitude to the differences previously measured in various soils, and therefore should be taken into account in order to accurately interpret the isotopic compositions of Cu in soils.

[3]Geology & Geography, Univ. Massachusetts, Amherst, MA 01003, USA

The origin, scale and location of mantle heterogeneities have been debated for over 50 years. Improved analytical precision for radiogenic isotopes, combined with statistical data analysis, allow for more detailed investigations into the geochemical variations of basalts related to mantle plumes and for modeling of the shallow and deep plume conduit and structure. Identification of two clear geochemical trends (Loa and Kea) among Hawaiian volcanoes [1, 2] in all radiogenic isotope systems [3], together with the recurrence of similar isotopic signatures at >350 kyr intervals, has implications for the dynamics and internal structure of the Hawaiian mantle plume [4] and for the scale of heterogeneities in the deep mantle. Recent isotopic data for over 850 samples from the shield, post-shield and rejuvenated stages on Hawaiian volcanoes indicate source differences between the Loa- and Kea-trend volcanoes that are maintained throughout the ~1 Myr activity of each volcano and that extend back in time on all the Hawaiian Islands (to ~5 Ma). Hawaiian post-shield and rejuvenated lavas have more Kea-like geochemical characteristics than the underlying shield lavas with only two exceptions. Loa-trend volcanoes have more heterogeneous compositions than Kea-trend volcanoes in all isotopic systems by a factor of ~1.5 and present an EM-component (most expressed in Ko'olau) as well as different geochemical trends with time (increase of Pb isotopic ratios in Loa). The Loa-Kea distinction reflects differences in the plume source, at the core-mantle boundary, where the Mauna Loa side of the Hawaiian plume samples a more heterogeneous source that may correspond to the northeast end of the Pacific ultra-low velocity zone (ULVZ). Kerguelen, an EM-I oceanic island, is located on the eastern end of the ULVZ African anomaly. We infer that these deep velocity anomalies at the CMB are the repositories for EM components brought to the surface by strong mantle plumes.

We recently demonstrated the intracellular precipitation of Pb by *Shewanella putrefaciens* CN32 during the reductive dissolution of Pb-jarosite [1]. In the present study, we build upon earlier research which focused on the abiotic dissolution of Pb-As-jarosite [2]. In this study we examine the reductive dissolution of Pb-As-jarosite ($PbFe_3(AsO_4)(SO_4)(OH)_6$) by bacteria under anaerobic circumneutral conditions. Microbial biomass, SEM, ATP, [Pb] and solution chemistry including As and Fe speciation were monitored over time to assess the influence of *S. putrefaciens* on As-Pb jarosite. The work will discuss the rates of Fe reduction versus As reduction and the fate of Pb providing new insight into Pb, Fe and As biogeochemical cycling in reduced environments.

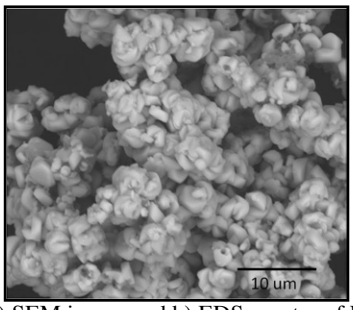

Figure 1: a) SEM image and b) EDS spectra of Pb-As-jarosite

High-Mg carbonatitic HDFs, kimberlites and the SCLM

Y. WEISS[1]*, W.L. GRIFFIN[2], D.R. BELL[3] AND O. NAVON[1]

[1]The Institute of Earth Sciences, the Hebrew University of Jerusalem, Israel (*yakov.weiss@mail.huji.ac.il)
[2]GEMOC, Macquarie University, NSW, Australia
[3]School of Earth and Space Exploration, Arizona State University, AZ, USA

Trace-element patterns of high-Mg carbonatitic high-density fluids (HDFs) trapped in Siberian fibrous diamonds are similar to those of Group I kimberlites, but are slightly more fractionated. The patterns of both are comparable in shape to the average pattern of peridotite xenoliths from the sub-continental lithospheric mantle (SCLM) [1].

Possible scenarios for explaining these similarities include mixing, fractionation and melting:

1) Adding 2.5% of kimberlitic magma or 0.7% of the Siberian high-Mg HDFs to a highly depleted peridotite closely reproduces the SCLM pattern.
2) The formation of the high-Mg HDFs through fractionation of kimberlitic magma calls for 70% crystallization of olivine, pyroxene garnet and carbonate. However, the alkalis and Ba of the calculated fluid are too low and the middle to heavy REE, Zr, Hf, Ti and Y are too high compared to the Siberian high-Mg HDFs.
3) Simple batch melting of 0.5% of a source with average SCLM modal abundance and trace-element composition closely reproduces the trace-element pattern of the Siberian high-Mg HDFs. Higher degrees of melting (~2%) of the same source yield patterns similar to those of Group I kimberlite.

High-Mg HDFs in diamonds from Kankan, Guinea have major-element compositions comparable to that of the Siberian high-Mg carbonatitic HDFs. However, they are depleted in K, Rb, Cs, Nb and Ta and enriched in Ba, Th, U and LREE relative to the Siberian ones. These differences closely correspond to those between the patterns of Group II and Group I kimberlites, respectively. Extending the melting scenario to the Kankan HDFs and Group II kimberlites, the two can be produced by 0.2 and 1% melting of SCLM that carries phlogopite (0.3% and 0.1%, respectively) and a trace of rutile.

Whether it is mixing, melting or combination of both, the new constraints indicate a very close genetic relation between high-Mg carbonatitic HDFs, kimberlites and the average SCLM.

Photolysis of iron(III) carboxylato complexes — Quantum yield determination and reactivity simulation in clouds and atmospheric particles

C. WELLER, A. TILGNER AND H. HERRMANN

Leibniz-Institut für Troposphärenforschung, 04318, Leipzig, Germany (weller@tropos.de)

Iron is always present in the atmosphere in concentrations from ~10^{-9} M (clouds, rain) up to ~10^{-3} M (fog, particles). Sources are mainly mineral dust emissions. Iron complexes are very good absorbers in the UV-Vis actinic region and therefore photo-chemically reactive. Iron complex photolysis can be an in important degradation pathway for organic compounds with the ability to bind iron.

Absorption spectra and Fe^{2+} quantum yields of iron(III) coordination compounds with oxalate, malonate, succinate, glutarate, tartronate, tartrate, glyoxalate and pyruvate were experimentally determined. Complex solutions were irradiated in a 1 cm quartz cell by excimer laser flash photolysis at wavelengths of 308 and 351 nm or by Hg(Xe) lamp photolysis at 436 nm (for Fe(III) oxalate system). Photochemically produced Fe^{2+} was spectroscopically detected at 510 nm as $[Fe(phenanthroline)_3]^{2+}$.

Measured quantum yields of malonate and glutarate complexes are in the range of $0.02 < \Phi < 0.05$, while succinate, tartrate, pyruvate, glyoxylate and tartronate complexes show values between $0.12 < \Phi < 1.21$. The measured overall quantum yields include contributions from secondary thermal reactions. Furthermore, in some systems a dependence of the measured quantum yield on the amount of the incident photons was determined. In the case of oxalate, a dependence of the quantum yield on the initial concentration of iron(III) oxalato complexes was observed. A kinetic simulation of the reaction system after the photolysis was performed for oxalate, succinate, glyoxalate and tartrate complexes to characterize the influence of secondary thermal reactions on the quantum yield.

A tropospheric chemistry simulation with the multi-phase chemistry mechanism CAPRAM (Chemical Aqueous Phase RAdical Mechanism) involving the photolysis of the studied complexes and subsequent reactions of the resulting fragments showed that Fe(III) complex photolysis represents a major sink for the ligands oxalate, tartronate, tartrate and pyruvate in addition to the oxidation via free radicals.

Technical and policy challenges in deep vadose zone remediation of metals and radionuclides

DAWN M. WELLMAN AND MICHAEL J. TRUEX

Pacific Northwest National Laboratory, Richland, Washington 99354; (dawn.wellman@pnl.gov, mj.truex@pnl.gov)

Deep vadose zone contamination is a significant issue in many regions of the world, although much of the focus has been on arid and semiarid regions where that zone is thickest. Contamination in deep vadose zone environments is isolated from exposure such that direct contact is not a factor in its risk to human health and the environment; rather, movement of contamination from the deep vadose zone to the groundwater creates the potential for exposure and risk to receptors. Therefore, while the deep vadose zone is not necessarily considered a resource requiring restoration, limiting flux from contaminated vadose zone is key for protection of groundwater resources and down-gradient receptors. However, technical challenges complicate the decision process for deep vadose zone remedial actions.

Remediation of metal and radionuclide contamination in the deep vadose zone is complicated by heterogeneous contaminant distribution and the preferential saturation-dependent flow in heterogeneous sediments. Thus, efforts to remove contaminants have generally been unsuccessful; and as a result, the magnitude of contaminant discharge (mass per time) from the vadose zone to the groundwater must be maintained low enough by natural attenuation (e.g., adsorption processes or radioactive decay) or through remedial actions (e.g., contaminant mass or mobility reduction) to meet the groundwater concentration goals.

Contaminant transport mechanisms through the vadose zone can attenuate the overall contaminant flux to the groundwater, and vadose zone contamination may not necessarily require remediation if the natural flux results in sufficiently low contaminant concentrations in the groundwater. In some cases, remediation to control transport, enhance attenuation mechanisms, or remove contaminants may be needed to limit flux so groundwater or surface water protection standards are maintained. This presentation reviews major processes viable for deep vadose zone metal and radionuclide remediation that form the practical constraints on remedial actions.

Lithium self-diffusion in $LiAlSi_2O_6$ glass and single crystals

A.-M. WELSCH[1]* H. BEHRENS[1], I. HORN[1], S. ROSS[1], P.J. VULIĆ[2], D. MURAWSKI[1] AND A. KREMENOVIĆ[2]

[1]Institut für Mineralogie, Leibniz Universität Hannover, Callinstr. 3, 30167 Hanover, Germany, (*correspondence: a.m.welsch@mineralogie.uni-hannover.de)

[2]Department of Crystallography, University of Belgrade, Đušina 7, 11000 Belgrade, Serbia

Understanding the mechanisms of lithium diffusion is of great interest for geo- and material sciences. Optimizing the performance of Li-bearing solid media has a significant impact in developing new technologies. Knowledge of kinetic Li-isotopic fractionation leads to better understanding of geological processes in which lithium geochemistry plays a major role.

Our ongoing research is aimed to investigate Li diffusion in aluminosilicate media. In the scope of this study, spodumene ($LiAlSi_2O_6$) like materials were selected as representative model system since lithium, as the only mobile species, migrates through a static aluminosilicate network. Crystalline and glassy materials are compared in order to determine the effect of structural order on Li-diffusion. Glasses were produced by melting of oxide and carbonate mixtures as well as by melting natural spodumene. Natural crystals are from different pegmatites worldwide. Synthetic single crystals were obtained in a slow crystallization process using a flux method. The samples were tested by impedance spectroscopy for ionic conductivity in the range between 1 Hz to 10 MHz at temperatures up to 940 K. Additionally, lithium self-diffusion coefficients were determined by diffusion couple experiments using two halves with same base composition but different Li isotopic abundancies. Li isotope profiles were measured using UV fs laser ablation coupled with ICP-MS. Raman spectroscopy aided in better understanding the local structural features which coordinate lithium migration.

Ionic conductivity was found to be 6 - 7 orders of magnitude slower in natural spodumene crystals than in the glasses while the activation energy for Li conduction is about the same for both materials (0.66 kJ/mol for the glass, 0.76. kJ/mol for the crystal). This implies that the barrier for Li-migration is not sensitive to structural order in aluminosilicate materials. Comparison of Li isotope diffusion data and dc ionic conductivity yields a correlation factor of 0.5 for Li-diffusion in $LiAlSi_2O_6$-glasses.

Basin evolution, lithofacies palaeogeography and manganese mineralization in Heqing basin, Yunnan province, Southwest of China

XING-PING WEN[1], RUN-SHENG HAN[1,2] AND XIAO-FENG YANG[3]

[1]Faculty of Land Resource Engineering, Kunming University of Science and Technology, Kunming, 650093, P. R. China (wfxyp2008@gmail.com)

[3]Research Center for Analysis and Measurement, Kunming University of Science and Technology, Kunming, 650093, P. R. China

Heqing basin is located in the northwest of Yungui plateau, southwest of China, a geological conjunction zone of three tectonic units separated by Jinshajiang, Honghe and Xiaojinhe-Lijiang fault belts. Heqing manganese deposit is situated in southwestern margin of Heqing basin. The Songgui formation of the Late Triassic series is the principal ore-host strata, composed mainly of mudstone, limestone and siltstone [1].

Heqing sedimentary manganese deposit formation is associated with Heqing basin evolution. The lithofacies paleogeography of Heqing basin is reconstructed. Sedimentary facies and palaeogeography of the Late Permian Changxingian ages reveal littoral deposits in Heqing manganese deposit. Then the sea level is continuously elevated in the Middle Triassic Ladinian age. Sedimentary facies and palaeogeography of the Late Triassic Carnian age expose shallow sea platform marginal bank facies in Heqing manganese deposit, which is beneficial to accumulation of ore-forming minerals under more stable geological and physicochemical conditions. In the Late triassic Norian age, the region marine regression lead to littoral deposits facies in Heqing manganese deposit, which terminates mineralization.

This study was jointly supported by the crisis of resource exploration mining project, China (20089943) and the innovation team of ore-forming dynamics and prediction of concealed deposits, KMUST, Kunming, China (2008).

Biogeochemical patterns and processes in buoyant, deep-sea hydrothermal plumes

KATHLEEN WENDT[1], KARTHIK ANANTHARAMAN[2], JOHN A. BREIER[3], GREGORY J. DICK[2], KATRINA J. EDWARDS[4], PETER R. GIRGUIS[5], JEFFRY V. SORENSEN[1], JASON SYLVAN[4] AND BRANDY M. TONER[1,*]

[4]University of Southern California, Los Angeles, CA, USA
[5]Harvard University, Cambridge, MA, USA

Along the global mid-ocean ridge, sub-seafloor hydrothermal circulation results in the exchange of heat and chemical species between seawater and the ocean crust. The resulting thermally and geochemically altered fluids are vented at the seafloor. The mixing of cold, oxic deep-ocean waters with hydrothermal fluids creates plumes with physically and chemically dynamic features. Hydrothermal plumes represent a globally distributed interface where marine hydrothermal circulation exerts its biogeochemical influence on elemental budgets of ocean basins.

The goal of the present study is to describe the microbiological niches created by physical and geochemical gradients in plumes. One of our central hypotheses is that microorganisms respond to and alter the geochemistry of hydrothermal plumes. To achieve this goal and test our hypothesis, a field study was undertaken at the Eastern Lau Spreading Center (ELSC). While multiple vent sites along the ELSC are included in the larger study, here we report on an integrated, biogeochemical investigation of a single buoyant plume within ABE vent field.

A series of replicate sample sets were collected by *in situ* filtration at 0.5m, 40m, 200m within a buoyant plume using the *ROV JASON*. Above plume background and near bottom background sample sets were also collected. Hydrothermal plume particles in sample replicates or splits have been queried for bulk geochemistry, particle-by-particle mineralogy, and microbial community composition. These three data streams are being evaluated individually to characterize the geochemical and microbiological changes throughout the plume with respect to above and below plume backgrounds. In addition, an iterative and integrated analysis is being used to compare: (1) calculated mineralogy to direct measurements; and (2) predicted energy yields from chemoautotrophy to observed microbial composition.

Biogeochemical cycling of iron, sulfur and carbon in the nutrient-rich meromictic acid pit lake Cueva de la Mora (Spain)

K. WENDT-POTTHOFF[1]*, M. KOSCHORRECK[1], M. DIEZ ERCILLA[2] AND J. SÁNCHEZ ESPAÑA[2]

[1]UFZ – Helmholtz Centre for Environmental Research, Department Lake Research, D-39114 Magdeburg, Germany (*correspondence: katrin.wendt-potthoff@ufz.de)
[2]Instituto Geológico y Minero de Espana (IGME), 28003 Madrid, Spain

Cueva de la Mora is a meromictic, nutrient-rich acid pit lake with pronounced vertical gradients of physicochemical parameters in the chemocline and monimolimnion [1]. We studied microbial activity, abundance and biomass, and biogeochemical cycling of iron, sulfur and carbon to find out if (1) the high nutrient content influenced alkalinity-producing microbial processes compared to other acid pit lakes, and (2) if sediments in the shallow, mixed and the deep, stagnant parts of the lake exhibited biogeochemical differences related to meromixis. We hypothesized that redox cycling was more intense in the mixed part and higher amounts of reduced components would accumulate in the stagnant part.

Several biogeochemical reaction rates were higher than in typical acid pit lakes and fell rather within the range of neutral or weakly acidic lakes, probably a consequence of nutrient levels. Anaerobic processes occurred mainly in the sediments, and methanogenesis was negligible for the carbon budget of the lake. Sediments from the mixed and stagnant parts of the lake differed markedly. Mixolimnetic sediments showed high iron and sulfate reduction rates, and they appeared to undergo substantial recycling, as supported by reactive Fe(II) and Fe(III) profiles, relation between sulphate reduction and accumulation of reduced sulphur, and viable counts of iron and sulphur reducing and oxidising bacteria. Monimolimnetic sediments exhibited lower anaerobic microbial activities, and surprisingly accumulated more Fe(II) than mixolimnetic sediments, but less carbon and reduced sulfur. This might be explained by a strong separation of the monimolimnetic water body, resulting in comparably less input of energy (light) and allochthonous matter. The effect of alkalinity-generating microbial processes is not sufficient to neutralize the lake within a few decades.

[5]Institute of Earth Sciences, University of Applied Sciences of Southern Switzerland, Switzerland
[6]Laboratory of Microbiology, University of Neuchâtel, Switzerland

In terrestrial and aquatic ecosystems, N_2O can be produced through two pathways: nitrification and incomplete denitrification. The measurement of the stable isotopic and isotopomeric composition of N_2O can help determine the relative importance of these processes in net N_2O production. To date, relatively little is known about the role of lakes as N_2O source to the atmosphere, and N_2O isotopomer dynamics in lakes have barely been studied.

Lake Lugano (South Basin) is a monomictic, eutrophic lake, where high bottom water N_2O concentrations are observed (900nM; 100x equilibrium saturation). Sediment core incubations with ^{15}N-labeled substrates suggest that sedimentary denitrification is the main N_2O source. These incubation data, however, appear to conflict with water column observations. A N_2O concentration maximum at the aerobic/anaerobic interface, together with the intramolecular distribution of ^{15}N (SP of ~33‰) in N_2O suggests that N_2O in the water column is mainly produced by nitrification. The investigated redox-transition zone is a net sink for NO_x, and N_2O gradients suggest N_2O reduction just below this zone. Yet, isotopomeric signatures that were previously assumed to be characteristic for N_2O production by denitrifying organisms were not observed. Our results raise doubts about the general validity of previously reported N_2O isotopomer effects from laboratory experiments for lake ecosystems.

Spins deep in the Earth

RE NATA WENTZCOVITCH

Department of Chemical Engineering and Materials Science, Minnesota Supercomputing Institute, University of Minnesota, MN, USA, 55403

There has been much interest in spin crossovers found in 2003 and 2004 in the most abundant minerals of Earth's lower mantle ((MgFe)O and (MgFe)(Si,Fe)O_3-perovskite) under pressure. Spin crossovers depend on thermodynamic conditions and a full understanding of this problem requires its investigation as function of pressure and temperature. There are several controversies, especially in the perovskite systems, and surprises are revealed by electronic structure calculations. The geophysical consequences of these crossovers are yet to be fully understood. I will review recent progress in the study of spin crossovers and give an overview of this phenomenon and its potential implications for the Earth.

The Santa Quitéria Batholith, NE Brazil: A mantle–crust interaction

E. WERNICK[1]*, S.A. ZINCONE[2] AND T.J.S. SANTOS[2]

[1]Instituto de Geociências, UNESP, Rio Claro, SP, Brazil (*correspondence: wernick@uol.com.br)
[2]Instituto de Geociências, UNICAMP, Campinas, SP, Brazil

Granitoid magmatism is an important tool for the characterization of mantle-crust interaction, a process which extremes are represented by M- type (mantelic) and S- type (crustal) granites. The huge (~15.000km^2) Brasiliano Santa Quitéria batholith (SQB) from the Borborema Province, state of Ceará, NE Brazil, comprises mainly high-K/shoshonitic megaporphyritic/evengrained monzodiorites, monzogranites and granites. Its long lasting (650-470 Ma.) magmatic evolution reflects part of the closure of the Pharusian Ocean and the collision between the Amazonas, São Luiz, São Francisco and West Congo cratons. 90 Sm-Nd data for SQB rocks [1-4] show that their parent magma represents an isotopic mixture of a juvenile mantelic component with older, mainly Paleoproterozoic, crustal rocks. The geological, petrographic and geochemical evidences for the mixture change from the syncolissional, via the syntranscurrent, to the late magmatic stage of the batholith, the last one related to the regional relaxing and collapsing of the orogen.

The fractionation of silicon isotopes during tropical, supply-limited weathering remains incompletely understood, a key missing link in being able to use the Si isotope system to infer the rates and character either of primary mineral weathering, or of biogeochemical cycling of Si. Samples of rock, soil, vegetation, and water from La Selva Biological Preserve, on the flanks of Volcan Barva in the Cordillera Central of Costa Rica, provide the opportunity to (i) better constrain the isotopic signature of dissolved Si associated with supply-limited weathering, and (ii) understand the mechanisms generating the observed isotopic characteristics in these settings. We collected samples from La Selva and analysed these samples for δ^{30}Si by MC-ICP-MS. Si-isotope analyses of samples from La Selva confirm that weathering in tropical, supply-limited environments generates the isotopically lightest dissolved Si that has been observed in stream and river waters measured globally. Streams with significant groundwater contribution, with flowpaths through less altered volcanic bedrock, have significantly higher isotopic compositions, reflecting primary mineral weathering. Analysis of bedrock and soils, including clay separates from soils, indicates that this light isotopic composition of dissolved Si is a consequence of the dissolution of clay minerals formed during previous weathering cycles. Contemporary weathering processes in the soil at La Selva are associated with precipitation of even lighter neo-formed clays, driving the bulk soil to increasingly light Si isotope ratios. Weathering of secondary minerals in such locations, as confirmed in this study, may complicate interpretation of the variability in dissolved riverine Si isotopes over large spatial scales and long temporal scales.

Mo isotope signature of OAE 1a: New insights from the Western Tethys

S. WESTERMANN[1]*, D. VANCE[1], C. ARCHER[1] AND S. ROBINSON

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Wills Memorial Building, BS8 1RJ, UK (*correspondence: stephane.westermann@bristol.ac.uk)
[2]University College London, Gower Street, London,WC1E 6BT (stuart.robinson@ucl.ac.uk)

Oceanic anoxic events (OAEs) record profound and rapid changes in the chemistry of the world ocean. Quantifying the oxygenation state of the oceans through OAEs is of fundamental importance to understanding the global perturbation of the carbon cycle observed during these events. The aim here is to trace global redox change in the wolrd ocean through the early Aptian anoxic event (OAE 1a, Selli event), one of the most significant and widespread black shale events of the Cretaceous.

We selected the Gorgo a Cerbara section (Italy), where evidence of euxinic conditions has recently been provided by biomarkers [1-2], and investigated the redox-sentive trace element (RSTE) distribution and the molybdenum (Mo) isotopes variations through the section.

All RSTE measured present similar behaviour, with a low background level contrasted by maxima in concentrations within the Selli level. A relatively good correlation is observed between total organic carbon (TOC) values and RSTE accumulation, suggesting well-developped anoxia. However, Mo isotopes show surprisingly negative values through the section. An increasing trend in $\delta^{98/95}$Mo is observed before the Selli interval, with values ranging from -0.89 up to 0.06 ‰. Then, $\delta^{98/95}$Mo values remain more or less constant fluctuating around -0.23 ‰, but with a shift towards more negative values within the Selli level. This trend is interrupted by a positive peak to 0.13 ‰, corresponding to samples with the highest Mo content (up to 94 ppm).

The RSTE behaviour indicates variations in the oxygenation state of the western Tethys, reaching anoxic/euxinic conditions during OAE 1a. However, the light $\delta^{98/95}$Mo values suggest that the redox conditions may not have been fully euxinic. Iron speciation measurments will be performed to further investigate the redox conditions during the deposition of the Selli interval, and its relationship to sedimentary Mo isotope evolution.

Melting and melt/rock reaction of sulphides in Middle Atlas spinel peridotite xenoliths

K.J. WESTNER*[1], N. WITTIG[1,2], R. KLEMD[1], H. BRÄTZ[1] AND I. OSBAHR[1]

[1]GeoZentrum Nordbayern, Mineralogie & Endogene Geodynamik, Universität Erlangen, Schlossgarten 5(a), 91052 Erlangen(*correspondence: katrin.westner@geo.stud.uni- erlangen.de)
[2]National High Magnetic Field Laboratory & Department of Earth, Ocean, and Atmospheric Science, FSU, 1800 E. Paul Dirac Drive, Tallahassee, FL 32310, USA

The major and siderophile and chalcophile trace element composition (n=25) in sulphides (58 analyses) and Fe-hydroxides (7 analyses) of seven spinel-facies peridotite xenoliths from the Moroccan Middle Atlas was determined at the University of Erlangen by electron microprobe and in-situ LA-ICP-MS. The sulphide assemblage comprises monosulphide solid solution, pentlandite and minor isocubanite. Sulphides occur as: (i) inclusions (eu- to subhedral) in primary silicates, usually associated with sulphide melt trails; (ii) anhedral grains on silicate grain boundaries, and (iii) within silicate glass in discrete melt pockets formed during the ascent of the xenoliths. Variably pervasive alteration of sulphides to hydroxides is generally associated with cracks in the peridotite matrix. Three PGE patterns were identified – often within the same sample and irrespective of the petrographic occurrence: [a] IPGE > PPGE; [b] no PGE fractionation and [c] PPGE > IPGE. Hydroxides show nearly identical PGE patterns with similar PGE abundances to their host sulphides. Relatively incompatible chalcophile elements correlate with the degree of PGE fractionation. The presence of such PGE fractionation ([a] & [c]) on thin-section scale is consistent with mantle melting experiments [1], which predict residual IPGE-rich sulphides and (trapped) PPGE-rich melt blebs. The close proximity of interstitial and enclosed grains with these patterns suggests contemporaneous sulphide-silicate crystallisation due to melt-rock reaction of olivine and pyroxene, hence trapping sulphide melt as inclusions and leaving potentially earlier residual IPGE-rich sulphides intact. Whole rock major and siderophile trace elements and Os isotopes are also in accordance with coupled sulphide-silicate introduction [2]. Our results allow deciphering the mobility and transport of upper mantle sulphide melts, which is a crucial prerequisite for understanding the generation of crustal noble metal deposits.

Noble gases and halogens in Icelandic basalts

B. WESTON*, R. BURGESS AND C.J. BALLENTINE

SEAES, The University of Manchester, Manchester, U. K. (*bridget.weston@postgrad.manchester.ac.uk)

We present noble gas and halogen data from a suite of samples taken from across Iceland. Iceland combines hotspot volcanism, a spreading ridge and abundant sub-glacially erupted basaltic sampes. This combination allows for samples which erupted under high enough presssures to retain a measurable noble gas content, and also display signatures representing interaction between ocean island and mid-ocean ridge basalt mantle sources. In terms of the isotopic composition of the light noble gases, this interaction has been the subject of a number of studies. However, the elemental heavy noble gas composition of Icelandic basalts has been less well investigated. Studies are hampered by the large, isotopically atmospheric component typically found in Icelandic sub-glacial samples; this late-stage contamination can swamp other signatures. In addition, the degassing process results in both elemental fractionation and loss of the noble gases. Taking full account of both these processes is crucial to resolving the elemental noble gas composition of Iceland's source mantle: Evidence for volatile recycling, volatile sources during the Earth's history and the nature of different mantle source zones are just a few topics that require elemental data as well as isotopic.

Isotopic neon and argon ratios show mixing between air and mantle components, allowing corrected abundances of krypton and xenon to be calculated: Although isotopically indistinguishable from air, these are elementally non-atmospheric, allowing the fit of the data to degassing models to be assessed. We use a variation on the model of Gonnermann and Mukhopadhyay to define possible degassing trends for these samples [1]. Known mantle production ratios for $^{4}He/^{40}Ar$ and $^{4}He/^{21}Ne$ then allow limits to be placed on elemental ratios from Iceland's source mantle.

In contrast to the noble gas analyses, elemental fractionation is not apparent in the halogen data; for example, I/Cl ratios are consistently close to the bulk earth value of 72 x 10^{-6} across a broad range of samples [2]. However, halogen concentrations vary widely, with the highest values found towards central Iceland. Combined with the noble gas results, this data can provide an insight into the halogen composition of the different mantle sources interacting at Iceland.

C-solubility in magmas at low fO_2

D.T. WETZEL[1]*, M.J. RUTHERFORD[1], S.D. JACOBSEN[2], E.H. HAURI[3] AND A.E. SAAL[1]

[1]Dept. of Geological Sciences, Brown University, Providence RI 02912 (*correspondence: Diane_Wetzel@brown.edu)
[2]Dept. of Earth and Planetary Sciences, Northwestern University, Evanston, IL 60208 (steven@earth.northwestern.edu)
[3]DTM Carnegie Institute of Washington, DC 20015 (hauri@DTM.ciw.edu)

Available evidence suggests that in the absence of water, carbon is the element responsible for generating the gas phase that drives fire-fountain eruptions in low oxidation-state magmas [1, 2]. For example, recent experiments show that C forms a CO-rich gas phase in ascending lunar picritic magmas at 40 MPa [3]. Indigenous H (H_2O), discovered in a range of lunar picritic glasses [4], affects this conclusion. Our study was designed to determine the solubility and speciation of C in H-bearing graphite-saturated picritic magmas and the effect of H on the initial gas phase generated.

Experimental A15 green glass samples were pre-set at IW, enclosed in graphite, and run in an IHPV. C and H contents determined by SIMS show 3-150 ppm C and 6-140 ppm H at lower pressures and up to 1400 ppm C and 1250 ppm H at 1 GPa. Carbon in the green glass has a strong positive correlation with pressure. Analyses also show a positive correlation between dissolved C and H in the experimental glasses. Raman spectroscopy indicates CH_4 present in the melt, which confirms the observed trend between C and H in the glasses. These results are consistent with experiments on Na-silicate [5] and haplobasaltic [6] melts. Magmatic C contents greater than ~20 ppm will cause the first gas phase to form from C-H (CH_4) species saturation assuming H contents were in the range 200-1000 ppm. Thermodynamic models [7] predict a CH_4- and H_2-rich gas phase in equilibrium with a reduced melt at P>40 MPa and CO-rich gas at lower pressures.

Diatom Si isotope variations from the Atlantic Sector of the Southern Ocean (ODP Site 1093) record environmental changes of the last 170 ka

F. WETZEL[1]*, A. SHEMESH[2], B.C. REYNOLDS[1]

[1]Institute of Geochemistry and Petrology, Department of Earth Sciences, ETH Zurich, Switzerland (*correspondence: wetzel@erdw.ethz.ch)

[2]Department of Environmental Sciences & Energy Research, The Weizmann Institute of Science, Rehovot, Israel

A number of recent studies utilized silicon isotopes to trace changes in the biogeochemical cycling of silicon in the paleocean [1, 2]. The main controling process on this cycle is the uptake of silicon by opal-precipitating phytoplankton. Accounting for about 60% of the oceanic primary production, diatoms link the dissolved silicon (nutrient) pool and oceanic CO_2 uptake from the atmosphere. Since the Southern Ocean plays a key role in ocean circulation and deep-sea ventilation, its underlying opal-rich sediments are particularly suitable for studying the link between atmospheric CO_2 variations and phytoplankton nutrient utilization. The degree of surface silicon utilization is to a first order a function of nutrient supply from below and should be reflected in the diatom silicon isotope composition. In combination with carbon isotope ($\delta^{13}C$), nitrogen isotope ($\delta^{15}N$) and micronutrient (esp. Fe) information it is possible to reconstruct the efficiency of the biological pump that determines whether the surface ocean acts as a net source or sink for atmospheric CO_2.

Here, we present down-core (0-170 ka) silicon isotope variations of diatoms from the Atlantic Sector of the Southern Ocean (OPD Site 1093) and examine the impact of glacial-interglacial climate change on the degree of silicon isotope utilization. The results show that the degree of silicon isotope utilization during interglacial periods is different from that of peak glacial periods. During peak glacial periods, silicon utilization is inefficient at a time where an efficient biological pump is assumed to draw down additional atmospheric CO_2, implying a more complex relationship between silicon in frustules and nutrients contributing to organic tissues. In addition, ambiguity exists as to whether the increased efficiency in the biological pump during glacials was, as commonly believed, a contributor to the low atmospheric CO_2 concentrations or a consequence and therefore 'only' a positive feedback.

The extent of oceanic anoxic events revealed by correlated Mo- and U isotope records

S. WEYER[1]*, C. MONTOYA-PINO[2], G.W. GORDON[3], B. VAN DE SCHOOTBRUGGE[2], W. OSCHMANN[2], J. PROSS[2] AND A.D. ANBAR[3]

[3]School of Earth and Space Exploration, Arizona State University, Tempe, Arizona 85287, USA

Isotopic signatures of redox-sensitive trace metals in black shales (e.g. Mo and U) have become a frequently used tool to estimate the extent of anoxic or euxinic conditions in ancient oceans [1-5]. A disadvantage of these tools is that they are sensitive to local redox conditions or other effects [4-6]. Here we show that combining Mo- and U isotopes provide a much more robust approach.

We studied black shales from and around both the Cretaceous OAE2 (Demerara Rise, Central Atlantic ocean) and the early Jurassic T-OAE (Dotternhausen, Germany, and Truc de Balduc, France) and compared our results with those from "recent" sapropels of the Black Sea (unit I and unit II). Samples from all investigated units display a distinct negative correlation of Mo- and U isotope records. This coupling of Mo- and U isotopes is likely generated during black shale formation under variable (redox) conditions.

Samples from the OAE2 and those from below- and above OAE2 together define a single trend of Mo- versus U isotopes. Individual trends are defined by sample suites from different subzones of the lower Toarcian (during- and slightly after the T-OAE). All these trends are significantly shifted towards lighter isotope compositions compared to the trend defined by Black Sea samples, except samples from the *bifrons* zone (the youngest lower Toarcian) which display almost modern Mo- and U isotope records. Our findings indicate significant enhancement of seafloor anoxia (5-10-fold compared to present) during both OAE2 and T-OAE. For both periods, enhancement of seafloor anoxia exceeded the duration of the OAEs, as defined by their $\delta^{13}C_{org}$ excursions.

Occurence of reduction induced sulfide saturation in oxidised arc magmas

TARUN H.E. WHAN*, JOHN A. MAVROGENES AND RICHARD J. ARCULUS

Research School of Earth Sciences, Australian National University, ACT Australia 0200
(*correspondence: tarun.whan@anu.edu.au)

It has been previously well documented that solubility of sulfur in silicate melts increases by order of magnitude as the sulfate $(SO_4)^{2-}$ compared to the sulfide (S^{2-}) species [1]. Also established is magnetite saturation, the first phase to appear on the liquid line of decent during fractional crystallisation that subtracts significant amounts of total Fe and also lowers the Fe^{3+}/Fe^{2+} of the residual magma, may trigger reduction in the evolving silicate melt [2]. This process of reduction induced sulfide saturation (RISS) can lead to a melt attaining sulfide saturation in a closed system, without the need of any external input i.e., crustal assimilation of sulfur or an enriched slab component.

We have explored the details of the processes subsequent to magnetite saturation in arc magmas. For example, preliminary analysis of melt inclusions contained within titanomagnetite separated from a suite of subaqueous quenched volcanic glasses from the Pual Ridge recovered during Marine National Facility Voyage (FR08-1991), while confirming predicted Cu and S abundances at peak enrichment of these elements, require some finite amount of magnetite fractionation before sulfide saturation is achieved.

Relatively oxidised sulfate-saturated, representative basaltic andesite compositions doped with a suite of chalcophile trace elements, have been experimentally equilibrated under reducing conditions to simulate RISS. The experiments yield Cu-Ag-Au rich sulfides, experimentally validating for the first time the plausibility of this process in evolving arc magmas.

Fluid pressure versus rock pressure: Their influence on metamorphic reactions

JOHN WHEELER[1], SERGIO LLANA-FUNEZ[2] AND DAN FAULKNER[1]

[1]School of Environmental Sciences, University of Liverpool, Liverpool, L69 3GP, UK
(*correspondence: johnwh@liv.ac.uk)
[2] Departamento de Geología, Universidad de Oviedo, calle Arias de Velasco s/n, 33005 Oviedo, Spain

In the upper part of the Earth aqueous and other fluids interact physically and chemically with their surroundings, naturally or during fluid disposal and extraction. Differences between rock and fluid pressure are common in the upper few km of the crust. Pressure affects chemical equilibrium: so how do these two different pressures affect chemical processes? Despite the fundamental nature of this question, there are no agreed answers and systematic tests are lacking. Here we discuss results from a set of experiments on gypsum dehydration, where confining and fluid pressure are independently varied.

Because they involve significant volume change, dehydration reactions are sensitive to pressure. Most dehydration reactions involve a net volume increase; hence in confined conditions overpressure develops unless the fluid can drain away. Thus, porosity and permeability development are key processes in nature and experiment. In addition, when confining pressure is greater than fluid pressure, the solids may compact. Reaction, fluid flow and compaction will all influence the evolving fluid pressure field and feedbacks are inevitable. Despite this we show how we can distinguish the effects of reaction rate from those of other processes.

We have run an extensive set of experiments on gypsum dehydration (to bassanite) and, in parallel, have developed a numerical model for dehydration. We show two results.

1. Experiments show that the rate of gypsum dehydration is strongly influenced by pore fluid pressure and not by confining pressure. This means that, even as the bassanite becomes the dominant load supporting phase, the confining pressure it supports is not influencing the thermodynamics of the reaction.

2. Experiments and the numerical model both show that under some conditions a reaction *front* develops, separating unaltered gypsum from substantially reacted regions. Such fronts, if they develop, exert a strong influence on behaviour in experiments and will equally influence natural systems.

Liposome study of MtrABC: A Porin cytochrome electron transport system from *Shewanella oneidensis*

G.F. WHITE*, M.J. EDWARDS, N.A. BAIDEN, A. HALL, J.N. BUTT, D.J. RICHARDSON AND T.A. CLARKE

University of East Anglia, Norwich NR4 7TJ, UK (*correspondence: gaye.white@uea.ac.uk)

S. Oneidensis are able to respire in the absence of oxygen because they can use oxidised metals, external to the cell, as terminal electron acceptors. This involves electron transfer across the bacterial cell envelope to the surface of minerals such as Fe(III) and Mn(IV) oxides. Genetic knockout studies have identified a suite of proteins associated with electron transport through the outer membrane [1]. This includes the MtrABC complex. Studies of these proteins led to the putative model for Porin-Cytochrome Electron Transport (PCET) shown in Fig. 1 below [2, 3].

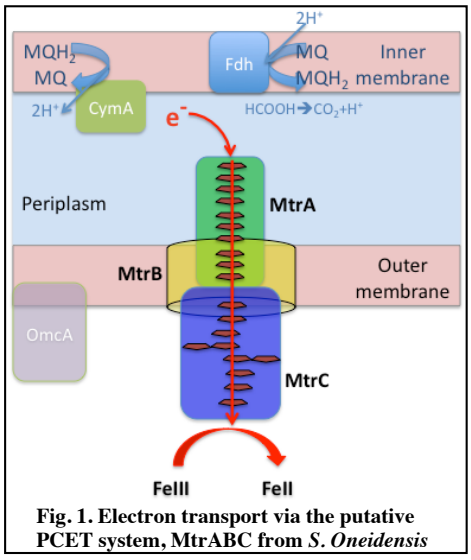

Fig. 1. Electron transport via the putative PCET system, MtrABC from *S. Oneidensis*

In this model the decaheme cytochromes MtrA and MtrC meet inside the transmembrane sheath, MtrB. The 20 hemes are closely aligned allowing electrons to flow through the MtrAC "wire". To test this model, we have inserted MtrABC into liposomes containing a hydrophyllic electron source, reduced methyl viologen, that also acts as a redox indicator. We describe the development of this technique and present our investigations into PCET via MtrABC across a lipid bilayer to a range of soluble and insoluble minerals.

Correlated uranium concentration, radiation damage, and increased SHRIMP U/Pb ages of zircon

LLOYD T. WHITE* AND TREVOR R. IRELAND

Research School of Earth Sciences, The Australian National University (*correspondance: lloyd.white@anu.edu.au)

SHRIMP U-Pb age calibrations require an accurate calibration of the observed ion ratios. Previous work has shown that there is a correlation between highly elevated uranium concentrations (>3000 ppm) and an increase in apparent age [1]. This "high uranium effect" has been attributed to U, Pb gain or loss, matrix-dependent sputtering, and changes in secondary ionisation effeciency of different species. If this process is systematic, then it may be possible to obtain a calibration that will allow correction of high U spots and allow comparison with more normal zircon.

We report results from SHRIMP I, II and RG analyses of several samples of varying uranium concentration and age (~20 Ma, ~50 Ma, ~100 Ma and ~180 Ma). Our results suggest that the "high uranium effect" can vary between different geometries of SHRIMP (i.e. I, II and RG) and may (at least in part) relate to how the machine is calibrated. It also appears that the "high-uranium effect" is more pronounced in the older zircons.

Raman spectroscopy was used to analyse some of the zircons that had been analysed previously with SHRIMP. This was done so that the uranium concentration and U/Pb age was known for each Raman analysis. The Raman results suggest that the correlation between uranium concentration and age is complex, but implies that the older apparent ages obtained from SHRIMP are related to zircons that have lost some, or all of their crystalline structure. Thus, the "high-uranium effect" is more problematic in older zircons because of accumulated radiation damage, which will also promote Pb redistribution.

Implications of a non-chondritic Earth for terrestrial heat production and geodynamics

WILLIAM M. WHITE AND JASON PHIPPS MORGAN

Dept. of Earth & Atmospheric Sciences, Cornell University, Ithaca, NY 14853 USA (wmw4@cornell.edu, jp369@cornell.edu)

Previous geochemical estimates of terrestrial radiogenic heat production were based on the assumption that refractory lithophile elements, such as the REE, U, and Th are present in the Earth in chondritic relative proportions (the "modified chondritic Earth' model). However, $^{142}Nd/^{144}Nd$ ratios in modern terrestrial materials imply that the Sm/Nd ratio in the Earth, or at least the observable part of it, that is about 6% higher than chondritic, and hence the Earth is non-chondritic, even for ratios of refractory lithophile elements. The most likely explanation is that a low Sm/Nd igneous protocrust that formed as as the Earth accreted was lost through collisional erosion. A protocrust 6% enriched in Nd relative to Sm would have been more strongly enriched in the more highly incompatible elements K, U, and Th. Calculations based on a model of protocrust formation and collisional erosion that satisfy both Sm-Nd and Lu-Hf isotopic constraints imply U and Th concentrations in the bulk silicate Earth (BSE) about 40% lower than in the 'modified chondritic Earth' model. Asumming a K/U = 13800 for the BSE, the K concentration is 30% lower than previously believed. This corresponds to a terrestrial heat production of 11.9 TW, compared to estimates ranging from 16 to 20 TW based on 'modified chondritic Earth' model. Of this, some 5 to 10 TW of heat production is in the continental crust, leaving <6 TW of heat production in the mantle. For comparison, recent estimates of U, Th, and K in the depleted mantle imply heat production in the range of 0.6–1.0μW/kg; if the depleted mantle occupies the entire mantle, this translates into mantle heat production of 3-4 TW. Mantle heat losses are roughly 33 TW, hence the mantle Urey ratio (ratio of heat production to heat loss) is in the range of 0.09 to 0.19. At present, heat generated by viscous dissapation of the gravitational energy released by sinking slabs is 12 to 15 TW, and <5 TW is released by the cooling core. Of this energy, only a fraction, 3.8 to 4.8 TW can produce new gravitational power to drive convection and plate tectonics. Thus gravitational energy is being consumed at a much higher rate than it is being regenerated. This is a clear indication that the present rate of slab subduction is not sustainable and that the mantle is in a phase of faster than normal slab subduction and plate spreading.

Hygroscopic and CCN properties of marine aerosol

J.D. WHITEHEAD[1]*, J.D. ALLAN[1], N. GOOD[2] AND G. MCFIGGANS[1]

[1]Centre for Atmospheric Science, SEAES, The University of Manchester, Oxford Road, Manchester, M13 9PL, UK (*correspondence: James.Whitehead@manchester.ac.uk).

[2]Centre for Atmospheric and Instrumentation Research, University of Hertfordshire College Lane, Hatfield, AL10 9AB, UK

The impact of marine aerosols on cloud properties is the subject of active research due to the high level of uncertainty associated with their effect on the climate. In order to quanitify these effects more accurately, it is important to measure and understand aerosol water uptake, which can vary greatly with particle size and composition. The tools available for this task include the Hygroscopicity Tandem Differential Mobility Analyser (HTDMA) and the Cloud Condensation Nuclei counter (CCNc), however consistency between the aerosol water uptake derived with these instruments can be affected by the composition in particular due to the presence of organic components [1].

Both instruments were operated at Mace Head, during winter 2010 and summer 2011. The site's location on the west coast of Ireland makes it ideal for sampling air masses from over the North Atlantic without significant local anthropogenic influence. During the winter, the aerosol particles in the clean marine air at this location consist largely of inorganic components, so it is expected that reconciliation between the hygroscopic and CCN properties of the aerosols will be straightforward. Owing to hotly-debated impacts of the contribution of organic aerosol components to droplet activation and to the expected higher summertime contribution to primary marine particulate of biogenically derived organic matter [2], reconciliation of aerosol water uptake derived with each instrument presents additional challenges. This can be examined with reference to aerosol composition data from an Aerosol Mass Spectrometer (AMS) simultaneously operating at the same location.

Recent progress with the analysis and comparison of the winter and summertime data will be presented and discussed in the context of previous marine experiments.

Quadruple sulfur isotope determination by SIMS: Limitations, progress and prospects

M.J. WHITEHOUSE

Swedish Museum of Natural History, Stockholm, Sweden (martin.whitehouse@nrm.se)

The discovery of mass independent fractionation effects in sulfur isotopes leading to what is commonly referred to as "anomalous" or "MIF" sulfur has revolutionised our understanding of the evolution and interaction of sulfur reservoirs. Of the four naturally occurring sulfur isotopes, variations in the abundance of ^{33}S and ^{36}S may be produced by upper atmosphere photo-catalysed reactions acting on SO_2. The distinctive and irreversible signatures preserved in sulfides or sulfates in the geological record are key to understanding the evolution of Earth's atmosphere [1], and provide important tracers in geobiological [2] and ore-forming processes [3]. Recent studies have also investigated ^{36}S abundance as a potential tracer of the MIF process [4].

Among the various methods available to measure sulfur isotopes, secondary ion mass spectrometry (SIMS) combines high-spatial and -volume resolution with a precision adequate for many studies, as well as the ability to efficiently analyse a large number of *in situ* targets. To date, SIMS studies have been limited to the three most abundant isotopes, ^{32}S, ^{33}S and ^{34}S, all of which may be measured simultaneously using Faraday cups (FC's) with typical precision on $\delta^{33}S$ (and $\Delta^{33}S$) and $\delta^{34}S$ of <0.2‰ (1σ). The low abundance of ^{36}S (ca. 0.02%) however presents a significant analytical challenge to SIMS. Under typical analytical conditions used for triple-sulfur isotope analysis, a ca. 10^9 cps ^{32}S will be accompanied by only 2 x 10^5 cps ^{36}S which is too low to yield acceptable precision using FC's. Furthermore, the ~5-10-fold signal increase needed to reach such precision can only be achieved with a considerable loss of spatial resolution. An alternative approach is to measure ^{36}S in a pulse-counting electron multiplier (EM) but the small Hamamatsu EM's on the IMS1270/80 experience significant gain drift at high count rates. Nonetheless, with appropriate within and between run drift correction, usable internal precision on $\Delta^{36}S$ of ~0.5‰ (1σ) can be achieved with spatial resolution <10 μm, as will be demonstrated with case studies from both early- and late-Archean sulfides. Lower noise FC amplifiers or substitution of a more robust EM can eventually improve precision.

Geomicrobiology of hyperalkaline Cr(VI) contaminated land

ROBERT A. WHITTLESTON[1], IAN T. BURKE[1], DOUGLAS I. STEWART[2] AND R.J.G. MORTIMER[1]

[1]School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, UK

[2]School of Civil Engineering, University of Leeds, Leeds, LS2 9JT, UK

Chromium in the form of its carcinogenic anion, chromate, has been entering the soils beneath a chromite ore processing residue (COPR) disposal site in the north of England for over 100 years, as a hyper alkaline (pH 13.5) liquor. This study reports the findings of a multi-disciplinary investigation into the biogeochemical processes occurring within the subsurface that influence contaminant fate.

The soil immediately beneath the waste was found to have a pH of 11→12.5, and contain 0.3→0.5% w/w chromium, and 45→75% of the microbially available iron is Fe(II). The soil pH and Cr concentrations were found to decrease with distance from the waste. XAS and (S)TEM analysis indicated that Cr is present throughout the soils as a mixed Cr(III)-Fe(III) oxy-hydroxide phase, resistant to air oxidation. This suggests that the elevated soil Cr content is due to reductive precipitation of Cr(VI) by Fe(II), producing a stable long term host for Cr(III). 16s rRNA community analysis of the soil immediately beneath the waste found a microbial population dominated by *Proteobacteria*, *Firmicutes* and *Bacteriodetes* species. Addition of this soil to alkaline Fe(III) containing growth media (pH=9.2) produced a consortium of iron reducing microorganisms dominated by the *Firmicutes* species, particularly *Anaerobranca*, *Anaerovirgula* and *Tissierella*.

Microcosm experiments demonstrated the capacity of COPR affected soil to abiotically remove all Cr(VI) from COPR leachate within 40 days. Amendment of the pH (~pH 9) resulted in the development of a cascade of microcrobially mediated terminal electron accepting processes, reaching Fe(III) reduction after complete Cr(VI) removal. A *Firmicutes* dominated population (73%) was identified in the pH amended microcosm systems during Fe(III) reduction, with *Dethiobacter sp* dominant, but *Anaerobranca sp* also present.

This work suggests that abiotic reductive precipitation of Cr(VI) by microbially produced Fe(II) can be effective at preventing the spread of chromium from COPR waste sites.

Lithium and its isotopes in Central European Rivers

U. WIECHERT[1]*, C.V. ULLMANN[1,2], D. UHLIG[1], T. PFAHL[1], M. RICKING[1] AND H. BECKER[1]

[1]Freie Universität Berlin, Germany (*correspondence: wiechert@zedat.fu-berlin.de)
[2]University of Copenhagen, Denmark

Lithium isotopes are a promising new means to study silicate weathering. To date most lithium isotope work on river systems has been done on ocean islands [1] or remote regions of, for example, the Himalayas [2] where human influence on rivers is minor. In this study we present lithium abundances and isotopic ratios for the central European rivers Danube, Elbe, and Rhine. The catchments of these rivers are highly populated, densely industrialised, and affected by a highly developed farming industry. The goal of this ongoing project is to identify major processes and anthropogenic sources which control lithium and its isotopes in central European rivers. The investigated waters show lithium concentrations (dissolved load) between ~2 and 22 µg/l and δ^7Li from +4 to +22 ‰ relative to L-SVEC. Some Danubian and upper Rhine waters have lithium abundances close to 2 µg/l and high δ^7Li up to +22 ‰. Similar concentrations (0.2-4.0 µg/l) and δ^7Li ~+23 ‰ are reported for more pristine river systems worldwide [3] indicating that lithium in the upper Danube and upper Rhine is largely controlled by silicate weathering. The catchments of the lower Elbe, in particular waters of the river Saale, are characterized by high lithium concentrations and ^{7}Li/^{6}Li. These waters have also high sulfate concentrations and δ^{34}S up to +8.5 ‰ CDT indicating a contribution from Permian evaporites. This is reasonable because evaporites have been mined in the region for more than a century. Samples from the river Elbe near Dresden, all Rhine and Danube samples show a good correlation between lithium isotope ratios and silicon fraction in the dissolved load (r^2 = 0.7). The highest molar fractions of silicon are connected to low δ^7Li ~5 ‰ and δ^{34}S ~3.4 ‰ in catchments of the river Elbe near Dresden. This is consistent with very intense weathering or a distinct style of weathering probably related to oxidation of sulfides and formation of highly acidic waters in old mining districts of the Erzgebirge.

Shale gas potential of the Upper Jurassic strata in the central part of the Polish Lowlands

D. WIĘCŁAW* AND P. KOSAKOWSKI

AGH University of Science and Technology, Al. Mickiewicza 30, 30-059 Krakow, Poland (*correspondence: wieclaw@agh.edu.pl)

The Upper Jurassic strata, rich in organic matter, are regarded as the main source rock of the large hydrocarbon accumulations in the Nowegian sector of the North Sea [1]. Also in Poland the Kimmeridge and Tithonian strata were subject of a large-scale exploration. In numerous wells only oil and gas shows were recorded. [2]. Our present study shows a new point of view on the posibility of shale gas accumulation in these strata. The investigations were conducted in the central part of the Polish Lowlands where the analysed strata are covered by thick Cretacous deposits.

In total, 126 samples (66 from the Kimmeridgian and 60 from the Tithonian strata, respectively) were collected. Rock-Eval pyrolysis indicates a large diversity in the total organic carbon (TOC) content, from 0.14 to 6.6 wt% (median 1.1 wt%) and from 0.19 to 10.2 wt% (median 1.6 wt%) in the Kimmeridgian and Tithonian strata, respectively. The total hydrocarbon content in the analysed rocks is not high and medians equal 1.32 and 4.2 mg HC/g rock, respectively. Hydrocarbon potential of the Kimmeridgian strata is usually low with the median value of 121 mg HC/g TOC indicating the presence of gas-prone kerogen, whereas for the Tithonian strata, the median of this index equals 272 mg HC/g TOC (mixed gas- and oil-prone kerogen). Maturity of organic matter corresponds with the initial phase of “oil window”. The BasinMod® 1-D modelling revealed that the generation of hydrocarbons from the Upper Jurassic source rocks occurred in the Late Cretaceous time. This process was interrupted by inversion on the Polish Lowlands.

In the selected areas of the Polish Lowlands the Kimmeridgian and Tithonian strata have generated sufficient amount of hydrocarbons to saturate rock and can be considered as a potential shale gas source.

The investigations were financed by the Ministry of Science and Higher Education (Project No. N307 3141 39).

Primary shape and nanomechanical properties of natural Fe-colloids studied by AFM and SEM

A.K. WIECZOREK*, A. FRITZSCHE AND K.U. TOTSCHE

Institut für Geowissenschaften, Hydrogeologie, Friedrich-Schiller-Universität Jena, Burgweg 11, D-07749 Jena, (*correspondence: arkadiusz-krzysztof.wieczorek@uni-jena.de)

Natural colloids and nanoparticles are involved in a multitude of biogeochemical and physicochemical processes and act as mobile reactive carriers [1]. Interactions with each other and with the immobile phase not only affect hydraulic properties, but may change geometric, mechanic and physicochemical properties of the pore network and its interfaces. Of particular importance are the nanoparticulate mineral-organic mixed phases, formed either by the way of heterogeneous nucleation, sorption or co-precipitation [2][3]. We studied natural colloids sampled from soils subjected to redoximorphosis combining Scanning Electron Microscopy, Energy-Dispersive X-ray Spectroscopy and Atomic Force Microscopy. We identified three types of material, i.e. bulky Fe-aggregates, linear-aligned Fe-aggregates and flat, circular, soft and adhesive patches, presumably pure organic in nature. The majority belongs to the bulky-type with mean sizes around 50nm. Yet they are formed of much smaller subunits. The linear-aligned aggregates, presumable representing the subunits of the bulky aggregates, have mean diameters around 20 nm with large variety of lengths. They seem to be “chained” along linear structures, which we hypothesize to be of biotic origin. Thus, biotic material may be important in the geometric structuring of the aggregation process of natural colloids.

Sequential extractions as a tool to investigate stable metal isotope fractionation between soil pools

JAN G. WIEDERHOLD[1,2]*, BERNARD BOURDON[2,3] AND RUBEN KRETZSCHMAR[1]

[1]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland (*correspondence: wiederhold@env.ethz.ch)

[2]Isotope Geochemistry, Institute of Geochemistry and Petrology, ETH Zurich, Switzerland

[3]ENS Lyon and CNRS, France

Stable isotope ratios contain information about sources and transformations in the biogeochemical cycle of metals in the environment. The recent development of high-precision methods to resolve metal isotope fractionation (e.g., Fe, Hg) now allows to apply these new isotope tracers to a variety of natural systems and sample matrices including soils. Biogeochemical metal cycling in soils plays an important role in chemical weathering processes, nutrient dynamics, and the fate of pollutants in terrestrial ecosystems.

The stable isotope signature of bulk soil samples can be assessed relatively easily by analysing total digest solutions. However, metals in soil samples are often present in various "pools" which can have very different histories and chemical properties. Thus, valuable information on isotopic differences between soil pools and fractionation between them is lost by analyzing only the isotope signature of bulk samples. Sequential chemical extractions are an established tool to separate metal pools from natural samples. However, the application of sequential extractions in stable isotope studies bears the risk of introducing fractionation artifacts during the extraction procedure. Thus, a careful method development is required to assess the suitability of specific extraction steps.

Here, we present iron isotope (δ^{56}Fe) and mass-dependent (MDF) and mass-independent (MIF) mercury isotope (δ^{202}Hg, Δ^{199}Hg) data from sequential extractions of different environmental samples measured by MC-ICP-MS. Newly-developed extraction methods were able to trace the evolution of secondary iron phases in young initial soils from a granitic glacier forefield, revealing that the imprint of a kinetic isotope effect during silicate weathering is preserved in pedogenic minerals. Mercury isotope ratios of sequential extracts from contaminated mine samples demonstrated that isotopically-distinct Hg pools exist within different tailing materials, exhibiting strong positive MDF and small negative MIF signatures in the more soluble extraction steps relative to the bulk isotopic composition. Future applications as well as potential limitations and pitfalls of sequential extraction methods in metal isotope studies will be discussed.

Life at the dry limit: Microbial colonization of evaporites in the Atacama Desert

J. WIERZCHOS[1]*, A. DE LOS RÍOS[1], A.F. DÁVILA[2], S. VALEA[1], B. CÁMARA[1], O. ARTIEDA[3] AND C. ASCASO[1]

[1]MNCN-CSIC, 28006 Madrid, Spain (*correspondence: j.wierzchos@mncn.csic.es)
[2]SETI Institute, Mountain View, CA 94043-2172, USA (adavila@seti.org)
[3]Universidad de Extremadura, 10600 Plasencia, Spain (oartieda@unex.es)

The hyper-arid core of the Atacama Desert is considered the driest region on Earth, one of the most challenging environments for life, and a Mars analog, due mainly to water scarcity. While Atacama soils are essentially lifeless, we have shown that hygroscopic halite crusts are colonized by endolithic communities composed of cyanobacteria, heterotrophic bacteria and archaea [1, 2]. The interior of the crusts provides shelter against extreme temperatures and UV radiation, and facilitates cell hydration through mineral deliquescence [3]. We also found that microporous and translucent gypsum crusts represent another evaporitic habitat for life in Atacama. This substrate is colonized by endolithic and hypoendolithic free living algae, fungi, cyanobacteria and heterotrophic bacteria, as well as by epilithic lichens [4]. The colonization of gypsum crusts appears to be controlled by atmospheric water potential. Based on our work in Atacama, we propose that putative Martian microorganisms withdrew to similar evaporitic micro environments as the planet dried out [5]. As such, evaporitic deposits would be primer targets for the search for life.

Trace element mobilisation in a natural analogue CO_2 storage site

MAX WIGLEY*, MIKE BICKLE, NIKO KAMPMAN, BENOIT DUBACQ AND HAZEL CHAPMAN

Dept. Earth Sciences, Downing Street, Cambridge CB2 3EQ, UK (*correspondence: mmw36@ cam.ac.uk)

Natural analogues present a unique opportunity to study fluid-mineral interactions and transport processes that may occur in geological CO_2 storage systems [1,2]. Near Green River, Utah, USA, regionally extensive portions of the red-bed Entrada sandstone have been locally bleached white/yellow by low temperature diagenetic fluids [3]. Fluid inclusion studies [3], field relationships and modelling suggest that the fluid responsible for the bleaching is a low Eh-pH, CO_2-rich brine, containing variable amounts of methane.

Analyses reveal systematic patterns of trace element mobilisation and transport resulting from CO_2-promoted oxide dissolution (Fig. 1). Trace metals and REE concentrations are enriched at the transition from bleached to red facies. Element distribution is controlled by partitioning between the fluid and secondary minerals (carbonate, oxide, and clay phases), that precipitate as geochemical fronts propagate through the host rock. These fronts separate reduced, acidic fluid from oxidized groundwater.

Modelling suggests that bleaching results from dissolution of hematite from the red sandstones by a reaction of the form:

$$20Fe_2O_3 + 64CO_2 + 5CH_4 + 19H_2O + 11H^+ = 30Fe^{+2} + 59HCO_3^- + 10FeHCO_3^+,$$

in which CO_2 and a small fraction of methane complex the iron in solution. This reaction combined with Eh-pH diagrams suggest the precipitation of an iron-bearing carbonate and/or iron oxide phase, consistent with petrological observations.

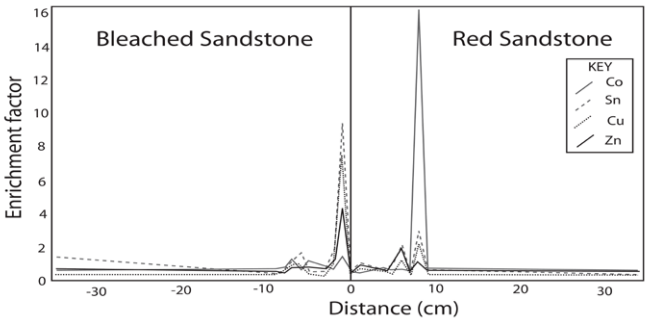

Figure 1. Plot of enrichment factor of metals relative to unaltered Entrada sandstone, versus distance from the bleached-unbleached contact.

Chemical composition of biomass used in co-combustion with coal in Polish power-plants

W. WILCZYŃSKA-MICHALIK[1]*, R. GASEK[1] AND M. MICHALIK[2]

[1]Institute of Geography, Pedagogical University, ul. Podchorążych 2, 30-085 Kraków, Poland (*correspondence: wmichali@up.krakow.pl; rgasek@ap.krakow.pl)

[2]Institute of Geological Sciences, Jagiellonian University, ul. Oleandry 2a, 30-063 Kraków, Poland; (marek.michalik@uj.edu.pl)

Biomass is considered as important non-fossil renewable energy source. Potential biomass resources in Poland are estimated to be around 30 millions Mg per year and the share of biomass in electricity production and other applications is increasing systematically. Lack of complex life cycle assessment studies is the reason that real environmental value of biomass usage as fuel is not fully understood.

Concentration of major and trace elements in biomass is very important in prediction of technological problems during combustion and usage of combustion co-products as well as their environmental impact. Composition of biomass is related to many factors, e.g.: type of biomass, age of plant, growth process, fertilizers and pesticides used, soils composition and contamination, atmospheric pollution of plantation area, harvesting, transportation and storage.

The study is based mineralogical (optical and electron microscopy, XRD) and chemical analyses of samples of biomass used in power-plants in southern Poland.

The content of mineral component is low. Mineral particles can be considered as detrital (i.e. introduced by water or wind during plant growth) and anthropogenic (introduced during harvesting, transportation, storage and processing).

Chemical variation of studied samples of biomass is significant (e.g. Ca from 0.1 to 1.1wt%; P from 0.2 to 0.89wt%; Al from <0.01 to 0.09wt%; Na from <0.001 to 0.106wt%; K from 0.05 to 2.4wt%; S from <0.01 to 0.22wt% and for selected trace elements: Mn from 7 to 333 ppm; Pb from 2.9 to 25.6 ppm; Zn from 8.3 to 79.4 ppm; Cu from 2.2 to 25.2 ppm; Mo from 0.03 to 0.72 ppm; Hg from <1 to 21 ppb). The content of several trace elements is within the range comparable with Polish coals (e.g. Mn, Cr, Cu, Ni, Pb, Zn).

Significant differences in chemical composition of various types of biomass suggest that it is possible to expect different behaviour during combustion and different environmental impact. It also suggests that careful blending of biomass may be important.

Hydrothermal alteration and Ni sulphide formation in the Bon Accord Ni-oxide body, Barberton, South Africa

ANTJE WILDAU[1]*, A.E. WILLIAMS-JONES[2] AND MARIAN TREDOUX[1]

[1]Department of Geology, University of the Free State, Bloemfontein, 9300, South Africa (*correspondence: antje@geologie-leipzig.de)

[2]Department of Earth and Planetary Sciences, McGill University, Montreal, QC, H3A 2A7, Canada

The Bon Accord deposit is a 3.5Ga Ni-oxide body in the Barberton Greenstone Belt, South Africa. This small, lens-shaped orebody (6 x 3 x 0.35 m) was discovered in 1920, and mined out in the 1960s. The Ni concentration ranged from 35wt.% NiO in the center to 10wt.% NiO at the rim. The deposit has attracted considerable attention because of its very unusual mineralogy (e.g., bonaccordite, cochromite, nimite, liebenbergite, willemseite, trevorite). The orebody is hosted by a talc-carbonate-serpentinite and is located in the contact metamorphic aureole of a younger granite. The genesis of the deposit is unknown and the two main hypotheses that have been advanced for its formation are controversial. One of these is that the deposit is the product of a meteorite impact and the other is that it is an oxidized body of nickel-iron from the Earth's core.

Petrographic and geochemical studies of the Bon Accord deposit show the influence of hydrothermal fluids. In the centre of the deposit, there are relicts of primary liebenbergite (Ni_2SiO_4), which was serpentinized and later altered to willemseite ($(Ni,Mg)_3Si_4O_{10}(OH)_2$). The rest of the orebody is completely devoid of liebenbergite (Ni_2SiO_4) but much richer in népouite ($Ni_3Si_2O_5(OH)_4$) and willemseite ($(Ni,Mg)_3Si_4O_{10}(OH)_2$). The outer parts contain abundant millerite (NiS) and heazlewoodite (Ni_3S_2), plus a number of Ni-arsenide and Cu-sulphide minerals (10 vol.%), whereas the centre is almost devoid of Ni-sulphide minerals (<1vol.%), These minerals occupy cracks in the ferroan trevorite ($NiFe_2O_4$) and nickeloan magnetite ($(Ni,Fe)_3O_4$). In some places, the secondary minerals replace these oxides.

The mineralogical and textural relationships described above are consistent with alteration of the primary silicate minerals by reactions of the type:

2 liebenbergite + H_2S + H_2O → millerite + népouite

These observations suggest that the Bon Accord deposit formed from Ni-rich komatiite that was altered by circulating hydrothermal fluids, forming secondary sulphide minerals.

A comparision of mm scale resolution techniques for sediment core analysis

D. WILHELMS-DICK[1]*, T. HANEBUTH[1], U. RÖHL[2], T. WESTERHOLD[2], M. KRIEWS[3], H. RÖMMERMANN[3] AND S. KASTEN[1]

[1]Bremen University, Postfach 330 440, 28334 Bremen, Germany (*correspondence: wilhelms@uni-bremen.de)
[2]Marum, Postfach 330 440, 28334 Bremen, Germany
[3]Alfred Wegener Institute for Polar and Marine Research, Postfach 120161, 27515 Bremerhaven, Germany

To study high-frequency variability in the Arabian Monsoon intensity, laminated sediments from the oxygen minimum zone (200-1200m) of the Arabian Sea offer a high-resolution climate archive [1]. The chemical signature which is used to reconstruct past climate can be obtained using several different analysing techniques. In the presented study a 5.3 m long sediment core from the northern Arabian Sea (GeoB12309-5: 24:52.3°N; 62:59.9°E, 960 m water depth), covers the past 4,900 cal yrs BP. The XRF core scanner data show highly varying signals in the upper 1.6 m core depth. Based on these results and radiograph images, samples were taken for LA-ICP-MS and ICP-MS/OES analysis.

The big advantages of analysing a sediment core via XRF core scanning are non-destruction and speed, but only relative variations for chemical elements are obtained and not element concentrations. The LA-ICP-MS methods is quasi non-detructive, you obtain element concentrations but is more time consuming. The most precise, but also most time consuming methods for main and trace element analysis are the ICP-MS/OES techniques after full acid digestion.

Results from all 3 methods show similar chemical patterns at distinct sediment structures (e.g. turbidites) for Ca, Rb and Sr. However, the comparability between the 3 methods is worse for Al, K, Ti, Fe and Zr. The particle size, water content of the sediment and surface roughness highly influences the XRF method, to some extent also the LA-ICP-MS technique. These results suggest that the soft sediment cores including its overall quality and surface conditions limit the ability of the sub-mm scale XRF scanning method to receive reliable data for Ca, Rb and Sr. However, the LA-ICP-MS technique as it was used here shows problems with long term drift, hence making it very difficult to accurately compare the 3 high resolution methods. Due to the relatively large amount of sediment digested, the ICP-MS/OES method delivers the most accurate results which are assumed to best serve as input data for frequency analysis.

Zircon solubility in Na-Si-Al-O-H fluids by *in situ* SR-XRF analysis

M. WILKE[1], C. SCHMIDT[1], J. DUBRAIL[1], K. APPEL[2] AND M. BORCHERT[2]

[1]Deutsches GeoForschungsZentrum GFZ, Potsdam, Germany (max@gfz-potsdam.de)
[2]Deutsches Elektronen-Synchrotron, Hamburg, Germany

The geochemical budget of high-field-strength elements (HFSE, i.e., Ti, Zr, Hf, Nb and Ta) in rocks is largely controlled by accessory phases such as zircon or rutile. Thus, the mobility of HFSE during processes in the Earth's crust and mantle is closely linked to solubility and stability of these phases. Fluid composition appears to be the most important parameter because it may drastically affect the complexation of HFSE. Earlier studies ([1],[2]) on rutile report enhanced solubility for aqueous fluids with $Na_2Si_3O_7$ (NS3) or $NaAlSi_3O_8$. Complexing of Ti with alkalies and silica (siloxan groups) dissolved in the fluid has been suggested as an important mechanism to explain these high solubilities. A similar mechanism for enhanced solubility can be expected for the zircon-hafnon series.

Synthetic zircon was equilibrated with fluids containing $Na_2Si_3O_7$, $Na_2Si_3O_7$ + 5 wt% Al_2O_3, or $NaAlSi_3O_8$ at *T* up to 750 ˚C and *P* up to 1.5 GPa using hydrothermal diamond-anvil cells. The Zr content of the fluids was determined *in situ* at *P* and *T* by confocal synchrotron radiation μXRF analysis at beamline L, HASYLAB. At *P* of 450–950 MPa and *T* of 500–750°C, Zr concentrations range from 20 to 90 ppm in H_2O + 10 wt% NS3 fluids. In H_2O + 18 wt% NS3 solutions, they increase to 200 to 500 ppm and drop to 100–150 ppm upon addition of Al. The highest concentrations of up to 1000 ppm were measured in fluids containing 30 wt% NS3. At constant NS3 content, the Zr concentration generally decreases with P and increases with T. One experiment with zircon *and* hafnon was done to measure Zr-Hf fractionation. At a NS3 content of 27 wt%, a molar Hf/Zr ratio of 2.7 was determined, which indicates significant Hf-Zr fractionation in these fluids. For a fluid with 6 wt% $NaAlSi_3O_8$ at ~1.45 GPa and 600°C, the XRF signal was at the detection limit, i.e. ~1 ppm Zr or below. These solubility data are qualitatively consistent with those on rutile ([1],[2]) and indicate strong differences in Zr speciation with *P*, *T*, and fluid composition. They represent another example for which efficient complexation of HFSE by siloxan-like units in the fluid is indicated (see also ref. [3]).

Compound-specific isotopic evidence of paleoenvironmental change Lake El'gygytgyn, NE Russia

K. WILKIE*, S.T. PETSCH, S. BURNS AND J. BRIGHAM-GRETTE

Dept. of Geosciences, University of Massachusetts, Amherst, MA, USA (*correspondence: kwilkie@geo.umass.edu)

Recent successful drilling operations at Lake El'gygytgyn, NE Russia have recovered sediment cores back to 3.6Ma, representing the longest time-continuous sediment record of past climate change in the terrestrial Arctic. Compound-specific isotopic analysis of sedimentary lipids from this remote basin spanning the last 120ka allows reconstruction of past hydrological conditions, thereby providing a powerful tool for reconstructing past Arctic climate changes.

The hydrogen isotopic composition of lipid biomarkers was determined from previously obtained Lake El'gygytgyn sediment cores and compared with other multi-proxy evidence of past climate change within the lake basin. Here we present δD measurements of individual sedimentary fatty acids representing aquatic and terrestrial sources (e.g. aquatic, δD_{AQ}: nC_{20}, nC_{22}; terrestrial, δD_{TER}: nC_{30}) over the past 120 ka. The δD_{AQ} record shows little variation on glacial-interglacial cycles, possibly due to perennial ice cover during full glacial conditions and/or changes in aquatic community structure and aquatic organic matter sources. The data from terrestrial components show significant variation (up to 70‰) between glacial-interglacial intervals as well as variation on millenial timescales (~200 yr resolution). The most negative δD_{TER} values occur during glacial conditions (i.e. the Last Glacial Maximum and MIS 4) while enriched values are observed during interglacial intervals (i.e. most notably during the Holocene and MIS 5e). Preliminary reconstruction of the isotopic composition of precipitation from these results allows for comparision with the δD ice core records from both Greenland and Antarctic to assess high latitude environmental change and global teleconnections. Initial comparison of these records shows high fidelity with speleothem records from Hulu and Dongge caves [1] as well as with δD_{GRIP} [2] and δD_{VOSTOK} [3] records.

The W isotopic composition of the Hadean mantle – Evidence for the late heavy bombardment

M. WILLBOLD[1], T. ELLIOTT[1] AND S. MOORBATH[2]

[1]University of Bristol, School of Earth Sciences, Wills Memorial Building, Queens Road, Bristol, BS8 1RJ, United Kingdom

[2]University of Oxford, Department of Earth Sciences, South Parks Road, Oxford, OX1 3AN, United Kingdom

The contrasting behaviour of its daughter and short-lived ($t_{1/2}$ ~9Ma) parent has made the ^{182}Hf-^{182}W system invaluable in determining the timescales of planetary core formation. However, Hf is also considerably less incompatible than W in many melting and crystallisation scenarios in purely silicate systems. Thus the ^{182}Hf-^{182}W pair has also been used with success in examining the evolution of the silicate portion of planetessimals. Recent $\varepsilon^{142}Nd$ data demonstrate that Hadean mantle fractionation events are recorded in the isotopic signatures of samples from Isua, Greenland. Notably one interpretation of terrestrial ^{142}Nd-^{143}Nd systematics invokes the formation of an enriched, deep reservoir within the first 30Ma of Earth History. It has further been suggested that the contrast between $\varepsilon^{142}Nd$ in the most ancient Greenland samples and present day mantle (~20ppm) is a result of partial remixing between this hidden reservoir and convecting mantle after ~3.5Ga. If so, the Greenland samples derived from mantle that pre-dates this event would be expected to show a difference in $\varepsilon^{182}W$ relative to modern mantle.

We have made high-precision (<5ppm; 2σ) $\varepsilon^{182}W$ measurements on some Isua samples. These document significant differences between these samples and modern mantle values (~13ppm). In contrast to previous studies [1,2] our analyses are considerably more precise and we are the first to document significant differences. However, the magnitude of the difference in our $\varepsilon^{182}W$ is smaller than predicted for a remixing scenario of early enriched reservoir with the convecting mantle that can account for the difference in $\varepsilon^{142}Nd$ between Isua and present mantle. We thus re-emphasise the conclusions of [1], that this change in $\varepsilon^{142}Nd$ with time does not provide good evidence for the existence of an early enriched reservoir. We further note that the addition of ~0.5% of primitive chondritic material after core formation, as suggested by the late veneer model, is sufficient to account for the lowering of $\varepsilon^{182}W$ from values we report in the Isua samples to present-day.

From thermochronometric ages to exhumation rates

S.D. WILLETT[1], M.T. BRANDON[2], M. FOX[1] AND F. HERMAN[1]

[1]Geological Institute, ETH, 8092 Zurich, Switzerland
[2]Yale University, New Haven, CT, USA

To render a thermochronometric age into a more useful exhumation rate, it is necessary to process that age through a thermal model. We present a set of analytical and numerical thermal modelling methods of increasing complexity; which we feel are as simple as possible, while still retaining the essential physics of the thermal processes. We consider first the simple case of converting a single age into an exhumation rate. We include the dependence of the closure temperature on cooling rate (Dodson, 1973) and the upward advection of heat and derive some simple, analytical expressions relating exhumation rate to age through the kinetic parameters of the thermochronometric system, first, by assuming the geothermal gradient has been constant in time, and, second, using the transient analytical solution for an advecting halfspace. The second problem we consider is the effects of topographic relief on the closure isotherm. We calculate the mean depth to a closure isotherm using the solution described above, and then use spectral methods to calculate topography on this isotherm in response to topography of the surface. Finally, we consider the problem of spatially-varying exhumation rate. For this problem we combine the approaches given above, calculating perturbations to isotherms using spectral methods, combined with 1-D models of heat advection and diffusion. The 1-D models are linked by imposing a spatial correlation structure on the exhumation rate, which is otherwise free to vary in space and time. This approach provides an efficient method to "invert" a large number of thermochronometic ages, distributed in space and elevation, providing maps of time-varying exhumation rate. We illustrate each of these methods with data from the European Alps.

Novel approaches to organic aerosol chemical characterization

B.J. WILLIAMS[1]*, Y. ZHANG[1], R. MARTINEZ[1], K.S. DOCHERTY[2,3], I.M. ULBRICH[2], J.L. JIMENEZ[2], S.V. HERING[4], N.M. KREISBERG[4], A.H. GOLDSTEIN[5], AND D.R. WORSNOP[6]

[1]Washington University, St. Louis, MO 63130, USA (*correspondence: brentw@seas.wustl.edu)
[2]University of Colorado and CIRES, Boulder, CO 89309, USA
[3]Alion Science and Technology, Research Triangle Park, NC 27709, USA

[5]University of California, Berkeley, CA 94720, USA
[6]Aerodyne Research Inc., Billerica, MA 01821

In recent years several new approaches have been introduced to improve the chemical characterization of atmospheric organic aerosol (OA). Here, we highlight two techniques, the thermal desorption aerosol gas chromatograph (TAG) for automated in-situ molecular level OA speciation [1], and the high resolution time-of-flight aerosol mass spectrometer (AMS), which in addition to inorganic speciation, measures total fine OA mass concentrations and determines O/C, H/C, and N/C elemental ratios [2]. While each technique has its strengths, the TAG system is not capable of complete OA analysis without prior chemical derivatization, and the AMS is not capable of separating individual compounds. Here, we will describe recent efforts to create a combined TAG-AMS system to provide measurements of total OA, elemental ratios, and individual compounds. Finally, we discuss our efforts to develop novel data analysis approaches. Positive matrix factorization (PMF) has been used to deconvolve timeseries of AMS mass spectra [3] and timeseries of TAG source-marking compounds [4] into major components contributing to atmospheric OA concentrations. The desire to have combined TAG-AMS input parameters for a single PMF analysis have inspired novel measurement ideas that will be introduced here.

Isotopic evidence for internal oxidation of the Earth's mantle during accretion

HELEN M. WILLIAMS[1,2]*, BERNARD J. WOOD[1], JON WADE[1], DANIEL J. FROST[2] AND JAMES TUFF[1]

[1]Department of Earth Sciences, The University of Oxford, South Parks Road, Oxford OX1 3AN, UK

[2]Department of Earth Sciences, Durham University, Science Labs, Durham DH1 3LE, UK (*correspondence: h.m.williams2@durham.ac.uk)

[3]Bayerrishes Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany

The Earth's mantle is currently oxidised and out of chemical equilibrium with the core. Why this should be the case, and why the Earth's mantle should be oxidised relative to other terrestrial planets is poorly understood. It has been proposed that the oxidised nature and high ferric iron (Fe^{3+}) content of Earth's mantle was produced internally by disproportionation of ferrous iron (Fe^{2+}) into Fe^{3+} and metallic iron by perovskite crystallisation during accretion [1]. Here we show that there is a substantial Fe isotope fractionation between experimentally equilibrated metal and perovskite, which can account for the heavy Fe isotope compositions of terrestrial basalts relative to equivalent samples derived from Mars and Vesta [2,3] as the latter are too small to stabilise perovskite. Mass balance calculations indicate that all of the mantle's Fe^{3+} could have been generated from a single disproportionation event, which is consistent with complete dissolution of perovskite in the lower mantle during the Moon-forming giant impact. The similar Fe isotope compositions of terrestrial and lunar basalts [2,3] is consistent with equilibration between the mantles of the Earth and Moon in the aftermath of the giant impact [4] and suggests that the heavy Fe isotope composition of the Earth's mantle was established prior to, or during the giant impact. The oxidation state and ferric iron content of the Earth's mantle was therefore plausibly set by the end of accretion, and is decoupled from later volatile additions [5], tectonic plate recycling and the rise of oxygen in the Earth's atmosphere at 2.45 Ga [6].

Characterization of elemental sulfur reducing bacteria using transmission electron microscopy and their impact on sulfur isotope fractionation

KENNETH H. WILLIAMS[1]*, MICHAEL J. WILKINS[2]*, ALICE C. DOHNALKOVA[2], JENNIFER L. DRUHAN[1], AND MARK E. CONRAD[1]

[1]Lawrence Berkeley National Laboratory, Berkeley, CA, 94720, USA (*khwilliams@lbl.gov)

[2]Pacific Northwest National Laboratory, Richland, WA, 99352, USA (*michael.wilkins@pnl.gov)

The process of elemental sulfur (S^0) reduction by a microorganism isolated from an acetate-stimulated aquifer at the Department of Energy's Rifle Integrated Field Research Challenge (IFRC) site in Rifle, Colorado (USA) was studied using a combination of transmission electron microscopy (TEM) and isotopic techniques. Results were compared to those obtained using the well-characterized S^0 reducer *Geobacter sulfurreducens*. The site isolate was obtained from Rifle groundwater using acetate and S^0 flowers as the electron donor and acceptor, respectively. Based on 16S rRNA analysis, the isolate was most closely related to the β-proteobacterium *Azospira orzyae* (syn *Dechlorosoma suillum*). TEM revealed the isolate to be a curved rod with a single polar flagellum. Finely particulate S^0 granules (<5nm) were observed along the outer membrane as aqueous sulfide concentrations reached peak values of ca. 1200μM. Prolonged growth resulted in an abundance of aggregated filaments bound within a sulfur-rich matrix; their biogenesis and relation to cell growth remains unknown. Microbial reduction of S^0 coupled to oxidation of acetate may lead to significant deviations in the $\delta^{34}S$ values of sulfide relative to $\delta^{34}S$ values of S^0.

Such studies are critical for understanding the process of sulfur reduction in reduced environments, hypothesized to enable prolonged U(VI) immobilization at the Rifle IFRC site. Research at the site has identified significant accumulation of S^0 accompanying oxidation of aqueous sulfide by Fe(III)-oxide minerals, with the process generating an abundant electron acceptor capable of supporting the activity strains implicated in enzymatic U(VI) reduction (e.g. *Geobacter)* following exhaustion of reactive Fe(III) minerals. These results will enable incorporation of rates of microbial S^0 reduction and $\delta^{34}S$ fractionation within reactive transport models describing biogeochemical processes at the Rifle site and provide additional insights into sulfur cycling pathways.

Atomistic simulation of oxygen transport in actinide oxides and at their interfaces

N.R. WILLLIAMS[1]*, S.C. PARKER[1] A. DEVEY[2] AND M. READ[2]

[1]Department of Chemistry, University of Bath, Bath BA2 7AY, United Kingdom (*correspondence: n.r.williams@bath.ac.uk)
[2]AWE, Aldermaston, Reading, RG7 4PR (mark.read@awe.co.uk, anthony.devey@awe.co.uk)

Actinides such as uranium and its oxides are receiving increasing attention because of the interest in nuclear fuels not least because of awareness of issues associated with CO_2 emissions, security of energy supply and waning fossil fuel reserves. This also has implications on the storage of these materials in both the long and short term. Computational methods provide a complementary route for studying the corrosion of nuclear fuels and transport through the environment.

We used computer simulation techniques, using both potential-based and electronic structure methodologies to investigate the structure and stability of the surfaces and interfaces, primarily of uranium dioxide as well as the factors controlling oxygen transport through the materials. The electronic structure simulations used the VASP code [1] using GGA+U method, but are further complicated by the magnetic contribution of the 5f electrons. The correct ground state and properties are obtained by correctly controlling the orbital occupation matrices [2]. The interatomic potentials were derived to reproduce the calculated and experimental properties and used to evaluate the grain boundary structures as a function of temperature using molecular dynamics with the DL_POLY code [3].

A number of grain boundary structures were investigated we found that at high temperatures but below the melting point that UO_2 undergoes a fast ion transition where oxygen becomes highly mobile. The grain boundaries showed enhanced diffusivity, displaying fast ionic conduction at significantly lower temperatures than observed in the bulk crystal.

In summary a number of computational techniques have been utilised to investigate actinides such as uranium and their oxides. Increased understanding of the intrinsic disorder present in these oxides and its effect on corrosion offers significant benefits for the safe storage and handling of nuclear fuel materials.

Transitional oxygenation recorded in the Paleoproterozoic Turee Creek Group, Western Australia

KENNETH H. WILLIFORD[1]*, MARTIN J. VAN KRANENDONK[2], TAKAYUKI USHIKUBO[1], REINHARD KOZDON[1] AND JOHN W. VALLEY[1]

[1]NASA Astrobiology Inst., WiscSIMS, Dept. of Geoscience, Univ. Wisconsin, Madison, WI 53706 USA, (*correspondence: kwilliford@geology.wisc.edu)
[2]Geol. Surv. Western Australia, Perth, WA 6004, Australia

In situ, multiple sulfur isotope data from pyrite in the glaciomarine Meteorite Bore Member of the Paleoproterozoic Turee Creek Group, Western Australia, indicate deposition during a transitional stage in the rise of atmospheric oxygen. Abundant detrital pyrite in one diamictite layer exhibits a range of $\Delta^{33}S$ (–3.6 to 11.6‰) encompassing the entire known range for the Archean. Small, but significant, S-MIF ($\Delta^{33}S$ from –0.8 to 1.0‰) is preserved in authigenic pyrite throughout the section. A >90‰ range in $\delta^{34}S$(Py) (–45.5 to 46.4‰ VCDT) is strong evidence for vigorous microbial sulfate reduction under non-sulfate limited conditions, an indication that oxidative continental weathering of sulfides was sufficient before and during deposition to deliver a large quantity of sulfate to the ocean. Multiple generations of pyrite were observed, distiguished by their isotopic and minor element compositions. Sharp gradients in $\delta^{34}S$ (30‰ over <4 μm; defined by 3 μm spots) constrain the degree of sulfur diffusion during metamorphism and thus the time-temperature history of the unit. This is the first observation of such a large range in $\delta^{34}S$ together with significant S-MIF, and it reveals a chapter in the history of atmospheric oxygenation heretofore unknown from similarly age-constrained glacial deposits in North America [1] and South Africa [2]. The new data highlight the critical role of microbial sulfate reduction in the oxidative transition and are consistent with the proposal by Zahnle *et al*. [3] that increasing seawater sulfate led to the shutdown of the Archean methane greenhouse, curtailing the preservation of S-MIF. However, the suggestion that S-MIF disappears completely before continental glaciation [3] is not supported by our data or those from North America [1] and South Africa [2], and details of the Great Oxidation Event remain to be elucidated.

High-resolution untargeted metabolomics was applied to 14 distinct biofilm samples retrieved from the air-solution interface of acid mine drainage (AMD) solutions within the Richmond Mine (Iron Mountain, Redding, CA). Among the detected metabolites, we identified and characterized a group of *lyso* phosphatidylethanolamine lipids which were highly abundant. The unusual polar head group structure of these molecules is similar to lipids found in phylogenetically unrelated acidophilic chemoautolithotrophs and may be related to the affinity of these lipids for iron and calcium ions. Correlations of *lyso* phospholipid and strain-resolved protein abundance patterns suggest a link between the *lyso* phospholipids and the UBA-type substrain of *Leptospirillum* group II. By combining high-resolution molecular "omic" technologies, we demonstrat Focusing of upward fluid migration due to mineral grain size variation

e the ability to identify cryptic but organism-specific small molecules that may be of paramount importance to biogeochemical processes occurring in mining impacted environments.

A spatial perspective on Nd isotope records from the Western Indian Ocean: Evidence for a 'boundary exchange' control?

D.J. WILSON*, A.M. PIOTROWSKI AND A. GALY

Department of Earth Sciences, University of Cambridge, Cambridge, CB2 3EQ (*correspondence: david.wilson@esc.cam.ac.uk)

Reconstructing past water mass mixing using Nd isotopes relies upon the quasi-conservative behaviour of this tracer. In contrast, recent studies in the modern oceans have demonstrated that 'boundary exchange' [1] and/or reversible scavenging [2] may be important processes in the Nd cycle. 'Boundary exchange' in particular would complicate our interpretation of down core Nd isotope records, since any significant addition of Nd from sediments would make the proxy behave non-conservatively. However, modelling studies at a global scale [3, 4] have been unable to distinguish between advection and 'boundary exchange' as the dominant control on the Nd isotopic distribution of seawater.

In this study, using 10 sediment cores from the deep western Indian Ocean, we address the importance of 'boundary exchange' from the Madagascar and Mascarene Plateau margins. Deep water ε_{Nd} composition is reconstructed using foraminiferal coatings, which agree within error with bulk sediment leachates. Holocene core tops located along the south-to-north flow path of Circumpolar Deep Water (CDW) record different ε_{Nd} values. Cores nearest to the inflow record an ε_{Nd} of -8.6, which shifts to -11.3 near Madagascar and -7.1 near Mascarene. Comparison to detrital ε_{Nd} in the same cores suggests a control by local sedimentary inputs from Madagascar and the Mascarene Plateau. This allows a first attempt to quantify 'boundary exchange' along this margin and potentially to reconstruct past changes. Cores to the south of the Madagascan margin (i.e. upstream in deep water flow) appear to record the changing advected composition of CDW across Termination I, whereas marginal sites record offset ε_{Nd} values and reduced glacial-interglacial variability. This underlines the importance of deciphering 'boundary exchange' before inferring global ocean circulation changes from Nd isotope records. Additionally, it may provide insight into temporal changes in the inputs, and therefore budget, of REE's and other particle-reactive elements in the oceans.

Tracing changes in the East Asian Monsoon using the Mg isotope record in a loess-paleosol sequence from Luochuan, China

JOSH WIMPENNY[1], QING-ZHU YIN[1]*, DARREN TOLLSTRUP[1], LIE-WEN XIE[2] AND JIMIN SUN[2]

[1]Department of Geology, University of California, Davis, CA
[2]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

We present Mg isotope data from a loess-paleosol sequence from Luochuan in the central Chinese Loess Plateau. The alternating loess-paleosol layers result from changes in climate and weathering intensity; loess layers representing cooler, drier periods when the winter monsoon was strong, while paleosol layers form during warmer, wetter periods with a stronger summer monsoon. Bulk δ^{26}Mg analyses show that both loess and paleosol layers are enriched in the light isotopes of Mg relative to the bulk continental crust. On average, loess layers contain lighter δ^{26}Mg values than the paleosol, with average values of -0.57‰ ± 0.19 (2σ), and -0.37‰ ± 0.18 (2σ) respectively. These light δ^{26}Mg values are a direct result of high amounts of carbonate in the sediment layers (up to ~15%) and the fact that carbonate is enriched in light Mg relative to silicates. The higher chemical weathering intensity subjected to the paleosol layers means more carbonate has been leached away, hence the remaining sediment is isotopically heavier than the loess layers where more carbonate remains. The high amplitude changes in δ^{26}Mg related to alternating loess-paleosol layers at Luochuan closely match changes in other weathering tracers including magnetic susceptibility, grain size and Na/Ca ratios. This suggests that all of these proxies are controlled by the same process, i.e. changing climate related to changes in northern hemisphere circulation. In addition, our δ^{26}Mg analyses also record a longer term change in chemical weathering, manifested as a shift to more positive δ^{26}Mg values ~500 to 900Ka. This coincides with the approximate timing of a strengthening in the summer monsoon and a reduction in the seasonality of precipitation. Thus, Mg isotopes record weathering changes on two different timescales in Chinese loess, that have implications for our understanding of how the East Asian Monsoon may have behaved over the last 2.6Ma. We suggest that the sensitivity of Mg isotopes to the presence of carbonate, and to the formation of secondary silicates makes the Mg system a powerful tool that can be used to enhance our understanding of past weathering processes.

Carbon isotopes in DIC trace benthic and pelagic processes in tidal areas of the North Sea

VERA WINDE[1], PETER ESCHER[1], NICOLE KOWALSKI[1], OLAF DELLWIG[1], BERND SCHNEIDER[1], MATTHIAS SCHULTZ[1], PHILLIP BÖNING[2], JUSTUS E.E. VAN BEUSEKOM[3], GERD LIEBEZEIT[2] AND MICHAEL E. BÖTTCHER[1]*

[1]Leibniz IOW, D-18119 Warnemünde, Germany. (*michael.boettcher@io-warnemuende.de)
[2]ICBM, CvO University of Oldenburg, D-26382 Wilhelmshaven/ D-26111 Oldenburg, Germany
[3]AWI Wadden Sea Station Sylt, D-25992 List, Germany

We investigate the spatial gradients and temporal dynamics of the dissolved inorganic carbonate system in tidal areas of the North Sea. We aim for an understanding of the impact of benthic processes on the production of alkalinity and its subsequent export to the open North Sea, as well as the role of benthic processes, e.g. the interaction (destruction, formation) of surface pore waters with sedimentary calcium carbonate. These processes in turn have the potential to modify the pore water and the bottom water composition that exchanges with the shallow North Sea. The benthic and pelagic processes may change in the future as the North Sea is facing increasing atmospheric CO_2 pressures, and decreasing pH and changes in nutrient inventories are expected.

Water column and pore water samples were taken at different seasons, during tidal cycles and on transects through different tidal basins of the German Wadden Sea (Jade Bay, Sylt, Spiekeroog) for measurements of alkalinity, DIC, pH, salinity, temperature, δ^{13}C(DIC), besides major and trace elements. The carbonate system demonstrates significant tidal, and spatial, as well as seasonal variations in the water column. Such variabilities reflect mixing processes with freshwater via coastal tributaries and the influence of benthic and pelagic (e.g. primary production) processes, changing with season. Results from the East-Frisian Wadden Sea are compared to measurements in the North-Frisian Wadden Sea system. Locally, pore waters in sandy sediment, influenced by upward methane fluxes and AOM, reveal steep physico-chemical gradients. Low-tide drainage of anoxic pore waters leads to the liberation of ^{12}C-enriched DIC, TA, nutrients and (H_2S, CH_4).

Field data will be integrated in a modelling environment of the North Sea carbonate system. Research is supported by BMBF within the BIOACID project, IOW, AWI, and ICBM.

100-year record of $^{236}U/^{238}U$ in coral as a step towards establishing ^{236}U as oceanic tracer

S. WINKLER[1]*, P. STEIER[1], J. CARILLI[2]

[1]Faculty of Physics, University of Vienna, 1090 Wien Austria (* correspondence: stephan.winkler@univie.ac.at)
[2]Institute for Environmental Research, Australian Nuclear Science and Technology Organisation

Since uranium is known to behave conservatively in ocean waters, ^{236}U has great potential in application as oceanic tracer. Approximately 600kg of ^{236}U ($t_{1/2}$=23.4Ma) were introduced into the oceans by atmospheric nuclear weapon testing [1]. A resulting initial average $^{236}U/^{238}U$ ratio of $5{\cdot}10^{-9}$ is expected for the oceanic mixed layer. This ratio is significantly higher than the expected natural pre-nuclear background, which is expected to be at 10^{-14} levels [2].

In order to place first experimental constraints the input term from global stratospheric fall-out we established a year-by-year record of $^{236}U/^{238}U$ for a core from the Caribbean Sea. The selected core was taken in 2006. It has shown well-defined annual banding structure under X-ray and stretches back more than 100 years, therefore covering the interesting period of global stratospheric fall-out.

We used the exceptional sensitivity and ultra-low background for ^{236}U of the Vienna Environmental Research Accelerator's Accelerator Mass Spectrometry system for this measurement and find a $^{236}U/^{238}U$ signature of $(1.84{\pm}0.08){\cdot}10^{-9}$ for the fall-out peak. Furthermore we set a first experimental upper limit of $4{\cdot}10^{-12}$ on the pre-anthropogenic $^{236}U/^{238}U$-ratio in ocean surface waters.

Aeolian iron flux in the South-Western Ross Sea, Antarctica

V.H.L. WINTON[1,2]*, M.-A. MILLET[3], N.A.N. BERTLER[1,2] G.B. DUNBAR[1], B. DELMONTE[4] AND P. ANDERSSON[5]

[5]Laboratory for Isotope Geology, Swedish Museum of Natural History, PO Box 50 007, 104 05 Stockholm

Each summer the waters in the south-western Ross Sea experience vast phytoplankton blooms. This phenomenon is thought to be stimulated by the addition of bio-available Fe in an otherwise Fe-limited environment. Amongst all the potential Fe sources, input from aeolian dust, which has accumulated on sea ice and is released to the ocean in summer as the sea ice melts, is heavily underestimated. The south-western Ross Sea provides an excellent example to study this biogeochemical process.

The amount of bio-available Fe supplied to the ocean depends on a number of factors including, but not limited to; the dust flux into the ocean, particle size distribution and its Fe content. However, none of these parameters are well constrained in the south-western Ross Sea region and, as a result, the significance of this Fe source in the biogeochemical cycle of plankton growth remains to be quantified.

Dust is shown to be sourced locally based on: a) elevated regional dust flux for the region which is higher by orders of magnitude than predicted in global dust distribution models [1] and in the Antarctic Plateau [e.g. 2]; b) Sr and Nd isotopic signature matching local potential source rocks. The regional dust flux for particles <10 μm in size (the potentially bio-available fraction) is ~0.08 g/m^2/yr. Fe-solubility measurements are currently being completed on the 0.4-10 μm size fraction following the leaching protocol of Aguilar-Islas *et al*. [3]. This will allow us to quantify the amount and estimate its importance for aeolian Fe-fertilisation for bio-productivity in this region.

Quantification of H in olivine: Direct calibration of FTIR and SIMS by ERDA

A.C. WITHERS[1]*, M.M. HIRSCHMANN[1], H. BUREAU[2] AND C. RAEPSAET[3]

[1]Department of Earth Sciences, University of Minnesota, Minneapolis, MN 55455, USA (*correspondence: withers@umn.edu)

[2]IMPMC, UMR CNRS 7590, Campus Jussieu, 4 place Jussieu, 75252 Paris, France

[3]Laboratoire Pierre Süe, CEA-CNRS, UMR9956, CEA Saclay, 91191 Gif sur Yvette, France

Experimental studies show that varying the H content of olivine has a marked effect on rheology and electrical conductivity, such that the H content of olivine can be said to control tectonic processes and to affect the observable properties of the mantle [1,2]. In order to apply experimental results to the Earth, we need to be able to measure accurately the H content of olivines in experiments. Calibrations for the commonly used infrared (FTIR) and ion probe (SIMS) techniques rely on just a handful of truly independent measurements of natural olivines by ^{15}N nuclear reaction analysis [3]. Moreover, it has been suggested, on the basis of comparative SIMS measurements, that the infrared absorption coefficient (k) for OH stretching bands in high pressure olivines could be greater by as much as a factor of 3 than that derived from natural samples [4], implying that H contents have been underestimated in many experimental studies.

We used elastic recoil detection analysis (ERDA) to determine k for OH bands in Fo_{90} olivines with 240-2000 ppm H_2O, synthesised at 3-10 GPa in multianvil experiments that were optimised for growth of large, homogeneous crystals. On the basis of 20 ERDA and >200 FTIR analyses of olivines from 7 experiments, the H content (in ppm H_2O) is given by 0.120±0.008×total integral absorption, corresponding to an integral extinction coefficient of 45,000 L/(mol·cm^2), i.e. k is ~35% *smaller* than the value previously derived for natural olivines. This implies that the H contents of experimental olivines have in fact been generally *overestimated*.

The samples that were analysed using ERDA are used as SIMS standards, thereby providing a direct calibration that avoids the baseline uncertainties that are inherent to FTIR. Direct calibration of SIMS using high pressure experimental samples allows for improved high accuracy analysis at high spatial resolution.

W-Os isotope systematics in IVB iron meteorites

N. WITTIG AND M. HUMAYUN

National High Magnetic Field Laboratory & Dept. of Earth, Ocean, & Atmospheric Science, Florida State University, Tallahassee, FL 32310, USA. (wittig@magnet.fsu.edu)

^{182}Hf-^{182}W dating implies contemporaneous condensation of the earliest solar system solids (CAIs) and magmatic differentiation of planetesimals (i.e., iron meteorite groups) [1]. IVB iron meteorites exhibit $\varepsilon^{182}W$ (-3.56±0.1) lower than CAIs ($\varepsilon^{182}W$ -3.28±0.2). The initial W isotope signature of CAIs may have been reset by metamorphism of chondrites [2] while IVB irons need to be corrected for thermal neutron capture due to galactic cosmic ray (GCR) exposure. Although GCR corrections have become more sophisticated, determining the true ^{182}W deficit remains problematic [3].

Using Os isotopes as *in situ* neutron dosimeters [4], we re-evaluated the degree of GCR modification of $\varepsilon^{182}W$. Our IVB $\varepsilon^{182}W$ data is derived from a more complete sampling of the IVB group (including Iquique, Weaver, Kokomo), but using smaller samples than [4-5]. MC-ICP-MS measurements (NEPTUNE™) of W isotopes were performed on 10-20ng aliquots using an Apex™ introduction system and Jet Ni sampler and X skimmer cones. The reproducibility of $\varepsilon^{182}W$ for NIST SRM 3163 is ±0.14ε (2σ, n=142) and ±0.32ε (2σ, n=19, 10-25ng) if a smaller, random standard population is considered to capture the analytical uncertainty expected from our IVB set. Since Tlacotepec has systematically lower $\varepsilon^{182}W$, the average $\varepsilon^{182}W$ (-3.31±0.22, 2σ) of IVBs is calculated for n=9 samples, excluding Tlacotepec. Our IVB average $\varepsilon^{182}W$ is more radiogenic than previously reported [1-3,5-6] but with larger analytical uncertainty. Importantly, our $\varepsilon^{182}W$ IVB average is identical to the most recent CAI value [1].

By using Tlacotepec with its large GCR-induced ^{182}W-^{190}Os shift as an anchor point, the Os-W isotope data of this group can be projected towards $\varepsilon^{190}Os$ of 0 [4] to yield a pre-irradiation $\varepsilon^{182}W$ of -2.95. This $\varepsilon^{182}W$ allows for ~4 Myr of accretion and planetesimal differentiation for IVBs and reconciles current models of solar system formation with the W isotope record. A follow-up higher-precision W-Os isotope study from the same digestions is underway.

Analysis of As and Sb in samples from Turtle Pits hydrothermal field using new standard material

C.C. WOHLGEMUTH-UEBERWASSER[1]*, S. SCHUTH[2], J. BERND[3] AND F. VILJOEN[1]

[1]Paleoproterozoic Mineralization Research Group (PPM), Department of Geology, University of Johannesburg, PO Box 524, Auckland Park 2006, South Africa (*correspondence: cora@geoinventio.de)

[2]Institut für Mineralogie, Leibniz Universität Hannover, Callinstr. 3, 30167 Hannover, Germany (s.schuth@mineralogie.uni-hannover.de)

[3]Institut für Mineralogie, Universität Münster, Corrensstr. 24, 48149 Münster, Germany (jberndt@uni-muenster.de)

New sulfide standard material was produced for the analysis of As, Sb, Se and Te in sulfides with LA-ICP-MS. The sulfide was synthesized from metal powders and elemental S. Trace metal concentrations are around 30 ppm and were added as chloride solutions. Reaction to sulfide powders proceeded in evacuated silica glass tubes at 973 K, then sintered in a piston–cylinder press for 4 hours at 2 GPa and 1373 K. About one third of the sulfide pellet was analysed with solution quadrupole ICP-MS for bulk trace metal concentrations. A part of the remainder was polished and analysed with an ArF excimer laser coupled to an Element 2 ICP-MS at the Universität Münster. Homogeneity given as 2-sigma relative standard deviation of 20 randomly distributed spot analyses is <7.6% for all trace elements.

The newly obtained standard material was used for the quantitative analysis of a pyrite sample from the Turtle Pits hydrothermal field by LA-ICP-MS. This allows for the spatial resolution of trace element distribution within the sample. Averages of 18 single spot analyses result in As concentrations of 140 – 2000 ppm and Sb contents of 1 – 60 ppm, with no obvious correlation of these two elements. In contrast, within single laser spectra from pyrite a strong correlation between As and Sb has been observed. As arsenic is assumed to be substituted non-stoichiometrically into the pyrite lattice, it seems obvious that in the sample under investigation, Sb is also substituted into the pyrite lattice and that it does not merely occur within inclusions as suggested in previous studies.

Analyses of coexisting sphalerite reveal higher Sb contents of up to 160 ppm, relative to pyrite. The ablation spectra are marked by abrupt elevations in the intensity of Sb which is probably caused by Sb-rich inclusion.

Primary phases in peridotites of the Ślęża ophiolite (SW Poland)

P. WOJTULEK[1], J. PUZIEWICZ[1]* AND T. NTAFLOS[2]

[1]Univ. Wrocław, Poland (*correspondence jacek.puziewicz@ing.uni.wroc.pl

[2]Univ. Wien, Austria (theodoros.ntaflos@univie.ac.at)

The peridotitic members of the Variscan Ślęża Ophiolite (SW Poland) are part of the complete ophiolitic sequence. WR trace element and REE patterns of gabbroic/basaltic ophiolite member show MORB affinity [1].

The peridotites are serpentinized but aggregates of olivine ± clinopyroxene ± spinel are preserved in the central part of the outcrop (Radunia Hill). Olivine ($Fo_{91.8 - 92.6}$) contains 0.2 – 0.4 wt % NiO. Clinopyroxene (mg# 0.92 – 0.94, Cr_2O_3 0.9 – 1.2, Al_2O_3 2.7 – 3.4, Na_2O <0.03 wt. %) is in places altered into clinopyroxene II (mg# 0.95 – 0. 97), chromian magnetite (Cr usually between 0.10 and 0.80 atoms pfu, C=3). Isolated grains of olivine and chromian magnetite occurring in serpentine groundmass are less magnesian ($Fo_{89.3 - 90.5}$), and rich in Cr, respectively. The whole-rock REE contents are below detection limits of ICP-MS method.

The mineral composition of the aggregates suggests dunitic composition of the protolith. Highly magnesian content of olivine is probably the record of depletion typical for MORB mantle. Clinopyroxene possibly is the result of late melt infiltration. Serpentinization obviously decreases forsterite content in olivine, thus the chemical composition of phases occurring in relics may be not representative for the primary mineral composition.

A fractal aggregate model of Early Earth organic hazes: UV shielding with minimal antigreenhouse cooling

E.T. WOLF[1,2]*, F. TIAN[1] AND O.B. TOON[1,2]

[1]Laboratory for Atmospheric and Space Physics, University of Colorado, UCB 392, Boulder, CO 80309 (*correspondence: eric.wolf@colorado.edu)

[2]Department of Atmospheric and Oceanic Sciences, University of Colorado

The Archean Earth (3.8 to 2.5 billion years ago) was probably enshrouded by a Titan-like photochemical haze composed of fractal aggregate hydrocarbon aerosols. In this study a three-dimensional fractal aggregate model of the early Earth photochemical haze is explored and compared with the standard liquid drop haze model used in earlier studies [1]. Fractal aggregate microphysical processes are modeled using the method introduced by Cabane *et al*. [2]. The optical properties of the aerosols are determined using a mean-field approximation of multiple scattering by fractal aggregates composed of identical spheres [3]. Early Earth fractal hazes are found to be optically thick in the ultraviolet wavelengths while remaining relatively transparent in the mid-visible wavelengths. At an annual production rate of 10^{14} grams per year and an average monomer radius of 50 nanometers, the haze has global mean effective optical depths of τ_{uv} = 11.2 and τ_{vis} = 0.5. Such a haze would provide a strong shield against UV light while causing only minimal antigreenhouse cooling. Protected by a strong UV shield, photolytically unstable greenhouse gases such as CH_4 and NH_3 may have been able to build up to high concentrations helping warm the young Earth despite the faint young Sun. Our findings reopen the hypothesis of Sagan and Mullen [4] that the young Earth may have been home to a reducing atmosphere.

Magma physical properties affect isotope variations in volcanic rocks: The example of high-T rhyolites

J.A. WOLFF*[1], B.S. ELLIS[1] AND F.C. RAMOS[2]

[1]School of Earth and Environmental Sciences, Washington State University, Pullman, WA 99164, USA (*correspondence: jawolff@mail.wsu.edu)

[2]Dept. of Geological Sciences, New Mexico State University, Las Cruces, NM 88003, USA

Volcanic rocks often exhibit internal heterogeneity in radiogenic isotopes. Isotopic disequilibrium between co-existing phenocrysts, phenocrysts and matrix, and isotopic zoning within single crystals ("crystal isotope stratigraphy") has been demonstrated in basalts, andesites, dacites, rhyolites and alkaline magmas. High-temperature "Snake River type" rhyolites appear to be an exception. Despite the occurrence of Snake River Plain rhyolites in a region of isotopically highly variable crust and mantle, and significant differences from rhyolite unit to rhyolite unit, internally they are near-homogeneous in $^{87}Sr/^{86}Sr$. Little or no zoning is found within feldspar phenocrysts, and feldpsars within a single unit are tightly grouped. Some units show minor contrasts between phenocrysts and matrix. In contrast, associated basalts and lower-T rhyolites in the same area represent different types of magmas that passed through the same crustal column, and have the relatively large internal $^{87}Sr/^{86}Sr$ variability exhibited by common volcanic rocks.

High temperature rhyolitic magmas possess a unique combination of temperature and melt viscosity. Although they are typically 200°C hotter than common rhyolites, the effect on viscosity is offset by lower water contents (~2 wt%), hence their melt viscosities are in the same range as common, water-rich, cool rhyolites (10^5 – 10^6 Pa s). However, the high magmatic temperatures dictate that cation diffusion rates are 2 – 3 orders of magnitude greater than in common rhyolites. We hypothesize that this combination of characteristics promotes Sr isotopic homogeneity: viscosities that are too high to permit crystal transfer and magma mixing on timescales shorter than those required for diffusive homogenization of Sr between phenocrysts and matrix (100 – 1000 years). This is untrue for the vast majority of magmas, in which either crystal transfer is rapid (<< 100 years) due to low melt viscosities (basalts and intermediate magmas), or else Sr diffusion rates are so slow that the equilibration time is longer than the lifetime of the system (high-silica minimum melt rhyolites: 10^5 – 10^6 years).

High–temperature hydrothermal activity in the lower oceanic crust: Petrological and geochemical evidence for fluid pathways in the Oman Ophiolite

P.E. WOLFF[1]*, D. GARBE–SCHÖNBERG[2], J. KOEPKE[1] AND K. STREUFF[2]

[1]Institute for Mineralogy, Leibniz University of Hannover, Callinstr. 3, 30167 Hannover, Germany (*correspondance: e.wolff@mineralogie.uni–hannover.de)
[2]Institute of Geosciences, Christian–Albrecht–University of Kiel, Ludewig–Meyn–Str. 10, 24118 Kiel, Germany

The Oman ophiolite is regarded as best example for fast–spreading oceanic crust on land. Petrological findings indicate that multiple intrusions of gabbroic sills play a significant role for the formation of the deep plutonic crust at fast–spreading oceanic ridges [1], a model which requires a substantial cooling of the deep oceanic crust, probably by seawater–derived high–temperature hydrothermal circulation [e.g.,2]. In this study we present petrological and geochemical data for veins and zones formed by hydrothermal alteration within the lower layered gabbro sequence of the Samail ophiolite in Oman (Wariyah, Wadi Tayin Massiv).

Veins and alteration zones of mm to m scale within an unaltered olivine gabbro record high (>800°C), medium (~600°C), and low temperature (~350–500°C) hydrous alteration indicating possible fluid pathways for hydrothermal circulation. Petrological results show mineral assemblages typical for predicted interaction between olivine gabbro and seawater–derived fluid [3]. High temperature veins display mineral assemblage of olivine + plagioclase + pyroxenes + pargasitic amphibole ± oxides. Decreasing temperature result in a change in alteration paragenesis, where hydrous minerals become more abundant. The typical medium temperature mineral assemblage is plagioclase + clinopyroxene + chlorite + magnesiohornblende ± oxides followed by low temperature veins mainly consitsting of epidote + prehnite + actinolite/tremolite.

Geochemical micro–analyses of sub–mm veinlets and adjacent host rocks show systematic enrichment of fluid mobile elements (e.g., LREE, Eu, Mo, W) in these veins and indicate possible element mobility during hydrothermal activity. These preliminary results suggest that hydrothermal circulation at very high temperatures exists.

Dissolution of mafic and ultramafic rocks in the presence of CO_2 is of great current interest due to the potential for carbon storage in basaltic and/or peridotitic rocks. This storage method involves converting gaseous or supercritical CO_2 into carbonate minerals for its safe, long-term storage. In-situ carbonatization of CO_2 faces a major challenge in that huge quantities of water are required to dissolve CO_2 to promote reactions. This challenge might be overcome by using seawater for the dissolution of CO_2 during its injection.

To assess the possible use of seawater during carbon storage efforts, steady-state silica release rates (r_{Si}) from basaltic glass and crystalline basalt of same chemical composition and dunitic peridotite have been determined in far-from-equilibrium dissolution experiments at 25°C and pH 3.6 in a) artificial seawater solutions under 4 bar pCO_2, b) varying ionic strength solutions, including acidified natural seawater, c) acidified natural seawater of varying fluoride concentrations, and d) acidified natural seawater of varying dissolved organic carbon concentrations. Glassy and crystalline basalts exhibit similar r_{Si} in solutions of varying ionic strength and cation concentrations. Rates of all solids increase by 0.3-0.5 log units in the presence of 4 bar pCO_2 compared to atmospheric CO_2 pressure. At atmospheric CO_2 pressure, basaltic glass r_{Si} were most increased by the addition of fluoride to solution whereas crystalline basalt rates were most enhanced by the addition of organic ligands. In contrast, peridotite rates are unaffected by either the addition of fluoride or organic acids. Most significantly, Si release rates from the basalts are found to be not more than 0.6 log units slower than corresponding peridotite rates at all conditions considered in this study. This rate difference becomes negligible in seawater suggesting that CO_2-charged seawater injected into basalt might be nearly as efficient for mineral sequestration as injection into peridotite.

Water structure at the structurally heterogeneous calcite surface

M. WOLTHERS[1,2,*], D. DI TOMMASO[2], Z. DU[2] AND N.H. DE LEEUW[2]

[1]Department of Earth Sciences, Utrecht University, P.O. Box 80021, 3508 TA Utrecht, The Netherlands. (*correspondence: wolthers@geo.uu.nl)

[2]Department of Chemistry, University College London, 20 Gordon Street, London WC1 H0AJ, United Kingdom.

The calcite surface has been subject of numerous simulation studies. These studies have generally focused on simulations of perfectly flat calcite surfaces, and in particular the dominant (10-14) face. In both natural environments and in experiments, the calcite surface is of course not atomically flat, and surface roughness is expected to have an effect on the reactivity of the surface sites. Indeed, it has been shown that trace elements differentially incorporate into the calcite surface depending on surface structure [1], while this differential reactivity is not at all captured in the current macroscopic surface chemical models [2,3]. The aim of this work is to obtain information on the interactions of water molecules with the different surface sites present in etch pits and on growth terraces at the calcite (10-14) surface. Results show that the local environment around the structurally distinct sites differs significantly, with the formation of more calcium–water bonds and H-bridges at less-coordinated sites, while the bond length of the metal-hydroxyl site does not vary with position at the surface. Temperature changes over the range of 300 to 340 K does not affect the local environment of the surface groups.

The information obtained in this study is crucial for the improvement of the existing macroscopic surface model for the reactivity of calcite [2]. This mineral surface structural model for calcite was developed using the Charge Distribution MUltiSite Ion Complexation (CD–MUSIC) modelling approach [4] to describe the chemical structure of carbonate mineral-aqueous solution interfaces. The high sensitivity of the model toward parameters describing hydrogen bridging and bond lengths at the mineral-water interface, currently limits the predictive application of the calcite CD–MUSIC model.

Mass-independent Cd isotope fractionation during evaporation

FRANK WOMBACHER

Universität zu Köln, Institut für Geologie und Mineralogie, 50674 Köln, Germany (fwombach@uni-koeln.de)

Modern mass spectrometry is capable to reveal mass-independent isotope fractionations (MIF) for many heavy elements [1].

Here, we investigate mass-independent Cd isotope fractionations that result from the evaporation of liquid Cd into vacuum. Three residues from evaporation display large mass-dependent Cd isotope fractionations with $1000\ln\alpha$ ranging from -23.2 to -48.3 ‰ for $^{110}Cd/^{114}Cd$ relative to the starting material [2]. These samples were repeatedly analyzed at high precision using a Neptune MC-ICP-MS, with ion beam intensities typically larger than 20V for ^{114}Cd and analysis times of about 30 minutes. Deficits ranging from 8 to 28 ppm were well resolved for $^{111,113,116}Cd/^{114}Cd$. The accurate quantification of the MIF requires that the mass-dependence of the evaporation induced isotope fractionation is accurately corrected. This was facilitated using the generalized power law and normalization to $^{110}Cd/^{114}Cd$ of the starting material. Note, that the mass-dependence for evaporation was found to be intermediate between that expected to describe kinetic and equilibrium fractionation [2, 3].

MIF for ^{111}Cd, ^{113}Cd and ^{116}Cd scales with deviations from a trend between nuclide mass and mean-squared nuclear charge radii defined by the other five Cd isotopes, thus suggesting that the MIF is due to nuclear volume effects. The preferential evaporation of ^{111}Cd, ^{113}Cd and ^{116}Cd may result from their more tightly bond 5s electrons that are thus not as easily delocalized and hence form weaker metallic bonds in the liquid. Our results are in accord with previous work [4] on the evaporation of Hg, another group 12 element.

Episodic estuarine hypoxic events: Integrating the biogeochemistry, hydrology and climate on a sub-tropical floodplain, Eastern Australia

V.N.L. WONG[1]*, S.G. JOHNSTON[1], S. WALSH[2], S. MORRIS[2], E.D. BURTON[1], R.T. BUSH[1], L.A. SULLIVAN[1], P.G. SLAVICH[2]

[2] NSW Department of Trade and Investment, Regional Infrastructure and Services, Wollongbar, NSW 2477, Australia

Globally, the frequency, magnitude and spatial extent of anthropogenically-induced coastal hypoxic events is increasing [1]. Episodic hypoxia in riverine and estuarine systems can follow high-flow events such as floods or the release of environmental allocations. These events can result in complete deoxygenation of the water column and significant effects on aquatic organisms and ecosystem function. This study integrates the biogeochemical, hydrological and climatic processes from four flood events on two sub-tropical floodplains in eastern Australia [2,3].

We found that a key driver of hypoxia was the extensive modification of floodplain surface hydrology through the construction of drainage networks. Backswamp basins were originally natural storage basins for floodwaters, supporting large areas of wetland vegetation. Drier conditions, due to drainage, has shifted vegetation assemblages from wetland-dominant species to flood-intolerant species. When inundated, senescent vegetation provides a source of labile carbon which rapidly consumes oxygen from the overlying waters, producing anoxic water with high oxygen demand. Carbon metabolism during these events is strongly coupled with microbially-mediated reduction of accumulated Fe and Mn oxides commonly found on coastal floodplains. These redox sensitive species provide a geochemical signature to identify the sources and causes of estuarine hypoxic events. Whilst anoxic floodwaters were previously retained in backswamp wetland basins during the flood recession phase, these waters are now exported rapidly to the main channel.

Post-flood hypoxic events frequently occur in summer, especially when long, dry periods are followed by rapid, intensive rainfall. These events will most likely increase in frequency and magnitude as a result of climate change due to more frequent and hotter summer floods.

Stable isotopes ratio in nitrate: A tool to unravel the biogeochemistry of nitrate in an estuarine environment

W.W. WONG[1]*, P.M. COOK[1], M.R. GRACE[1] AND I. CARTWRIGHT[2]

[1]Water Studies Centre, Monash University, Clayton, Melbourne 3800, Australia (*correspondence: weiwen.wong@monash.edu)

[2]School of Geosciences, Monash University, Clayton, Melbourne 3800, Australia

Port Philip Bay is a large coastal embayment in temperate south eastern Australia, with a population in excess of 4 million in the local catchment. Like other coastal waters, the bay is typically nitrogen limited and hence there is much interest in identifying sources and sinks of this nutrient within catchments and estuaries surrounding the bay.

This study was carried out in the Werribee estuary, one of the major estuarine systems within Port Philip Bay. Werribee estuary is eutrophic with nitrate concentrations exceeding 1mgN/L during base flow conditions. There are a number of potential sources of nitrogen to the estuary including treated sewage effluent, market gardens, groundwater and the Werribee River. We aimed to distinguish the sources and transformation processes of nitrate in this estuarine environment using a multidisciplinary approach, focussing on stable isotopes and radon measurements.

Monthly sampling of surface water and groundwater was carried out over a 12 month period. Our preliminary results showed that (i) there was a positive correlation between $\delta^{15}N\text{-}NO_3$ and $\delta^{18}O\text{-}NO_3$ with a 2:1 $\delta^{15}N{:}\delta^{18}O$ gradient in both surface and groundwaters suggesting that denitrification was occurring and led to considerable transformation of the isotope signatures from their sources values within groundwater and surface waters. (ii) There was a strong correlation between nitrate and radon concentrations (R^2=0.79) at a site in the upper estuary consistent with nitrate derived from groundwater. (iii) The $\delta^{15}N$ and $\delta^{18}O$ of nitrate were +18±4‰ and +11±4‰ respectively when nitrate concentrations in surface waters exceeded 0.2mgN/L, which was consistent with the signatures observed in ground water with high nitrate concentrations (>10mgN/L) beneath the market gardens.

Influence of cyanide on granite weathering

N. WONGFUN[1]*, M. PLÖTZE[2], H. BRANDL[3] AND G. FURRER[1]

[1]Inst. of Biogeochemistry and Pollutant Dynamics, ETH Zürich, Zürich 8092, Switzerland (*correspondence: nuttakan.wongfun@env.ethz.ch)
[2]Inst. for Geotechnical Engineering, ETH Zürich, Zürich 8093, Switzerland
[3]Inst. of Evolutionary Biology and Environmental Studies, University of Zürich, Zürich 8057, Switzerland

Availability of nutrients in the glacier forefield is usually very low. Mobilization of nutrients from rock through weathering processes plays an important role to overcome this limitation [1]. Microorganisms and plants modify their local environment by various exudates including cyanide [2], which is a crucial agent during the initial period of colonization and soil formation.

To elucidate the effect of cyanide on dissolution of granite minerals, the samples were collected from the Damma glacier area (Central Alps, Switzerland) at approximately 2,500 m a.s.l. After crushing and sieving, materials with size fraction <63 μm (surface area=1.55 m^2/g) were selected for abiotic dissolution experiment. Batch experiments were carried out with a solid/liquid ratio of 10 g/L in the absence or presence of cyanide under oxic conditions at 22±1 °C, I=0.01, pH range of 5-7 for 24 hours.

Among the elements released from granite, enhanced Fe concentrations were observed in presence of cyanide. This applies particularly with increasing pH, suggesting that deprotonated cyanide becomes more important for the formation of Fe compleses. Iron cyanide complexes presence at high concentrations in particular at pH above 6 [3] and allow high concentrations of dissolved Fe. The dissolved Al concentrations were considerably lower than those of Fe due to precipitation of secondary phases (e.g. gibbsite and kaolinite).

Accretion and initial differentiation of the Earth

B.J. WOOD

Department of Earth Sciences, University of Oxford, South Parks Road, Oxford OX1 3AN, U.K. (berniew@earth.ox.ac.uk)

A large number of moon- to Mars-sized planetary embryos with different metal/silicate/volatile ratios are believed to have formed around the young sun in ~1 M.yr. As Earth accreted from such embryos through a succession of impacts, the metallic core segregated and there was some loss of the most volatile elements. The chemical and isotopic composition of silicate Earth provides most evidence for these processes. Depletions of silicate Earth, relative to primitive meteorites, in elements known to have entered the core (e.g Mo, W, Ni, Co) place constraints on the physical conditions of accretion. Short and long-lived chronometers (^{182}Hf-^{182}W, ^{238,235}U-^{206,207}Pb, ^{205}Pb-^{205}Tl, ^{107}Pd-^{107}Ag) enable estimates of the timing of core formation, the influence of the moon-forming impact and the history of volatile accretion to the Earth. If we begin with the assumptions that core segregation was continuous during accretion and that metal and silicate fully equilibrated, simultaneous consideration of the depletion factors of a large number of elements in silicate Earth lead to the following general conclusions: (1) The average pressure of core segregation on Earth was high >30 GPa, implying depths of >800 km. (2) Earth began as a small, strongly reduced body and became more oxidised as it grew. (3) Si (~5%) and S (~2%) are major components of the "light" element in Earth's core. Relaxing the assumption of full equilibration (ie allowing for the addition of metal to the core without reaction with the mantle) and allowing for the influence of S and Si on partitioning does not significantly alter these conclusions.

The ^{182}Hf-^{182}W age of Earth's core [1], may be used in combination with other short- and long-lived radioactive systems to show (1) Moderately volatile elements were predominantly added to Earth towards the end of accretion [2] and (2) The fractionation of U from Pb at ~100 M.yr after the origin of the solar system is consistent with Pb extraction in a small amount of core material added during the moon-forming giant impact.

Core formation and volatile element addition to the Earth

B.J. WOOD[1] AND M. REHKÄMPER[2]

[1]Dept of Earth Sciences, University of Oxford, South Parks Road, Oxford, OX1 3AN; U.K.
[2]Dept of Earth Science & Engineering, Imperial College, London SW7 3AZ; U.K.

It is well known that the Pb isotopic composition of the silicate Earth indicates a fractionation of U from Pb at ~100 M.yr after the origin of the solar system. This fractionation has recently been ascribed to entry of Pb into the core (e.g.[1]) on an Earth with low U/Pb, and to late addition of Pb and other moderately volatile elements to an Earth which initially had very high U/Pb [2]. Use of extinct radioactive systems, combined with an understanding of volatile element partitioning into the core can elucidate the relative timings of core formation and volatile addition [3]. We have determined the metal-silicate partitioning of moderately volatile elements Ag, Pb, Tl, Mn and Cr in order to use the extinct systems ^{107}Pd-^{107}Ag, ^{205}Pb-^{205}Tl and ^{53}Mn-^{53}Cr in conjunction with ^{182}Hf-^{182}W and ^{238,235}U-^{206,207}Pb to investigate core formation and volatile element addition to the growing Earth.

Tl, which is chalcophile but only weakly siderophile at low pressure is found to become as siderophile as Pb at pressures >20 GPa. This means that, given the high pressures of core formation indicated by refractory siderophile element (Ni, Co, Mo etc) abundances in the mantle, the ^{205}Pb-^{205}Tl system is consistent with core formation being the principal reason for the low Pb and Tl abundances (relative to lithophile elements of similar volatility) in silicate Earth. Ag is moderately siderophile at all pressures while Mn and Cr are similar to one another in having weak siderophile character. When considered together the 3 short-lived systems are consistent with addition of moderately volatile elements during the principal period of core formation with timescale constrained by the ^{182}Hf-^{182}W system. ^{53}Mn-^{53}Cr and ^{107}Pd-^{107}Ag indicate that accreted materials became more volatile rich as accretion progressed with major addition of volatiles during the last 30-60% of accretion.

[3]Geol. Survey of Namibia, Windhoek
[4]School of Civil Eng. and Geosciences, Newcastle Univ, NE1 7RU, UK
[5]Dept. of Geosciences, University of Bremen, 28334 Bremen, Germany.

Animals require oxygen, and so the first appearance of metazoans during the Ediacaran (580-543 Ma) has been linked to the widespread development of oxygenated oceanic conditions [1, 2, 3]. However, the nature of ocean redox chemistry through this period is complex, with deeper water anoxia persisting in certain areas [4]. In addition, few studies have directly documented the nature of ocean chemistry at locations that coincide with palaeontological evidence for major biological innovation [3]. Thus, the precise environmental context for early animal evolution, particularly the rise of biomineralisation, remains unclear. Here, we present a high resolution reconstruction of carbon isotope and ocean redox dynamics, as recorded in sedimentary rocks deposited from ~553-549 million years ago in the Zaris Sub-Basin of the Nama Group, Namibia. The succession spans deep distal to shallow proximal carbonate settings, and coincides with the first appearance of skeletal metazoans. Iron-sulphur systematics demonstrate that oxic conditions developed only intermittently in the shallowest waters where the first skeletal metazoans are preserved, while deeper waters remained consistently anoxic and iron-rich (ferruginous). Thus, late Ediacaran surface-water oxygenation was unstable, inferring that the first skeletal metazoans developed in short-lived habitats. The opportunistic ecologies and characteristically simple biomineralisation styles of Ediacaran taxa are likely to be a direct consequence of these dynamic redox conditions.

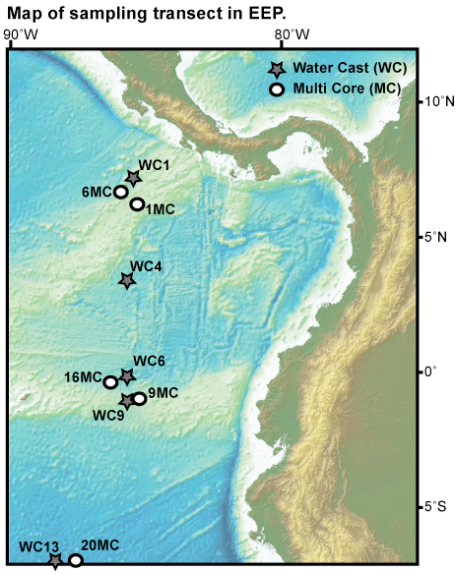
Testing boundary exchange of Nd isotopes in the Eastern tropical Pacific Ocean

STELLA WOODARD[1]*, FRANCO MARCANTONIO[2], DEBORAH THOMAS[1] AND MITCHELL LYLE[1]

[1]Department of Oceanography, Texas A&M University, College Station, TX 77843, USA (*correspondence: swoodard@ocean.tamu.edu)
[2]Department of Geology & Geophysics, Texas A&M University, College Station, TX 77843, USA

We investigate the possibility of boundary exchange as a mechanism for altering the Nd isotopic composition of seawater along the eastern margin of the equatorial Pacific Ocean by analyzing Nd isotopes and concentrations in seawater and sediment collected along a transect in the Panama and Peru Basins during the Fall of 2010. The region plays an important role in the global carbon cycle due to enhanced productivity, upwelling and venting of CO_2 rich waters and is affected by enhanced precipitation and riverine runoff. In addition, the area is interesting in terms of intermediate water circulation with the confluence of NPIW and AAIW near the equator at depths of ~500-1000m.

Seawater dissolved $^{143}Nd/^{144}Nd$ and [Nd] profiles were determined for five locations (see map) and compared with the Nd isotopic composition of biogenic apatite (thought to reflect bottom water εNd) and lithogenic material isolated from the tops of five multi-cores (see map). Preliminary data from seawater collected at site WC13 show a decrease in εNd from -2.1 at 500m to -3.4 at 2750m water depth.



Minor effect of physical size sorting on iron solubility of transported mineral dust

M.T. WOODHOUSE, Z.B. SHI, K.S. CARSLAW, M.D. KROM, G.W. MANN AND L.G. BENNING

School of Earth and Environment, University of Leeds, Leeds, United Kindom (m.woodhouse@see.leeds.ac.uk)

Observations show that the fractional solubility of Fe (FS-Fe, defined as the ratio of dissolved to total Fe) in dust aerosol increases from ~0.1% in regions of high dust mass concentration and up to 80% in remote oceanic regions where concentrations are lowest [1, 2]. Here, we combined laboratory geochemical measurements with global aerosol model simulations to test the hypothesis that the increase in FS-Fe is due to physical size sorting during dust transport. We determined the FS-Fe in size-fractionated dust generated from two representative Saharan dust source samples using a customized dust re-suspension and collection system. The results show that the FS-Fe is size-dependent and ranges from 0.1-0.8%. The size-resolved FS-Fe data were then combined with simulated (size-resolved) dust mass concentration data from a global aerosol model, GLOMAP, to calculate the FS-Fe of dust aerosol over the tropical and subtropical North Atlantic Ocean. We found that the calculated FS-Fe in the dust aerosol increased from ~0.1% at high dust mass concentrations (e.g., >100 $\mu g\ m^{-3}$) to ~0.2% at low concentrations (<1 $\mu g\ m^{-3}$) due to physical size sorting alone. These values are one to two orders of magnitude smaller than those observed on cruises across the tropical and sub-tropical North Atlantic Ocean [1, 3] under an important pathway of Saharan dust plumes for similar dust mass concentrations. Even when the FS-Fe of the sub-micrometer size fractions (0.18-0.32 μm, 0.32-0.56 μm, and 0.56-1.0 μm) in the model were increased by a factor of 10 over the measured values, the calculated FS-Fe of the dust was still more than an order of magnitude lower than that measured in the field. Therefore, the physical sorting of dust particles alone is unlikely to be an important factor in the observed inverse relationship between the FS-Fe and the atmospheric mineral dust mass concentrations. These results suggest that processes such as chemical reactions and/or mixing with combustion particles are the main mechanisms to cause the increased FS-Fe in long-range transported dust aerosols.

Structural systematics of Mg-Fe^{2+}-bearing spinels and spinelloids

A.B. WOODLAND[1]*, R.J. ANGEL[2] AND M. KOCH[3]

[1]Inst. für Geowissenschaften, Univeristät Frankfurt, Altenhöferallee 1, 60438 Frankfurt, Germany (*correspondence: woodland@em.uni-frankfurt.de)
[2]Dept. of Geosciences, Virginia Tech, Blacksburg, VA, 24060, U.S.A.
[3]Inst. für Geowissenschaften, Universität Heidelberg, Im Neuenheimer Feld 234-6, 69120 Heidelberg, Germany

Spinels and struturally related spinelloids have been synthesised in the geologically relevant system M_2SiO_4-$MFe^{3+}{}_2O_4$, where M = Mg and Fe^{2+} at 1100-1200°C and 3 to 16 GPa. Starting materials were mixtures of Fe_3O_4 and pre-synthesised olivine solid solutions. Unit-cell parameters were determined by Rietveld refinement of powder diffraction patterns containing Si as an internal standard.

Spinel exhibits a range in composition, which requires consideration of four endmembers: ringwoodite, Fe-ring-woodite, magnetite and magnesioferrite. As expected, the cell parameter decreases with increasing M_2SiO_4 content. A least squares fit to the dataset (n=53) suggests ideal or near ideal behaviour in this quaternary system. The derived molar volume for $MgFe_2O_4$ ($V° = 44.51(12)$ cm^3) implies a degree of inversion of x = 0.78 [1], although this was not explicitly accounted for in the fit.

Spinelloid II exhibits only a limited compositional range with nMg ≤ 0.26 cpfu. Molar volumes decrease with increasing Mg content. Single-crystal refinements indicate that Mg preferentially resides on the M3 site, which is the octahedral site containing the bridging oxygen of the T_3O_{10} tetrahedral group.

Compared with Mg-free [2] spinelloid III, the incorporation of Mg causes a systematic reduction in volume. Aweighted least squares fit yields $V°_{Fe3O4} = 45.04(6)$ cm^3, $V°_{Fe2SiO4} = 42.89(10)$ cm^3 and $V°_{Mg2SiO4} = 40.9(4)$ cm^3, assuming ideal mixing (non-ideality is not statistically significant). Mg prefers the M2 site, which is attached to the bridging oxygen of the T_2O_7 group.

The volume behaviour of spinelloid V is similar to the other spinelloids, except that the volume reduction from Mg addition is not so clearly defined. This could be due to changing ordering of i) Fe^{3+} and Si on the TO_4 and T_2O_7 sites, and/or ii) Mg, Fe^{2+} and Fe^{3+} across the octahedral sites. A weighted least squares fit yields $V°_{Fe3O4} = 44.96(4)$ cm^3, $V°_{Fe2SiO4} = 42.53(8)$ cm^3 and $V°_{Mg2SiO4} = 40.3(3)$ cm^3 for the theoretical endmembers, assuming ideal mixing.

F, Cl and S contents of olivine-hosted melt inclusions from picritic dike rocks, Etendeka, NW Namibia

L. WORGARD[1]*, , R.B. TRUMBULL[2], J. K. KEIDING[2], I.V. VEKSLER[2,3], M. WIEDENBECK[2], T. WENZEL[1] AND G. MARKL[1]

[3]Technical University Berlin, Department of Mineralogy and Petrology, Ackerstrasse, 71-76, D-13355 Berlin, Germany

Volatile contents and their evolution during magma differentiation are important to understand for better assessment of their role during volcanic eruptions and for estimation of atmospheric loading. Furthermore volatiles have shown potential to be used to put constraints on different mantle sources. Here we present for the first time F, Cl and S concentrations of olivine-hosted melt inclusions analyzed by SIMS from picritic dikes from the southern Etendeka region, NW Namibia.

The analyzed host olivines are Mg-rich (Fo_{84-93}) and their re-homogenized (and post-entrapment corrected) melt inclusions contain between 10 and 18 wt.% MgO and show SiO_2 contents of 45-52 wt.% and thus range from basalt to komatiite in composition.

F concentrations in the analyzed melt inclusions vary from 200 to 450 ppm, Cl varies from 5 to 40 ppm and S from 10 to 1100 ppm. F and S concentrations increase with decreasing forsterite content of the host olivine, whilst Cl does not. F/Cl ratios are variable and range from 4 to 45, with the highest values presumably being influenced by degassing prior to melt inclusion entrapment and/or post entrapment leaking. Most F/Cl ratios and low Cl/K ratios (≤ 0.3) indicate a depleted mantle source for these picritic dikes [1-3], which is consistent with earlier Sr and Nd isotope work of [4]. We plan to compare the volatile contents of the melt inclusions with that of the corresponding whole rocks (analyzed by pyrohydrolysis) in order to further constrain the significance of potential degassing processes.

[3]LPCS, ENSCP Chimie Paris Tech, Paris, France.

The interactions between biomolecules and inorganic surfaces play an important role in many natural environments and hence it is essential to understand the nature of the chemical interaction between the biomolecule and the surface, the resulting biomolecule conformation and the influence of other surface species notably water. This can be achieved by using atomistic simulation techniques and we have focused on the corundum structured oxide α-Cr_2O_3 and compared with the structural analogues of α-Fe_2O_3 and α-Al_2O_3.

We have used a combination of simulation techniques to investigate the surfaces and surface adsorption. These include potential-model based techniques using the static lattice code METADISE [1] for generating the initial structures of the surfaces and the molecular dynamics code: DL_POLY [2] on incorporation of water. The interatomic potentials were then tested with DFT using VASP [3].

The results from both interatomic potentials and DFT show that the {10.2} and {00.1} surfaces are the most stable and energetically prefer dissociative adsorption. The adsorption energies are in reasonable accord, for example DFT predicts -0.75 eV on the {10.0} surface compared to -0.84 eV. The DFT studies on the different forms (neutral, anionic and cationic) of glycine (Gly) 1, lysine (Lys) and glutamic acid (Glu) have been used to test and develop the potential models. The results show that the neutral amino acid molecules become anionic on adsorption at low coverage on anhydrous Al_2O_3 and Cr_2O_3. An oxido-amino acid complex is formed with the creation of an iono-covalent bond M-O(C). Finally, the results show that hydroxylation of the surfaces clearly modify amino acid adsorption.

Magnesium isotope fractionation in a hardwood forest of Southern Québec, Canada

S. WORSHAM[1]*, C. HOLMDEN[1] AND N. BÉLANGER[2]

[1]Saskatchewan Isotope Laboratory, University of Saskatchewan, Saskatoon, Canada (*correspondence: srw039@mail.usask.ca, ceh933@mail.usask.ca)

[2]Université du Québec à Montréal, Montréal, Canada (belanger.nicolas@teluq.uqam.ca)

Magnesium (Mg) is an essential macronutrient for plants, acting as the coordinating cation for chlorophyll as well as serving other important metabolic functions. Recent laboratory studies have demonstrated mass dependent fractionation of Mg within plants [1,2], while there is only one confirmation of plant fractionation in the field to date [3]. Our study builds on previous work through an investigation of Mg isotope fractionation in a forested ecosystem. Broader questions motivating this work include the potential impact of forest Mg cycling on the signature of the continental weathering flux of Mg delivered to the oceans by river flow.

Mg isotope fractionation is being examined in a forested first order catchment in southern Québec, Canada, dominated by sugar maple (*Acer saccharum)* and characterized by soils developed from granite, mangerite and anorthosite. Thus far, we observe fractionation coupled with the uptake of Mg into maple trees from the soil pool as well as significant internal plant fractionation. Preliminary δ^{26}Mg (^{26}Mg/^{24}Mg) values for the study plot exhibit an overall fractionation range of 1.15‰ (23% of reported terrestrial variation). Most interesting is considerable fractionation associated with the degradation of chlorophyll during leaf senescence. We believe translocation of light chlorophyll-bound Mg back into the tree accounts for this finding, driving whole leaf δ^{26}Mg to higher values prior to litter fall. Measured δ^{26}Mg values of senescent leaves and litter range from –0.88±0.10‰ to –1.32±0.09‰. Analyses of soil water and stream water samples during low and high flow indicate that Mg isotope values in the stream may be influenced by fractionation during plant uptake; however, a lithology driven (particularly silicate weathering [4]) control is still under investigation. With this presentation, we will review the progress made to date on factors influencing Mg isotope fractionation in a forested catchment.

Carbonate-associated sulfate: A seawater proxy with potential and weaknesses

T. WOTTE[1]*, H. STRAUSS[1] AND G.A. SHIELDS[2]

[1]Institut für Geologie und Paläontologie, WWU Münster, D-48149 Münster, Germany (*correspondence: thomas.wotte@uni-muenster.de)

[2]Department of Earth Sciences, University College London, London WC1E 6BT, UK

It is generally considered that the sulfate ion is incorporated into the carbonate lattice during precipitation, consequently called carbonate-associated sulfate (CAS). Even if the mechanism of incorporation as well as the potential effects that diagenesis might have on the sulfur isotopic composition of CAS are not completely understood, it is regarded as a powerful proxy for reconstructing the primary seawater sulfate sulfur composition. Both, analytical and diagenetic aspects can affect the isotopic composition of CAS and have to be carefully considered when talking about carbonate-associated sulfate in the context of primary seawater composition. Bacterial sulfate reduction, particularly under sulfate limiting conditions in the pore water realm, causes ^{34}S-enrichment in the residual dissolved sulfate. On the other hand, sulfide oxidation results in ^{34}S-depleted sulfate. If incorporated, both would alter $\delta^{34}S_{CAS}$.

When extracting the original CAS signal it is essential that any other sulfates, which could influence this primary information, are removed. Otherwise, a mixed δ^{34}S signal is generated, composed of primary and secondary sulfate sulfur, that does not represent the sulfate sulfur isotopic composition of the paleo-seawater. Various methods of CAS extraction were developd, using different chemicals (e.g., NaCl, NaOCl, H_2O_2) or only deionised water to exclude non-CAS, organic sulfur, and metastable sulfides. These different methods result in variations in $\delta^{34}S_{CAS}$, but, no thorough calibration or comparison between the methods is presently available.

Based on comprehensive leaching procedures and detailed data sets comparing several extraction methods for CAS, we are able to identify the sources of secondary sulfate which has the potential to affect the primary CAS isotopic signal during extraction. Further, we determined the effect of pyrite oxidation on CAS by using δ^{34}S data generated from chromium-reducible sulfur (CRS). The aim of our research is to establish a rigid protocol for CAS extraction that enables the interpretation of sulfur isotope data from carbonate-associated sulfate as a true seawater proxy.

Petrologic significance of high-precision zircon U-Pb dates from the Skaergaard intrusive complex

J.F. WOTZLAW[1]*, I.N. BINDEMAN[2], U. SCHALTEGGER[1], C.K. BROOKS[3] AND H.R. NASLUND[4]

[1]Earth Sciences, University of Geneva, Switzerland (*correspondence: joern.wotzlaw@unige.ch)

[3]Natural History Museum, Univ. Copenhagen, Denmark

[4]Geological Sciences, SUNY, Binghamton, USA

The Skaergaard intrusion (East Greenland) has long been regarded as a type example of a layered intrusion that essentially evolved by closed-system fractional crystallization. Late-stage ferrodiorites, however, are depleted with respect to ^{18}O ($\delta^{18}O_{magma}$ ~3-4 ‰), recording incorporation of meteoric water derived oxygen into the magma prior to final solidification [1]. Incorporation of meteoric water into these late-stage differentiates requires either devolatilization of hydrated stoped blocks or remelting after subsolidus hydrothermal alteration. Such processes probably operated on timescales of ~100 ka and are thus potentially resolvable by high-precision ID-TIMS U-Pb geochronology.

We present high-precision zircon U-Pb dates for low-δ^{18}O ferrodiorites from the Sandwich Horizon (SH), a normal-δ^{18}O pegmatite from the lower zone of the layered series and the tholeiitic Basistoppen sill, that was emplaced ~200 m above the SH shortly after solidification of the Skaergaard magma [2]. Weighted mean ^{206}Pb/^{238}U zircon dates of statistically equivalent clusters yield precise crystallization ages for the normal-δ^{18}O pegmatite and the Basistoppen sill that overlap within subpermil uncertainty. In contrast, ^{206}Pb/^{238}U zircon dates from the SH do not form a statistically equivalent cluster. We interpret the observed scatter to reflect 321 ± 182 ka of crystallization. Notably, the youngest zircon from the SH is 125 ± 84 ka younger than the age of intrusion of the Basistoppen sill. This requires that either the SH was still molten or was remelted after emplacement of the Basistoppen sill. If the latter interpretation is correct, it would support models for the generation of late-stage low-δ^{18}O magmas that involve remelting induced by intrusion of the Basistoppen sill. These results demonstrate the potential of high-precision U-Pb geochronology for resolving complex histories of Cenozoic intrusions.

[5]College of Natural Resources Biological Imaging Facility, University of California, Berkeley

Despite their importance in iron redox cycles and bioenergy production, the underlying physiological, biochemical, and genetic mechanisms of extracellular electron transfer by Gram-positive bacteria remain insufficiently understood. We investigated respiration by *Thermincola potens* strain JR of the insoluble electron acceptors Fe(III) oxyhydroxide and anode surface. This isolate, a member of the Firmicutes, was obtained from the anode surface of a microbial fuel cell [1]. We found no evidence for soluble redox-active components secreted into the surrounding medium based on cyclic voltammetry measurements in conjunction with medium replacement experiments. Confocal microscopy revealed highly stratified biofilms in which cells contacting the electrode surface were disproportionately viable relative to the rest of the biofilm. There was also no correlation between biofilm thickness and power production, suggesting cells in contact with the electrode were primarily responsible for current generation. These data, along with cryo-electron microscopy experiments, support contact-dependent electron transfer by *T. potens* strain JR from the cell membrane across the 37 nm cell envelope to the cell surface. Furthermore, we present physiological and genomic evidence that direct extracellular electron transfer is mediated by *c*-type cytochromes. Taken together, our findings provide the first evidence to implicate direct extracellular electron transfer by Gram-positive bacteria and identify *c*-type cytochromes as a potential molecular conduit for charge transport.

Fluid inclusion study of Haojiahe sandstone-type copper deposit, Yunnan province, China

HAI-ZHI WU, RUN-SHENG HAN AND PENG WU

Kunming University of Science and Technology, Southwest Institute of Geological Survey, Geological Survey Center for Non-ferrous Mineral Resources, Kunming, 650093, China (*correspondence: haizhiwu664@yahoo.com.cn)

Haojiahe sandstone-type copper deposit is located in the Chuxiong red bed basin, Yunnan province, China. Two dominant stages of fluid, rock-forming period and reworked mineralization period, are recorded in the gangue minerals of different types of ore.

The rock-forming period of fluid inclusions, mainly aqueous inclusions, can be observed in calcite and quartz cement and secondary enlargement of quartz in disseminated and lamellar ores. The homogenization temperatures range from 84.1 to 162.3ºC, with peak values between 122 and 146℃; and the salinities are from 3.3 to 14wt%$NaCl_{eq}$, with peak values between 5.5 and 7.5wt%$NaCl_{eq}$. The analytic results got by Laser Raman Spectroscopy, show that the gas components were mainly H_2O, SO_2 and CO_2, suggesting a relative oxidizing environment.

The reworked mineralization period of fluid inclusions, including aqueous inclusions and some hydrocarbon inclusions, can be observed in quartz paragenetic with copper minerals in banding or vein ores. The homogenization temperatures range from 145.5 to 227.2℃, with peak values between 170 and 200℃; and the salinities are from 4.5 to 15.2wt% $NaCl_{eq}$, with peak values between 7 and 9.5wt%$NaCl_{eq}$. The gas components were H_2O, CH_4, C_2H_6, CO and CO_2, suggesting a relative reducing environment.

Results of this study show the fluid evolution have experienced increased temperature, increased salinity and a environmental change from oxidizing to reducing.

Granted jointly by the project of State Crisis Mine (20089943) and the Distinguishing Discipline of KUST (2008).

Fluorine partitioning between hydrous minerals and aqueous fluid at 1 GPa and 770 – 850 ˚C

J. WU* AND K.T. KOGA

Laboratoire Magmas et Volcans, Clermont Université, BP 10448, Université Blaise Pascal, CNRS, IRD, Clermont-Ferrand, France
(*correspondence: j.wu@opgc.univ-bpclermont.fr)

Mechanisms of volatile transfer from subducting slab to melting region beneath arc volcanoes are probably the least undrestood process of arc magma genesis. Fluorine, which suffers minimum degassing in arc primitive melt inclusions, retains the information of magma genesis at the depths. It is our interest to understand geochemical behavior of F along with other trace element, and to characterize volatile transfer from the slab to the mantle. Experimentally determined solubility of F in aqueous fluid, and partition coefficients of F between fluid and minerals provide first order information about the character of the volatile-transporting agent. Here, we report experimentally determined the solubility of F in aqueous fluid. The solid starting materials contain 5% or 1.9% F, and an approximately same amount of pure water was added right before an experiment. The experiments are conducted at 1GPa and from 770 to 850°C, for the duration of 3 to 13 days, in gold capsule, with Ni/NiO buffer, using piston cylinder high-pressure apparatus. After quenching, the liquid part is retrieved into a known volume of deionized water for the liquid analysis and the solid part is measured by an electron microprobe. We also calculate the fluid composition with mass-balance.

All samples are equilibrated with hornblende, a humite group mineral, and fluid. With mass-balance calculation a range of partition coefficents are determined: D(fluid /hornblende) = 0.13-0.42; D(fluid/norbergite) = 0.02-0.04; D(hornblendes/norbergite) = 0.13-0.17. The D_F are constant over the temperature range within their uncertainties. Furthermore, F anions are preferentially incorporated into the humite group minerals than hornblende, and nearly all OH site of nobergite are occupied by F in our system. The concentration of F in the fluid is 0.22-0.78 wt% based on mass-balance, and direct analyses of fluids are under way. The F/H_2O values are 10-100 times larger for primitive arc melt inclusions (0.05-0.81) than for ours (0.0024-0.0085). This suggests either 1) drastic water loss in arc melt incusions, or 2) presence of fractionation phases other than ones in this study.

Advances and challenges in the study of mechanisms on salinization and contamination of deep groundwater in the North China Plain

J. F. WU*, Y. YANG, Y. ZHANG AND X. B. ZHU

Department of Hydrosciences, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China
(*correspondence: jfwu@nju.edu.cn)

Groundwater in deep aquifers is the main water source of households, industry and agriculture in the North China Plain (NCP). However, information on degradation of groundwater quality is often seen in this region, which poses a great threat to the intersts of society or ecosytems. This presentation reviews the recent advances in the study on mechanism of deep groundwater quality degradation over the last several decades in the NCP: salinization due to shallow saline groundwater intrusion and contamination by man-made sources. In general, degradation and deterioration of deep grouindwater quality found in the NCP was deductively explained by groundwater over-exploitation and mis-management, but the mechanism of groundwater quality degradation is largely unknown so far. As a consequence, further investigation is needed to uncover the mechanism of salinization and contamination of deep groundwater resource. Due to the compexity of the aquifers, some techniques developed for fractured rock systems [1, 2] may be used as a reference in highly heterogeneous porous aquifers, and the confronting issues and challenges can be summarized as: (i) how to address the heterogeneity of alluvial deposits including aquifers and aquitards [3]; (ii) how to characterize the spatial and temporal extent and intensity of downward salinity intrusion of shallow saline groundwater [4]; (iii) how to delineate the chemical and biochemical processes of man-made sources in aquifers [5]; and (iv) how to understand the apparent scale-effects on different hydrogeological parameters at a regional scale under field conditions [6, 7]. (Grant Nos. 2010CB428803 and 41072175)

Geochemical anomaly pattern in the Haojiahe sandstone-type copper deposit, Yunnan, China

PENG WU*, RUNSHENG HAN AND JING LI

Kunming University of Science and Technology; Southwest Institute of Geological Survey, Geological Survey Center for Non-ferrous Mineral Resources, Kunming 650093, China (*correspondence: wupeng8104@yahoo.com.cn)

Haojiahe deposit controlled by the Upper Cretaceous (K_2mx_2) is the typical one of sandstone-type copper deposits in the Chuxiong Basin. Ore-bodies (average grade: Cu 1.5%) are located in the interface between purple bed and grey bed. From purple bed to grey bed, the ore mineral zonality is hematite, chalcocite, bornite, chalcopyrite and pyrite.

Ore-forming elements association is Cu, Ag, As, Hg. The average contents of copper ores $\sum$REE=119.19×10^{-6}, LREE/HREE=8.93, δEu=0.74, δCe=0.95. Chondrite-normalized REE distribution patterns show oblique to the HREE side with the poor Eu and enrichment in LREE. From oxidized zone to transitional zone (purple bed→copper ore→grey bed), $\sum$REE and δCe decrease gradually with the increase of δEu. The geochemical characteristics well indicate the change of oxidation and reducing environment [1, 2]. These are probably related to the water-rock interaction or infiltration metasomatism.

The vertical zonation of indicator elements in K_2mx_2 from the top to the bottom is Zn, Cs→Pb, Tl, Mo→Cu, Ag, As→Sb, Hg, Co and the transversal zonation from grey belt to purple belt is Mo, Pb→Cu, Hg, Ag→Cu, Ag, As, Sb, Hg.

Geochemical anomaly pattern has been established, that is, the anomaly of Zn, Pb, Mo appears above the orebodies (average distance: Zn 30m, Mo 10m),and the anomaly of Sb, Hg, Co under the orebodies. The anomaly of Cu, Ag and the ratio of Cu/Ag>170, Cu/(Pb+Zn)>10, Cu/(As+Sb+Hg)>180 are concomitant with rich orebodies; the anomaly of Pb, Zn, Co, (Ni) and Cu/Ag<128, Cu/(Pb+Zn)<9, Cu/(As+Sb+Hg)<8 implies barren. The contents of Cu, Ag, As, Hg and the ratio of dual elements increase longitudinally, and it shows that the copper minealization is enhanced gradually. This pattern provides an important basis for the depth ore-forming prognosis.

Origins and sources of CO_2 in natural gas in Eastern Sichuan Basin, China

XIAOQI WU

PetroChina Research Institute of Petroleum Exploration & Development, Beijing 100083, China (wuxiaoqi@petrochina.com.cn)

The eastern Sichuan Basin in China is well-known for the development of H_2S-bearing gas fields such as Puguang, and the natural gas generally contains CO_2. High-content CO_2 was thought to accompany high-content H_2S, and this might be one of the proofs of TSR (Thermochemical Sulfate Reduction) [1]. The CO_2 contents of natural gas from eastern Sichuan Basin vary from 0% to 32.04%, and gas samples with low-content (<2%) and 6%-10% CO_2 account for 61.6% and 20.0% of the total respectively.

The $\delta^{13}C_{CO2}$ values vary from -23.4‰ to 3.3‰, and 34.4% of the samples have low $\delta^{13}C_{CO2}$ values (<-12‰) which are in accordance with those of typical organic CO_2 [2], and they are mainly with low contents of CO_2 (<3%). The corresponding H_2S contents are very low or zero. This type of CO_2 was derived from the oxidation of organic matters. However, the other type of CO_2 displays large $\delta^{13}C$ values (>-8.3‰) and shares similar carbon isotopic characteristics with inorganic CO_2 [2] and reservoir carbonates [1], and differs dramatically from that of TSR origin [3]. In this case, no obvious relation exists between the CO_2 and H_2S contents, so it does between the CO_2 and TSR as study by Huang *et al*. [4]. Under the precipitation in the deep-burial period, CO_2 generated during the TSR was mainly transformed into secondary calcite, which demonstrated low $\delta^{13}C$ values (-18.2‰~-10.3‰) [1].

Inorganic CO_2 can be divided into mantle-derived origin and decomposition or dissolution of carbonates [2]. The helium in the natural gas was crustal derived due to the low R/Ra ratios (<0.036) without significant contribution from the mantle. The temperature required for decomposition of carbonates was too high to reach for the deep-buried carbonate reservoirs. In consideration of substaintial uplift in late Jurassic, CO_2 with large $\delta^{13}C$ values was mainly derived from the dissolution of reservoir carbonates under the effect of acidic fluid.

The distribution of biomarkers and the geological significance of the severely biodegraded crude oil in Gudao reservoir

YINGQIN WU[1,2], YONGLI WANG[1], TIANZHU LEI[1], JIANG CHANG[1], YOUXIAO WANG[1] AND YANQING XIA[1]*

[1]Key Laboratory of Petroleum Resources Research, Institute of Geology and Geophysics, Chinese Academy of Science, Lanzhou 730000, China (*correspondence: yqxia@lzb.ac.cn)

[2]Graduate School of the Chinese Academy of Sciences, Beijing 100049, China (wuyingqin001@163.com)

Biodegraded crude oil in China are distributed widely and make up a certain portion of heavy-oil resources. An unresolved complex mixture (UCM) of hydrocarbons isolated from a biodegraded crude oil of the Gudao reservoir in the Shengli Oilfield, China. Some of the hydrocarbons were identified using GC-MS. The result showed that the hydrocarbons expect for tricyclic terpanes, steranes, hopanes, 25-norhopanes, were completely depleted in saturated fraction, as well as hydrocarbons expect for triaromatic steranes and few methylnaphthalenes, methylphenanthrenes, chrysene series in the aromatic fraction, which indicate that severe biodegradation occurred in this reservoir. Relatively abundant pentacyclic terpane characterized by high concentration of norhopane and gammacerane, low content of Ts and Tm, the "L"-type and asymmetrical "V"-type distribution of regular steranes and 4-methylsteranes, and high maturity as revealed by sterane and terpane parameters, suggesting aerobic depositional environment with a salt and stratified water body. Furthermore, The results also showed that the magnitude of "UCM" hump existed in the aromatic fraction is apparently larger than that of "UCM" hump existed in the saturated fraction, which implied that the biodegradation rate for aromatic hydrocarbons is parallel or even exceed that of saturated hydrocarbons and the alteration occurred in this reservoir was associated with biodegradation with water-washing.

Determination on nitrate use capacity in plants via isotope tracer

YANYOU WU* AND KUAN ZHAO

IAE, Jiangsu University, Zhenjiang, 212013, China (*correspondce: yanyouwu@ujs.edu.cn)

Materials and Treatments

Broussonetia papyrifera (BP) and *Morus alba* (MA) seedlings were cultured in the modified Hoagland nurient solution adding different concentrations (0, 20, 60 g L^{-1}) of polyethylene glycol (PEG, simulating drought) (pH5.5). *Orychophragmus violaceus* (OV) seedlings were cultured in the modified Hoagland nurient solution adding different concentrations (0, 2.5, 10 mM) of $NaHCO_3$ (BC) (pH 8.2). The sole nitrate N was potassium nitrate with 16.99‰ of the $\delta^{15}N$. The sole ammonium N was $NH_4H_2PO_4$ with -1.21‰ of the $\delta^{15}N$. The $\delta^{15}N$, net photosynthetic rate (Pn, μmol $m^{-2}s^{-1}$) and N content (Cn, mg g^{-1}) of the third or fourth fully expanded leaf were measured. The proportion (f_B) of nitrate to total inorganic N was calculated by a two-component mixing model. The nitrate use capacity (NUC, mg $m^{-2}h^{-1}$) in plants was calculated by the formula: $NUC= 90CnPnf_B$.

Results and discussion

From Table 1, we can found that OV under high concentration BC had the greatest NUC, MA under drought stress the least. Even under drought stress, BP had a great NUC. The great NUC of BP and OV under the Karst drought or high concentration bicarbonate resulted in their adaptability to Karst environment, partly. The plants of the adaptability to Karst environment alternately use nitrate and ammonium N under Karst environment.

PS-T	$\delta^{15}N$	Pn	f_B	NUC
MA-PEG/0	-2.41	6.3	0.11	1.59
MA-PEG/20	-1.51	1.0	0.15	0.40
MA-PEG/60	-1.53	0.1	0.15	0.03
BP-PEG/0	-1.25	2.8	0.17	1.04
BP-PEG/20	3.19	2.9	0.38	2.39
BP-PEG/60	2.91	3.9	0.37	3.10
OV-BC/0	12.73	3.9	0.84	6.28
OV-BC/2.5	15.95	2.1	0.99	4.77

Tectonic evolution of the Qinling-Tongbai-Dabie orogenic belt

YUAN-BAO WU[1] AND YONG-FEI ZHENGB[2]

[1]State Key Laboratory of Geological Processes and Mineral Resources, Faculty of Earth Sciences, China University of Geosciences, Wuhan 430074, China (*correspondence: yuanbaowu@cug.edu.cn)

[2]CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China

The Qinling-Tongbai-Dabie-Sulu orogenic belt marks the suture between the North and South China Blocks in Central China, forming one of the most important orogens in the eastern Asia. Although it has been extensively studied for more than 20 years, there are hot controversies about the location and number of sutures and the timing of arc-continent and continent-continent collisions during the convergence between the North and South China Blocks. The Dabie-Sulu orogenic belt is characterized by the occurrence of Triassic UHP eclogite-facies metamorphic rocks. On the other hand, there are Paleozoic events of arc-continent collision in the Qinling-Tongbai orogenic belts that were subsequently followed by the Triassic process of continental collision. Rifting occurred at the northern part of the Yangtze Block, synchronous with the middle Paleozoic collision, and was followed by the opening of the Paleo-Tethyan ocean during the Late Paleozoic. These indicate that the Qinling-Dabie-Sulu orogen is a typical multiple evolution orogen, including the Early to Middle Paleozoic continental subduction and collision, the Silurian extension and rifting in relation to the opening of the Paleo-Tethyan ocean during the Late Paleozoic, and the Triassic continental material subduction, HP-UHP metamorphism and subsequent exhumation. Therefore, it is a complex orogenic belt on the time and location of arc-continent and continent-continent collisions between the North and South China blocks, and the amalgamation of the two continental blocks along the Qinling-Tongbai-Dabie-Sulu orogenic belt is a multistage process that spans about 300 Ma.

Composition and structure of the 3.65 Å phase: A DHMS with exclusively six-fold coordinated Si

B. WUNDER*, R. WIRTH, M. KOCH-MÜLLER AND S. JAHN

GFZ German Research Centre for Geosciences, Section 3.3, Telegrafenberg, 14474 Potsdam, Germany (*correspondence: wunder@gfz-potsdam.de)

Dense Hydrous Magnesium Silicates (DHMS) are suggested to be important hosts and carriers of water under hydrous conditions of the Earth´s mantle and in subduction zones. Therefore, their study is central to the understanding of the Earth´s deep water cycle. The so-called 3.65 Å phase, named after the *d*-value of its prominent X-ray reflection, is the least well-characterized phase of the DHMS family, as neither its chemical composition nor its structure are well constrained.

In our recent study [1], the 3.65 Å phase was synthesized in the system MgO-SiO_2-H_2O at 10 GPa and 425 °C for 77 hours run duration in a multi-anvil press from a gel plus excess water. The composition of the 3.65 Å phase was determined to be $MgSi(OH)_6$ by combining results from SEM-, TEM-, EMP-, IR- and Raman-analysis. Powder XRD combined with Rietveld refinement revealed the 3.65 Å phase to be isostructural with δ-$Al(OH)_3$. Its structure can be described as an A-site vacant perovskite with probably long-range random distribution of Si and Mg at octahedral sites. The 3.65 Å phase represents beside phase D the second DHMS with exclusively six-fold coordinated Si.

The H-positions could not be determined by the powder XRD Rietveld refinement. Therefore, the apparent orthorhombic space group – either *Pnam* with protons in unordered configuration, or $P2_12_12_1$ with ordered H-positions – was ambiguous. Preliminary first-principles DFT-calculations predict the structure with $P2_12_12_1$ or monoclinic $P2_1$ symmetry with ordered Mg and Si as the most stable structure at ambient conditions.

The 3.65 Å phase is stable at pressures above about 9.0 GPa and decomposes above about 500 °C due to the reaction 3.65 Å phase = high-clinoenstatite + water. This limited P-T-stability together with its high water content of 35 wt.% makes it a rather unrealistic phase in the Earth´s mantle. If at all, the 3.65 Å phase might only exist under hydrous conditions in very limited areas, i.e., in the coldest parts of old and extremly fast subducted slabs, e.g., Tonga.

Exploring carbonate aquifers and their susceptibility for metal release during CO_2 leakage

A. WUNSCH[1]*, A.K. NAVARRE-SITCHLER[1], R.M. MAXWELL[2] AND J.E. MCCRAY[1]

[1]Environmental Science and Engineering Division, Colorado School of Mines, Golden, CO 80401, USA (*correspondence: awunsch@mines.edu)

[2]Geology and Geological Engineering Department, Colorado School of Mines, Golden, CO 80401, USA

Metal transport resulting from potential CO_2 leakage into freshwater aquifers is a major concern accompanying carbon sequestration operations. Acidity resulting from dissoluton of leaked CO_2 into aquifer waters may result in release of metals from aquifer minerals. Carbonate aquifers have the ability to buffer increased acidity through calcite and dolomite dissolution, and are therefore theoretically "safer" than non-buffering aquifers. However, carbonate minerals are rarely found as pure phases in nature, often containing impurities in the solid phase. These impurities substitute for either calcium or carbonate in the crystal lattice. Buffering of acidity requires dissolution of carbonate minerals, resulting in potential release of trace elements. Whole-rock analysis of natural carbonate rock samples show solid-phase concentrations of Pb and Cr on the order of several ppm, and of Ba, Co, Ni, Rb, Sc and Zn on the order of tens or hundreds of ppm. Prediction of the behavior of these metals through modeling is difficult, as there are several models of co-precipitation and dissolution in solid solutions. Simple stoiciometric dissolution predicts very different release behavior of these metals from calcite dissolution at various CO_2 partial-pressures. For example, at low P_{CO2}, cobalt concentrations in solution are as high as 776 ppb, and decrease with increasing P_{CO2}, whereas barium concentrations in solution increase with increasing P_{CO2}, following a trend similar to that of calcium. In this work, batch dissolution experiments are combined with SEM and electron microprobe analyses, to investigate dissolution rates and equilibrium release of metals from carbonate rocks and to determine their solid-phase source.

Uncovering the key processes involved in manganese biogeochemical cycling in the Ocean

K. WUTTIG[1], M. HELLER[1] AND P. CROOT[2]

[1]IFM-Geomar, Kiel, Germany (kwuttig@ifm-geomar.de, mheller@ifm-geomar.de)

[2]Plymouth Marine Laboratory, Plymouth, United Kingdom (pecr@pml.ac.uk)

Mn forms a critical part of many redox enyzmes most notably for photosynthesis, where as part of Photosystem II it converts H_2O to O_2. Many marine organisms also contain Mn superoxide dismutases (SOD), that act as part of the intracellular defences against reactive oxygen species (ROS) and in particular rapidly convert superoxide (O_2^-) into O_2 and H_2O_2. While laboratory studies have shown that the growth of marine phytoplankton is reduced for some species at the low Mn concentrations found in open ocean seawater, currently there is little evidence from fieldwork to suggest Mn limitation occurs, but this possibility remains, particularly for the Southern Ocean.

The supply of Mn to the open ocean is predominantly via the deposition of aeolian dust and subsequent dissolution of Mn(II) from the particles. The released Mn(II) is slowly oxidized (via biota or chemically) to insoluble MnO_2 which precipitates out of the water column. In the sunlit ocean, H_2O_2 can reduce MnO_2 back to Mn(II) completing a redox cycle. New work by a number of groups suggest that transient Mn(III) species, intermediate in the cycling between Mn(II) and MnO_2 may play an important role in both the Mn and Fe biogeochemical cycles in surface waters. In coastal waters Mn(II) can diffuse from reducing sediments with subsequent mixing into the photic zone.

In this presentation we will present data for Mn concentrations, speciation and kinetic reactivity from two research cruises in the Tropical Atlantic (M83-1 and MSM17-04) and from a dust deposition experiment performed in trace metal clean mesocosms in the Mediterranean (DUNE2). We will use our combined dataset to determine the predominant source of Mn to shelf waters in the Mauritanian upwelling region and the adjacent open ocean in the Tropical Atlantic, which are impacted by both Saharan dust and potentially coastal sedimentary sources that are advected offshore by the upwelling waters. Finally we will examine the evidence for Mn(III) in the euphotic zone of the open ocean and the implications this had for Mn biogeochemical cycling in the ocean.

XANES investigation of selenium speciation in silicate glasses

JEREMY L. WYKES, HUGH ST. C. O'NEILL AND JOHN A. MAVROGENES

Research School of Earth Sciences, Australian National University, Acton, ACT, 0200, Australia

The speciation of sulfur in silicate melts as a function of oxygen fugacity is an important factor in volcanic degassing and ore deposition. Due to the large number of electrons involved in the 2- to 6+ transition, sulfur changes from 2- to 6+ over a very narrow fO_2 interval, <2 log units. The 4+ valence state of sulfur does not appear to be an important species in silicate melts. Selenium lies directly below sulfur in group 16 of the periodic table and is considered to display similar geochemical behavior. However, differences in redox speciation between sulfur and selenium, either in the fO_2 of Se^{2-} to Se^{6+} relative to S^{2-} to S^{6+} transitions, or the existence of a Se^{4+} stability field will result in fractionation of Se from S in magmatic systems [1].

We have conducted high pressure, high temperature experiments under controlled fO_2 conditions to investigate the speciation of Se in silicate melts. Oxide mixes of basaltic composition were doped with 500 to 2500 ppm Se and equilibrated in Pt or graphite-Pt capsules at 1400°C for 36 hours. Chemical potential of oxygen was controlled by the addition of Ru-RuO_2, PtO_2 and the presence of graphite, to produce experiments reflecting reduced (graphite ≈ FMQ-2.2; [2]), oxidising (Ru-RuO_2 ≈ hematite-magnetite at 1400°C) and very oxidising conditions (PtO_2 produces O_2 gas phase).

Quenched glasses were recovered from the piston-cylinder experiments and the selenium K-edge XANES (X-Ray Absorption Near Edge Structure) spectra were collected in fluorescence mode at the Australian National Beamline Facility at the Photon Factory, Tsukuba, Japan.

Glasses from each redox condition produced a distinct Se K-edge spectra, with the absorbtion edge energy increasing with increasing fO_2. The spectra are interpreted to represent Se^{2-}, Se^{4+} and Se^{6+}. Thus, at moderate to high fO_2, selenium exhibits distict redox speciation to sulfur, with the existence of a significant stability field for Se^{4+}, and the Se^{2-} to Se^{4+} transition will occur over a larger fO_2 range than S^{2-} to S^{6+}. We suggest that Se^{6+} is not an important species in silicate metls at geologically relevant oxygen fugacities.

Geochemical evidence of source and process controls on Mid-Miocene silicic volcanism in the Idaho-Oregon-Nevada Region, USA

A. WYPYCH* AND W.K. HART

Geology Dept., Miami University, Oxford, OH 45056, USA (*correspondence: wypycha@muohio.edu)

In this study we report results of a geochemical and petrological investigation of Mid-Miocene silicic volcanism in the Idaho-Oregon-Nevada (ION) region aimed at examining models of continental crust formation and modification in the northwestern US. In the late Oligocene to Miocene portions of the northwestern US underwent extension accompanied by bimodal (mafic and silicic) volcanism [1,2]. The ION region resides in the northernmost Basin and Range Province on a "transitional" lithosphere between Mesozoic accreted lithosphere to the west and Precambrian Wyoming Craton to the east as marked by Sr isotopic composition (0.704 and > 0.706 respectivly). It is characterized by bimodal, silicic (~16 to ~13 Ma) and mafic (~17 to 15 Ma) volcanism temporally related to the main volumes of Columbia River flood basalt activity to the north. Mantle upwelling behind an active magmatic arc, mafic magma intrusion into crust, melting of heterogeneous lithosphere and mixing of the melts from heterogeneous sources are contributing to the ION region bimodal volcanism and its continuation in time and space to the NE (Snake River Plain-Yellowstone) and the NW (High Lava Plains-Newberry) [1,3,4].

To investigate the heterogeneity and spatial and temporal relationships between off craton, "transitional", and on craton sources and reservoirs five ION volcanic centers are investigated. We conducted petrological, geochemical and Sr, Nd and Pb isotopic analyses on 23 whole rock-glass separate pairs and Hf isotopic analyses on the glass separates [3]. In addition to the influence of sptaillay and temporally heterogeneous source regions open system behavior in crustal storage chambers plays an important role in ION area silicic magma evolution. This is evident from feldspar dissolution textures and differences in trace element and isotopic compositions between whole rock and glass separate pairs.

Generating Kermadec Arc SMS deposits: Roles of magmatic volatiles

R.J. WYSOCZANSKI[1]*, M.R. HANDLER [2], C.I. SCHIPPER[3], J. CREECH[2], M.D. ROTELLA[2], C.J.N. WILSON[2] AND R.B. STEWART[3]

[1]NIWA, PO Box 14901, Wellington, New Zealand (*correspondence: r.wysoczanski@niwa.co.nz)
[2]SGEES, Victoria University, Wellington, New Zealand
[3]INR, Massey University, Palmerston North, New Zealand

Seafloor massive sulphide (SMS) deposits in oceanic subduction zones, such as the Kermadec Arc/Havre Trough (KAHT), are a valuable commodity and may be viable as a precious metal source. The ultimate source, however, of S and metals in SMS deposits is unknown. Here, we present elemental data, including volatiles (H, C, S, Cl) of basalts from along the southern KAHT to address the relationship between magmatic composition and hydrothermal venting. The findings are as follow:

1. Back-arc melt inclusion (MI) water contents (~2.5 wt. %) are similar to the hydrothermally active arc, implying that the lack of back-arc hydrothermal activity is not due to lower magmatic water contents. Slab-derived fluid components do not differ between the southern and middle portions of the Kermadec Arc, implying that subduction of the thick Hikurangi Plateau crust in the south (cf. normal oceanic crust in the north) does not enrich the mantle in fluids.

2. SO_3 contents do not correlate with slab-derived components, suggesting that little S is added to the mantle source from the slab. S degasses as sulphate, resulting in more reduced rock compositions, which then interact with hydrothermal fluids. Pressures from H_2O contents of MIs imply that the magma chambers of arc front volcanoes that are hydrothermally inactive are deeper than for hydrothermally active volcanoes.

3. Basalt compositions from hydrothermally active arc front volcanoes do not significantly differ from those with no activity. This implies that factors other than magmatic composition determine the location and extent of hydrothermal activity.

4. Concentrations/ratios of metals in basalt magmas require metal enrichment over magmatic compositions to produce SMS deposits in the order Pb>Zn>>Cu. This may occur via crustal scavenging or magmatic fluid additions. Elemental ratios in chalcopyrite-bearing chimneys can, however, be achieved from basalt magmas by fractionation to evolved compositions.

Study on main sources of the sulfur in acid rain in Jiangxi province, China

F. XIA[1], J.-Y. PAN[1], FAN. XIA[2], S.-H. CHEN[1], H.-M. PENG[1] AND P. LIU[1]

[1]State Key Laboratory Breeding Base of Nuclear Rersources and Environmental, East China Institute of Technology, Nanchang 330013, China (xf730@163.com)

[2]Shanghai Environmental Monitoring Centre, Shanghai 200030, China (xiahoufan@sohu.com)

The main sources of sulfur in rain water include bio-organic sulfur and anthropogenic sulfur in Jiangxi province, China.

We analyzed the sulfur isotopic composition of rain water from Nanchang City in this paper. The results indicated that the sulfur isotopic composition possesses a seasonal variation trend. It is discussed individually that the different sulfur sources of rain water with the principle of mass balance, the relative contribution of the biogenic and the anthropogenic to sulfur source of acid rain in Nanchang each can be calculated quantitatively. In summer and autumn, the sulfur in rain water comes mainly from bio-organic sulfur, In winter and spring,the sulfur in rain water dominantly originates from anthropogenic sulfur (Fig.1). The sulfur in rain water from the sea may be very small in percentage.

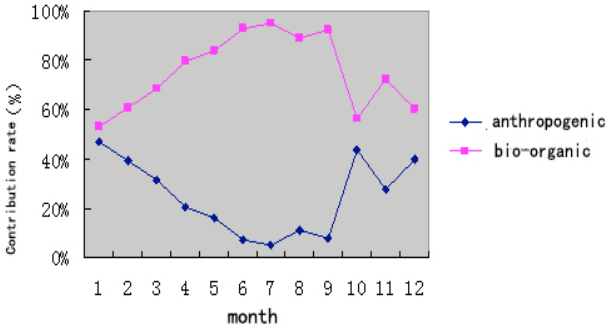

Figure 1: Two main sulfur sources' relative contribution to the precipitation in Jiangxi province

Multistage growth of garnet in UHP metagranite in the Dabie orogen

QIONG-XIA XIA, YONG-FEI ZHENG, XIAO-NAN LU

CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (qxxia@ustc.edu.cn)

Garnet is a common mineral in subduction-zone metamorphic rocks, and its growth and reworking can be linked to metamorphic P-T conditions. We performed a combined study of major and trace elements by means of EMP and LA-ICPMS analyses on garnet from UHP metagranite in the Dabie orogen. Three stages of garnet growth are deduced from the major element zonation based on the assumption that Ca contents and Fe/Mg ratios in metamorphic garnet are indicative of metamorphic pressure and temperature, respectively. The first stage of growth (Grt-I) occurs in the core of skeletal garnets, which is characterized by the homogeneously low X_{Grs} values and Fe/Mg ratios, indicative of the highest temperature but the lowest pressure. It is a residue of magmatic garnet that most likely nucleates in the stage of protolith granite formation. The second stage of growth (Grt-II) occurs in the mantle and core of garnets, which is indicated by the increased X_{Grs} values and Fe/Mg ratios, corresponding to continuous increase in temperature and pressure till peak pressure and thus garnet growth during the prograde subduction. The third stage of growth (Grt-III) occurs in the rims of all garnets, which is suggested by slightly decreased X_{Grs} values and Fe/Mg ratios in response to a pressure decrease but a temperature increase till peak temperature. These rims overgrew subsequent to the peak pressure with continuous heating during the initial exhumation. REE distributions in the three stages of garnets are also different from each other. Both Grt-I and Grt-II exhibit steep MREE-HREE patterns with high HREE contents, with obvious negative Eu anomalies and high REE contents for Grt-I. Grt-III displays obviously lowered REE contents compared to those for Grt-I and Grt-II, with two subtypes of MREE-HREE patterns: steep (IIIa) and plat MREE-HREE patterns (IIIb). Therefore, the garnet from low-T/UHP metagranites displays obvious multiple stages of growth during continental collision. Nevertheless, the highest pressure occurs in the cores or mantles whereas the maximum temperature occurs in the rims, suggesting that the peak pressure did not occur at the peak temperature during the continental collision. Thus the "hot" exhumation is recorded in the garnets from the low-T/UHP granitic gneiss. This provides a thermal condition for dehydration melting of the deeply subducted continental crust.

Diffusive anisotropy in low-permeability Ordovician sedimentary rocks from the Michigan basin in southwest Ontario

Y. XIANG[1], T. AL[1,*], L. CAVÉ[1,2] AND D. LOOMER[1]

[1]Department of Earth Sciences, University of New Brunswick, Fredericton, New Brunswick, Canada (*correspondence: TAL@UNB.CA)

[2]Present Address: Environment Canterbury, Christchurch, New Zealand

Diffusive anisotropy and its scale-dependence were investigated using samples from the Upper Ordovician Georgian Bay Formation (shale and thin interbeds or 'hardbeds' of limestone and siltstone) and Middle Ordovician argillaceous limestone from the Michigan Basin of southwest Ontario, Canada. Effective diffusion coefficients (D_e) were determined for iodide (I^-) and tritiated water (HTO) tracers on paired cm-scale subsamples oriented normal (NB) and parallel to bedding (PB). Measurements were conducted using X-ray radiography and through-diffusion methods. The D_e values range from 4.8×10^{-13} to 5.3×10^{-12} $m^2 \cdot s^{-1}$ for shale, 2.1×10^{-13} to 1.3×10^{-12} $m^2 \cdot s^{-1}$ for limestone, and 4.1×10^{-14} to 5.6×10^{-13} $m^2 \cdot s^{-1}$ for siltstone interbeds within the Georgian Bay shale formation. The sample-scale anisotropy ratios ($D_{e\text{-}PB}$: $D_{e\text{-}NB}$) for D_e values obtained using I^- tracer are 0.9 to 4.8, and the anisotropy ratios for HTO tracer are in the range of 1.1 to 7.0. A formation-scale anisotropy ratio of 8.0 was calculated for the Georgian Bay Formation from the ratio of the arithmetic to the harmonic mean of D_e data measured at the sample scale and weighted for the thickness of interbedded siltstone/limestone and shale units.

The influence of porosity distribution on diffusive anisotropy has been investigated using one-dimensional spatially-resolved profiles of I^--accessible porosity obtained from radiography experiments, and the use of $AgNO_3$ for fixation of I^- tracer in the pores, allowing for SEM visualization of I^--accessible pore networks. The porosity profiles generally display greatest heterogeneity in the direction normal to bedding. The SEM imaging suggests that diffusion pathways are preferentially oriented parallel to bedding in the shale, and that diffusion occurs dominantly within the argillaceous component of the limestone but fine clay-filled voids in the limestone are also accessible for diffusive transport.

Characteristics and prediction of high quality coal measure source rocks in Oligocene Yacheng Formation of Qiongdongnan Basin, Northwestern South China Sea

J. XIAO[1,2]*, H. WANG[1,2] AND B. ZHU[2]

[1]Faculty of Earth Resources, China University of Geosciences, Wuhan 430074, China (*correspondence: xj0930@cug.edu.cn)

[2]Key Laboratory of Tectonics and Petroleum Resources (CUG), Ministry of Education, Wuhan 430074, China (wanghua1@cug.edu.cn, zhubei@cug.edu.cn)

The coal measure strata of marine-terrigenous facies in Oligocene Yacheng Formation are the major source rocks of Qiongdongnan Basin. Through comprehensive studies, main characteristics of this set of coal measure source rocks can be concluded as following: (1) they consist chiefly of coals, carbonaceous mudstones and dark mudstones with relatively high organic matter abundance and type II_2-III kerogen. Among them, coals have been most noticed because of the highest organic carbon abundance (19.9-95.9%) and hydrocarbon-generating potential (14.3-142.8mg/g), (2) the drilling and logging data shows that coals are developed in multiple seams with thin single seam thickness and unstable plane distribution, and their logging responses are high neutron porosity, high acoustic interval transit time, high resistivity, low natural gamma ray, and low lithology density, (3) coal seams in Yacheng Formation mostly form by the gelatification and are deposited in the peat swamp environments of braided river delta plain, fan delta plain, and upper intertidal zone and supratidal zone in tidal flat, and (4) the relatively gentle paleotopography and the approximately equivalent sedimentary rate and subsidence rate are the two key control factors of the development of coal measure strata. According to the above conclusions, three favorable development areas of high quality coal measure source rocks in Yacheng Formation are predicted, including Yacheng area of western Qiongdongnan Basin, northeastern slope and southern slope of the basin.

Biogeochemical characteristics and environmental effects of low-molecular-weight organic acids in lacustrine ecosystem

M. XIAO[1] AND F.C. WU[2]*

[1]The State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (xiaomin@mails.gyig.ac.cn)
[2]Chinese Research Academy of Environmental Sciences, Beijing, 100012, China
(*correspondence: wufengchang@vip.skleg.cn)

Low molecular weight organic acids (LMWOAs), are generally considered as the important immediate products during the conversion of anaerobic organic substance (carbohydrates, fats, proteins, etc.) into CH_4 and CO_2, and closely related to lacustrine regional environmental evolution [1, 2]. In this research, the composition and contents of LMWOAs were determined, temporal-spatial variation trends and their contributions to dissolved organic carbon (DOC) were investigated in overlying waters of two plateau lakes in China: Lake Hongfeng (HF) and Lake Dianchi (DC) where two sampling sections were set as P1 and P2. Total organic acids (TOAs) were on average 6.55 μmol·L^{-1} in HF, 7.98 and 6.54 μmol·L^{-1} in DC, which can contribute to total DOC approximately 7.47%, 2.67% and 2.48%, respectively. This study identified 5 key organic acids such as lactic, acetic, pyruvic, sorbic and oxalic acid. The results show that pyruvic acid in these two lakes was confirmed as the major component among LMWOAs with the average concentrations of 2.35 μmol·L^{-1} in HF, 3.82 and 3.35 μmol·L^{-1} in DC. The sources and behaviors of LMWOAs during the photoradiation on lacustrine dissolved organic matter were also discussed. Differential physicochemical parameters indicated that the increasing-decreasing and decreasing-increasing diurnal variation trends of TOAs at two sampling sections in DC were dependent on autochthonous biological and photochemical activity. TOAs in HF decreased with time, mainly due to strong microbial assimilation and mineralization in hypolimnion. LMWOAs' photochemical production from allochthonous humus and consumptiom in epilimnion of HF basically leveled off with time except for significant increase at 18:00, indicative of their direct terrestrial import. The increase of pyruvic acid in epilimnion in HF at night reflected a photoradiation hysteresis effect, and resulted from great algal decomposition. Various hydrochemical conditions revealed that massive algal cover in DC and thermal stratification in HF primarily controlled the profile behavior of decrease and increase for LMWOAs. This research would benefit for management and eco-regulation of lacustrine aquatic environment.

Redefine Bulunkuole group in eastern Pamirs syntaxis and its signification – From the evidence of LA-ICP-MS isotope dating of detrital zircon

PEI-XI XIAO, XIAO-FENG GAO, LEI KANG, ZENG-CHAN DONG, LEI GUO AND REN-GANG XI

Xi'an Center of Geological Survey (Xi'an Institute of Geology and Mineral Resource), CGS, Xi'an, Shaanxi 710054, China (xaxpeixi@163.com)

The Bulunkuole Group is riching in iron ore Paleoproterozoic mesometamorphic rock series distributing in the eastern Pamirs syntaxis. According to sedimentary formation, metamorphism, ore-bearing potential and isotope dating, we disassemble these high pressure rock association (metamorphosed in 220Ma) which is composed of granulite, spinel olivine, garnet pyroxenolite from Bulunkuole Group, belong to the part of Kangxiwar tectonic mélange; The rock series of alterative volcanic rock folding alterative detrital rock (age is 522Ma) belongs to Ordovician. In fact, the Bulunkuole Group is composed of alumina rich gneiss and schist, gneiss and schist folding quartzite and griotte, schist and calc-silicate rock folding metavolcanite and iron ore depsits from bottom to top, and it is intruded by early Palaeozoic (506-542 Ma) acidic to intermediate rocks. There are four peak values of age region: 2.7-2.1Ga, 1700-554Ma, 536-344Ma and 302-230Ma in age frequency diagram according to 127 isotope data of detrital zircon (Fig 1). The zircons of the first peak value (2.7-2.06Ga) show the characteristic of magmatic origin, the others were metamorphic origin(or recrystallization). In consequence, the Bulunkuole Group should formed in Paleo-Mesoproterozoic (from 2.14-2.06Ga to 1.14Ga).

Effects of melt percolation on platinum group elements and Re-Os systematics of peridotites from the Tan-Lu fault zone, eastern North China Craton

YAN XIAO AND HONG-FU ZHANG

Institute of Geology and Geophysics, Chinese Academy of Sciences (xiaoyan@mail.iggcas.ac.cn, hfzhang@mail.igcas.ac.cn)

Concentrations of PGE and Re-Os isotopic compositions were determined for a suite of variably metasomatised peridotite xenoliths from Cenozoic Beiyan volcanoes within the Tan-Lu fault zone, eastern North China Craton. The majorities of Beiyan peridotites have flat chondrite-normalized PGE patterns whereas their total PGE contents range between 0.97 and 61.4 ppb, which was reduced by more than 90% from lherzolite, cpx-rich lherzolite to wehrlite, probably because intergranular sulfides were completely removed by silicate melt. Meanwhile, Beiyan peridotites have low and variable Re (0.0002-0.5118ppb) and Os (0.194-10.4ppb) abundances and high $^{187}Os/^{188}Os$ (0.12167-0.14978) ratios. The $^{187}Os/^{188}Os$ ratios in some wehrlites are much higher than the value of the primitive mantle. The high $^{187}Os/^{188}Os$ ratios have also been observed in peridotites found in other localities within the Tan-Lu fault zone such as Shanwang and Nüshan. This could be the result of the addition of radiogenic Os during the melt percolation. Extremely low Os abundances in Beiyan peridotites suggest that Os may behave as an incompatible element during melt percolation and could mobilize with the dissolution of sulfides. The suprachondritic $^{187}Os/^{188}Os$ ratios in peridotites within the Tan-Lu fault zone relative to those away from the Tan-Lu fault zone indicate that the Tan-Lu fault zone as a melt infiltrating channel had played an important role in the radiogenic Os enrichment induced by the melt percolation. This could be the reason for the Os isotopic heterogeneity observed in eastern NCC.

Octanol-water partition coefficient (K_{OW}): Is it a good measure of hydrophobicity of nanoparticles?

Y. XIAO AND M. WIESNER*

Duke University, Civil & Environmental Engineering, Durham, NC 27708, USA (*correspondance: weisner@duke.edu)

Hydrophobicity, as one of the key properties of NPs, plays a significant role in the fate, transport and bioavailability of NPs. Octanol-water partition coefficient (K_{OW}) is a traditional measure of hydrophobicity of organic compounds, and has been recently applied to NPs. However, due to the larger size, NPs may not diffuse freely between the phases, which may undermine the fundamental assumption of the application of K_{OW}. Based on thermodynamic models, we hypothesize: (1) partitioning of NPs is controlled by both hydrophobicity and size; (2) amphiphilic NPs with larger size are more likely to stay at the liquid-liquid interface rather than in the bulk phase.

We conducted the K_{OW} measurement using shake-flask method for seven different NPs in aqueous suspensions, including aqueous C_{60} (aqu-C_{60}), tetrahydrofuran-C_{60} (THF-C_{60}), fullerol, nano-gold coated with citrate (Au-Ci), nano-silver coated with PVP (Ag-PVP), citrate (Ag-Ci) and gum arabic (Ag-GA). The hydrophobicity of these NPs was determined in Rose Bengal adsorption experiments. According to our results, the NPs that exhibited greater hydrophobicity showed larger K_{OW}. We also measured the K_{OW} of Au-Ci and aqu-C_{60} NPs aggregates with different size (10 ~ 100 nm). Our results showed that as size increased, K_{OW} of aqu-C_{60} increased, however, K_{OW} of Au-Ci was not dependent on size. Dark field microscopy revealed that Au-Ci NPs with size less than 30 nm mainly remained in bulk water phase; while the majority of Au-Ci NPs with size around 100 nm were accumulated near the water-octanol interface. These results may be due to the amphiphilic property (K_{OW}=0.38) and larger size of Au-Ci NPs, which might elevate the attachment energy of particles to the interface and consequently the attachment became irreversible. Overall, our study demonstrated that size, in addition to hydrophobicity, is an important factor to determine the partitioning of NPs. The current application of K_{OW} as a measure of hydrophobicity for NPs is inherently flawed and needs further investigation.

Li isotopic composition of subduction-related leucogranites: Source tracking and tectonic implications

YILIN XIAO,[1]* LIJUN XU[1], YONGJUN GAO[2], SHUGUANG LI[1], HE SUN[1] AND HAIOU GU[1]

[1]School of Earth and Space Sciences, University of Science and Technology of China, Hefei, 230026, China (ylxiao@ustc.edu.cn)

[2]Department of Earth and Atmospheric Sciences, University of Houston, Houston, TX 77204, USA

We report lithium (Li) elemental and isotopic data for a suite of leucogranitic and gneissic rocks (presumed protolith of the leucogranites) from the boundary between the North China craton (NCC) and the South China plate (SCP), which represents an important repository for understanding the Mesozoic thinning processes of the NCC. The leucogranites have very low Li concentrations (around 1-8 ppm) but extremely heavy isotopic compositions (from 8.6 to 16.1). Overall, Li concentrations and isotopic compositions of the leucogranites are different from those of associated rocks from adjacent areas, including granites (δ^7Li =2.7-3.8) and gneisses (δ^7Li = 0.8-6.5) from North Dabie, garnet-bearing gneisses (δ^7Li =2.2-4.2) from South Dabie, as well as those of their host rock–the Archean gneisses (δ^7Li =-0.6 to 0.0), but are similar to those of garnet-bearing gneisses (δ^7Li =1.2- 22.5) from the Sulu area. Based on Li isotope data, with the combination of mineralogical (e.g., garnet) and other geochemical data, we suggest that the leucogranites resulted from the partial melting of the subducted gneisses from the Sulu area. Such an observation is very important for providing constraints on the subduction direction of the SCP during the Triassic UHP metamorphic event.

Trace element redistribution in oceanic crust during subduction-zone metamorphism – Evidence from Western Tianshan, China

[3]Tianjin Institute of Geology, China (tjlhuaikun@cgs.gov.cn; tjwhuichu@163.com);

[4]Northwest University, China (xmliu@nwu.edu.cn)

Constraining the geochemical consequences of subduction-zone metamorphism (SZM) is important for understanding subduction-zone magamism, crustal growth and the origin of mantle compositional heterogeneity. For this purpose, we have conducted a detailed trace element study on ultra-high pressure metamophic (UHP) rocks of both basaltic and sedimentary protoliths from Western Tianshan, China using *in situ* LA-ICP-MS.

We found that during SZM, phengite, and to a lesser extent, paragonite, are major hosts of all the Ba, Rb and Cs. Paragonite also hosts some Sr and Pb. Epidote group minerals host 95% of LREEs, Th, U, Pb and Sr, 60% of MREEs and 30% of HREEs. Garnet preferentially hosts HREEs relative to progressively lighter REEs. Rutile and titanite host essentially all the Ti, Nb and Ta. Titanite also hosts some Sr, Pb and REEs. Retrograde albite can host some Sr and Ba. Glaucophane and (sodic-)calcic amphiboles, omphacite and chlorite contain very low contents of these incompatible elements (except Li). In addition, analyses of coexisting paragonite and clinozoisite, preserved as lawsonite pseudomorphs in garnet, show $Kd^{clinozoisite/paragonite}$ for Pb and Sr to be ~ 20 and 4-10 respectively.

Because lawsonite, epidote, garnet, titanite and rutile are stable over a large P-T range during SZM and can exchange REEs, Th, U and HFSEs among each other, these elements are largly redistributed in the newly-formed minerals without significant loss from the system, explaining their relatively immobile nature. Sr and Pb may have been mobilized as shown by their decrease towards rims of prograde clinozoisite, which is also consistent with the insignificant correlations of bulk-rock Sr and Pb with immobie HFSEs. Ba, Cs and Rb are mobile in rocks of basaltic protolith and could have been re-enriched by late infiltrated fluids (e.g., some retrograde mica crystals have very high Ba, Cs and Rb), whereas these same elements may be immobile in rocks of sedimentary protolith, reflecting stronger protolith controls on elemental behavior.

Mobilization and re-distribution of major and trace elements during extreme weathering of basalt in Guangzhou Province, South China

XIAO ZHONGFENG[1,2] AND ZHAO XIMEI[1,2]

[1]Shandong Provincial Key Laboratory of Eco-Environmental Science for Yellow River Delta, Binzhou 256603, China (xzfazxm@163.com)

[2]Binzhou University, Binzhou 256603, China

Chemical weathering is one of the most important processes that change the chemical composition of the Earth's surface. Weathering products are easily carried out of weathering profiles and deposited in lakes and oceans as the main lithogeneous component in sediments. Therefore, the mobilization and re-distribution of elements during chemical weathering may influence the chemical composition of sediments. Generally, sedimental compositions can be used to trace the provenance of sediments and to reconstruct paleoclimate record [1]. Comprehensive understanding of the behavior of elements during chemical weathering may help to better explain the records found in sediments(Ma et al, 2007; Wei et al, 2004)

Major elements of a laterite profile developed on Neogene basalts in Guangzhou Province, South China were reported in this study. The results indicate that most of the elements have been mobilized and transferred downwards along the profile by aqueous solution. conservative elements during incipient chemical weathering, such as Fe, Ti, Zr, Hf, Nb and Ta, the removals are up to 25–43% in the upper profile. Al, Mn，Ti were significantly enriched in the middle (2-3m) profile, this may indicate there has an paleo-water level. All the REEs are remarkably enriched in the middle and the lower profile.

All the characters of the maior and trace elements are similar as it in the weathering profile of basalt in Hainan island mentioned in Ma *et al*. (2007). These may indicated that the basalt in south China underwent the same process of weathering conditions.

Impact of water-level fluctuations on concentration trends of petroleum contaminants in pipeline leakage area

SU-XIAOSI[1,2] ,WANG-WEI[1,2]* AND ZHENG-ZHAOXIAN[1,2]

[1]Key Laboratory of Groundwater Resources and Environment, Ministry of Education, Jilin University, Changchun, 130021, China (*correspondence:wangwei_wangwei@126.com)

[2]Institute of Water Resources and Environment, Jilin University, Changchun, 130021, China

Overview of Case Study

Monitored natural attenuation is one of the most commonly used remediation technologies which means that groundwater contamination was reduced to safety range by the effect of natural degradation and dilution. In typical area of certain oilfield of china, after the leakage oil cleaning up□most of the high level contamination areas ofgroundwater are at pipeline leakage site and sewage infiltration area. Detected from continuous 12 months monitoring, the TPH□Total petroleum hydrocarbons□ concentration of groundwater show tow types of correlation with water-level fluctuations. Firstly, at the border of pollution plume, water-level fluctuations are positive correlation with TPH concentrations that as the water level raises, The TPH concentration increases in January to June. Secondly, at the middle of pollution plume, water-level fluctuations were always positive correlation with TPH concentrations during the whole monitoring period.

Discussion of Results

The monitoring results show that attenuation of petroleum hydrocarbon contamination did not show a simple exponential or linear law with water-level fluctuations [1]. These results demonstrate that the TPH concentration at the high level (0.1-0.2mg/l), convection-dispersion is main process of monitored natural attenuation, and it is affected by water-level fluctuations significantly. Meanwhile at the low level (0.1-0.2mg/l),adsorption and biodegradation are the main process, which shows Linear attenuation characteristics. All the results indicate that in the study area, if the petroleum hydrocarbon contamination is higher than threshold (0.1-0.2mg/l), it would be appropriate to apply active remediation projects to local groundwater remediation, when lower than the threshold monitored natural attenuation will be more suitable.

Granitic porphyry dykes in the Qitianling batholith, Hunan Province, South China: Evidence for the multistage mineralization

LEI XIE*, RUCHENG WANG, JINCHU ZHU AND WENLAN ZHANG

State Key Laboratory for Mineral Deposits Research (Nanjing University), School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China (*correspondence: xielei@nju.edu.cn)

The Qitianling Sn deposit, Hunan Province, China, is famous for its super-large reserves. Two granitic dykes enriched in Sn at Qitianling are subvolcanic counterpart of Sn-bearing granites. Textural relationships provide evidence for a quenched silicate melt with phenocrysts, consisting of albite, quartz, K-feldspar, and zinnwaldite. The porphyry tin deposit arises from abundant cassiterite and rutile enriched in W and Nb. An affinity with Qitinaling (amphibole-) biotite granites arises from the geochemistry and their compositions are quite similar to each other. It is highly evolved, strongly peraluminous and enriched in W, Sn, Nb, Ta, Li and F. The melt belongs to the residual melt throughout the fractional crystallization. Analyses of zircon proved the high evolution of the source. Different textures of cassiterite grains provided the magmatic and hydrothermal process. The result of geochronological work shows the zircon U-Pb age of the dyke of 147.15 ± 0.45 Ma, providing that it belongs to the third stage of Qitinaling magmatism. The formation of a porphyry tin deposit is believed to be one of the last events at Qitianling. This super hypabyssal intrusive mass contains cryptoexplosive breccia. The occurrence at depth of a hidden granitic body could be the source of the granitic dykes. Therefore the fine-grained Qitinaling felsic dykes is appropriate recorder for the concealed granitic body and mineralization. The late-stage mineralization related to the fine-grained granitic dyke is believed to be distinguished important in the multi-stage mineralization.

Response of Antarctic Intermediate Water to weaker Atlantic Meridional Overturning Circulation during the last deglaciation

RUIFANG XIE[1]*, FRANCO MARCANTONIO[1] AND MATTHEW W. SCHMIDT[2]

[1]Texas A&M University, Department of Geology and Geophysics, MS 3115, College Station, Texas 77843 (*correspondence: xie_1984@tamu.edu, marcantonio@geos.tamu.edu)

[2]Texas A&M University, Department of Oceanography, MS 3146, College Station, Texas 77843 (schmidt@ocean.tamu.edu)

The modes of ocean circulation in response to climate change have been a subject of intense interest. During the last deglaciation, cold periods such as the Younger Dryas (YD) and Heinrich 1 (H1) are thought to be coincident with significant reductions in North Atlantic Deep Water (NADW) formation. Yet, the role that Antarctic Intermediate Water (AAIW) played during these cold events is still poorly constrained. Benthic Cd/Ca data from sediment cores in the Florida Straits suggest a reduced contribution of AAIW in the North Atlantic western boundary current during the YD [1]. However, ε_{Nd} evidence in sediment cores from Tobago basin and Brazil margin suggests a greater influence of AAIW in the North Atlantic during YD and H1 [2].

In this study, we measure Nd radiogenic isotope ratios of the authigenic Fe-Mn hydroxides in two sediment cores, KNR166-2-26JPC (546 m water depth) and KNR166-2-31JPC (751 m water depth), within the Florida Straits in an effort to investigate the waxing and waning of AAIW during the last deglaciation. Both cores are located within the Florida Current, which under modern conditions represents a mixture of recirculated North Atlantic subtropical gyre water and Southern origin waters. Our preliminary results for both cores show significantly less radiogenic ε_{Nd} values during the YD than during the Holocene (~1 epsilon unit for 26JPC and ~0.6 epsilon units for 31JPC). We interpret the lower ε_{Nd} during the YD as signifying a decreased input of Southern-sourced waters arriving at these sites, in agreement with the study of Came et al.[1]. Additional high-resolution Nd isotope analyses of Florida Straits sediments deposited during earlier Heinrich Events and the Last Glacial Maximum will be presented in an effort to constrain the role of intermediate waters during periods of reduced NADW formation.

According to the survey on water quality, hydrology, geography of ShaYing River, water pollution situation is analyzed. Aiming at this serious problem, the present situation of water pollution is analysed, the decision support system of ShaYing River water pollution control is analyzed completely and studied. From the standpoint of development process, functional design, framework and modularization design, using GIS technology and object-oriented programming language Visual Basic, the system with visual interface is exploited with MapObjects of GIS and database. Intelligent management of ShaYing River water pollution control come true, the system achieves functions of inputting information , treating data , searching information, thematic maps, water quality evaluation and water quality prediction, which can help data management, searching and assistant decision for water environment. It will provide a powerful tool and intelligent decision information for ShaYing River's water environment management in the future.

The geochemical characteristics of the Mashan complex, Guangxi, and its geological implications

Z. XIE*, B. WANG, J.F. CHEN AND Z. LI

School of Earth and Space Sciences, University of Science and Technology of China, Hefei, 230026 (*correspondence: zxie@ustc.edu.cn)

Previous Nd isotope studies about the Mesozoic granitoid intrusions in South China suggested that some bodies formed a southwest-northeast belt with low Nd model ages (T_{DM}) in range of 1.7-1.2 Ga, lower than those of adjacent intrusions. It is also suggested that their magma sources and formation progresses should be related to the crustal extension and asthenosphere upwelling.

The detailed geochemical and geochronological studies about the Mashan complex, Guangxi suggest one possibility that the the magma source of the low T_{DM} intrusions was derived from the partial melting of the Neoproterozoic juvenile mantle. The complex includes diabase porphyrite, diorite porphyrite, syenite porphyry, quartz-syenite porphyry and granite porphyry. Their zircon SHRIMP U-Pb ages are in range of 154-148 Ma, indicating that the complex was formed in a short time. The major and trace element compositions of these rocks suggest that they were derived from one mantle source without Nb, Ta negative anomaly. The $\varepsilon_{Nd}(t)$ of diabase is +2.3, T_{DM}(II) is 0.7 Ga, those of diorite and syenite are +5.9~-+2.6 and 0.7~0.5 Ga, those of quartz-syenite are +0.4 and 0.9 Ga, and those of granitic rocks are -0.3~-2.4 and 1.1~1.0 Ga. The zircon $\delta^{18}O$ of diabase is 6.2‰, that of diorite is 5.7‰, which are close to the mantle value of 5.6‰, however, those of granitic and quartz-syenite are 7.2‰ and 7.5‰, respectively, suggesting that the quzrtz-syenite and granites were slightly contaminated by crustal rocks. The zircon Hf model ages of the grains with ages in 160-140 Ma are mainly in range of 1500-600 Ma calculated by felsic crust, and form a peak value at 1000 Ma.

It is conlcuded that the complex was derived from the partial melting of juvenile lithosphere mantle formed in the Neoproterozoic, triggered by the lithosphere extension and asthenoshphere upwelling. After that, the magma was experienced strongly fractional crystallization. However, the granitic magma was contaminated by crustal materials, which may differentiated from the mantle during the Neoproterozoic and remelted in about 175-160 Ma. It should not be ruled out the contribution of the asthenosphere to the basic rocks.

This study is supported by funds from the Natural Science Foundation of China (40873002, KZCX2-EW-QN508).

Rare earths are relatively abundant in the Earth's crust, but discovered minable concentrations are less common than for most other ores. China, the United States, Russia, India, Malaysia and Brazil constitute the largest percentage of the world's rare earth economic resources. The REE deposits in China are mainly related with carbonatite-alkaline complexes, weathered granite and placer (Fig. 1). The Bayan Obo is largest LREE deposit in the world, and its reserves are more than 13500 Mt. LREE deposits in carbonatite-alkaline complexes from Panxi region (West China) and Miaoya (Central China) are also large. The weathered granite-type REE deposits in South China are characterized by REE, especially HREE adsorption in clay minerals. The origin of Bayan Obo deposit is disputed, including carbonatite magmas, sediment, and carbonatite-derived fluid mixing sediment [1]. Studies suggested that the anomaly high REE compositions in mantle source and mineral fractional crystals and carbonate cumulate processes are key cases for the REE deposit formation related with carbonatite-alkaline rocks [1, 2]. The weathered REE deposits in South China were formed by leaching granites, and REE adsorbed by clay minerals. The precondition requires the granites contain abundant REE minerals. But how the granite can produce the primary REE minerals is not clear. Granite is quite normal rock in world, but not all of them can supply sufficient REE for mineralization. It is necessary to study the primary granite magma type REE deposits.

Re-Os geochronology of black shale from the Barents Sea: Refining the Triassic time scale

G. XU[1,2], J.L. HANNAH[1,2], H.J. STEIN[1,2], A. MØRK[3,4], B. BINGEN[2] AND B.A. LUNDSCHIEN[5]

[1]AIRIE Program, Colorado State University, Fort Collins, CO 80523-1482 USA (Guangping.Xu@colostate.edu)

[4]Norwegian University of Sciences and Technology, NO-7491 Trondheim, Norway
[5]Norwegian Petroleum Directorate, NO-4003 Stavanger, Norway

Stage boundaries in the currently accepted Triassic time scale differ by as much as 8 Ma from those in a proposed "alternate" Triassic time scale [1]. Re-Os isochron ages combined with biostratigraphy for black shales from Kong Karls Land, Spitsbergen, and Svalis Dome in the Barents Sea help resolve these differences.

Drill core samples of black shales of the upper Ladinian Botneheia Formation next to the Kong Karls Land (easternmost Svalbard archipelago) [2], inferred to be near the Ladinian-Carnian boundary, yield a precise Model 1 Re-Os isochron age of 239.2 ± 0.4 Ma. Another section from 8 meters deeper in the same drill core yields a less precise but nominally younger age of 237.1 ± 2.3 Ma, though the two ages overlap within uncertainty. The black shale section from a nearby drill core [2], inferred to be the Carnian Tschermakfjellet Formation, yields a Model 1 age of 228.9 ± 1.4 Ma. In a previous study at Svalis Dome in the Barents Sea [3], a Re-Os isochron age of 239.3 ± 2.7 Ma was determined for the Botneheia Formation, shown by palynology to be uppermost Anisian. Together these results suggest a very short duration for the Ladinian Stage (a few million years), and support the "Alternate Time Scale for the Triassic" proposed by Ogg et al. [1], where the Ladinian Stage is from 240.5 to 236.8 Ma.

Our results affirm the utility of the Re-Os chronometer for dating black shales and correlating paleogeographically separated regions in absolute time.

Nickel hydroxide, $Ni(OH)_2$, belongs to the CdI_2-type, layered hydroxide family $M(OH)_2$ (M = Mg, Ca, Ni, Co, etc.) and is of interest from the crystal-chemical viewpoint, as it provides a model structure for studying hydrogen-mediated interatomic interactions. $M(OH)_2$ phases are also interesting for studying Earth's deep water cycle. Though uncommon in the deep Earth, they are present as component units in the structures of many hydrous minerals (such as hydrous magnesium silicate phase E), which are potential hosts for water in the mantle. In addition, $Ni(OH)_2$ is a cathode material in Ni-based rechargeable alkaline batteries. Thus studying the structure and stability of $Ni(OH)_2$ at various conditions is of significance both geologically and for its practical applications.

In this study, using *in situ* time-of-flight neutron and energy-dispersive synchrotron X-ray diffraction, we have examined the structure and stability of nickel hydroxide at temperatures up to 623 K and/or pressures up to 8 GPa. To avoid the large incoherent scattering of neutrons by hydrogen, a deuterated sample $Ni(OD)_2$ was synthesized and used for neutron experiments. For synchrotron experiments, both $Ni(OH)_2$ and $Ni(OD)_2$ were measured, allowing studying the H/D isotopic effects. Rietveld analysis of neutron data and peak fitting of synchrotron patterns allowed determination of coefficients of thermal expansion, bulk moduli and other thermoelastic parameters. Moreover, the atomic positions and atomic displacement parameters, particularly of D, have been obtained, and the role of hydrogen-mediated interatomic interactions in the mechanisms of compression, thermal expansion and phase stability of nickel hydroxide are discussed. These results are also compared with those of other $M(OH)_2$ phases to determine the structural and stability systematics of the $M(OH)_2$ family.

Recycling of lower continental crust in an intra-continental setting: Mineral chemistry and oxygen isotope insights from websterite xenoliths in the North China Craton

W.L. XU[1,2], Q.J. ZHOU[1], F.P. PEI[1], D.B. YANG[1], S. GAO[2], W. WANG[1] AND H. FENG[1]

[1]College of Earth Sciences, Jilin University, Changchun 130061, China (xuwl@jlu.edu.cn, perplesky@126.com, peifp@jlu.edu.cn, yangdebin@jlu.edu.cn, wangwei@jlu.edu.cn, hfeng@263.net)
[2]State Key Lab of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China (sgao@263.net)

A suite of websterite xenoliths entrained by the Early Cretaceous Feixian basalts in the eastern North China Craton provide direct evidence for recycling of dense lower continental crust in an intracontinental setting. Petrographic observations indicate that olivines within the xenoliths are replaced by orthopyroxenes, which in turn are replaced by clinopyroxenes. The $\delta^{18}O$ values of olivines from websterite xenoliths vary from 7.1 ‰ to 7.6 ‰ (±0.4‰, 2SD). The Ni contents of the orthopyroxenes and clinopyroxenes in the websterites are much higher than those of mantle-derived harzburgite and lherzolite xenoliths within the Early Cretaceous high-Mg diorites, and of phenocrysts within the Late Cretaceous basalts. Clinopyroxenes in the websterite xenoliths have high $^{87}Sr/^{86}Sr$ ratios (0.70862–0.70979). These findings, together with high initial $^{86}Sr/^{87}Sr$ ratios (0.70977–0.70990) and low Nd(t) values of the host basalts (–13.1 to 13.4) [1], indicate that the melt, which modified the lithospheric mantle, could be derived from partial melting of the delaminated eclogitic continental crust. Therefore, our study shows that the intracontinental recycling of lower continental crust is a key factor not only to result in chemical and isotopic enrichment in the subcontinental lithospheric mantle [2], but also to result in compositonal variations of intracontinental basalts [1, 3].

Geochemistry and petrogenesis of the Carboniferous-Permian granitic magmatism in Tianshan, Northwestern China

XUE-YI XU[1], HONG-LIANG WANG[1,2], PING LI[1], JUN-LU CHEN[1] AND WANG NING[1]

[1]Xi'an Center of Geological Survey (Xi'an Institute of Geology and Mineral Resource), CGS, Xi'an, Shanxi 710054, China

[2]State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi'an, Shanxi 710069, China)

The Carboniferous-Permian grantic magmatism developed strongly in Tianshan orogenic belt , which are composed of various rock types in diversified geodynamic settings. It not only concludes diorite, monzogranite, tonalite, plagiogranite of calc-alkaline series, but also syenite, quartz syenite, albitophyre of alkaline series. Via comparison of petrogenesis, geochemistry, and magma- processes of granitic rocks , the granitic rocks related to different tectonic units can show that the granitic rocks formed during the period of Carboniferous-Permian are mainly calc-alkali series. The Carboniferous-Permian granitic rocks developed in Eastern Tianshan and Bogda rift zone, containing more MgO, TiO_2, Na_2O and less K_2O, Nb, and Th than the granitic rocks developed in ancient micro-terrain and its edge, means a different source. The granitic rocks in the rift zone formed by the mixing processes of the crust and mantle, containing different degrees of crust-derived components, usually are closely related to intermediate-acid volcanics. However, the granitic rocks developed in ancient micro-terraint mainly show strong information about crust source. The chemical composition of granitic rocks formed in the same tectonic settings but developed in different regions also is different. For example, the Tomor Peak granitic rocks developed in Western Tianshan, and the Kuruktag granitic rocks developed in the south of Central and Eastern Tianshan are all formed by crust source. But the former rocks possesses more Mg, K, Nb, Sr and less Zr, Ba than the latter. This shows some differences of crustal components added in Eastern Tianshan and western sections. Moreover, the positive εNd value of granitic rocks developed in the study region may be caused by partially melting of mantle-derived volcanic rocks.

Geochemical characteristic contrast of heavy metals between sulphide mines and oxide mines

ZHENGQI XU[1,2,*], SHIJUN NI[2], YANGUO TENG[1] AND CHENGJIANG ZHANG[2]

[1]College of Water Science, Beijing Normal University, Beijing, 100875, China (*correspondence: xuzhengq@163.com)

[2]Department of Geochemistry and Nuclear Resource Engineering, Chengdu University of Technology, Chengdu, 610059, China

Sulphide mines have always been the concerns of people because of their various forms and the resultant environmental problems, whereas oxide mines are paid less attention and not studied much because they do not cause obvious environmental problems. However, the potential environmental problems caused by oxide mines can not be ignored. The author chooses Panzhihua V-Ti-Magnetite, a famous oxide mine in China, as the subject of research. The geochemical characteristics of heavy metals in various environmental media (such as water, soil, and atmosphere) during the process of mining are systematically studied by using the above media as research carriers and employing the analyzing methods of ICP-MS and ICP-AES.

The results show that the geochemical characteristics of heavy metals in the sulphide mines and oxide mines have both similarity and difference. The biggest differences are: the content of chalcophile elements in environmental media of sulphide mines is far higher than that in oxide mines; the worst pollution of oxide mines is caused by atmosphere dust and heavy metals, while the worst pollution of sulphide mines is caused by acid mine drainage. The similarity between the two mines is that their morphological features are same.

Moreover, compared with the sulphide mines, the geochemical characteristics of the oxide mines are: it is mainly polluted through atmosphere circulation; its primary pollution medium is lithometeor; its most remarkable environmental problem is heavy metal pollution and geologic disasters. The oxide mine has potential geochemical hazards, which always break out with change of physical and chemical conditions.

Environmental effects of the Zarand coal mines and coal washing plant in Kerman Province, Southeast Iran

ABDOLMAJID YAGHUBPUR AND BAHAREH HAKKAKZADEH

Tarbiat Moallem Univ. 49 Mofateh Av. Tehran , Iran. (ayaghubpur@yahoo.com)

The Zarand coal mines are located 80 Km northwest of Kerman, southeast Iran. The coal seams are situated in a large synclinal structure and the age of the coal based on their fossil contents is late Triassic to early Jurassic. Several openings in this mining area are presently operating with various names such as Pabdana, Babnizu, Khomrud, etc. In the vicinity of the Zarand coal mines there is a coal washing plant that reduces the amounts of coal ash to 10-12 percent. The excess amounts of the ashes are sent to a pool that was constructed near the plant.

At present more than 6 million tons of waste materials are piled up in the dumping areas and the sedimentary basins near the coal washing plant. Every year the amounts of the additional wastes are estimated to be more than 400000 tons.

In this investigation water, soil, mines wastes of the coal washing plant (ancient and recent), coal concentrates, and the coals from various active and abandoned mines were sampled. After accurate sampling, the samples were precisely prepared for laboratory examinations.

The results of different chemical analyses on the waste materials of the coal washing plant indicated that the amounts of As Pb, Cu, Fe, K, Mn, Mg, Ni and Ca are higher than the standard amounts of these elements in the coal mining industries of other parts of the world. The amounts of As, Cu, Fe, Mo, Mn, Pb and Zn are also high in the coal samples of the of the coal mines. The abundance of these elements in coal during mining and coal washing processes could be considered as the source of contamination of soils and water(underground) in the mining areas. So, the water from the wells located in the areas downwards the coal washing plant are contaminated with the several toxic and semi toxic elements and should not be used for drinking purposes.

Direct (U-Th)/He dating of native metals

Relatively quick migration of helium from crystal structures has been known for a long time. However, there is a group of minerals – native metals – where the stability of helium is anomalously high: (a) native metals have the highest volume density, therefore helium migration is hindered in comparison with other minerals; (b) helium, due to its very low solubility in metals, assembles in atomic clusters - "bubbles" of nanometre size. Migration of helium "bubbles" as a whole from the crystal structures needs relatively high temperature near the melting point of metals [1].

Native metals contain ~10^{-7} g/g of uranium in average. Nevertheless, the concentration of radiogenic helium in native metals is sufficient for detection.

In our work we used the following experimental setup: mass-spectrometer complex MSU-G-01-M ("Spektron-Analit", Russia) with a constant magnetic field. The sensitivity of the spectrometer for ^{4}He determination is ~10^{5} atoms. It allows us to reliably detect radiogenic ^{4}He in the samples of microgram weight. The concentration of U was determined by the isotope dilution analysis with ^{235}U tracer. The results of U analyses in parallel aliquots are reproduced within the accuracy of 0.5%. The blank level did not exceed 1 pg of U. Isotopic composition of U was determined on Finnigan MAT-261 multicollector mass-spectrometer.

Due to a strong heterogenity of uranuim distribution in native gold we have performed the measurements of uranium and helium concentrations in a single gold granule. In order to avoid uranium loss during the helium extraction, the gold sample was put in a sealed pumped out quartz tube.

We are going to discuss the first results and draw a conclusion about the possibility of using (U-Th)/He method for the direct dating of native gold and other native metals.

Modeling of the role of organic matter in the carbonate system seasonal changes in the Barents Sea

EVGENIY YAKUSHEV AND KAI SØRENSEN

Norwegian Institute for Water Research, Gaustadalleen 21, Oslo, 0349, Norway, (eya@niva.no)

This work aimed in studying of the role of seasonality of the biogeochemical processes of organic matter production and decay in the seasonal changes of the carbonate system (pH, pCO2, aragonite saturation). Data received at a transect Tromsø – Spitsbergen with a Ferrybox equipped SOOP vessel was used for verification. A 2D simplified vertical model was used to parameterize the hydrophysical processes of at a Coast-Open Arctic section. The biogeochemical processes were parameterized using OxyDep, simplified biogeochemical model aiming time scales seasonal and larger, that considered inorganic nutrient (NUT), dissolved (DOM) and particular (POM) organic matter and biota (BIO). Dissolved inorganic carbon (DIC) and alkalinity (Alk) were considered as independent model parameters. DIC changes were correlated with NUT using Redfield ratio, Alk was changed in the marine boundary of the modeled transect. The carbonate system equilibration was considered as a fast process and calculated at every time step using an iteration procedure. The carbonate system modeling was described on the base of standard approach. According to the model estimates the summer formation of DOC and POC and their further destruction can play a compatible role in the carbonate system seasonal dynamics. Modeled seasonal variations of pH (~0.2) are close to the observed ones t, i.e. 7.94-7.99 in February and 8.04-8.16 in August (pH(Tot)).The received results allowed to demonstrate that the upper layer water pCO2 varies from 480 ppm in winter to minimum values of 280 ppm during the OM production period. Therefore summer invasion of CO2 should be replaced by winter evasion.

Decompression melting in tectonics: Where's the melt?

C. YAKYMCHUK[1], F. KORHONEN[2] AND M. BROWN[1]*

[1]Laboratory for Crustal Petrology, Department of Geology, University of Maryland, College Park, MD 20742, USA (*correspondence: mbrown@umd.edu)

[2]Department of Applied Geology, Curtin University, Perth, WA 6845, Australia

The presence of melt in the continental crust influences tectonics. Using petrogenetic grids and pseudosections for fertile bulk compositions, multiple authors have invoked decompression across hydrate-breakdown melting reactions as an important factor enhancing exhumation and the development of gneiss domes, and in the production of late orogenic granites. However, the amount of melt that can be produced during decompression is strongly dependent on the fertility of the crust at the *T* of interest and the melt generated may be quite small if, as expected, melt is lost each time the melt fraction reaches the melt connectivity transition (MCT) at 7 mol% (~7 vol%). Thermodynamic modeling of an average amphibolite facies metapelite was undertaken in the NCKFMASHTO system using THERMOCALC and the Holland & Powell dataset to investigate decompression across the major melt-producing reactions following prograde heating and episodic melt loss. The modeling places constraints on the quantity of melt that can be produced from progressively more residual rocks during decompression. *P–T* pseudosections were calculated for isobaric heating at 1.2 GPa followed by decompression to 0.4 GPa at 750°C, 820°C, and 890°C. Melt was periodically removed from the system at the *P–T* conditions where the melt fraction reached the MCT (85 % of the available melt is extracted); a new bulk composition was obtained and a new *P–T* pseudosection was calculated. For isothermal decompression at 750°C, the protolith produces ~20 mol% total melt; ~8 mol% melt is produced prior to crossing the field where melting associated with Ms + Qtz breakdown is initiated and Kfs starts to grow, and an additional ~6 mol% is produced at $P < 0.5$ GPa. For isothermal decompression at 820°C, the residual composition produces ~3 mol% melt to 0.6 GPa and another ~13 mol% melt within the Crd stability field to 0.4 GPa. At 890°C, isothermal decompression occurs at ~5°C above the elevated solidus in the most residual composition, which produces ~3 mol% melt. These results demonstrate that integrating melt loss into model *P–T* paths involving prograde heating and suprasolidus decompression yields lower quantities of melt during the decompression segment than commonly invoked. Based on these results, tectonic and petrogenetic models that require decompression melting may need re-evaluation.

Sulfur supplied by basaltic magma injection into the magma feeding system of Asama volcano, central Japan – A melt inclusion study

Y. YAMAGUCHI

Shinshu Univ. Matsumoto, 390-8621, Japan (yoshia_ygutti@d4.dion.ne.jp)

Asama volcano is situated at the junction of the volcanic fronts of the North Japan arc and the Izu-Mariana arc. Most of the erupted materials have andesitic whole-rock compositions. However, previous melt inclusion studies found no sign of primary andesitic melt and revealed that basaltic liquid formed a part of the ejecta [1].

For four eruption events of Asama volcano in the past 23,000 years, I here discuss a large sulfur supply by basaltic magma injections into the Asama magma system, based on microprobe analyses of olivine-hosted melt inclusions from the following eruption events; Itahana Brown Pumice fall (23 ka), Scoria in Komoro Pumice flows (11 ka), 1783 (Tenmei) Pumice fall (1783 AD), 2004 scoria fall (2004 AD).

In the evolution of Asama volcano, basaltic magma is believed to have been repeatedly injected into a long-lived crystal-rich felsic reservoir beneath the volcano [2]. The major phenocrysts (plagioclase, ortho- and clinopyroxene, and Fe-Ti oxides) were principally derived from the felsic magma and trapped sulfur-poor felsic melt inclusions (SiO_2 66-76wt%, S <400 ppm). In contrast, olivine (>Fo_{80}), a rare phenocryst in most cases, was derived from basaltic magma, trapping sulfur-rich mafic melts of basalt-basaltic andesite composition (SiO_2 48-65wt%, S <3600 ppm) before the mixing.

Olivine phenocrysts commonly include crystalline phases of esseneitic ($CaFe^{3+}AlSiO_6$) clinopyroxene, pargasitic amphibole, and a spinel solid solution (magnetite-hercynite-chromite), suggesting a high oxygen fugacity and hydrous conditions of the basaltic magma. Measured S-Kα wavelength shifts for the trapped melt indicate that the dominant sulfur-bearing species is SO_4^{2-} (> NNO + 1), with a corresponding high sulfur solubility in the magma. In most of the trapped melts, however, this primary high sulfur concentration was decreased by extensive early sulfide precipitation and distillation by vapor-boiling before the melt entrapment. High sulfur concentration is recorded in the composition of some pre-boiling, and the most mafic melt inclusions (SiO_2 48-53wt%). Basaltic magmas are expected to transport more than 3000 gram sulfur/tons of magma from the mantle source region into the felsic reservoir beneath Asama volcano.

Noble gas isotopic compositions of mantle xenoliths in a kimberlite

JUNJI YAMAMOTO[1], MARK D. KURZ[2], HIDEMI ISHIBASHI[3] AND JOSHUA CURTICE[2]

[1]Institute for Geothermal Sciences, Kyoto University, Noguchibaru, Beppu 874-0903, Japan (*correspondence: jyama@bep.vgs.kyoto-u.ac.jp)

[2]Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA

[3]University of Tokyo, Tokyo 113-0032, Japan

Oceanic island basalt (OIB) provides an important window into the heterogeneous Earth's interior. The terrestrial inventory of radiogenic noble gas nuclides such as ^{40}Ar implies that the OIB source is less degassed (e.g., [1]). Assuming a K content and $^{40}Ar/^{36}Ar$ of OIB source, we can evaluate non-radiogenic ^{36}Ar content of the source, which enables us to assess the degassing state of the Earth's interior. Mantle-derived xenoliths entrained by OIB magma are potentially useful to consider a pristine feature of OIB magma because the OIB magma might have been captured in a source mantle of the xenoliths during ascent of the magma. Kimberlite is regarded as OIB erupted at continents (e.g., [2]). Mantle xenoliths in kimberlite are often metasomatized by the host kimberlite and could inherit the noble gases.

Here we report noble gas isotopic compositions of nine mantle xenoliths in a kimberlite erupted in Siberia at 380 Ma. The xenoliths are appropriate samples to explore the kimberlite magma because they are well metasomatized by the kimberlite magma. The noble gas isotopic compositions are all dominated by both radiogenic nuclides and atmospheric components. Firstly we corrected the atmospheric contribution to $^{40}Ar/^{36}Ar$ using an assumed relationship with a solar-like end-member of Ne. Then we corrected the effect of radiogenic addition to He and Ar isotopic ratios as follows. Assuming that the mantle xenoliths originally had homogeneous noble gas isotopic compositions, the present radiogenic noble gas isotopic compositions of the xenoliths are mainly caused by subsequent addition of radiogenic nuclides. Thus $^{3}He/^{4}He$ and $^{40}Ar/^{36}Ar$ of nine xenoliths corrected for the radiogenic contribution should converge into the original compositions. Actually, subtraction of ^{4}He and ^{40}Ar from the measured $^{3}He/^{4}He$ and $^{40}Ar/^{36}Ar$ at a rate of measured $^{4}He/^{40}Ar^*$ shows a converged point with $^{40}Ar/^{36}Ar$ of ~1800 and $^{3}He/^{4}He$ of ~50 Ra in a diagram of $^{3}He/^{4}He$ vs. $^{40}Ar/^{36}Ar$. Combination of the $^{40}Ar/^{36}Ar$ with a K content of OIB source will elucidate degassing state and layered structure of the Earth's interior.

Behavior of rare earth elements during chemical alteration of deep granitic rocks at Tono, Central Japan

Y. YAMAMOTO[1]*, Y. TAKAHASHI[2], H. SAKAMI[2], T. MIZUNO[1], K. AMANO[1], K. HAMA[1] AND H. SHIMIZU[2]

[1]Japan Atomic Energy Agency, Gifu 509-6132, Japan (*correspondence: yamamoto.yuhei@jaea.go.jp, mizuno.takashi@jaea.go.jp, hama.katsuhiro@jaea.go.jp, amano.kenji@jaea.go.jp)

[2]Hiroshima Univ., Hiroshima 739-8526, Japan (ytakaha@hiroshima-u.ac.jp, hiro-shim@mm.em-net.ne.jp)

Behavior of rare earth elements (REEs) in deep subsurface (from 85 to 1010 meter below ground level) during groundwater–granite interaction was investigated using chemical analysis of bulk rock and microscopic observation. It was revealed that REEs provide information on chemical alteration of granite even in the early stage of alteration, when the chemical index of alteration (CIA) using major element composition does not reflect the effect. REE patterns of granite with higher phosphorous concentration show a steeper slope in the lighter REE part relative to patterns of granite with lower phosphorous concentration. The relationship between the relative shape of REE patterns and phosphorous concentration suggests that phosphate minerals play a significant role in the release and incorporation of REEs at depth in granite, as they do in the surface environment. Allanite also plays a role as a REE host phase in granite indicated by the similarities in the relative shape of REE patterns, especially those with steep slopes. The steep slope in REE patterns corresponds to fresh granite, whereas the gentle slope in REE patterns corresponds to relatively altered granite in terms of chemical alteration. Change in the REE host minerals as granite alteration progress has an effect on the relative shape of the REE pattern of granite. Slope of REE pattern of granite can be explained using the patterns of accessory minerals. Presence of the accessory minerals and their alteration were also observed by electron microscopic analysis. Our results demonstrate that, during granite alteration, behavior of REEs in deep subsurface depends on dissolution and precipitation of accessory minerals, similar to the behavior in surface environments. REE pattern of granite is sensitive to the early stage of granite alteration, suggesting that the relative shape of REE pattern can be used as an indicator of the weak water–rock interaction in deep subsurface.

D/H exchange of hydrogen on fatty acids

Compound-specific stable isotope analysis of biomarkers has been employed in a number of geochemical studies as a powerful tool to track delivery of organic matter and to reconstruct climates and ecosystems in the geological past. Stable hydrogen isotopic composition of lipid molecules such as fatty acids has been employed as an effective tool to understand modern to paleo environments. In this study, to further evaluate the reliability of hydrogen isotope information (δD) of H-C bounds on organic compounds, we examine the isotope exchanges on fatty acids in phospholipid bilayer of pseudo cell membranes that exposed with 0 to 50% of D_2O at room temperature or 85ºC for 12 hours. Exchange of D/H is the maximum when 50% D_2O is used, in which increase of δD values is between 93 and 328‰. These results indicate that hydrogen isotopes are clearly exchanged even hydrogen on C-H bound in fatty acids and that its magnitude may depend on type of fatty acids (chain-length and unsaturation degree) and state of bilayers (gel vs liquid crystal). Based on these results, we roughly estimated that hydrogen isotopic composition should be change by up to a maximum 0.0099‰ when it is expected in water with enrichment in D by 100‰ for 12 hours.

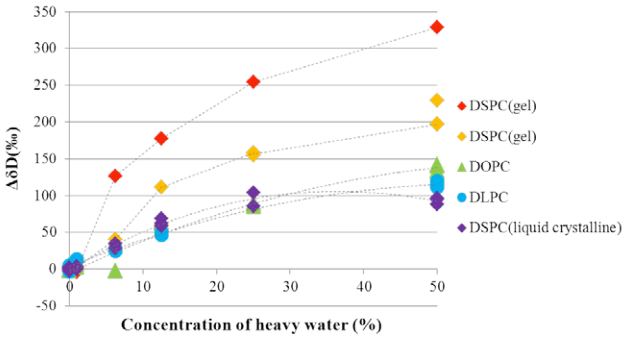

Figure 1: Change in δD value with respect to difference concentration of heavy water.

Pressure-induced phase transitions and electron spin state changes of iron bearing spinels

T. YAMANAKA[1]*, A. KYONO[1], S. KHARLAMOVA[2], V. STRUZHKIN[1], H-K, MAO[1,2] AND R.J. HEMLEY[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC 20015, USA (*correspondence tyamanaka@ciw.edu)

[2]High Pressure Collaboration Access Team, Carnegie Institution of Washington, Argonne, IL 60439, USA

High-pressure phase transitions of iron bearing spinel compounds in the earth crust attract a large attention in order to understand strong electronic correlation such as charge transfer, electron hopping, electron high-low spin transition, Jahn-Teller distortion and charge disproponation in the lower mantle or subduction zone. To prove the Jahn-Teller transition and electron spin state change of Fe_3O_4, Fe_2TiO_4, $FeCr_2O_4$ and Fe_2SiO_4, we executed a series of the diffraction studies of these polycrystalline and single-crystal and X-ray emission study (XES) using DAC and SR facilities at ambient temperature and Raman spectroscopic study under high pressures up to 90GPa.

Fe_2TiO_4 and $FeCr_2O_4$ show the transformation from cubic (*Fd3m*) to tetragonal ($I4_1/amd$) with c/a<1.0 and transform to orthorhombic (*Cmcm*) due to the Jahn-Teller effect of Fe^{2+} ($3d^6$) at the tetrahedral site[1]. The transition to orthorhombic post-spinel structure at high pressures is confirmed in these whole solid solutions. The transition pressures decrease from 27GPa (Fe_3O_4) to 12GPa (Fe_2TiO_4) with increasing Ti content.

XES reveals the spin transition between high spin (HS) and low spin (LP). The transition pressures of Fe_5O_4, Fe_2TiO_4, Fe_2SiO_4 are 22GPa, 18GPa and over 80GPa, respectively. The HP-LP transition induces their structure transitions due to the enormous reduction in iron ionic radius. A new further high-pressure phase (*Pmma*) of Fe_2TiO_4 was found. Rietveld analyses of the powder diffraction data have been conducted and the bulk modulus of each phase was observed.

Boron contents and isotope compositions of oceanic crusts from the Oman and Troodos ophiolites

K. YAMAOKA[1]*, S. MATSUKURA[2], T. ISHIKAWA[3] AND H. KAWAHATA[2]

[1]Geological Survey of Japan, National institute of Advanced Industrial Science and Technology, 1-1-1 Higashi, Tsukuba, Ibaraki 305-8567 Japan (*correspondence: k.yamaoka@aist.go.jp)

[2]Atmosphere and Ocean Research Institute, The University of Tokyo, 5-1-5 Kashiwanoha, Kashiwa, Chiba, 277-8564 Japan

[3]Kochi Institute for Core Sample Research, JAMSTEC, 200 Monobe Otsu, Nankoku, Kochi, 783-8502 Japan

Boron is excellent tracer for elucidating crustal recycling in subduction zones because of the high concentration of boron in the upper part of the slab and the high mobility of boron during dehydration of the slab. However, fundamental data for vertical distribution of boron in hydrothermally altered oceanic crust are still limited. In this study, boron contents and isotopic compositions were determined for complete section of the oceanic crusts in the Oman and Troodos ophiolite.

Although the boron contents of rocks decreased with depth in both the oceanic crusts, altered rocks from deep section showed obvious boron enrichment relative to fresh rocks. The pillow lavas in the Troodos ophiolite, which have been weathered on the seafloor for ~80 Myrs, was highly enriched in boron (>100 ppm), supporting that boron inventory of pillow lava section strongly depends on the crustal age. The $\delta^{11}B$ of rocks in the Oman ophiolite systematically increased with depth and negatively correltate with the $\delta^{18}O$ values, suggesting that the $\delta^{11}B$ values are eccentially controlled by alteration temperature. On the othre hand, the $\delta^{11}B$ profile in the Troodos ophiolite didn't show clear increase trend.

The boron contents for the bulk oceanic crusts of the Oman and Troodos ophiolites are estimated to be 3.6 ppm and 12 ppm, respectively. About 8‰ of $\delta^{11}B$ was estimated for both the bulk oceanic crusts. In contrast to previous views, hydrothermally altered gabbro section can be a large sink of boron. This boron-enriched, high-$\delta^{11}B$ lower oceanic crust may impact on the estimate of the $\delta^{11}B$ value for fluids librated from the subducted oceanic slab, which is believed to largely control the $\delta^{11}B$ values of arc magmas generated in the mantle wedge.

Constraining timing of brittle deformation – A case study from fault zones in Toki Granite, Japan

S. YAMASAKI[1]*, H. ZWINGMANN[2], A. TODD[2], K. YAMADA[1], K. UMEDA[1] AND T. TAGAMI[3]

[1]Tono Geoscience Center, Japan Atomic Energy Agency, 959-31 Toki, Gifu, 509-5102, Japan (*correspondence: yamasaki.seiko@jaea.go.jp)
[2]CSIRO ESRE, Bentley, WA 6102, Australia
[3]Earth and Planetary Sci., Kyoto Univ., Kyoto, 606-8502, Japan

Early studies [e.g. [1]] highlighted the potential for determining the timing of near-surface brittle deformation using isotopic dating of authigenic illites in fault gouge. However, it has remained difficult owing to the possibility of contaminantion. In recent years, precise size separation combined with mineral characterization of gouge samples has demonstrated the suitability of illite K-Ar dating for constraining the timing of brittle deformation [e.g. [2]].

We present K-Ar age data from two gouge samples collected from a fault in the Cretaceous Toki granite, central Japan. The fault occurs sub-vertically along the wall of a shaft, and the minimum age of the fault deformation is estimated as ~20 Ma, as the Miocene sedimentary formation is not displaced by the fault. The samples were collected from the gouge zone at the depth of 252.9 and 403.7 m. The gouge samples were separated into four grain-size fractions (<0.1, <0.4, <2, 2-6 μm) and characterized by XRD, SEM, and TEM.

The fine fractions give younger K-Ar ages, suggesting enrichment in more recently grown authigenic illites. The finest fractions (<0.1 μm) give ages of 46 ±1 and 43 ±1 Ma (±2 sigma). The K-Ar ages of the fractions with no detectable contamination from detrital K-bearing minerals range from 53 to 43 Ma. This range is consistent with the stability field of illite and the main temperature field of brittle deformation (<300°C) within the cooling history of the host granite body of the fault, which was evaluated by apatite and zircon fission-track and K-Ar biotite ages from the host rock.

Effects of pH and coexisting ions on hydrodynamic size of various humic substances evaluated by flow field flow fractionation

Y. YAMASHITA*, S. TANAKA, S. NAGASAKI AND T. SAITO

Department of Nuclear Engineering and Management, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, Japan (*correspondence: yyamashita@n.t.u-tokyo.ac.jp)

Humic substances (HSs) can behave as carriers for heavy metals and radionuclides in soil and aquatic environments. Understanding their molilities is essential for the fate of toxic ions. In the present study, we determined the hydrodynamic properties of the several IHSS standard HSs and evaluated the effects of pH and coexisting ions on their sizes by flow field flow fractionation (Fl-FFF) that provides a continuous and less-invasive size fractionation under wide ranges of chemical conditions.

We used the asymmetrical Fl-FFF system (AF2000 FOCUS, Postnova Analytics) with a UV-VIS detector at the wavelength of 255 nm and a fluorescence detector at the excitation/emission wavelength of 255/475 nm to obtain the fractogram of HSs.

Fig shows the fractrgrams of Suwannee river humic acid (SHA) and Elliot Soil humic acid (EHA) at pH 9.1, 7.0 and 5.5, respectively. SHA shows monomodal fractograms at all pH investigated. In addtion, the modal hydrodynamic diameters of SHA at both pH 5.5 and 9.1 are larger than that at pH 7.0, indicating that the intramolecular electrostatic repulsion between their deprotonated functional groups causes the expansion of SHA molecules at the basic condition, while intermolecular coagulation occurs at the acidic condition because of a decrease of the negative charge. On the other hand, EHA exhibits the bimodal size distributions at pH 7.0 and 5.5. This implies that some fractions EHA can easily coagulate by a pH decrease and that others hardly coagulte. We will present the pH-dependent fractograms of other HSs together with the effects of mono-, di- and trivalent cations.

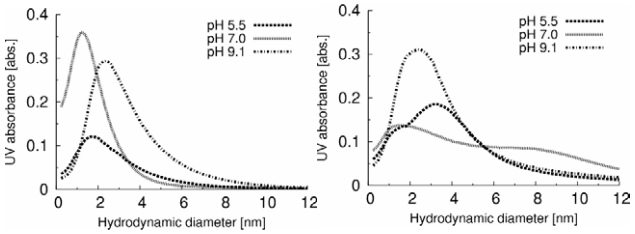

Figure 1 The fractgrams of SHA and EHA at various pH.

Sn isotopes was proposed to verify recycling of bronze products[1]. In order to evaluate recycling by Sn isotopes, we need an assumption that raw materials of tin ore (cassiterite) have uniform Sn isotopic composition independent of regional differences. Recently, Haustein *et al*.[2] reported a series of Sn isotopic data for cassiterite samples and observed the largest significant variation of the isotopic composition (about 0.6 ‰ per mass). In this study, we investigated the variation of Sn isotopic compositions for cassiterite samples mainly in Japan. Prior to this challenge, we developed a new method to decompose cassiterite samples[3] and analyze their Sn isotopic compositions.

We analyzed 7 cassiterite samples from Japanese deposits and one cassiterite from Peru. And we found a linear correlation that follow a mass dependent fractionation in the cassiterite samples. Sn isotopic variation in Japanese cassiterites was limited to be within ±0.16‰ per mass. Such an isotopic fractionation presumably reflect differences in mineralization environment of cassiterite, such as precipitation processes and redox reactions. However, the classification of deposit types and Sn isotopic ratio seem to have no correlation. Therefore, more information is required to explain the observed Sn isotopic fractionation in cassiterite. On the other hand, in our preliminary experiments, bronze artifact from China shows fractionation of ±0.7‰ per mass [3], which exceeds the range of mass fractionation observed in the cassiterite samples. Therefore, Sn isotopes might be useful in detecting recycling. We are also planning to analyze these bronze artifacts again and to verify isotopic fractionation.

The author thanks Dr. Shunso Ishihara for providing cassiterite samples.

Paleoenvironmental reconstructions of the Yangtze Sea, South China, through the Ordivician and Silurian transition

YAN DETIAN

Key Laboratory of Tectonics and Petroleum Resources of Ministry of Education, China University of Geosciences, Wuhan 430074, China (*correspondence: yandetian@cug.edu.cn)

The Yangtze Sea covering the Yangtze Craton in the South China received deposits mainly of black shale, with some shell limestone interlayers during the Late Ordovician and Earily Silurian periods [1]. Sedimentary facies and isopach data indicate that several highlands, either emerging or submerging, developed in the Yangtze Sea. Both Chemical Index of Alteration (CIA) and Chemical Index of Weathering (CIW) changes indicated a moderate chemistry weathering in the Late Ordovician under cold and dry climate, and suggested a peri-glacial period [2]. Before and after the peri-glacial period, climate of the Yangtze Sea was characterized by warm and humid condition [3, 4].

A series of geochemical data implied that deep water mass above the submerging highland differed from shallow water mass in redox. The deep water mass, represented by samples from the Wangjiawan section located in Yichang, was characterized by reduction with DOP > 0.45 and FeHR/FeT > 0.38 in most time of the Late Ordovician to Early Silurian, excepting in the peri-glacial period that showed an oxidation with DOP <0.45 and FeHR/FeT < 0.38. On the other hand, the shallow water mass, represented by samples from the Sanjiaguan section located in Yichang, was characterized by oxidation with DOP <0.45 and FeHR/FeT < 0.38, quite similar to that of the deep water in the peri-glacial period.

The $\delta^{13}C$ of sedimentary organic carbon data showed positive excursion in the peri-glaical period in both deep and shallow water sections [5]. It might reflect the "high-low-high" changes in organic productivity. It is the high organic productivity and reduction of the deep water that have promoted deposition of hydrocarbon source rocks in the Yangtze Sea, South China.

(*correspondence: S.Peiffer@uni-bayreuth.de)

Denitrification coupled to pyrite oxidation is a major process that has been observed in many groundwater aquifers, although a direct reaction between nitrate and pyrite could not be detected [1, 2].Our understanding of the mechanisms of this redox process is, however, still limited. Since Fe(III) is detected as a well-known oxidant for pyrite in the presence of oxygen even at neutral pH [3], we postulate that electron transfer is being mediated through this reaction also in the presence of nitrate as terminal electron acceptor. Microbial catalysis by bacteria, such as Fe(II) oxidizing or sulfide reducing bacteria, is considered to affect the denitrification and pyrite oxidation rates significantly. Therefore, bacteria are supposed to simulate the electron transfer from pyrite to nitrate.

The goal of the work is to understand the mechanism of the anaerobic oxidation of pyrite coupled to nitrate reduction in anoxic groundwater sediments. To this end batch experiments have been set up in which synthesized pyrite is exposed to nitrate-dependent Fe(II)-oxidizer strain BoFEN1 [4] testing the effect of Fe(II), Fe(III), and ferrihydrite as chemical activators. These batch experiments are separated into abiotic and biotic conditions to individually assess the pure chemical and microbial stimulation. First results from these epxeriments will be presented in this conference.

Effect of soil sand on ^{13}C CP-MAS NMR spectra quality

I.H. YANARDAĞ*, A. FAZ, M.A. MUÑOZ, A. BÜYÜKKILIÇ YANARDAĞ AND R. GALLARDO

Technical Univ. of Cartagena, Sustainable Use, Management and Reclamation Soil and Water Research Group. Cartagena Spain.
(*correspondence: ibrahim.yanardag@upct.es)

Under semiarid climate condition such as Spain, soil consist of low organic matter concentrations therefore low organic compound effects on spectra quality and their organic fraction is often excluded from characterization by means of solid-state ^{13}C NMR spectroscopy **[1]**. That's way quantitative interpretation of such spectra becomes difficult and sometimes impossible. The aim of this study is to compare the effects of soil sand on ^{13}CP-MAS NMR spectra quality soil C mass balance in similar soil, in Albacete region, South-East Spain.

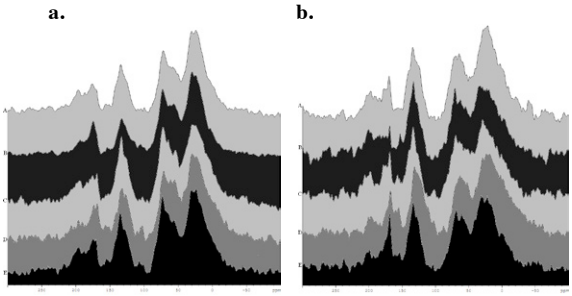

Figure 1. ^{13}C NMR results **a.** with sand **b.** without sand.

The result presented (Figure 1) that there were significantly differences between O-Alkyl, Aromatic and Phenolic groups with removal sand from soil, but this treatment was not significantly effected on Alkyl, Methoxyl and Carboxyl groups in functional groups of organic matter.

Consequently the peaks of NMR spectra became more pronounced with removal of sand from the soil in Aromatic, Phenolic and Carboxyl groups of soil organic matter.

Quantitative exploration of the system $MgCl_2$-H_2O using cryogenic Raman spectrum

YANG DAN[1,2]* AND XU WENYI[1,2]

[1]Institute of Mineral Resources, CAGS, Beijing 100037, China (*correspondence:yangd_2004@yahoo.com.cn)
[2]Key Laboratory of Metallogeny and Mineral Assessment, MLR, Beijing 100037, P.R. China

The fluid is play a very important role in geological processes. With respect to hydrothermal deposits, the composition and nature of ore-forming fluids is the key to understanding the mechanism of mineralization. Raman spectroscopy can not analyze the ions such as Na^{+}, Ca^{2+}, Mg^{2+} and so on, but these ions are common in ore-forming fluids.

In this paper, we obtained Raman spectrum of $MgCl_2$ standard solutions with different concentrations (Fig.1). This experimental condition is rapidly cooling to -180°C and slow warming to observe hydrate formation process (that is manifested as a darkening of the vision in the microscope), and finally, rapidly cooling down to -180°C. Through the analysis of peak parameters, we has founded two quantitative relationships: (1) the peak intensity ratio (I_{3514}/I_{3090} and I_{3401}/I_{3090} and I_{3464}/I_{3090}) and concentration; (2) the total integration area of $MgCl_2$ hydrate peaks (the total integration area of 3401、3464、3514cm^{-1})and the concentration. These findings are important to quantitatively analyze the $MgCl_2$ by Raman spectroscopy in natural inclusions.

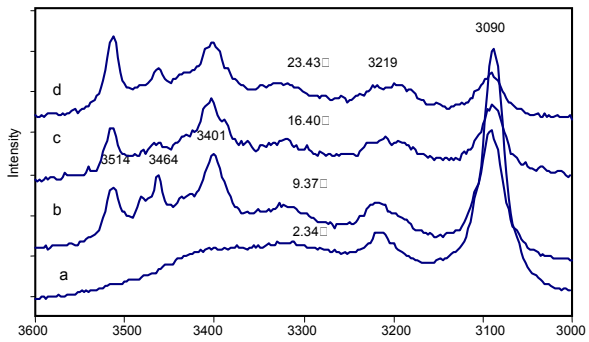

Figure 1 Raman spectrum of $MgCl_2$-H_2O with different concentrations at -180°C(experimental conditions as described in the text; 3401、3464、3514$cm^{-1}$is $MgCl_2$ hydrate peaks, 3090cm^{-1} is ice peak)

Chronology of detrital zircons from Jurassic sandstones in Western Shandong Province, China: Constraints on the nature of the Tan–Lu Fault Zone

D.B. YANG[1,2], W.L. XU[1], Y.G. XU[2] AND F.P. PEI[1]

[1]College of Earth Sciences, Jilin University, Changchun 130061, China (yangdb@jlu.edu.cn, xuwl@jlu.edu.cn, peifp@jlu.edu.cn)
[2]Key Laboratory of Isotope Geochronology and Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China (yigangxu@gig.ac.cn)

It has been controversial when the large-scale sinistral strike-slip of the Tan–Lu Fault Zone occurred, while LA-ICP-MS U-Pb dating data of the detrital zircons from the Jurassic sandstones in the western Shandong Province provides constraints on this issue. The dating results indicate that the detrital zircons from the Early-Middle Jurassic Fangzi Formation in the Mengyin and Zhoucun basins have age populations of 2452, 1950-2050, 1755, 431, 315, 282, 227, 171 Ma, and 2494, 1844, 322, 273, 223, 159 Ma, respectively, whereas ones from the Middle-Late Jurassic Santai Formation in the Mengyin and Pingyi basins are dominated by the 2519, 1883, 277, 191, 150 Ma, and 2558, 607, 181, 137 Ma, respectively. The former suggests that the sedimentary rocks from the Fangzi Formation formed after 159-171 Ma, the latter implies that deposition of the Santai Formation took place after 137-150 Ma. In addition, the detrital zircons with ages of 218-244 Ma (mean=225±3 Ma, MSWD=0.6, n=22) from the Early-Middle Jurassic Fangzi Formation display typical growth zoning and have high Th/U ratios (generally >0.51), suggesting a magmatic origin. These Triassic detrital zircons are in age similar to emplacement ages (205-225 Ma) of post-collisional Shidao complex within the Sulu Orogen. Based on the regional geology, it is suggested that the latter is the only source of the Triassic detrital zircons. Therefore, we conclude that the Sulu Orogen had located in the present position during the Middle-Late Jurassic, i.e., the large-scale sinistral strike-slip movement of the Tan–Lu Fault Zone did not happen in the Early Cretaceous.

Pb, C, H, O and S isotope geochemistry of the Maoping carbonate-hosted Pb-Zn(-Ag-Ge) deposit in Northeast Yunnan province, China

G.S. YANG[1]*, Y. ZHANG[1], R.S. HAN[1,2] AND P. WU[1,2]

[1]Kunming University of Science and Technology, Kunming 650093, China (*correspondence: ygs0080009@163.com)
[2]Kunming University of Science and Technology, Southwest Institute of Geological Survey, Kunming 650093, China

In order to trace the sources of the ore metals and ore-forming fluids of the large-sized carbonate-hosted Maoping Pb-Zn(-Ag-Ge) deposit, Pb, C, H, O and S isotopic compositions of the deposit are presented in this paper.

The Pb isotopic ratios of the ores range from 18.340 to 18.914 for $^{206}Pb/^{204}Pb$, 15.510 to 15.796 for $^{207}Pb/^{204}Pb$ and 38.845 to 39.573 for $^{208}Pb/^{204}Pb$, which are similar to those of the host carbonate rocks and the Emeishan basalts, indicating that these rocks may have provided metals to the ore fluid. The $\delta^{34}S$ values of the ores show a total range from 7.96‰ to 24.1‰, most of which are between 10‰ and 16‰, indicating that the sulfur should be derived from the sedimentary strata. The $\delta^{13}C_{PDB}$ values of the gangue minerals range from-1.1‰ to -3.7‰, indicating that the carbon of the ore-forming fluid was derived from the mixture of the crust-source carbon in the strata and deep-source carbon. The fluid inclusions δD values of the sphalerite, pyrite and calcite range from -37‰ ~ -49‰, -42‰ ~ -61‰, and -45‰ ~ -64‰ , the corresponding $\delta^{18}O_{SMOW}$ values range from -9.0‰ ~ 3.4‰, -6.8‰ ~ -12.7 ‰ and 14.9‰ ~ 18.8‰. The calculated $\delta^{18}O_{H2O}$ values of calcite range from 5.2‰ to 9.7‰, if the formation temperature is 200°C. These data indicate that the ore-forming fluids were likely a mixture of magmatic hydrothermal fluid and metamorphic water, and had water-rock interaction and isotope exchange with the underlain ore-bearing strata during their ascending process from the depth.

Genesis of barite in eclogite from the main-hole of the Chinese Continental Scientific Drilling (CCSD)

H. YANG[1], L-F. ZHANG[2]* AND F-L. LIU[1]

[1]Institute of Geology, Chinese Academy of Geological Sciences, Beijing 100037, China (hyang@cags.ac.cn, lfl0225@sina.com)
[2]School of Earth and Space Sciences, Peking University, Beijing 100871, China (*correspondence: lfzhang@pku.edu.cn)

Barite was found as an accessory mineral in eclogite from the main-hole core (in the depth intervals of 0~700 m) of CCSD. It is a diagnostic mineral of fluid activity, which is uncommon to be found in metamorphic rocks. The presence or absence of this mineral helps to constrain interpretation of the redox conditions [1]. Strontium-isotope analyses have been used to constrain the genesis of barite and thus make it possible to supply the origin information of related fluid.

Barite in eclogite has various occurrences during the metamorphic process. (1) UHP metamorphic eclogite-facies stage. Barite mainly exists as mineral inclusions in garnet, omphacite and the aggregates of K-feldspar ± albite + Quartz. It is rich in Sr, and the $SrSO_4$ content is about 45 mol%. (2) Early retrograde stage. Barite (0~20 mol% $SrSO_4$) was preserved among the mineral grains and dispersing in symplectite composed of clinopyroxene and albite. It is associated with allanite, epidote, hyalophane, celsian, K-feldspar. (3) Retrogressive amphibolite-facies stage. Barite (<5 mol% $SrSO_4$) exists as the oxidized outmost rim of pyrite. The Sr content in barite almost decreases during the retrogressive process. Barite together with the associated minerals constrain the change of redox conditions throughout the there metamorphic stages, which is oxidition-reduction-oxidition.

Barite separated from eclogite samples have $^{87}Sr/^{86}Sr$ values of 0.70621~0.71043. It shows that barite is mainly originated from the continental crust and may be precipitated from the fluid exsoluted from the continental crust during the plate exhumation.

In situ diamonds and moissanite in podiform chromitites of the Luobusa and Ray-Iz ophiolites, Tibet and Russia

J.-S. YANG[1] AND P.T. ROBINSON[2]

[1]Institute of Geology, Chinese Academy of Geological Sciences, 26 Baiwanzhuang Road, Beijing, 100037, China (yangjingsui@yahoo.com.cn)

[2]Department of Earth Sciences, Dalhousie University, Halifax, Nova Scotia, Canada, B3H, 4J1, (p.robinson@ns.sympatico.ca)

Podiform chromitites and peridotites of several ophiolites, including the Luobusa and Donqiao bodies of Tibet, the Semail ophiolite of Oman and the Ray-iz ophiolite of Russia, contain various combinations of deep mantle minerals, such as diamond, coesite, moissanite, base-metal and PGE alloys and native elements. These are associated with a range of crustal minerals, including zircon, corundum, kyanite, sillimanite, almandine garnet and rutile. Most of these minerals have been recovered from heavy mineral separates but in-situ grains of diamond, moissanite and corundum occur in podiform chromitites of the Luobusa and Ray-Iz ophiolites. Coesite, possibly after stishovite, from the Luobusa ophiolite is intergrown with kyanite on the rim of an Fe-Ti alloy grain recovered from chromitite. The in-situ diamonds, moissanite and corundum consist of euhedral to subhedral grains about 200-500 μm across, enclosed in small, irregular to spherical patches of carbon hosted in chromite grains. Both the diamonds and moissanite are characterized by having exceedingly low C isotopic values (mean $\delta^{13}C$ = -28), much lower than typical kimberlite diamonds. The in-situ UHP minerals in chromite grains suggest that at least some of the chromite crystallized at depth. Based on the occurrence of these minerals in widely separated ophiolites of variable age, we suggest that diamonds and associated minerals may be common in the upper oceanic mantle.

Gabbroic xenoliths in Pleisto-Holocene alkali basalts from Jeju Island, South Korea

KYOUNGHEE YANG

Dept. of Geological Sciences, Pusan National University, Busan, 609-735, South Korea (yangkyhe@pusan.ac.kr)

Gabbroic xenoliths occur in Pleisto-Holocene alkali basalts from Jeju Island, Korea, consisting of plagioclase + clinopyroxene + orthopyroxene. The coarse grain size (up to 3 mm), moderate mg# of pyroxenes (70-77) and textural features (e.g., poikilitic) indicate that gabbroic xenoliths are cumulates of igneous origin. Clinopyroxene from these xenoliths is constantly enriched in REEs with smooth convex-upward patterns, as expected for cumulus minerals formed from a melt enriched in incompatible-trace elements. Strikingly similar major and trace element variations and patterns of constituent minerals between gabbroic xenoliths and the host basalt indicate that cumulates are genetically related to the host basalt, but more evolved. The xenoliths crystallized at the margins in a volatile-rich roof environment of magma reservoirs, which had emplaced above the present Moho estimates beneath Jeju Island, suggesting the presence of ancient high-level magma storage reservoir beneath hotspot or plume-impacted areas. Following consolidation of the xenolith lithologies, volatile- and incompatible-elements enriched melt infiltrated through grain boundaries, and metasomatized the anhydrous cumulate phases, producing amphiboles. This volatile-enriched melt, as metasomatic agents, could have resulted from initially anhydrous to volatile-saturated compositions, being evolved by fractional crystallization. The studied xenoliths appear to represent cumulus remnants of melt compositions leading to more evolved rocks which related with the prior volcanism in the southern part of Jeju Island. It is noteworthy that this metasomatism is a relatively young event at the continental margin near the back arc basin (East Sea) in the Western Pacific.

Ore-forming age and origin of the Donggou porphyry Mo deposit in the Eastern Qinling orogenic belt, central China

LI YANG[1], F. CHEN[2] AND X.-Y. ZHU[1]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China
[2]School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China

The Qinling orogenic belt geologically consists of four tectonically juxtaposed zones, from south to north, the northern margin of the Yangtze Craton, South Qinling terrain, North Qinling terrain, and the southern margin of the North China Craton. The gigantic Mo-bearing metallogenic belt of East Qinling is mainly situated in the southern margin of the North China Craton and extends east-western from the Jinduicheng Mo deposit in west to the Tangjiaping Mo deposit in east. Previous studies have shown that the Mo mineralization in East Qinling occurred in three periods: 233-221 Ma, 148-138 Ma and 131-112 Ma, origin of the molybdenum ore-forming and related geodynamic setting but are still debated.

In this study, we report U-Pb zircon and Re-Os molybdenite ages and Sr-Nd-Pb isotopic compositions of the Donggou porphyry molybdenum deposit, being one of the superlarge deposits in this molybdenum mineralization belt. It is spatially associated with the fine-grained Donggou granite porphyry, and hosted in the Mesoproterozoic rhyolite, andesite, and tuffaceous siltstone of the Xiong'er Group. Re-Os molybdenite dating results constrain two stages of the Mo mineralization in an interval of 3 Ma. Zircon U-Pb ages demonstrate the earlier Mo mineralization was almost simultaneous with the formation of the host Donggou granitic porphyry. Geochemically, this porphyry belongs to A-type granite, being enriched in contents of LILEs (such as K, Rb, Th and U) and HFSEs (such as Nb, Ta and Zr), strongly depleted in contents of Ba, Sr, Eu and Ti, and high Ga/Al ratios. Whole-rock Sr-Nd-Pb isotopic compositions of the porphyry implies that the Mo-bearing magma were derived from crustal material by partial melting in an intra-continental extensional environment.

Modeling of co-metabolic Cr(VI) reduction under denitrifying conditions

L. YANG, S. MOLINS, C.I. STEEFEL, AND H.R. BELLER

Lawrence Berkeley National Laboratory, Berkeley CA 97020 USA, (LYang@lbl.gov, SMolins@lbl.gov, CISteefel@lbl.gov, HRBeller@lbl.gov)

Bioremediation of chromium contamination in groundwater often relies on *in situ* reductive immobilization strategies mediated by indigenous microbial communities stimulated with the injection of an organic electron donor. Depending on the presence of electron acceptors, a series of biogeochemical reactions and parallel abiotic geochemical reactions can occur, resulting in a complex network of enzymatic and indirect reaction pathways.

We used a reactive transport model [1] to interpret the rate of chromate reduction in a flow-through column experiment using natural Hanford 100H aquifer sediment into which a solution containing chromate, nitrate, and lactate was injected. The model includes biomass growth and decay, and thermodynamic limitations on reaction rates [2]. Further, we implemented a formulation that accounts for co-metabolic reduction of Cr(VI) based on previous studies on a pseudomonad isolated from the Hanford 100H aquifer [3]. Analysis of the experimental results indicate that the chromate reduction rates increased with the increasing denitrification rates, which is consistent with a co-metabolic mechanism. The reactive transport modeling agrees with this observation and was used to quantify the efficiency of the process. Model results also illuminate a change in reaction pathways as the nutrient ammonium was depleted, with the apparent result that another nitrogen source (i.e., nitrate) was used instead. Further, a kinetic conversion of nitrite to N_2 was needed to reproduce the observed pH behavior.

Geochemical characteristics of heavy metals in soil profile from an old metalliferous mining area in China

L.S. YANG , Y.H. LI* AND H.R. LI

Institute of Geographical Sciences and Natural Resources Research, CAS, Beijing 100101, China (*correspondence: yhli@igsnrr.ac.cn)

Factors affecting the geochemical behavior of HMs

Heavy metals (HMs) is a major concern due to its potentially adverse impacts on public health [1, 2]. In mining areas, the essential of the natural pedogenesis is the elemental recombination and migration [3]. However, the process can be greatly accelerated by human mining activities.

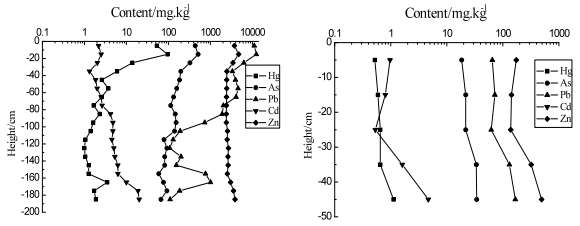

Figure 1: Vertical distribution of HMs in the soil profile. (Left-soil from mining area; Right-soil from control site)

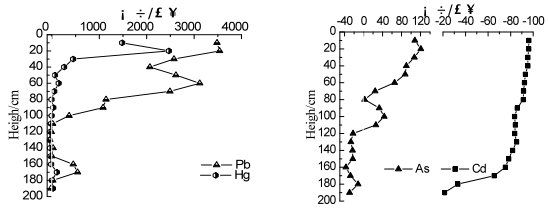

Figure 2: Migration ratio (Δ) of HMs in comparison with Fe.

Discussion of Results

The migration features of the major elements revealed that the soil from the mining area finished the primary process of chemical weathering characterized by leaching of Ca, and initiated the secondary process accompanying by leaching of K. Except the element Cd, other HMs such as Pb, Hg and As were enriched (Figure 2). It might be caused by both the pedogenesis and human mining activities. Extensive human mining activities made a major contribution to the accumulation of HMs in top soil.

Computational studies of structural, magnetic, and spectroscopic properties of actinide species

PING YANG

W.R. Wiley Environmental Molecular Science Laboratory, Pacific Northwest National Laobratory, Richland, WA, 99352, USA. (ping.yang@pnl.gov)

The complicated electronic structure of actinide complexes leads to their versatility of chemical reactivity, spectral and magnetic properties, and dynamical behavior. We will show that first-principle computational chemistry modeling can be used as an effective tool to provide insight into these properties. Recent theoretical and spectroscopic studies indicate that variations of orbital character in bonding interactions are connected with differences in chemical reactivity. In this study, we applied density functional theory (DFT) to probe the electronic structure of the ground state of actinide complexes. We found that calculations provide a quantitatively accurate microscopic picture of the bonding interactions of the actinide-ligand bonds. Based on the understanding of fundamental bonding interactions, we will discuss the magnetic and dynamic properties. We found that time-dependent density functional theory (TD-DFT) correctly reproduces the experimental spectroscopic results, lending confidence to characterize the transition nature of excitations. These fundamental findings provide a solid foundation towards a more complete and accurate understanding of the physico-chemical properties of actinide complexes in the natural environment.

This research is supported by the DOE Basic Energy Sciences Heavy Element Program. Part of the computing was performed using the MSCF in the EMSL, a national scientific user facility sponsored by the Department of Energy's Office of Biological and Environmental Research located at Pacific Northwest National Laboratory.

Are the silicate reference glasses BAM-S005 A and B suitable for *in situ* microanalysis?

Q.C. YANG[1]*, K.P. JOCHUM[1], B. STOLL[1], U. WEIS[1] AND M. WIEDENBECK[2]

[1]Max-Plank-Institut für Chemie, Postfach 3060, 55020 Mainz, Germany (*correspondence: Qichao.Yang@mpic.de)
[2]Deutsches GeoForschungsZentrum, 14473 Potsdam, Germany

BAM-S005 Type A and B from the Federal Institute for Materials Research and Testing (BAM, Germany) are soda-lime reference glasses certified for bulk analysis. In order to test whether these glasses are also suitable for microanalysis, we have assessed the homogeneity of major and trace elements, including the 22 certified trace elements using LA-ICP-MS, EPMA and SIMS [1]. The results show that all major elements and most trace elements are homogeneously distributed. Possible exceptions are Se and Cl which might be heterogeneously distributed.

Figure 1 shows our LA-ICP-MS results for BAM-S005-A calibrated against the new reference values for NIST 610 [2] following ISO guidelines. All data agree within uncertainty limits with the BAM certified reference values. Figure 1 also shows our LA-ICP-MS data using the 14 years old NIST 610 values [3] for calibration. Under this calibration, significant differences for As, Cd, Mo, Sn, Sb, expecially for Se and Cl, are observed.

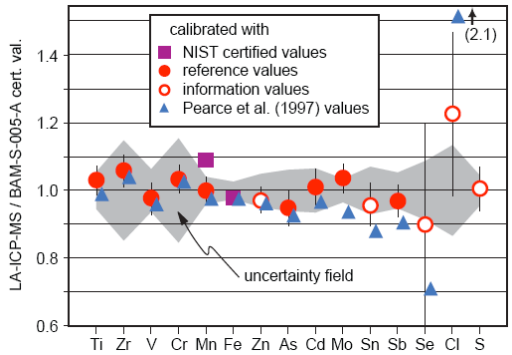

Figure 1: Normalized LA-ICP-MS data for BAM-S005-A using different calibration procedures [2, 3]. Uncertainties include the analytical error of LA-ICP-MS and the uncertainties of the NIST reference values.

Geochemical constraints on the sediment source-to-sink process of the Changjiang (Yangtze) River

S. Y. YANG*, C. LI, Q. WANG AND J.Q. SHAO

State Key Lab. of Marine Geology, Tongji Uni., Shanghai 200092, China (*correspondence: syyang@tongji.edu.cn)

As the largest river originated from the Himalayan-Tibetan Plateau, the Changjiang delivers huge amount of terrigenous matter into East Asian marginal seas, which exerts a great control on marine sedimentation and biogeochemical cycle. The sediment source-to-sink (S2S) process of the Changjiang is significantly different from those of well-known MARGINS sites and widely-documented island rivers such as the Kaoping River in Taiwan, because of its complicated provenance geology, weathering regime and rapidly increasing human impacts on the drainage system.

We have systematically investigated the sediment S2S process of the Changjiang river system by using various geochemical proxies including REE and Sr-Nd isotopic compositions and detrital zircon chemistry. Source rock compositions and chemical weathering intensities in the drainage basin account for the compositional variations of the modern Changjiang sediments. The bulk Sr-Nd isotopic compositions and age spectrum of zircon provide good constraints on sediment recycling and evolution of weathered upper continental crust in the Yangtze Craton. Geochemical composition of the sediment into the sea is complicated by hydrodynamic sorting and changing sediment suppliers in relation to variability of monsoon-induced precipitation in the river basin. The Three Gorges Reservoir also complicates the sediment S2S process and changes river geochemistry.

Despite spatial and seasonal variations in geochemical compositions are clearly registered in the modern Changjiang sediments, the proxies for deciphering sediment provenance and chemical weathering intensity can be established for the study of river-sea interaction and paleoenvironmental reconstruction at different temporal scales.

Two episodes of the Early Cretaceous magmatic activity in the Gan-Hang Rift, South China: *In situ* zircon U-Pb dating

SHUI-YUAN YANG, SHAO-YONG JIANG*, YAO-HUI JIANG AND KUI-DONG ZHAO

State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China (*correspondence: shyjiang@nju.edu.cn)

Results of *in situ* zircon U–Pb ages using high-precision dating methods (SHRIMP or LA-ICP-MS) are reported for magmatic activity in the Gan-Hang Rift, South China. The Gan-Hang Rift, trending at least 450 km in a NE-SW direction, is a part of a Mesozoic BRP (Basin and Range Province) in southeastern China, and is an important magmatic zone composed of both volcanic-intrusive complex and A type granites.

Zircon U–Pb dating of the volcanic-intrusive complex from Xiangshan basin, Center Jiangxi Province, provides insights into the extrusive and intrusive activity at Xiangshan, which took place within a short time span (135–137 Ma) [1-2]. SHRIMP zircon U–Pb dating for two A type granitic plutons (Tongshan and Damaoshan plutons) and a diabasic dike in the northwest of the Gan-Hang Rift shows that the granitic plutons and diabasic dike were emplaced in the Early Cretaceous (122–129 Ma) [3]. A zircon U–Pb dating on a newly discovered A-type granitic pluton in Baijuhuashan (126±3 Ma), western Zhejiang Province, was carried out recently [4]. Our new study concerns a volcanic-instrusive complex in Xinlu basin, western Zhejiang Province, which produced zircon U–Pb ages of 134–135 Ma. All these *in situ* zircon U–Pb dating results indicate that two major episodes of magmatic activity occurred in the Gan-Hang Rift. The first stage (134-137Ma) generated the volcanic-intrusive complex, which marked the onset of the extension. With ongoing extension the crust and lithospheric mantle became progressively thinned and formed the second stage of granitic plutons between 122 Ma and 129 Ma. These A-type magma in the Gan-Hang Rift were likely generated with the peak episode of an extensional tectonic regime during the Cretaceous in South China, perhaps corresponding to the rollback of the Pacific plate.

Halogen profiles of pore waters from gas hydrate potential area offshore of SW Taiwan

T.F. YANG[1]*, H.-C. CHEN[1], H.-W. CHEN[1], W.-L. HONG[1], P.-C. CHUANG[1], N.-C. CHEN[1], S. LIN[2], S.-H. CHUNG[3] AND Y. WANG[3]

[1]Department of Geosciences, National Taiwan University, Taipei 106, Taiwan (*correspondence: tyyang@ntu.edu.tw)

[2]Institute of Oceanography, National Taiwan University, Taipei 106, Taiwan (swlin@ntu.edu.tw)

[3]Central Geological Survey, MOEA, New Taipei City 235, Taiwan (chung@moeacgs.gov.tw, wangys@moeacgs.gov.tw)

Variations of halogen concentra-tions (Cl^-, Br^- and I^-) and ammonium (NH_4^+) in pore water of marine sediments of selected sites were studied to help understanding the fluid source and the pathway of sulfate reduction in the potential gas hydrate area of offshore SW Taiwan, where has been characterized with very high methane flux [1, 2, 3, 4]. According to the concentration profiles (I^-, Br^-, CH_4, SO_4^{-2}, NH_4^+), we can classify those studied sites into four groups. In group-1, which represents background group, concentrations show no clear variations with depth. In group-2, rapid reduction of sulfate and significant increase in NH_4^+ and/or CH_4 are observed. In group-3, CH_4, I^-, Br^- and NH_4^+ all increase with increasing depth. Unlike group-2, NH_4^+ concentration increases faster than those in group-2. In group-4, the CH_4 concentration increases at depth, while there are only very low I^-, Br^- and NH_4^+ concentrations. Those category except group-1 indicated the mixing of in situ and deep source fluids.

Based on the stoichiometry ratio between sulfate consumption and DIC increasing from the profiles of the studied coring sites, we can summary the pathway of sulfate reduction for group-2 to -4 as followings: For group 2, which could represent the majority sites in offshore SW Taiwan, sulfate is mainly consumed by AMO process with methane from the depth. For group-3, sulfate is consumed by decomposition of local organic matters with very few fluid input from depth. For group-4, almost all sulfates are consumed by AMO process.

Application of nano-powders in the sewage treatment

XIAOJING YANG AND LEI JI

School of Energy and Environment, Xihua University, Chengdu 610039,China(yangfmrl@sina.com)

A certain amount of nano-powders have been added in different concentrations of chemical oxygen demand (COD) of water samples and putting a certain period of time. The change of water turbidity, conductivity and chemical oxygen demand (COD) were used as the criterion of sewage purification. The chemical oxygen demand (COD) of experimental sewage solution is 500mg/L、1500mg/L、2000mg/L、3000mg/L and 5000mg/L respectively. The barium titanate nano-powders and activated carbon nano-powders, the size of 200nm, were added in these solutions and laid up for seven days. The experimental results showed that activated carbon nano-powders and barium titanate nano-powders did not affect on the conductivity of water samples obviously.

The barium titanate nano-powders can significantly reduce the turbidity of water samples. The turbidity of water samples changed from 123 to 9 degree when the weight ratio of barium titanate nano-powders were from 0.25%; 0.5%; 0.75% to 1% respectively. However, the purification of the chemical oxygen demand (COD) was not effective. When the chemical oxygen demand (COD) is not high, purifying rate of sewage is about 45%. When the chemical oxygen demand (COD) exceed 1650 mg/L, purifying rate of sewage is only 25%. If the content of barium titanate nano-powders increased, purifying rate did not change obviously.

The effect of activated carbon nano-powders on the turbidity and chemical oxygen demand (COD) of sewage was obvious. The turbidity of water samples changed from 123 to 13 degree and the purifying rate of chemical oxygen demand (COD) from 60% to 95% when the weight ratio of activated carbon nano-powders were from 0.25%; 0.5%; 0.75% to 1% respectively. Even the chemical oxygen demand (COD) exceed 5000mg/L, the purifying rate of of chemical oxygen demand (COD) of sewage can reach 92% and a high concentration of chemical oxygen amount of (COD) could be reduced to meet the requirement of waste water discharge standards during some period.

Platinum-Group Element mineralization in black shales in Xinjiang, China

Y.Q. YANG [1], Y.Y. ZHAO [2] AND F. PIRAJNO[3]

[1]State Key Laboratory of Geological Processes and Mineral Resources, Beijing 100083, China (dxqy8@cugb.edu.cn)

[2]Institute of Mineral Resourcesof Chinese Academy of Geological Sciences, Beijing 100037, China (yuanyizhao2@sina.com)

[3]School of Earth and Environment, The University of Western Australia, 35 Stirling Highway, Crawley, WA 6009, Australia

Geological Setting

Black shales are favorable host rocks for many types of ore deposits. Among them gold and PGE are very important deposits to black shales. There exists vast areas of the black shales in Xinjiang of China, which distribute among Tianshan Mountains, Tarim Basins and Beishan districts. The mains bearing-ore strata are Sawayaertun formation at SW Tianshan and Heijieshan formation at East Tianshan (Fig.1).

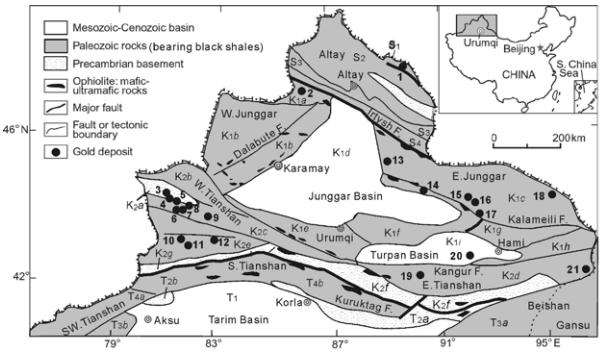

Figure 1 The sketch map of structures and rocks

Although PGE ore deposits have not yet discovered in Xinjiang at present, but many exceptionally vestiges of PGE to be demonstrated [1], and had discovered gold ore deposits related with black shales, such as Sawayaertun Gold deposit. Up on flood plain sediment, a geochemical province of Pt and Pd of a content of 0.8 ng/g is delineated at East Tianshan .

Forming Conditions

Hercynian-Indosinian tectono-magmatism under a post-collision extensional environment provided heat and metal extracted from basement rocks and mafic body.Shear zones control the metallic fluid,such as Muruntau gold deposit in Uzbekistan, located in the southwest Tianshan mountains and hosted in Early Paleozoic black carbonaceous shales [2].

Rb-Sr dating of the Wangpingxigou Pb-Zn deposit, China

JUN-MING YAO[1]*, YAN-JING CHEN[1,2], TAI-PING ZHAO[1] AND XIANG-HUI LI[3]

[1]Key Laboratory of Mineralogy and Metallogeny, Guangzhou Institute of Geochemistry, CAS, Guangzhou 510640, China (yaojunming@gig.ac.cn)

[2]Key Laboratory of Orogen and Crust Evolution, PKU, Beijing 100871, China (yjchen@pku.edu.cn)

[3]Laboratory for Radiogenic Isotope Geochemistry, Institute of Geology and Geophysics, CAS, Beijing 100029, China

Unlike their big brothers, SEDEX and MVT types of Pb-Zn ore deposits which are distinguished for their large reserves and stable occurrence and have long been the focus of scientific research and industrial exploration, vein-type Pb-Zn deposits are often ignored for the small scales and diverse occurrence. However, in the last few years, numerous vein-type Pb-Zn deposits have been discovered in the East Qinling orogenic belt, which include several large to super-large Pb-Zn ore deposits, such as Wangpingxigou, Tieluping and Lengshuibeigou etc. These vein-type Pb-Zn deposits possess important economic value and huge exploration potentials.

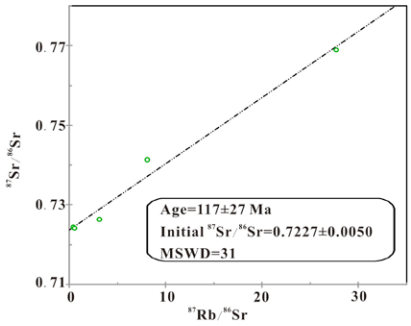

Figure 1: The Rb-Sr isochron age of single-grain sphalerite from Wangpingxigou Pb-Zn deposit, Henan province.

The single-grain Rb-Sr analytical technique was employed on sphalerite to date the Pb-Zn mineralization of the Wangpingxigou deposit. Five sphalerite grains from sulfide ores yield an Rb-Sr isochron age of 117 ± 27 Ma with the initial 87Rb/86Sr value of 0.7227 ± 0.0050 (Figure 1), significantly higher than those of Yanshanian intermediate-felsic porphyries and granite plutons. This age agrees with the Re-Os model age (116 ± 1.7 Ma) of Donggou Mo deposit located in Waifangshan district. This suggests that the Mo-Au polymetallic deposits in Waifangshan area were formed in the same period.

Quantitative research on nanopores of coal using atomic force microscope

SUPING YAO*, KUN JIAO AND MIAOCHUN LI

State Key Laboratory for Mineral Deposits Research (Nanjing University), School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China (*correspondence: spyao@nju.edu.cn)

Atomic Force Microscope (AFM) is a new approach to nanopore structure study and porosity measuring by observing the nanopores of coal directly and processing the quantitative measurement of pore structure parameter.

AFM could study the surface nature of samples under contact mode using several methods. The section analysis could characterize the nanopore geometry, the grain analysis could study the nanopore distribution of coal, and the parameters got from bearing analysis are important in porosity measurement. A large amount of nanopores with different shapes shows in anthracite (Sample QS), the section analysis shows that the diameter and the depth of the largest pore in the analized area is 354.4nm and 13.5nm respectively, while those of the smallest pore is 33.2nm and 1.6nm respectively. The statistic data of scanning area (Table.1) implies that the number of pores in anthracite is 5 times more than gas coal, the Pore Area / Total Area ratio of anthracite is also higher. However, the average pore size of anthracite is abviously smaller than gas coal. The hydrocabon generation process of coal with the increase of coalification degree (maturity) could account for the increase of pore size.

The high resolution imaging and quantitative analysis of advantage of AFM could be utilized to pore structure reasearch, quantitative pore size analysis and porosimetry, which could help to understand the nanopore generation, pore geometry and adsorption mechanism.

Sample	Ro (%)	Pore Acount (/mm^2)	Average Pore Size (nm^2)	Total Pore Area (μm^2)	Pore/ Total Area (%)
Spm	0.67	5.33×10^5	71816	1915	3.83
CX	0.72	5.55×10^5	74829	2090	4.18
QS	2.47	2.57×10^6	23871	3075	6.15
SX	4.34	3.32×10^6	19441	3230	6.46

New geochemical and geochronological constraints for the origin of Orhaneli-Dursunbey volcanic rocks, NW Anatolia (Turkey)

O.S. YARAR*, O. KAMACI AND S. ALTUNKAYNAK

Department of Geology, Istanbul Technical University, 34469, Maslak, Istanbul, Turkey, (*correspondence: serhatyarar@gmail.com)

An extensive volcanism constructed through multiple eruptions of basic to silicic magmas developed during the Late Cenozoic in NW Anatolia (Turkey). New radiometric age and geochemical data are presented from the volcanic activity in the study area which is situated between the towns of Orhaneli (Bursa) and Dursunbey (Balıkesir). The felsic lavas are volumetrically more dominant than mafic lavas.Volcanism in the region began with felsic pyroclastic rocks and rhyolitic-rhyodasitic lavas. K/Ar radiometric age data obtained from rhyolite lavas indicates that their age varies from 19.4 to 19.0 Ma corresponding to the Early Miocene. According to their mode of occurrences, pyroclastic rocks of felsic phase may be divided into two groups; the pryoclastic fall deposits and the pyroclastic flow deposits. The pyroclastic fall deposits are represented by pumice fall, pumice-ash, ash and ash-block fall deposits. The pyroclastic flow deposits may also divided into two subgroups; ash-block deposit and ignimbrites. Our field observations indicate that the volcanic rocks were formed from a number of small vents which set along approximately NNE-SSE trending fault zones by the plinian/sub-plinian eruptions. Felsic volcanism was followed by transitional basalts, basaltic andesite lavas with the age of 18.7 to 17.5 Ma as the last products of volcanism in the Orhaneli-Dursunbey volcanic field.

Geochemically, the volcanic association is high-K calc-alkaline in nature and show similar characteristics to post-collisional volcanic rocks. Both volcanic suites exposed in Orhaneli and Dursunbey area display a gap in silica concentrations. Trace element characteristics and Sr-Nd isotope data indicate that coexisting mafic and felsic magmas derived from lithospheric mantle source yielding depleted but LILE-enriched compositions, with subsequent contamination. Basic parental magmas of mafic and intermediate volcanic rocks were generated from EM1-type mantle previously modified by subduction, whereas felsic volcanic rocks were produced by assimilation of silicic crust and combined fractional crystallization (AFC).

Rates and mechanisms of hydration in crystalline crust

BRUCE W.D. YARDLEY*[1], HANS-PETER NABEIN[2] AND WILHELM HEINRICH[2]

[1]School of Earth & Environment, University of Leeds, Leeds LS2 9JT, UK, (*correspondence: b.w.d.yardley@leeds.ac.uk)

[2]Deutsches GeoForschungsZentrum (GFZ), D-14473 Potsdam, Germany (hans-peter.nabein@gfz-potsdam.de)

A free water phase in crystalline rocks of the mid to lower crust fulfils two roles: it enhances deformation while present, but participates in hydration reactions that lead to its consumption. The precise rate of hydration has important implications for crustal rheology as it determines whether the continental crust normally contains free water. We have investigated hydration rates for powdered enstatite-oligoclase-quartz under mid-crustal conditions of 400ºC and 300 MPa and find that c. 2.0E-07 g H_2O is consumed per m^2 enstatite surface per second. This rate is comparable to the rates of hydration of andalusite + K-feldspar from Schramke *et al*. [1].

Such rates are dependent on calculated surface areas, which may change during the run. We therefore carried out a series of experiments using 4mm diameter cores of fine grained (100-200 microns) basaltic hornfels. These hydrated too slowly for accurate weight loss measurements, consistent with only the outer surface of the cylinder being effectively reactive. This result validates the approach in earlier work [2], in which we calculated that water films with a half width of 100 μm can only persist for periods of a few tens of years under these conditions.

Experiments with hollow cores resulted in marked segregation as product minerals grew as well-formed crystals creating vein-like material in the available space.

[4]Institut für Geowissenschaften, Universität Frankfurt, Frankfurt/M, Germany
[5]Australian Synchrotron, Clayton VIC 3168, Australia

In cratonic lithosphere the oxygen fugacity (fO_2) of peridotite is expected to broadly decrease with increasing depth. However metasomatic events may locally perturb this trend, often leading to oxidation [1,2].

We have investigated the fO_2-depth variation in the Siberian Craton using a suite of fresh garnet lherzolites from the Udachnaya East kimberlite. Garnet $Fe^{3+}/\sum Fe$ was detemined using XANES spectroscopy [3] on the X-ray Fluorescence Microscopy beamline of the Australian Synchrotron.

Thermobarometry established that the samples range in pressure from 3.9-7.1 GPa and lie along a typical cratonic geotherm. Several samples exhibit evidence for metasomatic enrichment, with elevated abundances of Ti, Zr and Y in garnet and clinopyroxene, broadly consistent with an earlier study of another Udachnaya xenolith suite [4]. Others are less or unaffected by metasomatism, with very low abundances of these elements.

$\Delta \log_{10}[fO_2]^{FMQ}$ [52] varies from -2.5 to -5.9 log units and broadly decreases with increasing pressure. The metasomatised samples all derive from P > 5 GPa and most exhibit a resolvable shift to fO_2 values ≈1.5-2.0 log units higher than the unmetasomatised ones, at given pressure.

Assessment of heavy metal contamination in soils around Gebze industrial area, NW-Turkey

GÜLTEN YAYLALI-ABANUZ

Department of Geological Engineering, Karadeniz Technical University, 61080, Trabzon, Turkey (gultenyaylali@yahoo.com)

Soil contamination poses a serious risk to human health, particularly in densely populated areas. Pollution from industries activities can be introduced into the food chain via soil, plant and water and threatens human health. Increase in heavy metal pollution in the soils of Gebze (Turkey) due to intense industrialization and urbanization has become a serious environmental problem. There are two large organized industrial zones in Gebze; the Gebze Organized Industrial Zone (GOIZ) and the Dilovası Organized Industrial Zone (DOIZ). This region hosts several industrial facilities which are the main source for hazardous wastes which include paint, plastic, electric, metal, textile, wood, automotive supply industry, food, cosmetics, packing, machinery, and chemicals. Soil samples were collected from these two industrial zones and analyzed for their metal contents. Results of the analysis show that the soils are characterized by high concentrations of Cd, As, Pb, Zn, Mn, Cu, Cr and Hg. Since concentrations of other elements do not exceed the permissible levels, they are not evaluated. Concentrations are 0.05-176 mg/kg of Cd, 10-1161 mg/kg of Cr, 7.87-725 mg/kg of Cu, 1.50-65.60 mg/kg of As, 17.07-8469 mg/kg of Pb, 1.96-10000 mg/kg of Mn, 29.5-10000 mg/kg of Zn, and 9-2721 µg/kg of Hg. Application of factor, cluster and correlation analysis showed that heavy metal contamination in soils originates from industrial activities and heavy traffic which are of anthropogenic origin. Contaminations in soils were classified as geoaccumulation index, enrichment factor, contamination factor, and contamination degree. Integrated pollution index (IPI) values indicate that heavy metal pollution levels of soils collected from industrialization sites are greater than those from distal parts of industrialization. Spreading of hazardous wastes from industrial facilities in the study area via rain or wind is the main source of soil pollution. In addition, traffic-related metal pollution is also observed. In order to mitigate the impact of environmental pollution, factory wastes must be reliably disposed.

Nb/Ta fractionation resulted by fluid-rock interaction in subducted oceanic crust

KAI YE, SHUN GUO, YI, CHEN AND JINGBO LIU

State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijng 100029, China

Nb/Ta ratios in the silicate Earth reservoirs (Earth's mantle and crust) are almost all subchondritic and thus document a clear deficit of Nb relative to Ta in the silicate Earth, known as the terrestrial Nb–Ta paradox. One proposed solution is a hidden reservoir of subducted eclogitic oceanic crust with superchondritic Nb/Ta ratios in the Earth's lowermost mantle. However, many high-pressure experiments demonstrate that the melts and fluids equilibrating with the eclogite commonly have higher Nb/Ta ratios than the residue rutile-bearing eclogites, and recent observations proved that natural eclogites commonly have subchondritic Nb/Ta ratios, suggesting that the down going subducted oceanic crust could not be the superchondritic Nb/Ta reservoir. We reported here data of Nb/Ta ratios of natural eclogites and internal HP veins from Dabieshan UHP terrane. The host eclogites have chondritic Nb/Ta ratios (19-21), but some of the HP veins, which crystallized from the UHP fluids released from the host eclogites have superchondritic Nb/Ta ratios (35-38). Our data demonstrate that UHP fluid-rock interactions in subducted oceanic crust resulted in great Nb/Ta fractionation with UHP fluid have much higher Nb/Ta ratios than the residue solid eclogite, and the superchondritic Nb/Ta reservoir are expected in the mantle wedge which reacted with the high Nb/Ta fluid.

Oxygen triple-isotope evidence for enhancement of CO_2 sequestration efficiency by diatom-diazotroph assemblages in a giant river plume

LAURENCE Y. YEUNG[1,2], WILLIAM M. BERELSON[1], EDWARD D. YOUNG[2], MARIA G. PROKOPENKO[1], EDWARD J. CARPENTER[3] AND PATRICIA L. YAGER[4]

[4]Dept. of Marine Sciences, University of Georgia, Athens, GA 30602, USA

The Amazon river outflow influences biogeochemistry hundreds to thousands of kilometers from the river mouth, out to the western region of the oligotrophic tropical North Atlantic (TNA). This dynamic and evolving "plume" is characterized by a significant CO_2 undersaturation in surface waters associated with biological new production.

Observations and inverse modeling suggest that the TNA is typically a carbon source to the atmosphere of ~2.5 Tmol C yr^{-1} [1,2]. Net production in the Amazon plume, however, reverses the normal TNA surface condition, removing up to 1.7 Tmol C yr^{-1} from the atmosphere [3]. ANACONDAS (NSF OCE-0934095) hypothesized that this efficient biological pump is driven by an unusual assemblage of diatoms and diazotrophic (N_2-fixing) cyanobacteria; our team studied the carbon cycling and ecology of the plume during its maximum extent in May-June 2010 on the *R/V Knorr*.

We present new *in situ* net-community and gross primary production data from the expedition. We observe a peak enhancement in export production efficiency over a narrow sea-surface salinity window (S = 32–33 psu) using the O_2/Ar and oxygen triple-isotope (i.e., $^{17}\Delta$) methods. This striking increase in export production coincides with similar increases in biological carbon drawdown and counts of *Hemiaulus hauckii*, a diatom often found in symbiosis with the diazotroph *Richelia intracellularis*. These data support the diatom-diazotroph assemblage mechanism for enhancing new production and carbon sequestration in tropical river plumes. The strength of this CO_2 sink is likely sensitive to changes in tropical hydrology and terriginous runoff over time.

Spatial prediction of soil organic carbon using digital soil mapping techniques in Slovakia

YUSUF YIGINI*, PANOS PANAGOS AND LUCA MONTANARELLA

European Commission Joint Research Centre 21027 Ispra (VA) Italy (*correspondence: yusuf.yigini@jrc.ec.europa.eu, panos.panagos@jrc.ec.europa.eu, luca.montanarella@jrc.ec.europa.eu)

High-resolution and continuous soil maps are an essential prerequisite for precision agriculture and many environmental studies. Conventional, sample-based soil mapping is costly and time consuming, and the data collected are available only for discrete points in any landscape. Thus, sample-based soil mapping is not reasonably applicable for large areas like countries. Due to these limitations, geostatistical techniques can be used to map soil properties. Soil organic carbon (SOC) is one of the most important parameters shaping soil environment and it plays a key role in determining soil quality. Spatial prediction of soil organic carbon in a large scale has an important role in environmental studies and field practices for both soil quality and carbon sequestration. This study was conducted to interpolation of point data to produce continuous map of soil organic carbon content in Slovakia. The measured point data were extracted from LUCAS (Land Use/Cover Area Frame Survey) results for Slovakia region. The regression kriging approach is applied and Corine Land Cover (CLC), SRTM 90m, European Soil Database (ESDB), climate and land management data were used as covariates. Finally, the soil organic carbon prediction map was produced in raster format at a spatial resolution of 100×100m.

Geochemistry and $^{40}Ar/^{39}Ar$ geochronology of adakite-like porphyries in NW Turkey: Implications for slab breakoff induced adakitic magmatism

M. YILDIZ* AND S. ALTUNKAYNAK

Department of Geological Engineering, Istanbul Technical University, 34469, Istanbul, Turkey (myildizitu@gmail.com)

A number of plutons and porphyries emplaced into the Izmir-Ankara suture zone (IASZ), which marks the collision zone between Anatolide-Tauride platform and Sakarya continent in NW Turkey. This study focuses on the geochemistry and geochronology of Adakite-like porphyries exposed in the IASZ.

Adakite-like porphyries are spatially and temporally associated with Eocene plutons that are intrusive into ophiolitic and blueschist rocks along the IASZ. The plutons range in age from 54 to 48 Ma and include granodiorite, quartz diorite, and syenite. They are medium- to high-K calcalkaline in composition and are predominantly metaluminous I-type granitoids. Geochemical compositions and Nd-Sr isotope systematics indicate that these plutons represent the products of hybrid magmas evolved from partial melting of subduction modified lithospheric mantle and, through assimilation, fractional crystallization of these melts at crustal levels.

Adakitic rocks are represented by rhyolite and dacite porphyries. They are peraluminous, and exhibit adakitic characteristics. They have high SiO_2, Al_2O_3, Na_2O contents, Sr/Y and La/Yb ratios and low Y, Yb contents, and display enrichments of LILE and LREE, depletion of HFSE and lack of Eu anomaly. Our $^{40}Ar/^{39}Ar$ ages are 53.7 to 54 Ma for the adakite-like porphyries.

These geochemical features, timing and nature of Adakite-like porphyries and geology of the region indicate that, collectivelly, adakitic magmatism was not formed above an actively dehydrating subducted slab but are consistent with a magmatism that is more typical of intraplate tectonic settings. We suggest that adakite-like porphyries likely formed by as a result of interaction between crustal and lithospheric mantle melts. These partial melts requere increased heat flow at about 54 Ma. High heat flow could have occurred by slab breakoff that is compatible with the geodynamic evolution of the region. As a consequence of slab breakoff, upwelling asthenospheric mantle would raise the geothermal gradient beneath the suture zone.

Genesis of ultramafic related magnesite in Northwest Turkey along the Izmir-Ankara Suture: A stable isotope study

ASUMAN YILMAZ AND MUSTAFA KUSCU

[1]Aksaray University, Geology Department, 68100, Aksaray, Turkey
[2]Suleyman Demirel University, Geology Department,32260, Isparta, Turkey

The magnesite occurrences of Eskisehir area (Süleymaniye, Margı, Tutluca), which are hosted by Alpine type ultramafic rocks, have been studied, in order to elucidate the origin of water, carbon and are compared with similar magnesite occurring in Turkey and other countries. Süleymaniye magnesite occurences have δ ^{13}C (PDB) values ranging from -2,71 ‰ to -7.69 ‰; Margı magnesite occurrences δ ^{13}C (PDB) values ranging from -7.59 ‰ to -11.24 and Tutluca magnesite occurences have δ ^{13}C (PDB) values ranging from -8.69 ‰ to -10.4 ‰. Süleymaniye magnesite occurrences have havier isotopic value of others. They have similar δ ^{18}O (SMOW) isotopic values ranging from 27.35 δ ^{13}C ‰ to 30.78 ‰. Petrographic, mineralogic and isotopic data indicate that magnesite precipitation of Eskisehir area in near surface environment at low P and T.

Critical review of Hf-W and U-Pb clocks for terrestrial core formation

Q.-Z. YIN[1], C.-T. LEE[2], J. BLICHERT-TOFT[3] AND F. ALBARÈDE[3]

[1]Univ. of California, Davis, CA, USA (qyin@ucdavis.edu)
[2]Rice University, Houston, TX 77005, USA
[3]Ecole Normale Supérieure de Lyon, 69007 Lyon, France

Since the discovery of radiogenic ^{182}W in the Earth's mantle in 2002, the extent to which the incoming accreting bodies (impactor) isotopically equilibrated with the proto-Earth before the two cores merged to form Earth's core has been hotly debated. Resolving this issue is critical for interpreting Hf-W constraints on terrestrial core formation and the origin of the Earth and Moon. Models of accretion highlight that either (i) the Hf-W age of terrestrial core formation is well constrained between 10-30 Myr [1] as long as the degree of metal-silicate equilibration is between 40-100% [2], or that (ii) the Hf-W systematics constrains the degree of equilibration to 40% and do not constrain timing at all [2]. In the latter case, the U-Pb system has been used to argue for a much later time of core formation [3].

Problems with the late core formation model are as follows. (a) the Moon and the Bulk Silicate Earth (BSE) have nearly identical O, Cr and W isotopes [4], which is difficult to explain if the impactor and the proto-Earth equilibrated only to 40%. (b) Coudpled ^{142}Nd-^{182}W modeling suggests that silicate differentiation would occur before core-mantle segregation [5]. (c) The basic premise of using U-Pb systematics of the BSE to estimate timing of core formation may be incorrect. Ref. [6] emphasized the fact that the BSE, as represented by oceanic basalts, lies to the right of the geochron in Pb-Pb space. In order to resolve this "paradox", ref. [6] computed a model age for the BSE and suggested a 100-200 Myr age for Pb segregation to the core, but because Canyon Diablo troilite was assumed to represent the core, these model ages are minimum estimates for the timing of Pb segregation. In ref. [7], we show that Pb segregation could have been much later, but instead of the core, Pb segregation may have been controlled by sulfide-silicate differentiation associated with the formation of continents. (d). Finally, the similar ^{182}W of the Earth and Moon [4] does not necessarily imply that the Earth-Moon system formed after ^{182}Hf had decayed (>60Myr) because both bodies are still radiogenic compared to chondrites. The key question is whether Hf/W ratios for BSE and the Moon are distinguishable?

Early degassing of the Earth

REIKA YOKOCHI

The University of Chicago, 5734 South Ellis Avenue, Chicago, IL 60637 (yokochi@uchicago.edu)

Some of noble gas isotopes are produced by radioactivities having different half-lives: the β-decay of ^{129}I produces ^{129}Xe with $T_{1/2}$ = 15.7 Myr, the spontaneous fission of ^{244}Pu produces $^{131\text{-}136}$Xe with $T_{1/2}$ = 82 Myr, and the still active decay of ^{238}U also produces ^{4}He and $^{131\text{-}136}$Xe by spontaneous fission with $T_{1/2}$ = 4.45 Gyr. Argon-40 is also produced by the β-decay of ^{40}K with $T_{1/2}$ = 1.27 Gyr. These contrasted production rates of noble gas isotopes allow investigation of terrestrial degassing during the accretional period, the Hadean, and from the Archean to present (e.g. [1-9]).

The xenon isotopic composition of the mantle-derived rocks suggests an extended degassing history of the Earth during Hadean, which can be modeled assuming the degassing to be a first-order rate process, i.e. the amount of noble gas extracted from the mantle is proportional to its total amount in the mantle reservoir [9]. In the model, it was assumed that the mangle degassing decreased gradually as expected for a progressively cooling Earth. The efficiency of degassing was estimated to be 1.2×10^{-8} duing Hadean in this model [9], whereas the degassing efficiency of the mantle at present is $0.6\text{-}3.8 \times 10^{-11}$ based on the recent global ^{3}He flux estimate [2]. We investigate how the transition between these two modes of degassing occurred using radiogenic noble gas isotopes.

[3]IRAP-OMP, University Paul Sabatier, Toulouse, France (baratoux@dtp.obs-mip.fr; gilles.berger@lmtg.obs-mip.fr)

The Vargeão impact structure

Hypervelocity impact phenomena are of primary importance in the evolution of solid bodies of the Solar System[1]. But craters on basaltic rocks, which are the best analogs for the surface of other planets and satellites, are rare on Earth. The 12 km wide Vargeão, which is a well-preserved complex structure formed on basaltic flows of the Serra Geral Formation (about 133-131 Ma) [2]. At Vargeão, the impact-related materials are chiefly represented by centimeter breccia-veins that are found in all lithologies (basalts and ryodacites). We conducted a detailed petrological study (petrography, microprobe, SEM and XRD) on these veins.

Results

Our results show that the veins were strongly affected by the post-impact hydrothermal fluids. The hydrothermal alteration varies geographically in the structure. On the rim area this alteration consists of total or partial substitution of the melt matrix by quartz, calcite and iron oxides. At the central area, the alteration mineral assembly is composed of quartz, iron oxides, zeolites and rarely calcite. Usually, the alteration shows a zoned setting, which also varies locally. At some outcrops on the rim area, we also observed the occurrence of disseminated native copper. Clay minerals (smectites) were observed in all samples and are probably related to weathering. The post-impact hydrothermalism on basaltic craters and their possible implications for the evolution of planetary bodies surface will be discussed.

Influence of microbiology and photochemistry on iodine cycling

L. YOKOYAMA[2], K. WAGENER[1] AND A. DE L.R. WAGENER[1]*

[1]Departamento de Quimica, PUC-Rio, 22453-900 RJ, Brazil (*correspondence: angela@puc-rio.br)
[2]Escola de Quimica, UFRJ, 21941-909 RJ, Brazil

Investigation of microalgae, bacteria and photochemistry influence on the cycling of iodine in seawater was carried out. Axenic cultures of *Tetraselmis sp*. and natural bacteria found in seawater were prepared and samples were collected over 54h at 3 and 6h interval, respectively. Determinations included I^-, IO_3^-, O_{dis}, NO_3^-, NO_2^-, NH_4^+, DOC, pH, I in biomass, biomass growth and chorophylls.

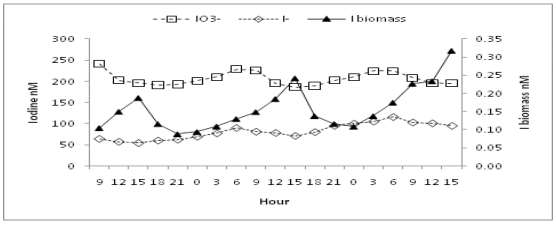

Figure 1: I^-, IO_3^- and I in biomass (*Tetraselmis sp*)

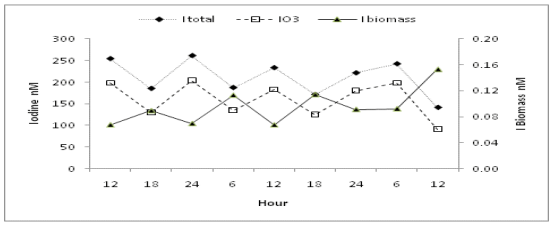

Figure 2: IO_3^-, I total and I biomass (bacteria culture)

Discussion and results

Dissolved iodine was absorbed during photosynthesis of *Tetraselmis* and released in respiration. A net production of 52 nM of I^- occurred while ΔIO_3^- was < 4 nM. The shift by 3h in oscillations of IO_3^- and O_{dis} indicates partipation of the former in enzymatic reactions as suggetesd by [1].Significant correlations between I^- concentration and primary production were found. Sorption of iodine seems to involve I^- and organic I and may involve compounds that act storing energy. This would explain the liberation of I^- at night. Iodate showed cyclic variation in the bacteria culture with 12 hours amplitude. A significant activity of nitrifying and denitrifying bacteria was observed.

Reactive transport analysis on chemical weathering of a porous rhyolite

T. YOKOYAMA

Department of Earth and Space Science, Osaka University, 1-1 Machikaneyama, Toyonaka, Osaka 560-0043, Japan (tadashi@ess.sci.osaka-u.ac.jp)

Reaction and transport in chemical weathering of a porous rhyolite from Kozushima, a volcanic island in Japan, were studied. The mass balance in the rhyolite can be described by the following reaction-transport equation:

$$\partial c/\partial t = R_d(1-c/c_{eq})A/\Phi + D\partial^2 c/\partial x^2 - v\partial c/\partial x \qquad (1)$$

where c is the concentration (dissolved Si), t time, x depth from the surface of the rock, R_d dissolution rate (far from equilibrium), c_{eq} equilibrium concentration, A reactive surface area, Φ porosity, D apparent diffusion coefficient, and v fluid flow rate. Each of the parameters in eq. (1) has been determined by the laboratory experiments designed to simulate natural condition. The dissolution rate of Si and hydraulic conductivity of the rhyolite were measured by flowing pure water into a rock coulmn under a constant water head. The apparent diffusion coefficient of dissolved Si was determined by a through diffusion experiment [1]. Reactive surface area was measured by BET method. The depth profiles of the concentration of dissolved Si and dissolution rate calculated by eq. (1) (Fig. 1) reveal that an average dissolution rate for a depth of 1 m is ~2E−18 mol Si cm^{-2} sec^{-1}. The dissolution rate of the rhyolite during 52,000 years of weathering has been estimated by the field based study to be ~6E−19 mol Si cm^{-2} sec^{-1} [2]. The calculated dissolution rate is within one order of magnitude of the field rate.

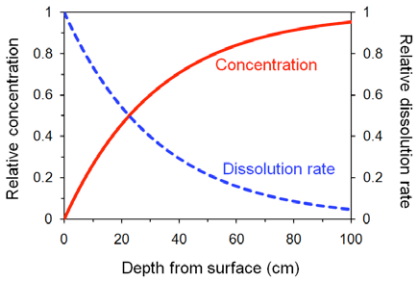

Figure 1: Depth profiles of the concentration of dissolved Si and dissolution rate.

Evaluation of in-house metallic standard for siderophile elements using fs-LA-ICPMS

T.D. YOKOYAMA*, T. IMAI[2], Y. UCHIYAMA[2], T. SUZUKI[3], T. YOKOYAMA[1], M. TAKEYAMA[4], E. TAKAHASHI[2] AND T. HIRATA[1]

[1]Dept. Earth and Planet. Sci., Kyoto Univ., Kyoto 606-8502, Japan (*correspondence: yokoyama@kueps.kyoto-u.ac.jp)
[2]Dept. Earth and Planet. Sci., Tokyo Ins. Tech., Tokyo 152-8551, Japan
[3]IFREE, Japan Agency for Marine Sci. and Tech., Yokosuka 237-0061, Japan
[4]Dept. Metallurgical Engin., Tokyo Ins. Tech., Tokyo 152-8551, Japan

Siderophile elements were preferentially distributed into the metallic phase or metallic core during the planetary formation sequence. Abundance data for siderophile elements can provide key information concerning the chemical evolution of metallic core or metallic phase in the meteoritic parent. However, pricise determination of the siderophile elements in the metallic samples have been retarded by the analytical difficlty mainly due to poor analytical precision or sensitivities achieved by the conventional laser ablation-ICP-mass spectrometry[1]. However, most of commercially available standard materials for elemental analysis does not cover many siderophile elements. To overcome this, we have prepared the in-house calibration standard material of Fe-Ni metal for determination of siderophile elements using femtosecond laser ablation ICP-mass spectrometry. The in-house metallic standard was prepered through arc melting technique from a mixture of high purity Fe, Ni and 20 siderohile and chalcophile elements powders, and heating treatment to minimize the elemental heterogeneity. The nominal concentrations of trace elements were 150 μg/g. The resulting metal button was subsidized to evalation of major and trace element abundance using EPMA and the fs-LA-ICPMS. The abundance data for both the major elements and trace elements reveraled that the abundance for trace elements did not vary measurably within the analytical precisions achived here. In this precision, we will present the abundance data. In this presentation, we will present the abundance data for several iron meteorites to comparing the previously reported value. Availability of in-house metallic standard for meteoritic metals will be discussed in this presentation.

Effect of oxidation state on arsenic and selenium incorporation into calcite

Y. YOKOYAMA* AND Y. TAKAHASHI

Hiroshima University, Hiroshima 739-8526, Japan (*correspondence: yoshiyuka@hiroshima-u.ac.jp)

The influences of oxidation state on arsenic (As) and selenium (Se) coprecipitation with calcite were evaluated with the information of their oxidation states both in water and calcite, and thermodynamic stability in water. To assess these reaction quantitatively, As and Se distribution coefficients (K_d) into calcite were determined using reproducible experimental system of their partition at low precipitation rates such as in natural systems.

The XAFS measurements showed that calcite selectively incorporated pentavalent As (arsenate) rather than trivalent As (arsenite)[1], and tetravalent Se (selenite) was selectively incorporated rather than hexavalent Se (selenate). Molecular geometries of dissolved selenite and selenate are similar to that of arsenite and arsenate, respectively. However, there was no relationship in their incorporation behavior into calcite. Interestingly, the XANES analysis detected arsenate and selenite in calcite precipitated only from arsenite or selenate spiked systems, respectively. Moreover, our cyclic voltammetric measurement observed arsenate stabilization in solution containing calcium ion indicating the shift of arsenite/arsenate redox boundary. These phenomena are associated with high stability of calcium arsenate and calcium selenite complexes compared with those for arsenite and selenate, respectively. Considering the abundance of calcium in natural water, the valence change effects by calcium is important as a (geo)chemical reaction which may have been overlooked so far. Hence, we conclude that the factor controlling incorporation behavior of As and Se into calcite is the stabilities of their complexes with calcium ion. These thermodynamic properties should be explained by quantum chemical approaches. In view of the valence change effects by calcium, ratios of their net K_d into calcite were determined at pH ~7 : $K_{As(V)}/K_{As(III)}$ was >2500 and $K_{Se(IV)}/K_{Se(VI)}$ was 150.

Immobilization of As and Se with calcite in groundwater are of great interest for remediation of contaminated drinking water such as in Bangladesh and for inhibition of ^{79}Se migration from nuclear waste repositories, respectively. Therefore, the present findings should provide some insights into those concerns because As and Se oxidation states are variable in subsurface environment.

Silicic acid removal as calcium or magnesium silicate from geothermal water

KOTARO YONEZU[1], YOHEI KAWABATA[1], KOICHIRO WATANABE[1] AND TAKUSHI YOKOYAMA[2]

[1]744 Motooka, Nishi-ku, Fukuoka 819-0395 Japan, (yone@mine.kyushu-u.ac.jp)
[2]6-10-1 Hakozaki, Higashi-ku, Fukuoka 812-8581 Japan

Geothermal energy is one of the most probable clean energy in Japan; however the total power supply from geothermal energy has recently plateaued due to short lifetime of reinjection well caused by siliceous deposit from geothermal water. Removal of silicic acid as calcium or magnesium silicate is investigated towards an effective utilization of geothermal energy.

Sample solutions were prepared to be an initial Ca/Si or Mg/Si molar ratio = 1.4 to 4.0 (Si concentration: 400 ppm). The solutions were magnetically stirred and the pH was maintained at 11 or 12 with NaOH solution. At appropriate intervals, an aliquot of the suspensions was filtered using a 0.45 μm membrane filter. At an initial Ca/Si or Mg/Si ratio = 2.1, silicic acid in the solution can be effectively removed within 1 h. The precipitates are identified as calcium silicate or amorphous magnesium silicate by XRD patterns. In addition to removal of silicic acid, simultaneous removal of boron coprecipitated with silicate was investigated (B concentration: 40 ppm). In the case of calcium silicate, around 50 % of boron can be removed. In contrast, almost all boron can be removed from the solution by magnesium silicate. ^{11}B NMR result showed that boron coprecipitated with magnesium silicate exists as 4-coordinated, suggesting that the coprecipitated boron may be incorporated by substitution of Si with B.

Advantages of this removal method are realization of longer lifetime implement at geothermal power plant and simultaneous removal of hazardous elements. The treatment of enormous amount of silicate removed from geothermal water remains an issue to be solved.

Christina River Basin Critical Zone Observatory: Carbon-mineral interactions from molecular to basin scales in the Anthropocene

KYUNGSOO YOO[1], ANTHONY K. AUFDENKAMPE[2], CHUNMEI CHEN[3] AND DONALD L. SPARKS[3]

[1]Dept. of Soil, Water, and Climate, University of Minnesota, St.Paul, MN.USA. (*correspondence: kyoo@umn.edu)
[2]Stroud Water Research Center, Avondale, PA. USA. (aufdenkampe@stroudcenter.org)
[3]University of Delaware Environmental Institute, DE, USA. (cmchen@udel.edu and dlsparks@udel.edu

Over the last several decades, biogeochemical studies on terrestrial carbon cycle have converged on a consensus that tight association of organic matter (OM) with minerals through physical occlusion or surface complexation is crtical in lengthening the turnover time of carbon (C).

The primary goal of the Christian River Basin Critical Zone Observatory (CRB-CZO) is to scale up C-mineral interactions that occur at molecular and mineral grain scales to soil profiles to hillslopes and finally to basin scales. While small (nano to mineral grain) scale characterizations of C-mineral interactions are being made, physical movment of OM and minerals –such as soil mixing at soil profile scale, physical erosion and deposition in watershed scales, and stream turbulence in streams – is investigated as responsible for their contacts. Chemical weathering of minerals and minerals' interaction with water are considered as processes that generate the surface area and reactivity of minerals where OM could be complexed. Additionally, biological cycling of OM prepares OM's chemical affinity to minerals.

Preliminary analyses suggest that the extents of physical contacts between OM and minerals – which are required for C-mineral complexation – are indeed limited by their physical movements and that these movements are highly sensitive to land use types. Furthermore, eroded minerals from agricultural fileds appear to complex C during their fluvial transit. The preliminary data support the core assumptions of our hypothesis that accelerated erosion and deposition in agricultural and constructional watershed may generate greater amount of mineral-complexed C.

In the end, we expect that our intensive field sampling and installation of wireless sensor network and data management toward testing our hypothesis should build our CRB-CZO as an excellent resource for entire scientific community.

Uranium and radium isotope ratio at Korean hot spring water

YOON YEOL YOON, SEUNG GU LEE, SOO YOUNG CHO, KIL YONG LEE AND TAE JONG LEE

Korea Institute of Geoscience and Mineral Resources, Gwahang-no 92, Yuseong-gu, Daejeon, 305-350, Korea (yyyoon@kigam.re.kr, sgl@kigam.re.kr, sycho@kigam.re.kr, kylee@kigam.re.kr, megi@kigam.re.kr)

The hydrological characteristics of the groundwater were affected by surrounding geology and water-rock interaction. To understand hydrogeology, various applications of isotope geochemical techniques for geothermal investigations have been applied.

Uranium and Radium are natural radionuclides and they have isotopes. To understand water-rock interaction and hot spring water environments ^{234}U, ^{238}U, ^{226}Ra, and ^{228}Ra were analyzed using extractive radiochemistry and LSC measurements.

Uranium isotope was extracted with HDEHP and counted with LSC. Radium isotopes were separated using Ba coprecipitation and ^{226}Ra was counted with LAC and ^{228}Ra was analyzed with HPGe γ-detector. Among them ^{228}Ra is below detection limit.

Relative B-Li-Cl compositions: Capability and limitation to direct observation of deep geofluid

K. YOSHIDA[1]*, Y. SENGEN[1], S. TSUCHIYA[1], K. MINAGAWA[1], T. KOBAYASHI[2], T. MISHIMA[3], S. OHSAWA[3] AND T. HIRAJIMA[1]

Some recent studies invoked that the variation of some fluid soluble light elements, e.g., Li, B and Cl, are capable of suggesting fluid generation depths [1, 2]. To evaluate this idea, we mesured relative B-Li-Cl compositions of fluid inclusions in quartz veins intercalated with basic/pelitic schists and eclogites of the Sambagawa belt, Japan, as foliation parallel quartz veins are capable of preserving the characteristics of syn-metamorphic fluid inclusion [3].

Li/B ratio of the crush-leached fluid extracted from quartz veins intercalated with basic schists and eclogites from Wakayama and Besshi area show a positive correlation with peak *P-T* conditions of their host rocks [4]. However, some fluid samples extracted from quartz veins hosted in pelitic schists from Besshi area have much higher Li/B ratios than those of the basic schist of the same metamorphic grade [5]. Hydrochemical facies of those samples are characterized by the dominance of Na-Cl or Na/K-HCO_3. Optical and SEM-CL observation indicate that those quartz veins are deformed with various degrees and most of them show polygonal texture. On the other hand, most crush-leached fluid extracted from quartz veins of Asemi-gawa area show discrete Li/B value. Their hydrochemical facies are characterized by the dominance of Ca-HCO_3, which is known as the characteristics of pore fluid in near surface fracture of continental crust [6], and quartz veins have strongly deformed fabric.

These results suggest that deformation during the exhumation stage, accompanied with fluid infiltration, can severely modify the compositions of fluid trapped in the corresponding veins. Despite that there are several problems in using fluid inclusions in quartz veins as a means to investigate geofluid activity, hydrochemical facies of the crush-leached fluid and quartz fabric can be clues to find the syn-metamorphic fluid.

Carbon isotope evolution in magmatic systems by CO_2 fluxing

SHUMPEI YOSHIMURA[1]* AND MICHIHIKO NAKAMURA[2]

[1]Natural History Sciences, Hokkaido University, Sapporo 060-0810, Japan (*correspondence: shumpyos@ep.sci.hokudai.ac.jp)
[2]Department of Earth Science, Tohoku University, Sendai 980-8578, Japan (nakamm@m.tohoku.ac.jp)

Simple degassing models often fail to explain the high CO_2/H_2O ratio of melt inclusions and obsidian pyroclasts. This suggests that the fluxing of a deep-derived CO_2-rich fluid is common in crustal magmatic systems (e.g., [1]). This process, called "CO_2 fluxing", is believed to be a combination of the advective flow of a CO_2-rich fluid through a magma column and the resulting volatile exchange. However, other processes, such as closed-system equilibrium degassing under the presence of a buffering CO_2-rich fluid [2] and disequilibrium open-system degassing [3], can explain such data. In this study, we show that carbon isotope ($\delta^{13}C$)–CO_2 systematics may discriminate these processes.

We present a theoretical framework of carbon isotope evolution caused by CO_2 fluxing based on a reactive transport model. We assumed that a CO_2-rich fluid with a constant CO_2/H_2O ratio and a constant $\delta^{13}C$ value is introduced into a magma column and flows upward through the column, exchanging volatile components chemically and isotopically with the melt. The governing equations consist of an advection equation, the solubility law of CO_2-H_2O and an equation of isotope equilibration. The equilibrium volatile exchange is assumed at each level of the column.

The calculations show that initial carbon isotope distribution is immediately modified as the fluxing proceeds. When the first incremental of the introduced fluid reached the top of the column, the $\delta^{13}C$ value was almost constant along the column, whereas CO_2-H_2O concentrations were still changing towards entire equilibrium between the magma and the introduced fluid. These results are in contrast to those for other processes such as equilibrium degassing where $\delta^{13}C$ decreases as degassing proceeds, or disequilibrium degassing where $\delta^{13}C$ is expected to increase because $^{12}CO_2$ may diffuse faster than $^{13}CO_2$.

[5]Usa Marine Biological Institute, Kochi Univ., Kochi, Japam

This study presents magnesium isotopic composition and its temperature dependence of high Mg biogenic calcium carbonates to evaluate their potential proxy of paleo seawater temperature. Degrees of Mg isotope fractionation compared to present seawater were measured in deep-sea coral. The mean $\delta^{26}Mg$ value of deep-sea corals was –2.5‰. Moreover, Mg isotope fractionation in deep-sea coral showed a clear temperature dependence from 2.5 to 19.5 °C. The observed temperature dependence of Mg isotope fractionation in deep-sea coral skeletons allows potential application of Mg isotopes of high-Mg calcite to an environmental proxy for water temperature, and one possible way for robust temperature reconstruction is a multi-proxy approach which provides complementary and more robust temperature data using traditional and non-traditional temperature proxies. The mean $\delta^{26}Mg$ value of large benthic foraminifera which are also composed of high-Mg calcite was -2.34‰. Deep-sea coral and benthic foraminifera both plot on the same regression line within uncertainty. Deep-sea corals and benthic foraminifera also showed similar Mg isotope fractionation factor to inorganically precipitated calcite, and the slope of temperature dependence in Mg isotope fractionation is similar to that for an inorganically precipitated calcite speleothem. Moreover, Mg concentrations and the relationship between Mg/Ca and temperature were also similar between deep-sea corals and inorganically precipitated calcite. Taking into account elemental partitioning and the calcification rate of biogenic CaCO3, the similarity among inorganic minerals, deep-sea corals and benthic foraminiferas may indicate a strong mineralogical control on Mg isotope fractionation for high-Mg calcite.

Laboratory-based conductivity structure in the mantle transition zone

T. YOSHINO[1], A. SHIMOJUKU[1] AND T. KATSURA [2]*

[1]Institute for Study of the Earth's Interior, Okayama Univ., 682-0193 Misasa, Japan (tyoshino@misasa.okayama-u.ac.jp, simojuku@misasa.okayama-u.ac.jp)
[2]Bayerisches Geoinstitut, Univ. Bayreuth, 95440 Bayreuth, Germany (*correspondence: tomo.katsura@uni-bayreuth.de)

It is essential to assess the species and amount of volatile components in the mantle for understanding its dynamics and evolution. For this reason, we studied conductivity of the upper-mantle minerals as a function of temperature and incorporated water content. Our measurements on hydrous olivine, wadsleyite and ringwoodite demonstrated that, although the water incorporation to these minerals increases their conductivity, this effect is relatively small. In contrast, other research groups claimed significantly larger effects. Our measurement was criticized due to lack of impedance spectroscopy for wadsleyite although we adopted this method for olivine and partly ringwoodite. For this reason, we reinvestigated conductivity of hydrous wadsleyite by means of impedance spectroscopy.

Our measurement demonstrated that conductivity of a fluid phase released from hydrous wadsleyite masks that of wadsleyite itself above 1000 K. It was also found that the impedance arcs in the Nyquist plot are significantly distorted when the fluid phase is released, probably because impedance arcs of the grain boundary fluid and reaction on the electrodes overlap with each other. The measurement results given by our conventional low frequency method and impedance sprectroscopy show excellent agreement. These observations prove appropreateness of our previous conclusion.

We constructed a laboratory-based conductivity model of the upper mantle using our experimental data. This model shows the following features. The conductivity jump at 410-km depth is very small even if it exists. In contrast, the conductivity jump at 520-km depth is remarkable. There is no evidence from conductivity for presence of water in the mantle transition zone beneath the Pacific Ocean. Very high amount of water (0.5 %) would be required to explain the high conductivity beneath the Philippine Sea if it is explained by hydration of the upper-mantle minerals.

In situ iron isotope analyses of pyrites from 3.5 to 3.2 Ga sedimentary rocks of the Barberton Greenstone Belt, Kaapvaal Craton

KAZUMI YOSHIYA[1], YUSUKE SAWAKI[2], TAKAZO SHIBUYA[2], SHINJI YAMAMOTO[3], TSUYOSHI KOMIYA[3], SHIGENORI MARUYAMA[1] AND TAKAFUMI HIRATA[4]

[1]Dept. of Earth and Planetary Sci., Tokyo Institute of Technology, Japan (yoshiya.k.aa@m.titech.ac.jp)
[2]Japan Agency for Marine-Earth Sci. & Tech., Japan
[3]Dept. of Earth Sci. and Astro., Komaba, Univ. Tokyo, Japan
[4]Dept. of Geology and Mineralogy, Kyoto Univ. Japan

The Barberton Greenstone Belt (BGB), South Africa consists of volcano-sedimentary successions and sedimentary rock sequences deposited between 3.5 and 3.2 Ga, and is subdivided into three groups: the Onverwacht, Fig Tree, and Moodies Groups. Several putative morphological fossils (filamentous and sphere type) and trace fossils were reported from the Hooggenoeg and Kromberg Formations in the Onverwacht Group [1,2,3]. On the other hand, isotopic data suggest the activities of sulphate-reducing bacteria and photosynthetic bacteria at 3.4 Ga [4]. Dissimilatory iron reduction (DIR) is also considered to be one of the earliest metabolisms on Earth [5], but the previously reported oldest isotopic evidence for the DIR by bacteria is from 2.9 Ga [6]. We report the in-situ iron isotope analysis of individual pyrites in sedimentary rocks from the BGB, using femtosecond laser ablation multi-collector ICP-MS technique (fs-LA-MC-ICP-MS) [7]. We obtained a large variation of iron isotope data from -1.9 to +3.6 ‰ in δ^{56}Fe values, from 94 pyrite grains in 16 samples: five cherts from the Hooggenoeg Formation, eight cherts from the Kromberg Formation, one sandstone from the Fig Tree Group, and three sandstones from the Moodies Group. The δ^{56}Fe values of pyrite from Hooggenoeg Formation show positive values, whereas those from the Kromberg Formation show wide variation from positive to negative values. The negative δ^{56}Fe values of pyrites with a nadir down to -1.9 ‰ in the Kromberg Formation indicates DIR by bacteria. This result shows that the activity of iron-reducing bacteria can date back to, at least, the middle Archean.

Geological characteristics of black shale series in southern Anhui Province

HAIJIAO YOU[1,2], YONG ZHAN[1,2] AND YOUFEI GUAN[1,2]

[1]China Gezhouba Group Corporation, P.R. China (youhaijiao@yahoo.cn)
[2]Anhui University of Architecture, P.R. China

The black shale series in southern Anhui are developed widely. The southern Anhui area is located in the northeast margin of Lower Yangtze block and adjacent to Jiangnan uplift zone. The occurrence of Paleozoic strata is relative complete, and the Lower Cambrian shale black shale series are relatively well developed in Hetang Formation and Huangbailing Formation that locate on both sides of Jiangnan deep-fault zone. The area developed the Sinian and Early-Middle Triassic sedimentary cover, late Yanshanian intrusions, NE Jura-type folds and a series of the NE tthrusting (sliding) nappe structure, and suffered multi-stage tecteonic movements with a polycyclic feature of magmatic activities.

Lower Cambrain Hetang Formation and Huangbailing Formation are the primary strata of black shale series, and they are different on lithology and thickness. Then former is divided into three parts from bottom to top on lithology: the lower part is carbonaceous siliceous mudstone member intercalating with limestone, composing of Si-bearing carbonaceous shale, carbonaceous limestone, calcipulverite and phosphatic nodule with obvious rhythm, and the middle part is carbonaceous mudstone member that comprises carbonaceous mudstone, siliceous mudstone and silty carbonaceous mudstone, intercalating with a layer of fine-grained calcipulverite, and the carbonaceous materials are enriched to form stone coal layer in the lower section of the middle part, and the upper part is mudstone member with horizontal laminar, mostly composed of gray calcareous mudstone and carbonaceous mudstone with obvious horizontal laminar. The later is also divided into three parts: the lower part is black carbonaceous siliceous shale member with lentoid stone coal layer at the bottom, and the middle part is gray medium-bedded calcipulverite and black carbonaceous shale, and the upper part is yellow green mudstone with silty shale. The thickness of Huangbailing Formation is more than Hetang Formation's.

The middle members of Hetang Formation and Huangbailing Formation both have poly-metallic enrichment layer where enriched useful elements (Ni, Mo, Au, Ag, etc.), rare elements (Cd, Se, Ti, Cs, etc.) and radioactive elements (U, Th, etc.). Therefore, the systematic study on black shale series in the area has important theoretical significance and potential economic value.

This research was financially supported by the Natural Science Foundation of Anhui Provincial Education Department of China (NO.KJ2010A070).

Microbial dolomite in Cambrian stromatolites of Tarim basin, northwest China

XUELIAN YOU

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China (youxuelian007@gmail.com)

Microbial mediation is the only proven mechanism to precipitate experimental dolomite under Earth's surface conditions [1]. Proving a biogenic microbial origin for ancient stromatolites is very difficult, but there are dumbbell dolomite with nanoglobule texture within micritic dolomite crystal (Fig 1A) and aggregates of nanoglobules dolomite (Fig 1B) in dark stromatolitic laminae in a inter-supratidal of the lower sabkha deposits. Nanoglobules (indicated by red arrows in Fig 1A) are 50–90 nm in diameter and aggregates of nanoglobules (indicated by black arrows in Fig 1B) are 100–160 nm (large globules).

The characteristic texture, morphology and sizes in diameter are very similar to the results of dolomite precipitation in anerobic or aerobic culture experiments [2, 3]. These results reveal that these observed may be microbial signatures preserved in the rock record .

These results provide microbial tracers evidences in Cambrian dolomite stromatolites which are proposed a microbial dolomite origin.

This work is granted by the National major Science and Technology Project of China (No. 2008ZX05008-003)

Study of evolution model of Triassic K-rich brine in Sichuan Basin

ZHOU YOU[1] AND ZHANG HANG[2]

[1]key lab of Geomathematics of Sichuan province, chengdu sichuan China, 610059 (*correspondence: zhouyou06@cdut.cn)

[2]Chengdu university of technology , chengdu sichuan China, 610059 (zhanghang@cdut.edu.cn)

Sichuan Basin has rich brine resources in China. It has 2000 years of mining history of Salt in it's southwest mine.

This paper forms the ancient brine hydrogeological conditions, and establishes the Sichuan basin evolution model of K-rich brine. This paper argues that causes of K-rich brine in eastern Sichuan and western Sichuan is not entirely consistent.K-rich Brine formation process in Triassic can be summarized as follows:

1. Early and Middle Triassic, Sichuan Basin become marginal sea with seawater intrusion. Water salinity increased and the initial potassium concentrated. In the end of Early Triassic, the submarine volcanic eruption formed about 1 m thick mung bean rock, and provided a wealth of potassium resources.

2. Indo-China movement in the end of Middle Triassic, almost the entire Sichuan Basin rised above the sea surface. Triassic strata was impact of erosion and denudation. Original sedimentary brine was poured and mixed by leaching water.

3. Late Triassic Basin decreased, seawater intrusion until the Cretaceous. In this period, basin accumulated a thick layer of sediment over 1000m. Original sedimentary brine was deep closed and metamorphism. Rock salt, mung bean rock and plaster provided potassium and water.

4. In the end of Cretaceous, Sichuan movement maked the basin to rise again and also to make the basin have a large number of drapes and fractures,which have become reservoir space of K-rich brine. Sichuan movement has also brought deep hydrothermal which Contain potassium and other elements. K-rich Brine Enriched in the fornix trap structure, formed Brine deposits

In Sichuan basin, K-rich brine was found in eastern Sichuan and western Sichuan. PL4 well in western Sichuan, Boron content is up to 4767.6mg/l, and potassium content is 49.95g/l. The content is about twice the eastern C25 well. This paper argues that PL4 well is deeply influenced by the deep hydrothermal than C25 well, and East Tethys seawater had supply the western basin in the end of Middle Triassic. This view was support by trace element and isotope geochemistry.

High mass resolution gas-source mass spectrometry

E.D. YOUNG[1]*, D. RUMBLE III[2] , P. A. FREEDMAN[3], E.A. SCHAUBLE[1] AND W. GUO[2]

[1]Department of Earth and Space Sciences, UCLA, Los Angeles, CA 90095 (eyoung@ess.ucla.edu)

[2]Geophysical Laboratory, Carnegie Institution of Washington, Washington DC, 20015

[3]Nu Instruments Ltd., Wrexham, UK

Conventional gas-source isotope ratio mass spectrometers are fully capable of measuring the relative abundance of the rare $^{13}C^{18}O^{16}O$ isotopologue (m/e ~ 47) in CO_2. Abundances of rare isotopologues of other gases are promising tracers of provenance in geochemistry and atmospheric chemistry, but measurements are not possible at present due to the limitations imposed by gas-source mass spectrometers on the market today. A critical step forward is an increase in the mass resolving power (MRP) of these instruments.

We have begun a project to build a high-MRP gas-source isotope ratio mass spectrometer designed expressly for the purpose of resolving rare isotopologues of a variety of gases, including those of CH_4. The latter have driven the design in large part because of the difficulty in resolving $^{13}CDH_3$ from $^{12}CD_2H_2$ (m/Δm = 6178) together with the great potential that these species would have in establishing the provenance of CH_4.

We utilize the so-called "Matsuda" post-ESA lens arrangement for minimizing aberrations. The design maximizes MRP while minimizing vertical dispersion along the flight path. With a magnetic sector radius of 800 mm the anticipated MRP is ~ 30,000 to 40,000 with acceptable sensitivity. This is sufficient for flat-top peak resolution of a wide variety of rare isotopologues of gases that include CH_4, O_2, N_2O, SO_2, among others. An example calculation of the effect of MRP on separating mass-18 isotopologues of CH_4 is presented in the figure below. Results show that an MRP approaching 30,000 is required for flat-top resolution of $^{18}CH_4$ species.

Assessment of the geochemical processes and environmental pollution in the Trincomalee bay, Sri Lanka

SANSFICA M. YOUNG[1]*, A. PITAWALA[2] AND H. ISHIGA[1]

[1]Department of Geosciences, Shimane University, 690-8504, Matsue, Japan

[2]Department of Geology, University of Peradeniya, Peradeniya, Sri Lanka

Trace and major elements of surface sediments in bay environment are often used to study the geochemical processes, environmental issues, transportation of weathered products. The Trincomalee bay can be divided into three parts as for sediment distribution; Koddiyar Bay (KB), Thanmbalagam Bay (TB) and Inner Harbor (IH). Surface samples from all three areas have been collected and XRF analysis was carried out to determine As, Pb, Zn, Cu, Ni, Cr, V, Sr, Y, Nb, Zr, Th, Sc, Fe_2O_3, TiO_2, MnO, CaO, P_2O_5 and total sulphur contents. Geographical Information System (GIS) maps for ratio plots Th/Zr was used to consider heavy mineral (HM) accumulation and dilution and the surface distribution of Th and Zr individually to further explain many HM faces involved. The GIS maps for other individual elements also were used to explain the geochemical processes within the bay area upon the input of the river sediments and also the pollution activities.

Th/Sc-Zr/Sc shows that the sediments are of andesite to rhyolite in composition, while the KB shows Zr enrichment. Cr/V-Y/Ni shows a Cr dilution with carbonates while the Cr-Ni shows a quartz dilution in the IH indicating marine influence. Environmental contamination of Cu, Pb As, Zn is seen in the IH due to the harbour and in the KB and TB with natural issues.

Weighting stream sediment geochemical samples as exploration indicator of deposit-type

M. YOUSEFI[1], A. KAMKAR-ROUHANI[1] AND E.J.M. CARRANZA[2]

[1]Mining Department, Shahrood University, Iran (*correspondence: m.yousefi.eng@gmail.com, kamkarr@yahoo.com)

[2]Faculty of Geo-Information and Earth Observation (ITC), University of Twente, Netherlands (carranza@itc.nl)

Factor analysis has been widely used for classification of stream sediment geochemical data in mapping of prospective areas for certain type of mineral deposits [1, 2]. However, interpretation of the results of factor analysis remains challenging in terms of selecting the factor (or association of elements) that best predicts the location of known mineral deposits of a certain type. Here, we used stepwise factor analysis to recognize and omit non-predictive geochemical elements from the data to elicit the best factor representing the presence of mineral deposits of the type being examined. Then, to obtain a geochemical mineralization probability index of mineral deposits of the type sought X ($GMPI_X$) for each stream sediment geochemical sample, we used multivariate and logistic regression analyses sequentially. The generalized model of $GMPI_X$ for mineral deposits of the type sought (X) is

$$GMPI_X = \frac{e^{\alpha_0+\alpha_1 y_1+\alpha_2 y_2+\cdots+\alpha_n y_n}}{1+e^{\alpha_0+\alpha_1 y_1+\alpha_2 y_2+\cdots+\alpha_n y_n}},$$

where $y_1, y_2,\ldots,y_n$ are 'predictor' elements of the deposit-type of interest, which were obtained from the results of stepwise factor analysis; $\alpha_1, \alpha_2,\ldots, \alpha_n$ are multivariate regression coefficients. The values of $GMPI_X$ range between 0 and 1. These values can be mapped to delineate areas upstream of geochemical samples where mineral deposits of the type sought are likely present. Successful application of the proposed methodology is demonstrated for fluorite deposits in a study area in Iran.

Oxidative weathering of black shale: A long-term humidity cell test

C.X. YU[1]*, M. ÅSTRÖM[1], P. PELTOLA AND H. DRAKE

School of Natural Science, Linnaeus University, 39182 Kalmar, Sweden (*correspondence: changxun.yu@lnu.se)

Weathering of black shale is of large envionmental interest, and is characterized by oxidation of sulfide minerals (mainly pyrite) and organic matter [1]. When oxidized large amount of trace elements could be liberated and subsequently transferred into the broader environment. Here we present a long-term humidity cell test of non-weathered black shale (NBS) and weathered black shale (WBS). The NBS and WBS was leached for 137 (66 leaching cycles) and 53 weeks (40 leaching cycles), respectively.

BET surface area of NBS increased by 26 %, which is mainly contributed by euhedral pits caused by the oxidation of pyrite embedded in the illite matrix (Fig. 1a). XRD analyses confirmed that the amount of pyrite decreased from ~4.3% to 2.8% during the experiment. As a result, large proportions (27% to 61%) of Co, Ni, Cd, Zn, Mn, U and Cu have been leached from NBS, whereas the proportions leached of As, Cr, Ba, Pb and V were lower than 2.3%. Major cations Fe and Al in NBS leachates showed significant correlation with S after cycle 32 at pH 5.5, implying that their behaviours were controlled by common sulphate minerals thereafter. The pore-rich grains of leached NBS, structured by a silicate matrix (illite and quartz) resistant to the oxidative weathering, were characterized by abundant precipitation of siderite and/or gypsum within pores and schwertmannite coating onto their surface (Fig. 1a). Three types of encrustations were identified in both leached NBS and WBS: schwertmannite with minor amount of Fe^{3+} phosphate (Fig. 1b), Fe^{3+} phosphate and apatite. These encrustations have strong affinity for trace elements occurred as negative charged aqueous species (e.g $H_2AsSO_4^-$), providing potential filters for natural trace element cyling.

Assessing impact of aerosol intercontinental transport on regional air quality and climate: What satellites can help

HONGBIN YU[1,2]

[1]Earth System Science Interdisciplinary Center, University of Maryland, College Park, MD 20740, USA
[2]Laboratory for Atmospheres Research, NASA Goddard Space Flight Ceneter, Greenbelt, MD 20771, USA (Hongbin.Yu@nasa.gov)

Mounting evidence for intercontinental transport of aerosols suggests that aerosols from a region could significantly affect climate and air quality in downwind regions and continents. Current assessment of these impacts for the most part has been based on global model simulations that show large variability. The aerosol intercontinental transport and its influence on air quality and climate involve many processes at local, regional, and intercontinental scales. There is a pressing need to establish modeling systems that bridge the wide range of scales. The modeling systems need to be evaluated and constrained by observations, including satellite measurements. Columnar loadings of dust and combustion aerosols can be derived from the MODIS and MISR measurements of total aerosol optical depth and particle size and shape information. Characteristic transport heights of dust and combustion aerosols can be determined from the CALIPSO lidar and AIRS measurements. CALIPSO lidar and OMI UV technique also have a unique capability of detecting aerosols above clouds, which could offer some insights into aerosol lofting processes and the importance of above-cloud transport pathway. In this presentation, I will discuss our efforts of integrating these satellite measurements and models to assess the significance of intercontinental transport of dust and combustion aerosols on regional air quality and climate.

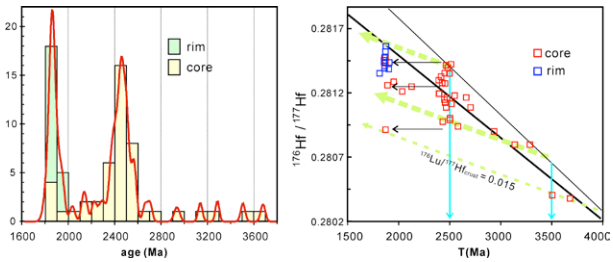
Formation of the oldest rocks in the Cathaysia Block, Southern China

JIN-HAI YU[1,2], SUZANNE Y. O'REILLY[2], LIJUAN WANG[1,2] AND W.L. GRIFFIN[2]

[1]State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China

[2]GEMOC ARC National Key Centre, Department of Earth and Planetary Sciences, Macquarie University, Sydney, N.S.W. 2109, Australia

Precambrian basement in the Cathaysia Block of South China is mainly found in the Wuyishan area (southern Zhejiang and northwestern Fujian Provinces). The Badu Complex which is the oldest rock in the area consists of various mets-sedimentary rocks and was intruded by Paleoproterozoic (1.88-1.86 Ga) granites. CL images, U-Pb dating results and trace element compositions of zircons from the high-grade metamorphic rocks in the Badu Complex indicate that inherited zircon cores are of magmatic origin and predominantly formed ca. 2500 Ma ago, while the rims overgrew at 1886-1882 Ma and 252-234 Ma. Although some zircon cores have Paleoproterozoic ages similar to the rims, the similarity in the trace element and Hf-isotopic compositions between these Paleoproterozoic cores and those Neoarchean cores suggests that these zircon cores underwent intense Pb-loss resulting from late high-grade metamorphism. The unimodal age (~2.5 Ga) distribution of detrital zircons and positive εHf(t) of most Neoarchean zircons (Fig. 1) suggests that the detritus of these sedimentary protoliths probably came from a proximal volcanic arc, implying that they were deposited in an arc basin and almost synchronously with ~2.5 Ga volcanism. These are the oldest rocks in the Cathaysia Block found so far. The combination of zircon U-Pb ages and Hf-isotope data suggests that both generation of juvenile crust and reworking of 2.8 Ga and 3.5-3.3 Ga crust occurred at ~2.5 Ga.



Strong ~1.9 Ga thermal event only involved the reworking of older crust material without the input of juvenile crust.

Geochemical characters and LA-ICP-MS zircon U-Pb dating of the Lenglonglin volcanic rocks in North Qilian tectonic belt

JI-YUAN YU, XIANG-MIN LI, GUO-QIANG WANG AND PENG WU

Xi'an Center of Geological Survey(Xi'an Institute of Geology and Mineral Resource), CGS, Xi'an, haanxi 710054. China (yujiyuan111@163.com)

The Qilian Orogen is divided into the Northern, Central and Southern Qilian. Lenglonglin area of Menyuan is located in the east segment of Northern Qilian and is composed of volcanic rocks and little acid volcanic rocks. Geochemical analyses show that Lenglonglin rocks have SiO_2 ranging from 48.94 to 60.97 wt %, K_2O/Na_2O less than 1, SiO_2-Nb/Y and SiO_2 - FeOT/MgO diagram shows the samples belong entirely to the tholeiitic series. Low Ti and high Al,Fe indicating that they are typically characterized as is land arc volcanic rocks. These monzogranites are depleted in HFSE, such as Ta, Nb and Ti, such as enriched in LILE, such as K, Th, Rb and Ba, with total REE contents ranging from 9.88 to 42.21 ppm and ∑LREE/ ∑HREE ratios of 0.81-5.70. The Chondrite-normalized REE patterns of these volcanic rocks is weak negative Eu anomalies (δEu = 0.58-1.10), These results with the accepted Kermadec island volcanic of New Zealand is very similar.At the same time, Zr/Y-Zr、Ti-Zr、Tb-Th-Ta*2 and Hf/3-Th-Ta indicate that these volcanic rocks could represent typical land arc volcanic rocks. In order to limit accurate formation time of Lenglongling volcanic rocks in the east segment of North Qilian orogenic belt by LA-ICP-MS U-Pb isotope dating technique, combined with cathodoluminescence image(CL) study, was used to determine the zircons from Lenglongling Dacite. Two main populations of zircons from Lenglongling Dacite obtained, giving an average $^{206}Pb/^{238}U$ ages of 460. 17±0.92Ma and 203.2Ma±3.8Ma. With the relevantdata synthesized, Lenglongling Intermediate-Basic volcanic rocks were considered to form in the Middle Ordovician, It was transformated by the Yanshan collision orogeny. These new data have important significance for further research on the tectonic evolution and the ore prospecting directions in the east segment of the north Qilian orogenic belt .

Structural effect of Zn^{2+} on biogenic Mn oxides: EXAFS analysis of solid residues after concomitant immobilization

QIANQIAN YU[1]*, KEIKO SASAKI[1], TSUYOSHI HIRAJIMA[1], KAZUYA TANAKA[2] AND TOSHIHIKO OHNUKI[2]

[1]Department of Earth Resources Engineering, Kyushu University, Fukuoka, Japan (q-yu09@mine.kyushu-u.ac.jp)
[2]Advanced Science Research Center, Japan Atomic Energy Agency, Ibaraki, Japan

Manganese oxides which are thought to be the potential scavenger of trace metals are commonly believed to be biogenic origin. Zn^{2+} in aquatic phase can be immobilized in Mn oxide phase during the biotic oxidation of Mn^{2+}. The amounts of immobilized Zn^{2+} were around twice in microbial Mn^{2+} oxidation in the presence of Zn^{2+} than in simple sorption of Zn^{2+} on biogenic Mn oxides which was produced in advance (Fig. 1). Analysis of Zn K-edge EXAFS spectrum for the solid residue after the concomitant immobilization of Zn^{2+} suggests that Zn atoms are coordinated to O atoms via triple-corner sharing (TC) at Mn vacant site in tetrahedral coordination. The XRD patterns showed that it belongs to poorly crystalline birnessite, its crystal size was calculated to less than 100 nm by Scherrer equation, and there is a lack of stacking in c axis. The measurement of zeta potential for the solid residue after the concomitant immobilization of Zn^{2+} indicated that the surface charge was more negative compared with fresh biogenic birnessite. XAFS/EXAFS analysis revealed that it contains less Mn(III) contents and larger numbers of vacant sites than fresh biogenic birnessite. Co-existence of Zn^{2+} influences Mn oxide formation during bio-oxidation, resulting in poorly crystallized birnessite and other types of Mn oxides which can be commonly found in the natural environments.

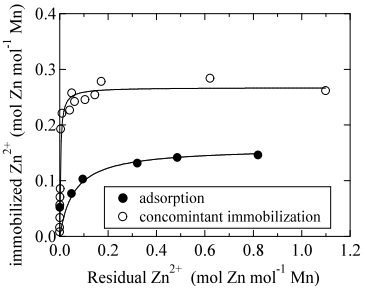

Figure 1: Sorption isotherms of Zn^{2+} on biogenic birnessite (●), and in concomitant immobilization with microbial oxidation of Mn^{2+} ions (○) at 25 °C and pH 6.5.

Metastable phase equilibria for the aqueous system containing lithium, rubidium and chloride at 298.15 K

X. D. YU[1], Y. ZENG[1,2]*, J.Q. ZHANG[1], J.Y. YANG[3]

[1]Department of Geochemistry, Chengdu University of Technology, Chengdu, 610059, China; (*correspondence: zengyster@gmail.com)
[2]Mineral Resources Chemistry Key Laboratory of Sichuan Higher Education Institutions, Chengdu, 610059, China;
[3]Development & Comprehensive Utilization of Marine Sedimentary Brine Sichuan Provincial Key Laboratory, Chengdu, 610059, China

The Pingluoba underground brine (Southwest China), belongs to the marine sedimentary deep brine. The components of the brines are sodium, potassium, lithium, borate, and the rare alkaline elements rubidium and cesium. However, the utilization of the underground brine scarcely has been reported because of a lack of relative solubilities and metastable phase diagram. The system containing lithium, rubidium and chloride is one of the subsystems of the underground brine and has not been reported. In this paper, the metastable equilibria of this system were studied at 298.15 K using an isothermal evaporation method.

Figure 1 is the metastable phase diagram of the system at 298.15 K. The diagram consists of one invariant point, two univariant curves and two crystallization fields. No double salt or solid solution is formed in this system at 298.15 K. The invariant point E is cosaturated with $LiCl{\cdot}H_2O$ and RbCl, and the mass fraction of its equilibrium solution is *w*(LiCl) 29.74 % and *w*(RbCl) 23.21 %. $LiCl{\cdot}H_2O$ is the only crystallization form of lithium chloride at 298.15 K.

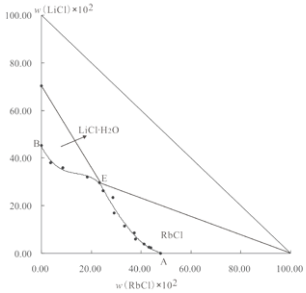

Figure 1: Metastable phase diagram of the system containing lithium, rubidium and chloride at 298.15 K

Water contents in the Cenozoic subcontinental lithospheric mantle beneath the Cathaysia block, SE China

Y. YU[1,2]*, X.S. XU[1,2], W.L. GRIFFIN[2] AND S.Y. O'REILLY[2]

[1]State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing Univ., Nanjing 210093, China (*correspondence: yao.yu@mq.edu.au)

[2]GEMOC, Department of Earth and Planetary Sciences, Macquarie University, NSW 2109, Australia

Refractory subcontinental lithospheric mantle (SCLM) is produced by the removal of partial melts from mantle rocks; this process includes the removal of H_2O. The nature and stability of the SCLM are also strongly influenced by hydrous melts and fluids, which affect the physical and chemical properties of mantle minerals and rocks.

Our recent work has focussed on determining the H_2O contents of peridotite xenoliths from the Cathaysia block, SE China using Fourier transform infrared spectrometry (FTIR). The xenoliths consist mainly of nominally anhydrous minerals (NAMs, e.g., olivine, pyroxene) and are direct samples that may reflect the actual H_2O budget of SCLM.

The homogeneity in H_2O distribution within single pyroxene grains, equilibrium partitioning of H_2O between cpx and opx ($D_{cpx/opx} \approx 2.3$) and correlations between H_2O contents and major elements suggest that the xenoliths preserve the H_2O contents of their mantle source. The average whole-rock water contents calculated from mineral modes is 60±20 ppm. This is much higher than the H_2O contents of peridotites from the North China Craton (average 26±17 ppm). However, it is still low compared to other SCLM inferred from typical cratonic (122±54 ppm) and off-cratonic (81±40 ppm) peridotites.

This medium-dry SCLM can be explained by the refertilization of old lithospheric mantle which has undergone multiple geological events through time, e.g., hydration due to paleo-Pacific plate subduction and massive H_2O extraction during large-scale Late Mesozoic magmatism in SE China. The redox state is another factor in controlling the H_2O contents in the SCLM. This is supported by the negative correlations between pyroxene H_2O contents and spinel $Fe^{3+}/\sum Fe$ in xenoliths from Niutoushan (Mg#<90). This locality lies astride the Changle–Nan'ao fault, which facilitated the infiltration of peridotites by oxidized fluids or melts rising from the subducting Pacific plate.

Automated fitting of XRD profiles of interstratified phyllosilicates

HONGJI YUAN* AND DAVID L. BISH

Dept of Geol. Sciences, Indiana University, Bloomington, IN 47405 USA (*correspondence: honyuan@indiana.edu)

Phyllosilicate minerals are common constituents of soils and many rocks, but quantitative analysis of such materials using X-ray diffraction (XRD) is difficult due to the presence of interstratification within many phyllosilicates. Interstratification refers to the occurrence of two or more types of layers in a single crystallite (also termed "coherent scattering domain"). Diffraction from interstratified phyllosilicate minerals has been successfully modeled, and several software codes (e.g., NEWMOD [1], Diffax [2] and Sybilla [3]) have been developed. However, these programs rely on trial-and-error methods, making the results sensitive to user input. FITMOD, an automated parametric fitting program based on Reynolds' [6] methodology and incorporating recent progress in the structures of phyllosilicate minerals, has been developed [4]. The downhill simplex method [5] was applied in FITMOD to minimize the discrepancies between experimental and simulated XRD profiles by simultaneously varying all adjustable model parameters including the chemical composition (e.g., cation content) and structure (e.g., proportion of the two components, crystal-size distribution, stacking order). Both previously simulated and experimental XRD profiles were used to evaluate the performance of FITMOD in terms of the goodness of fit (R_{wp}, R_p), accuracy, as well as efficiency. Fits to simulated profiles yielded values of R_{wp} as low as <0.3%. Very good fits to experimental profiles were also obtained, with results in excellent agreement with previously published data. Importantly, final results were quite insensitive to starting model parameters, and the method allows fitting with minimal operator intervention.

K-feldspar glasses syntheses for external calibration of *in situ* Pb isotope analysis using LA-MC-ICPMS

H.L. YUAN*, J.Y. SONG, K.Y. CHEN, M.N. DAI, Z.A. BAO AND G.F. HE

State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi'an, 710069 (*correspondence: sklcd@nwu.edu.cn)

Laser ablation Quadruple and multiple collector ICP-MS (LA-Q&MC-ICPMS) is one of the most important analytical technique in terms of in situ analysis of trace elements and isotopic compositions. Matrix matched standards could impair the obstacles of precise measurements including fractionation and matrix effect. Lead isotopic composition of K-feldspar is one of the important ways to trace the history of rock formation and evolution [1]. However, there is no appropriate external standard for in situ Pb isotope analyses using LA-MC-ICPMS. This work describes the synthesis of K-feldspar glasses with a high temperature furnace. The final experimental conditions of the synthesis are melting the 1300mesh K-feldspar powders at 1680 ºC for 2 hours followed by liquid nitrogen quenching. The surface glasses are slightly heterogeneous due to lead evaporation at high temperature while the inside of the glasses are homogenous. The lead isotopic compositions of the glasses are 1.90779 ± 0.00009 ($^{208}Pb/^{206}Pb$,2s), 0.75899 ± 0.00004 ($^{207}Pb/^{206}Pb$, 2s), 20.909 ± 0.002 ($^{206}Pb/^{204}Pb$, 2s), 15.871 ± 0.002 ($^{207}Pb/^{204}Pb$, 2s) and 39.888 ± 0.005 ($^{208}Pb/^{204}Pb$, 2s), and the RSD are 0.007%, 0.008%, 0.016%, 0.016% and 0.021% (Fig. 1), respectively. The results show that the synthesized K-feldspar glasses could be potentially served as external calibration standard for in situ lead isotope measurements.

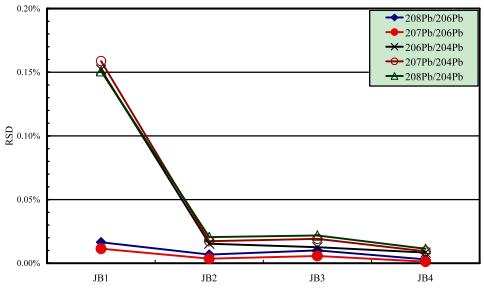

Figure 1 Relative standard deviation of Pb isotope ratio of synthesized K-Feldspar glasses

The zircon fission track constraint on the mineralizing ages of the Jiapigou gold deposits, Northeastern China

WANMING YUAN, JUN DENG AND ZHIXIN HUANG

State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, 100083, China

The Jiapigou gold district is located at the north margin of the North China Craton, and its evolution is closely related to the Siberian Plate in the north, Yangtze Craton in the southeast and Pacific Plate in the east. The gold deposits belong to quartz vein type and are close related to a NE shear zone and the magmatic activities.

Samples for zircon fission track analyses were collected from different ores and alteration rocks. A total of 12 zircon samples were successfully analyzed. All the sample fission track ages have $P(\chi^2)$ values >5% and all grains counted belong to a single population of ages. The zircon ages range between 78 Ma and 158 Ma and centralize at 4 age groups of 158-152 Ma, 126-116 Ma, 108-98 Ma and 88-78 Ma.

A lot of homogenization temperature values of the metallogenic fluid inclusions from different ore deposits mainly range from 180 °C to 280 °C. This temperature could represent the mineralization temperature of the research gold deposits. The zircon fission tracks have a retention temperature of about 250 °C. Apparently, the zircon fission track ages can represent metallogenic ages in the gold districts.

Therefore, the 4 zircon age groups for different ores and alteration rocks could indicate the 4 epochs of gold mineralization. This could be confirmed by some geological evidences, such as, the different alteration cycle, the multiple periods of intrusions, coincident other thermochronological data and so on.

Migration and speciation of heavy metals in stream sediments of a mining-influenced basin, China

XUYIN YUAN, QUAN LIU AND QI ZHANG

School of the Environment, Hohai University, Nanjing 210098, China (*correspondence: yxy_hjy@hhu.edu.cn)

Tongling mine, located in the lower reaches of Yangtze River, is a multi-metal deposit with dominant Cu. Size fraction, the metal concentrations (Cu, Pb, Zn, Cr, Cd) and speciation, the acidic extractable metals (oxalic acid) were determined in order to investigate the impact of mining on stream sediments.

The enrichment factors (EFs) of heavy metals in the sediment nearby mine area were Cd(585) > Cu(289) >> Zn(81.9) >Pb(34.8) > Cr (2.3). The EFs of sediment in the site adjacent the Yangtze River decreased with Cd(15.3) > Pb(7.9) > Cu(5.4) > Zn (2.2) > Cr(1.3). It is indicated that heavy metals in sediments decrease obviously by transportation of about ten kilometers. The proportions of clay decreased and sand increased in sediments, which also altered the metal speciation in sediment by transportation. The oxidizable fraction (B2) decreased and the residual fraction (B4) increased for Cu. The exchangeable fraction (B1) and the reducible fraction (B3) of Cr descended. The significant variations of Pb speciation presented in the sediments. B1 and B2 ascended, but B4 descended. B3 notably increased and B4 decreased for Cd. The geochemical fractions of Zn showed the stable proportions in sediments of different sites. The acidic extractable fractions (oxalic acid) of five metals in sediments revealed different peculiarities. The proportion of extractable Cu decreased and the proportion of extractable Cr increased with distance from the mine site. But the proportions of extractable Zn, Pb, Cd showed less fluctuations during migration.

The stream sediments show different metal attenuation and removable metal variations during the transportation. These variations of metals depend on sediment size, mineral components and geochemical properties of metals.

Selenite reduction by *Bacillus L*

Y.-Q. YUAN[1,2], J.-M. ZHU[1]*, L. LEI[1,2], C.-Q. LIU[1] AND H.-B. QIN[1,2]

[1]The State Key Lab. of Environmental Geochemistry, Inst. of Geochemistry, CAS, Guiyang 550002, China (*correspondence: zhujianming@vip.gyig.ac.cn)

[2]Graduate University of Chinese Academy of Sciences, Beijing 100049, China.

A bacterium was isolated and purified from the selenium(Se)-high carbonaceous mudstone of Enshi, China. It was named as YTB-BL(*Bacillus L.*) in our lab. In order to investigate its potential tolerance and reduction for selenium oxyanions. This strain was inoculated in liquid medium (yeast extract and glucose)containing 5, 25, 100, 300, 500 and 800 mM of sodium selenite and selenate under aerobic, anaerobic and facultative anaerobic conditions, respectively. The results showed that this strain can be resistant to the SeO_3^{2-} and SeO_4^{2-} concentration of as high as 800 mM in the above three conditions. However, the doubling time(DT)of the strain was increased from 100.3h to 219.7h when SeO_3^{2-} concentration was changed from 500 mM to 800 mM under facultative cultivation, so did under the other two conditions. But this bacterium grew fastest under aerobic condition. Furthermore, it was able to reduce the soluble selenite anion(SeO_3^{2-}) to red elemental selenium(Se^0), which were present nanospheres distributed around or within the cells. The averagely transformed efficiency of Se^{+4} to Se^0 by YTB-BL was approximately 57% in the liquid medium containing 5-25 mM of sodium selenite. YTB-BL is a special kind of strain with wide adaptative and higher resistant selenite-reducing abilities, which would provide the better chance for microbial remediation of Se polluted areas.

The study was supported by the Knowledge Innovation Program of the Chinese Academy of Sciences (KZCX2-YW-JC101) and the National Natural Science Foundation of China (40721002, 40973085, 40573050).

Whole-rock chemostratigraphy of diverse magma series in the Tertiary alkaline volcanics of Trabzon-Giresun area, NE Turkey

C. YÜCEL*, M. ARSLAN, İ. TEMIZEL AND E. ABDIOĞLU

Department of Geological Engineering, Karadeniz Technical University, 61080-Trabzon, Turkey
(*correspondence: cyucel@ktu.edu.tr)

The Tertiary volcanics of the Trabzon-Giresun area have a narrow extend lying along the Black Sea coast in NE Turkey as a part of Eastern Pontide Tertiary Volcanic Province (EPTVP) [1]. Petrochemically, the volcanics can be divided into mildly alkaline group with medium to high-K, and moderately alkaline group with sodic-potassic in characters. The mildly alkaline group contains two sub-suites as basalt, trachy-basalt and basaltic trachy-andesite (BTB) suite croping out as dikes and sills, lava flows-pillow lavas and breccias, and trachyte and trachy-andesite (TT) suite croping out as dikes and domes. The moderately alkaline group consists of basanite-tephrite (BT) suite croping out as brecciated lavas and breccias [2]. Major oxide and trace element versus SiO_2 variation plots suggest fractionation of common mineral phases such as cpx+olivine+Fe-Ti oxide in the BTB suite, plagioclase±sanidine+biotite+Fe-Ti oxide in the TT suite, and cpx+Fe-Ti oxide+apatite in the BT suite.

N-type MORB normalized trace element patterns exhibit subduction signatures with enrichment in LILE (Sr, K_2O, Rb, Ba), Th and Ce and depletion in Zr, Y, Nb, Ta and TiO_2 contents. The chondrite-normalized REE patterns show two diversing trends with moderately enriched (La_N/Lu_N=2.27-7.95) for mildly alkaline, and highly enriched patterns (La_N/Lu_N=29-49) for moderately alkaline volcanics The patterns have also concave shape with marked light REE enrichment and heavy REE depletion, implying effect of significant clinopyroxene fractional crystallization during the evolution of the mafic volcanic suites. Volcanic facies, chemostrigraphy and whole-rock petrochemistry of the Trabzon-Giresun area Tertiary alkaline volcanics reveal that there might have been diversing parental magmas derived from different degrees of partial melting of enriched lithospeheric mantle which was modified by paleo-subduction induced fluids and/or melts.

Metals and As in mine tailings drainage systems: Mobility and removal

N.V. YURKEVICH* AND O.P. SAEVA

Trofimuk Institute of Petroleum Geology and Geophysics SB RAS, Koptyug av., 3, Novosibirsk, Russia, 630090
(*correspondence: YurkevichNV@ipgg.nsc.ru)

Sulfide-bearing mill wastes are sources of high concentrations of acid, soluble metals and As. These are serious problems for ore mining areas such as the Kemerovo and Cheljabinsk regions in Russia. Contents of Cu, Zn, Cd, Pb, As, and Sb in wastes of the Belovo Zn-processing and the Karabash Cu-smelting plants are 2-3 orders of magnitude higher than the content of continental crust. Main mineral forms are pyrite FeS_2, chalcopyrite $CuFeS_2$, sphalerite ZnS, arsenopyrite FeAsS and scorodite $FeAsO_4*2H_2O$. High dissolved metals, As and Sb concentrations are found in drainage waters and influenced rivers; their concentration often exceeds Maximum Permissible Concentrations and background levels. Concentrations of metals, As and Sb in bottom sediments of the affected rivers are elevated a hundred meters below the input of drainage. These sediments become a source of secondary contamination.

Field experiments were conducted on the wastes – natural water interaction. Results of the experiments showed that 10-86 % of elements contained in the wastes pass into solution. Two groups of elements can be defined by their leaching behavior: relatively immobile – Sb, Pb, and Fe (10-16 %), and elements that are readily leached – As (67 %), Zn (70 %), Cd (71 %), and Cu (86 %). Leachates were used as influent to additional columns that tested limestone and a mixture of natural clay as geochemical barriers. The decrease in elements mobility in the clay and limestone columns is consistent with the accumulation detected in bottom sediments in the Belovo settling pond. In both the column and natural environment, Cd, As, and Sb is adsorbed on Fe (III) hydroxides at pH > 4 in oxidizing waters; changes of conditions to lower pH result in transfer of adsorbed elements into solution. An alternative to adsorption in oxic systems elements mobility is also decreased by the formation of sulfides and arsenides ($CuFe_2S_3$, Cu_3BiS_3, $NiAs_2$, $Ni_{11}As_8$, $Cu_9Sb_8S_{21}$, $CoAs_3$).

In addition, we propose electrochemical method for the treatment of high mineralized acid drainage (pH = 3.5, total concentration of Al, Cu, Zn, Cd, Pb, Fe, As, and Sb up to 10 g/L and sulfate-ion concentration up to 20 g/L) which is based on addition of metallic aluminium and allow to reach concentrations of elements in solution by 2-3 orders of magnitude lower then initial.

Modeling of column experiments – Influence of glass micro balls

VRATISLAV ŽABKA, IVAN BRUSKÝ AND JAN ŠEMBERA

Institute of Novel Technologies and Aapplied Informatics Technical University of Liberec, Studentska 2, 46117 Liberec, Czech Republic (ivan.brusky@tul.cz)

Our paper is focused on modeling of a laboratory experiment using the software package The Geochemist's Workbench. We simulate a column experiment in which water solution flows trough a porous soil. The subjects of our interest are the interactions between water solution and porous soil. In some in-situ decontamination technologies, sinking-in reagents are used to be used. Column experiments are important for preparation and verification of such decontamination activities.

To verify the experiment configuration we decided to begin with the simplest case of the column experiment: the flowing water solution is pure distilled water and the porous medium is inert glass micro balls. Even in such a simple experiment we could observe unexpected change of pH of water solution after passage through the column. We try to understand this observation and simulated in mentioned software.

The results of the study will be presented.

Platinum group minerals (PGM) in chromite lode deposits from the Sulawesi ophiolite belt

F. ZACCARINI[1]*, A. IDRUS [2], G. GARUTI[1], O.A.R. THALHAMMER[1] AND F.M. MEYER[3]

[1]University of Leoben, Dept. Appl. Geol. Sci. Geophysics, Leoben, Austria(*correspondence: federica.zaccarini@unileoben.ac.at)

[2]Gadjah Mada University·Dept. Geol, Eng., Yogyakarta, Indonesia

[3]RWTH Aachen University, Inst. Min. Econ. Geol., Aachen, Germany

Some localities in Indonesia including Borneo and Sulawesi host PGM-bearing podiform (ophiolite)-type chromitites. Borneo is the locality type of two platinum group minerals (PGM), the rare vincentite and laurite, the most common Ru minerals. These PGM have been found in placers, however, data on the occurrence of PGM in lode deposits of Indonesian Archipelago are very poor. We present a mineralogical investigation on lode chromite deposits and associated PGM from the Sulawesi ophiolite belt. The investigated chromitites were sampled in the South and Southeast Arms of Sulawesi. According to the #Cr (0.51-0.88), in both the localities chromite composition varies from Cr-rich to Al-rich. TiO_2 is low in the Southeast Arm chromitites (0.07-0.28 wt%), whereas in the South Arm chromitites its values are comprised between 0.08 up to 0.55 wt%. Small PGM, 1 to 10 μm in size, have been found in both the localities and in Cr- and Al-rich chromitites. The most abundant PGM is laurite that occur included in fresh chromite or in contact with chlorite along cracks of the chromite. Laurite forms polygonal crystals and it occurs as single phase or in association with amphibole, chlorite, Co-pentlandite, apatite and other PGM. Small grains of irarsite (less than 3 μm) have been found associated with small blebs of awaruite and Co-pentlandite in the chromite gangue composed of chlorite. One grain (2 μm in size) containing Ru and Fe was found in the rim of a laurite occurring with Co-pentlandite in the chromite crack, filled with chlorite. The results suggest that the studied chromitites could have crystallized from different melts varying in composition from MORB formed in back-arc setting (Al-rich) to boninites related with subduction zone (Cr-rich). The bimodal composition and the anomalous enrichment in TiO_2 observed in some chromitites, may also indicate vertical zoning due to the fractionation of a single magma batch during its ascent, implying accumulation of Cr-rich chromitites at deep mantle levels and formation of the Al-rich ones close to the Moho-Transition Zone. All the laurite are considered to be magmatic in origin, i.e. entrapped as solid phases during the crystallization of chromite. Irarsite possibly represents a low temperature exolution product.

Challenges in the identification of redox reactive Fe(II) mineral phases in suboxic aquifer sediments

J.M. ZACHARA, T. PERETYAZHKO, J.P. MCKINLEY, CHONGXUAN LIU AND A.R. FELMY

Pacific Northwest National Laboratory, Richland, WA, USA

The kinetics of ^{99}Tc(VII) reduction, as the pertechnetate anion [$^{99}TcO_4^{2-}$ = 10^{-6} mol/L], were investigated in a series of suboxic aquifer sediments from the U.S. DOE, Hanford site exhibiting an average pH = 8. Reaction rates varied markedly displaying half-lives ranging from 2 to 110 d. Rate constants did not normalize to extractable Fe(II) concentration. The heterogeneous reaction products, as identified by EXAFS analysis, were adsorbed ^{99}Tc(IV) clusters (n = 2-4) that did not vary in size with reduction rate. Iron was not observed in the second coordination sphere. The Fe mineralogy of the sediments was investigated using a combination of chemical extraction, x-ray diffraction, variable temperature Mossbauer spectroscopy, and analytical electron microscopies; revealing the presence of a complex Fe(II) mineral suite containing variable concentrations of pyroxenes, siderite, Fe(II)-phyllosilicates (smectites, illites, and mica), and magnetite. Direct correlations between ^{99}Tc reaction rates and Fe(II) mineralogy were not evident. The most reactive sediment was titrated with higher levels of ^{99}Tc (10^{-4} mol/L), with the distribution of Fe(II) mineral phases monitored by Mossbauer spectroscopy after ^{99}Tc(VII) reaction. Spectral peak positions for siderite at 4.5 K decreased during titration from 29% to 6% of the total area, transforming to those of Fe(III) oxide, providing presumptive evidence that siderite was one of several reactive phases. Additionally, ^{99}Tc(VII)-oxidized sediment was screened by digital autoradiography to identify ^{99}Tc(IV)-containing mineral phases. These phases were manipulated for analysis by electron microprobe and micro-x-ray diffraction. A significant fraction of the ^{99}Tc(IV)-containing phases were Fe-micas as observed in a previous investigation with sediments from another location. Residual siderite did not appear to contain ^{99}Tc(IV). We conclude with a discussion of: i.) the challenges involved in the identification of redox active phases using macroscopic and microscopic techniques and ii.) kinetic versus thermodynamic controls on redox reactivity in mineralogically heterogeneous subsurface sediments.

Evaluation of rock properties and rock structures in the micron-range with sub-micron X-ray Computed Tomography

G. ZACHER[1]*, M. HALISCH[2], O. BRUNKE[1] AND T. MAYER[1]

[1]GE Sensing & Inspection Technologies GmbH, Niels-Bohr-Str. 7, 31515 Wunstorf, Germany

[2]Leibniz Institute for Applied Geophysics, Stilleweg 2, 30655 Hannover, Germany

In recent years high resolution X-ray Computed Tomography (CT) for geological purposes contribute increasing value to the quantitative analysis of rock properties. Especially spatial distribution of minerals, pores and fractures are extremely important in the evaluation of reservoir properties. The possibility to visualize a whole plug volume in a non-destructive way and to use the same plug for further analysis is undoubtedly currently the most valuable feature of this new type of rock analysis and will be a new area for routine application of high resolution X-ray CT in the near future.

The paper outlines new developments in hard- and software requirements for high resolution CT. It showcases several geological applications.

The results were performed with the phoenix nanotom and recently phoenix nanotom m, the first 180 kV nanofocus CT system tailored specifically for extremely high resolution scans of samples up to 240 mm in diameter and weighing up to 3 kg with voxel-resolutions down to <300 nm. These characteristics with respect to spatial resolution principally allow CT measurements which valuably complement many absorption contrast setups at synchrotron radiation facilities (Withers 2007 [1]; Brunke *et al*. 2008 [2]; Kastner *et al*. 2010 [3]).

Robust trace element analysis of rutile by LA-ICP-MS

T. ZACK* AND M. BARTH

Institut für Geowissenschaften, Universität Mainz, Germany (*correspondence: zack@uni-mainz.de)

Several recent studies reporting trace element results for rutile by LA-ICP-MS using spot sizes as large as 40 μm. However, even Q-ICP-MS are sensitive enough to have a suitable signal-to-background ratio for a number of important trace elements in most natural rutiles (*e.g.*, V, Cr, Fe, Zr, Nb, Sn, Hf, Ta, W and U) at spot sizes of only 10 μm. Here, counting statistics give errors better than 5% for Zr concentrations on the 100 ppm level (translating to analytical errors in metamorphic temperatures of only a few °C). Still, the level of accuracy is so far unknown at such small spot sizes mostly due to a lack of suitable rutile standards.

Recently, we have proposed to use three natural (R10, R19, Diss) and one synthetic (Sy) rutiles as secondary mineral standards [1]. These minerals are sufficiently homogeneous and analyzed by several techniques (EMP, SIMS, ID-MC-ICP-MS) for a range of trace elements to test LA-ICP-MS performances. Therefore, we have run several LA-ICP-MS profiles with variable spot sizes (10-40 μm) along the same EMP and SIMS profiles as reported in [1].

Most importantly, it is found that spot size differences can have a severe effect on calculated rutile concentrations for such small spots. For example, calculated Zr concentrations for rutile systematically deviate by 40% between 10 and 40 μm. This makes it an absolute neccessity to always use identical spot sizes at such small scales. Furthermore, it can be demonstrated that an accuracy of <10% is reached for most trace elements for the rutile standards R19 and Diss when R10 is used as a matrix matched standard under the exact same analytical conditions.

The demonstration of an accuracy of <10% for 10 μm spot analysis for rutile by LA-ICP-MS significantly opens up the field of rutile geochemistry. In Mainz, with the help of a fast-washout large format cell and automization, we routinely use such small spot sizes for rutile trace element analysis with a sample throughput of >60 samples/hour. Applications are found *e.g.*, in pre-scanning for high-U detrital rutiles suitable for U/Pb dating [2] and fine-scale Nb diffusion profiles [3].

Effect of plant-microbial associations on weathering of basalt, granite, schist, and rhyolite

DRAGOS ZAHARESCU[1]*, KATERINA DONTSOVA[12], JON CHOROVER[12], TRAVIS HUXMAN[13], RAINA MAIER[2] AND JULIA PERDRIAL[2]

[1]B2 Earthscience, The Univ. of Arizona, Tucson, AZ, USA, (zaharescu@email.arizona.edu, dontsova@email.arizona.edu, chorover@cals.arizona.edu)

[2]Dep. of Soil, Water & Environmental Science, The Univ. of Arizona, Tucson, AZ, USA (rmaier@ag.arizona.edu, jnperdri@email.arizona.edu)

[3]Dep. of Ecology and Evolutionary Biology, Univ. of Arizona, Tucson, AZ, USA, (huxman@email.arizona.edu)

The goal of this study was to measure how plant–microbe interactions affect the initial weathering of four distinct rock types (basalt, granite, schist, and rhyolite) and the extent to which this weathering results in chemical denudation versus biomass accumulation or re-precipitation of dissolution products. This initial phase of experiment focused on denudation. We hypothesised that the presence of plants will increase weathering but decrease denudation (i.e., we will see more mineral transformation but less element loss from system in the presence versus absence of plants). To achieve research objectives, we conducted a series of environmentally–controlled, greenhouse experiments that involved measuring plant uptake, mineral transformation and chemical denudation in basalt (35.9% An64 plagioclase, 6.5% diopside, 11.9% forsterite, and 45.7% basaltic glass), granite (28.8% quartz, 31.1% K-feldspar, 32.8% albite, and 7.2% muscovite), rhyolite (32.6% quartz, 15.9% albite, and 51.5% K-feldspar in crystalline form, plus yet unquantified glass fraction), and schist (23.8% quartz, 22.8% K-feldspar, 14.2% albite, 7.6% amphibole, and 31.7% biotite), as affected by presence and growth of microbiota and vascular plants. The experiments also included plant-free (but microbially-colonized) and abiotic (sterile) controls. Buffalo Grass (Buchloe dactyloides) and Ponderosa Pine (Pinus ponderosa) were employed as model plant species. Plants were grown in 4 cm (diameter) by 30 cm (length) Plexiglas columns filled with granular study materials. Columns were equipped with micro-suction cup solution samplers to collect soil solution. Solution was analysed to deptermine pH, cations and metals, anions, and aqueous phase organic matter chemistry. Concentrations of low molecular weight organic acids in soil solution and drainage water were also determined.

Did the glacial Atlantic overturning circulation run backwards?

R. ZAHN[1]*, I.R. HALL[2], G.M. HENDERSON[3], P. MASQUÉ[1] AND A.L. THOMAS[3]

[1]Universitat Autònoma de Barcelona, Institut de Ciència i Tecnologia Ambientals, Departament de Física, 08193 Bellaterra, Spain (*correspondance: rainer.zahn@uab.cat)
[2]School of Earth and Ocean Sciences, Cardiff University, Cardiff CF10 3AT, U.K.
[3]Department of Earth Sciences, University of Oxford, Oxford OX1 3AN, UK

Recently Pa/Th profiles from the South Atlantic were published [1] that display structures very different from Pa/Th profiles in the North Atlantic. It was argued that these profiles indicate i) deep waters leaving the glacial Southern Ocean had a Pa/Th fingerprint not much different from that of NADW today, due to extensive Pa scavenging; ii) a basin-scale meridional Pa/Th gradient developed in the glacial Atlantic that run opposite to that of today, reflecting a more substantive northward flow of "southern sourced water" (SSW). This concept, in our view, reconciles an apparent conflict between εNd measured on Fe-Mn oxide coatings on planktonic foraminifera at the Bermuda Rise and Pa/Th data at the same location: the first indicating northward flowing SSW at the LGM while the second supposedly reflecting southward flowing "northern source water" (NSW) [2].

We borrow the provocative title from the conveners because it reflects the debate over how far we can take the proxy records. The interplay between NSW and SSW is reflected by a suite of proxy data e.g., stable carbon isotopes ($\delta^{13}C$), Pa/Th and nutrient-based trace element ratios (Cd/Ca). Pa/Th profiles are scarce and meridional gradients must be mapped using Pa/Th from a range of different water depths while gas-exchange normalized $\delta^{13}C_{as}$ suggests a prominent role of SSW in the glacial AMOC. Taking all evidence at face value suggests the glacial AMOC received a stronger water mass contribution from the southern hemisphere oceans. At the same time several questions arise: does scavenging of Pa in the Southern Ocean outcompete lateral advection and so depleting the water column of Pa? Do radiogenic isotope and nutrient-based proxies uniquely identify water mass end members? How robustly do the proxies reflect the AMOC in the past, including physical near-bottom flow speeds? These questions are not easy to answer but they help refine the direction of future work.

Xenon the magnificent

KEVIN ZAHNLE

NASA Ames Research Center, Moffett Field CA 94035 (Kevin.J.Zahnle@NASA.gov)

Xenon is the heaviest noble gas and the heaviest gas likely to be found in a primoridal atmosphere. It would seem to be the least likely gas to escape. Yet there is probably more evidence for massive Xe escape from Earth than for any other element save helium. Nonradiogenic atmospheric Xe is strongly mass fractionated (by about 4% per amu) compared to any of its plausible solar system sources. By contrast, Kr is only mildly fractionated, if at all. Xenon is also relatively underabundant with respect to Kr.

Radiogenic Xe also suggests escape. Radiogenic ^{129}Xe (from ^{129}I decay, half-life 15.7 Myr) is present in the atmospheres of Earth and Mars but at less than 1% the qunatity expected given the primoridal abundance of ^{129}I, Radiogenic Xe from spontaneous fission of ^{244}Pu (half-life 82 Myr) is also notably underabundant. The upper limit on fissogenic ^{136}Xe in air is about 1 part in 6 of Earth's cosmic complement from ^{244}Pu. This is an upper limit because it depends on U-Xe (rather than solar Xe) being the primordial Xe of Earth. U-Xe makes modeling Earth's Xe much easier, but it has not otherwise been seen in the solar system.

For Xe escape to explain the dearth of fission Xe in air, escape must have taken place late enough in Earth's story that ^{244}Pu was extinct. The mechanism would have affected Xe but not Kr or Ar. One possibility is that Xe escaped as an ion, probably in polar winds of hydrogen and hydrogen ions channelled by planetary magnetic fields. This can occur because Xe, alone among the noble gases, is more easily ionized than hydrogen. Thus Xe will tend to be present oin the H-H+ wind as Xe+, whilst the other noble gases would be neutral. Because of the Coulomb force, at 2000 K and 1% H ionization, diffusivity of Xe^+ is 3 orders of magnitude lower than that of neutral Xe or Kr. The Xe^+ ions are therefore dragged to space by the protons. Under these circumstances fractionating hydrodynamic escape can apply uniquely to xenon among the noble gases over a wide range of hydrogen escape fluxes.

The solubility of Au and Cu in andesite melts

ZOLTAN ZAJACZ[1,2], PHILIP A. CANDELA[1], PHILIP M. PICCOLI[1], MARKUS WÄLLE[2] AND CARMEN SANCHEZ-VALLE[2]

[1]Laboratory for mineral deposits research, University of Maryland, College Park, MD, USA, (zoltan.zajacz@erdw.ethz.ch)

[2]Institute of Geochemistry and Petrology, ETH Zürich, 8092 Switzerland

We conducted experiments in MHC cold seal vessels at 1000 ºC and 200 MPa to study the solubility of Cu and Au in andesite melts as a function of the Cl and S content of the silicate melt and oxygen fugacity of the system. A gold activity of 0.99 and a Cu activity of 0.01 were imposed by using AuCu alloy capsules.

At an fO_2 of NNO-0.2, the solubility of Au shows a positive linear correlation with the S concentration in the melt, and increases from 41±8 ng/g (1σ) in a S-free melt to 1547±52 ng/g in a melt with 344±20 μg/g S, a condition near pyrrhotite saturation. Chlorine has a relatively minor positive effect on Au solubilty; a S-free andesite melt with 1.00±0.01 wt% Cl contained only 112±20 ng/g Au.

The effect of fO_2 on the solubility of Au is significant, leading to 0.18±0.04 log unit increase in Au solubility for 1 log unit increase in fO_2 in a S-free, Cl-bearing melt, which is approximately consistent with +1 valence of Au in the silicate melt. In S-bearing melts, the effect of fO_2 on gold solubilty is further complicated by the following (or a similar) reaction: $Au+FeS(melt)+H_2O(melt)=AuSH(melt)+FeO(melt)+0.5H_2(g)$ Accordingly, a maximum in Au solubility is observed just at the low fO_2 end of the S^{2-}/S^{6+} transition, however, it is much smaller than that shown by Botcharnikov *et al*. (2011) [1].

The apparent solubility of Cu at an fO_2 of NNO-0.2 and aCu of 0.01, ranges between 45±1 and 78±1 μg/g and shows a weak positive correlation with the S and Cl concentration in the melt. Moderate excess solubitly over that predicted assuming a dominant $CuO_{0.5}$(melt) species is observed in S-bearing experiments in the fO_2 range of the S^{2-} to S^{6+} transition and above. Variation in the K_2O/Na_2O and FeO/Na_2O ratios in the melt did not siginificantly affect Au and Cu solubilites.

Model volatile/melt parition coefficients of Cu and Au suggest that volatiles exsolving from andesite magmas are efficient at extracting Au, but inefficient at extracting Cu.

Cryogenic cave carbonates – A new tool for estimation of former permafrost depths

K. ŽÁK[1]*, M. FILIPPI[1], R. ŽIVOR[1] AND D.K. RICHTER[2]

[1]Institute of Geology AS CR, v.v.i., Rozvojová 269, 165 00 Praha 6, Czech Republic (*correspondence zak@gli.cas.cz, filippi@gli.cas.cz, zivor@gli.cas.cz)

[2]Ruhr-University Bochum, Institute of Geology, Mineralogy and Geophysics, Universitätsstr. 150, 44801 Bochum, Germany (detlev.richter@rub.de)

Geochemical processes in the Earth's critical zone largely depend on the presence or absence of a permafrost (perennially frozen ground, i.e. soil and rock remaining at or below 0 °C for at least two consecutive years, [1]). While the areal extent and depth of present-day permafrost zone are relatively well known [1], the extent, duration, and depth of permafrost during Pleistocene glacials are much less understood. Here we present a new tool for the estimation of former permafrost minimum depth based on the occurrence of a specific type of secondary carbonate in caves.

Cryogenic cave carbonate (CCC) is a unique type of secondary carbonate formed in caves during freezing of common calcium bicarbonate water by the expulsion of dissolved load by the growing ice. CCCs can be identified based on their typical morphology and occurrence, by U-series dating fitting into glacials, and especially by specific C- and O-isotope geochemistry, which proves their formation during water freezing [2, 3, 4]. CCCs were formed at the transitions from glacials to interglacials or from stadials to interstadials and occur as accumulations of loose crystals and crystal aggregates on the cavity bottom, where they were deposited after melting of the ice filling of the cavity. CCCs show a unique isotope composition with $\delta^{18}O$ values down to -25 ‰ (PDB), and $\delta^{13}C$ values up to +6 ‰.

We collected data for all known CCC occurrences in a belt parallel to the southern edge of the Weichselian continental glaciation (southern Poland, Slovakia, Czech Republic, central Germany), dated them by U-series method, and evaluated their depths under the surface. When using data from isolated cavities only, which cannot be cooled by air circulation, a minimum Weichselian permafrost depths in this belt can be estimated at 30–70 m under the surface (the study was supported by the project GA CR P210/10/1760).

A combined Earth-Moon Si isotopes model to track rocks petrogenesis

T. ZAMBARDI AND F. POITRASSON

Géosciences Environnement Toulouse, CNRS– UPS – IRD, France. (zambardi@get.obs-mip.fr)

Silicon is after oxygen the second most abundant element in the Earth's crust. As such, its stable isotope variations in geological materials may represent important mass transfer between terrestrial reservoirs. Despite early analytical limitations and although Si isotopes were not expected to fractionate significantly during high temperature magmatism, studies conducted more than 15 years ago [1, 2] hinted that Si isotope compositions of granitoids may be heavier than that of mafic igneous rocks.

In this study, we determined the silicon isotope signatures of a set of igneous terrestrial rocks that includes andesites, monzogranites, granites of different types, as well as 8 lunar samples including basalts and highlands anorthosites. Analytical methods involved alkaline fusion of the powdered samples, cationic exchange chromatography and high resolution MC-ICP-MS in the wet plasma mode. Long-term (3 years) external reproducibility for $\delta^{30}Si$ and $\delta^{29}Si$ was given by repeated measurements of BHVO-2. It yielded 2 standard deviations (2SD) of 0.076‰ and 0.047‰, respectively, for individual measurements.

A comparison between lunar and terrestrial bulk igneous rocks reveals that Si isotope composition become slightly, thought significantly enriched in heavy isotopes as a function of felsic mineral abundances. We interpret this in terms of global planetary differentiation processes. However, the terrestrial trend is more scattered, which reveal the occurrence of sources and processes that do not exist on the Moon, probably because they involve water. Terrestrial andesites may be isotopically heavier than other lunar and terrestrial igneous rocks with similar silicon contents whereas S-type granites are isotopically much lighter than other granite types. These results are interpreted as the influence of seawater or hydrothermal fluids on andesitic sources and the occurrence of sediments containing the products of aqueous weathering in S-type granite protoliths. The fact that Si is a major element in igneous rocks, but not a major constituent of water like O, makes its isotopic composition likely more robust against alteration and weathering of the studied rocks, yet delivering significant information in terms of source of the magmatic bodies studied.

Melting condition and evolution of fissural volcanism in the island of Faial (Azores archipelago)

VITTORIO ZANON[1], ANGELO PECCERILLO[2] AND JOSÉ MANUEL PACHECO[1]

[1]Centro de Vulcanologia e Avaliação de Riscos Geológicos, Universidade dos Açores, Rua Mãe de Deus 9500-501, Ponta Delgada, Portugal (Vittorio.VZ.Zanon@azores.gov.pt)

[2]Dipartimento di Scienze della Terra, Univeristà di Perugia, Piazza Università, 1 06100 Perugia, Italy (peccean@unipg.it)

Two WNW-ESE-trending fissure zones, which are separated by NNW-SSE transtensional faults, are the expression of the regional extensional tectonics in the island of Faial. Several monogenetic centres and a large stratovolcano were generated along these faults.

Erupted magmas are nepheline- to hypersthene normative basalts to hawaiites, generated at about 2110-1600 MPa (~63 km deep, in the spinel facies) and 1367-1407°C.

Mafic rocks of the westernmost fissure zone have lower MgO and HREE, and higher Na_2O, P_2O_5, TiO_2, Zr, Nb, Th, LILE and LREE than those from the easternmost fissure zone. All these differences are related to slightly different melting degrees (between 3 and 5%), which also reflect the different silica saturation degrees. However, near-primary melts of these two fissure zones show LILE contents, particularly Ba, which are among the highest in the whole Atlantic area. This feature, together with the common presence of fluid inclusions in many ultramafic xenoliths sampled, evidence the occurrence of a metasomatic event prior to mantle source melting.

Hawaiites evolved from basalts by 18-25% fractional crystallization of Mg-olivine, diopside and Ca-plagioclase, at 560-700 MPa (~17-21 km deep). There is no evidence for magma ponding at intracrustal depths.

Fractionation of mafic phases generated cumulate layers at the crust-mantle boundary. Ascending basaltic melts sampled these olivine-and-clinopyroxene bearing layers to generate ankaramites which show MgO content lower than primary melts. These peculiar lithologies crop out along the western margin of the stratovolcano, possibly along faults that directly tapped the cumulate layers.

Release of silica from micas by alkaliphilic anaerobes

D. G. ZAVARZINA[1]*, A. V. SAVENKO[2], N. I. CHISTYAKOVA[3], A. A. SHAPKIN[3] , T. N. ZHILINA[1] AND G.A. ZAVARZIN[1]

[1]Winogradsky Institute of Microbiology RAS, Moscow 117312, Prospect 60-letiya Oktyabrya 7/2, Russia (*correspondence: zavarzinatwo@mail.ru)

[2,3] Lomonosov Moscow State University,

[2] Geographic and [3]Physics Depart., Leninskie Gory, Moscow 119992, Russia

Soda deposits are formed at the final stages of continental CO_2-weathering. It could occur under alkaline conditions either chemically, which seems favorable, or biotically. There are two main groups of alkaliphilic microbial agents that act in anaerobic conditions on the water-rock contact: a) fermentative hydrolytic decomposers of particulate organic matter, e.g. cellulose, capable to produce organic acids as the products of metabolism; b) respiratory anaerobes, utilizing dissolved compounds with external electron acceptors.

We studied the interaction of pure cultures of microbes with biotite and glauconite during 165 days under alkaline conditions at pH 9.5 and total mineralization was 15 g/l. Mössbauer spectroscopy, IR-specrtoscopy and solubility of micas in water were used for the investigation of the solid phase. Fermentation products were recorded during the bacterial growth.

Following combinations were studied: (i) chemical alkalinolysis of micas under sterile conditions; (ii) biotic alkalinolysis of micas by alkaliphilic *Clostridium alkalicellulosi* [1], which produces organic acids and ethanol from cellulose; (iii) biotic alkalinolysis by alkaliphilic dissimilatory iron-reducer *Geoalkalibacter ferrihydriticus* [2] with acetate as an electron donor; (iiii) combined binary culture of *Cl. alkalicellulosi* and *G. ferrihydriticus* with cellulose as organic substrate.

Release of silica under experimental conditions for the both minerals was as following: (i) no release; (ii) no release; (iii) release of silica, formation of new soluble phase; (iiii) release of silica, formation of new soluble phase.

It is proposed that the anaerobes with respiratory metabolism are more effective than fermentative in bioweathering of rock-forming minerals as micas with release of silica. Chemical weathering even under most favorable conditions is far less pronounced than microbe-mineral interactions.

Evidence for evolution of growth media in superdeep diamonds from Sao-Luis (Brasil)

D.A. ZEDGENIZOV[1]*, A.L. RAGOZIN[1], V.S. SHATSKY[1], H. KAGI[2], S. ODAKE[2], W.L. GRIFFIN[3] D. ARAUJO[3] AND O.P. YURYEVA[1]

[1]V.S. Sobolev Institute of Geology and Mineralogy, 3 Koptyuga ave., 630090, Novosibirsk, Russia (*correspondence: zed@igm.nsc.ru)

[2] Geochemical Research Center, Graduate School of Science, University of Tokyo, Tokyo 113-0033, Japan

[3]GEMOC ARC National Key Centre, Macquarie University, NSW 2109, Australia

Diamonds from Sao-Luis (Brazil) are known to be originated from the depths of transition zone and lower mantle [1]. In this study we consider some aspects of the composition and evolution of growth media for diamonds from this locality.

CL imaging has revealed the complex growth history for most diamonds, reflecting their formation in several stages. Nitrogen content in an individual diamonds varies from several to 500 ppm. An apparent tendency for the 3107 cm^{-1} peak intensity to increase with increasing the nitrogen content gives support to the idea that the conditions favouring the incorporation of nitrogen in these diamonds might also favour the incorporation of hydrogen. Specific feature of diamonds from Sao-Luis is extremely high nitrogen aggregation state (90-100 %B1). The set of luminescence centers N3, H3, H4, 490.7 is typical for all diamonds. Radiation-induced centers with peaks at 536 and 576 nm are often observed.

The total range of carbon isotope composition in diamonds studied by SIMS makes up from -3.3 to -20.3 ‰ of $\delta^{13}C$. Some diamonds show local variations of $\delta^{13}C$ between different growth zones (up to 7 ‰).

The dominant inclusions in studied diamonds are CaSi-perovskite and AlSi-phases. MgSi- and CaTi-perovskites, ferropericlase, native iron, coesite and zircon have also been found. Raman shift of coesite peak show high residual pressure (>3 GPa at ambient temperature).

FTIR study of some microinclusion-bearing diamonds showed that water and carbonates are not major components of diamond-forming fluids. LA-ICPMS bulk composition has significant enrichment in Ca, Fe and Al and strong depletion in Mg. Trace elements show general enrichment in Ti and V and depletion in Sr, LREE and Ni. Most probable source for such environments might be fluids from deeply subducted rocks of metasomatized oceanic lithosphere.

Mobility of trace elements in ombrotrophic peat bogs

LEONA ZEMANOVA[1]*, MARTIN NOVAK[1], PETRA PACHEROVA[1], ARNOST KOMAREK[2]

[1]Czech Geological Survey, Geologicka 6, 152 00 Prague 5, Czech Republic (*correspondence: leona.zemanova@geology.cz)

[2] Faculty of Mathematics and Physics, Charles University, Sokolovska 83, 186 75 Prague 8, Czech Republic

The geochemical cycles of many trace elements have been altered by human activity. Peat bogs are often used as an archives of past pollution. Concentration patterns of individual elements downcore can be recalculated into rates of historical atmospheric deposition. However, vertical mobility of trace elements in the petlands could "smear out" the historical record. We performed a peat transplant experiment to test the mobility/immobility of six trace elements (Mn, Fe, Pb, Zn, Cu and Ti), buried in organic soil. Three replicated cores from a peat bog situated in a heavily polluted area in northern Czech Republic were transplanted into a peat bog situated in unpolluted southern Czech Republic, and vice-versa. After 18-months, peat cores were excavated, taken to the laboratory and analyzed. Two different patterns were observed. The first group of elements (Fe, Mn) was characterized by convergence of concentration patterns to their host site, regardless of whether the host site was originally richer or more deficient in these elements. The second group of elements (Pb, Zn, Cu, Ti) was resistant to change during the transplant experiment, with concentration patterns unchanged. Our transplant experiment showed that not just lead but also copper and zinc could be used in retrospective peat pollution studies because there was no evidence of post-depositional mobility.

Concurrence of Mid-Miocene high Sr/Y granite and leucogranite in the Yardoi gneiss dome, Tethyan Himalaya, Southern Tibet

LINGSEN ZENG[1]*, LI-E GAO[1], KEJIA XIE[2] AND GUYUE HU[1]

[1]Institute of Geology, Chinese Acadmy of Geological Sciences, Beijing 100037 (*correspondence: zls1970@gmail.com)

[2]Institute of Tibetan Research, Chinese Academy of Sciences, Beijing 100085

We report a new suite of porphyric granite and leucogranite in the Yardoi gneiss dome (YGD) in the easternmost of the Northern Himalayan Gneiss Domes (NHGD), south of the Yarlung-Tsangpo suture. SHRIMP and LA-ICP-MS zircon U/Pb dating show that the porphyric granite dikes (PGD) and garnet-bearing leucogranites (LG) formed at ~17.7 Ma to ~20.0 Ma and at ~17.1 Ma, respectively. Both suites of granite have high Na/K (>1.30) ratios. The PGDs are characterized by (1) high Sr (>450 ppm), low Rb (<95 ppm) and Y (<6 ppm), and high Sr/Y (>86) ratios; (2) no Eu anomalies; and (3) low initial $^{87}Sr/^{86}Sr$ ratios (<0.7098) and higher ε_{Nd} (>-8.5) values. In contrast, the LGs have (1) lower Sr (<130 ppm) and higher Rb (92-130 ppm); (2) pronounced negative Eu anomalies with Eu/Eu*<0.55; and (3) relatively higher Sr ($^{87}Sr/^{86}Sr(t)$=0.7136-0.7148) and unradiogenic Nd ($\varepsilon_{Nd}(t)$=-7.7~-11.1). These data demonstrate that these Mid-Miocene granites have major and trace element and radiogenic isotope compositions similar to those of >35 Ma granites[1,2], but significantly different from those granites of similar ages in the High Himalya as well as in the NHGD[3]. High Sr/Y and relatively unadiogenic Sr isotope compositions in the PGDs could be derived from partial melting of mafic materials formed during previous compressional thickening event which was triggered by the input of juvenile heat and material associated with the Miocene E-W extension. An AFC process (plagioclase fractional crystallization and comtamination by crustal materials) could be a primary factor leading to the formation of these LGs. Concurrence of high Sr/Y granites and leucogranites in NHGD indicates that the Miocene rifting could have played an important but previously unrecognized role in producing the Himalayan leucogranite.

Organic geochemistry characteristics for mudstones in the Permian Zhesi Formation, Eastern Inner Mongolia, China: A new instance showing good hydrocarbon potential in the marine strata

X.P. ZENG*, X.L. PENG, N. LIU AND C. CHEN

College of Earth Sciences, Jilin University, Changchun, 130061, China
(*correspondence: zengxiangpeng111@yahoo.cn)

More and more instances show that the marine strata has an effiective hydrocarbon potential as the terrestrial one did. And the study on the characteristics of organic geochemistry of the Permian Zhesi Formation in eastern Inner Mongolia provides an opportunity to achieve a breakthrough in marine petroleum exploration in northeastern China. The thickness of the mudstones in the Zhesi Formation is about 1000 m and 30 dark mudstone outcrop samples were collected. The values of TOC are distributed in 0.3%~1.67% (average 0.81%). 90% of the values are greater than 0.5% which is taken as the lower limit of the abundance of organic matter, while 20% of the values exceed 1.0%. It suggests that the source rocks are up to the medium-good hydrocarbon potential. The kerogen type is mainly II_2 and the highest pyrolysis temperatures are in the range of 469~549°C. Ro values are between 2.5% and 4.28%. The source rocks are in high to over mature stages. It is worth noting that the geochemical index of the outcrop samples in the study area are similar to the core ones in the Zhesi Formation, Songliao Basin which have been proved to have a good hydrocarbon potential. Therefore the outcrop mudstones in the eastern Inner Mongolia should be considered to be of a good hydrocarbon generated prospect.

Phase equilibrium for the aqueous system containing ammonium, magnesium and chloride at 323.15 K

Y. ZENG[1,2]*, X. D. YU[1], J. Y. YANG[3] AND J. HONG[1]

[1]Department of Geochemistry, Chengdu University of Technology, Chengdu, 610059, China (*correspondence: zengyster@gmail.com)
[2] Mineral Resources Chemistry Key Laboratory of Sichuan Higher Education Institutions, Chengdu, 610059, China;
[3] Development & Comprehensive Utilization of Marine Sedimentary Brine Sichuan Provincial Key Laboratory, Chengdu, 611530, China

Phase equilibrium and phase diagram can give basic data for crystallization process. In the technology of exploit potassium from Pingluoba underground brine (Sichuan, China), magnesium ion accumulates in the mother liquid to form an aqueous system containing magnesium, ammonium and chloride. In this paper, the solubility of the system was measured using an isothermal solution method at 323.15 K.

Figure 1 is the phase diagram of the system at 323.15 K. The diagram consists of two invariant points, three univariant curves and three crystallization fields corresponding to single salts $MgCl_2 \cdot 6H_2O$, NH_4Cl and the double salt $NH_4Cl \cdot MgCl_2 \cdot 6H_2O$. The incommensurate invariant point E_1 is saturated with salts NH_4Cl and $NH_4Cl \cdot MgCl_2 \cdot 6H_2O$, and the mass fraction of its equilibrium solution is w (NH_4Cl) 7.27 % and w ($MgCl_2$) 25.87 %. The other invariant point E_2 is saturated with salts $MgCl_2 \cdot 6H_2O$ and $NH_4Cl \cdot MgCl_2 \cdot 6H_2O$, and the mass fraction of its equilibrium solution is w (NH_4Cl) 0.30 % and w ($MgCl_2$) 35.98 %. Results show that the salt $MgCl_2$ has salting out effect to the salt NH_4Cl.

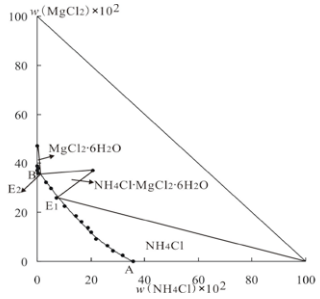

Figure 1 Phase diagram of the system containing ammonium magnesium and chloride at 323.15 K

S isotope investigation of a redox-stratified system dominated by chemotrophic sulfide oxidation

AUBREY L. ZERKLE[1,2], JENNIFER L. MACALADY[3], DANIEL S. JONES[3] AND JAMES FARQUHAR[1]

[1]Dept. of Geology and ESSIC, University of Maryland, College Park, MD, USA
[2]Currently at School of Civil Engineering and Geosciences, Newcastle University, Drummond Building, Newcastle upon Tyne, NE1 7RU, UK, (aubrey.zerkle@ncl.ac.uk)
[3]Dept. of Geosciences, Pennsylvania State University, University Park, PA, USA

Anoxic and sulfidic conditions seem to have been common in parts of stratified Precambrian oceans. The fate of sulfide in these systems would presumably have depended on the availability of oxidants and the depth of the redox interface. Before widespread oxygenation of the surface oceans, sulfide in shallow waters reaching the photic zone would have been oxidized by anoxygenic phototrophs. Increasing oxygenation of surface waters would have driven the redox interface deeper into the ocean (and eventually into the sediments), where chemotrophic oxidation utilizing newly available oxidants (e.g., O_2 and NO_3^-) would have taken over. We are using multiple S isotopes to examine S cycling processes and resulting isotope signatures in biofilms dominated by chemotrophic S-oxidizing organisms in the sulfidic Frasassi cave system (central Italy). Fractionations between sulfide and S^0 in these biofilms are larger than those previously measured in the laboratory, and vary with stream chemistry, with larger fractionations occurring at higher O_2/H_2S. Mass balance models of sulfate, sulfide, and S^0 isotope values point to a complex sulfur cycle within the biofilms. Fractionations between sulfate and sulfide plot outside the range of $\delta^{34}S$ vs $\Delta^{33}S$ published for natural systems dominated by sulfate reduction, and could provide a fingerprint for oxidative S cycling in modern (and potentially ancient) environments.

Density and apparent molar volume of binary electrolyte aqueous solutions at elevated temperatures

D. ZEZIN*, T. DRIESNER AND C. SANCHEZ-VALLE

Institute of Geochemistry and Petrology, ETH Zurich, Clausiusstrasse 25, 8092 Zurich, Switzerland (*correspondence: denis.zezin@erdw.ethz.ch; thomas.driesner@erdw.ethz.ch, carmen.sanchez@erdw.ethz.ch)

Essentially all aqueous fluids encountered in geothermal and hydrothermal environments represent multicomponent electrolyte mixtures. Quantitative modeling of geothermal reservoir processes therefore requires thermodynamic properties of such solutions. While experimental data are available for most pure electrolyte solutions, the properties of multi-electrolyte solutions are largely unstudied at elevated temperatures and pressures above the vapour pressure saturation curve. This lack of experimental data precludes the derivation of accurate pressure dependencies in thermodynamic models of excess thermodynamic properties of aqueous species in geothermal fluids.

We present the results of an experimental study on the volumetric properties of binary electrolyte solutions at temperatures up to 300 °C and pressures up to 400 bar over a wide range of compositions and ionic strengths. We used a vibrating-tube densimeter to measure the relative density of aqueous solutions containing mixtures of alkali and alkali earth chlorides. Pressure, temperature and composition dependence of density and other derived properties of binary mixtures were constrained. Mean apparent molar volumes of the electrolyte solutions were calculated from the experimental data and compared to various mixing models from the lterature. The data will be used in the ongoing development and/or parameterization of models for the calculation of excess thermodynamic properties (Hingerl *et al.*, this conference). The results of this study will permit a quantitative modeling of the properties of complex aqueous solutions and simulation of fluid-rock interaction processes occurring in geothermal systems.

The solubility of gold in water-hydrogen sulphide vapours

D. ZEZIN[1]*, A. MIGDISOV[2] AND A.E. WILLIAMS-JONES[2]

[1]Institute of Geochemistry and Petrology, ETH Zurich, Clausiusstrasse 25, 8092 Zurich, Switzerland (*correspondence: denis.zezin@erdw.ethz.ch)
[2]Department of Earth & Planetary Sciences, McGill University, Montreal, H3A 2A7 Canada

Although the formation of high-suphidation epithermal deposits of Au has generally been attributed to hydrothermal mobilization of ore components by saline aqueous liquid, pressure-temperature conditions favour the domination of vapour over liquid in these magmatic hydrothermal ore-forming systems. In view of this and the longevity of many magmatic-hydrothermal systems, it is reasonable to consider the possibility, that vapour rather than liquid may be the principal ore fluid for high-sulphidation epithermal deposits. To test this hypothesis, we have experimentally investigated the solubility of gold in H_2O-H_2S gas mixtures. The speciation and stability of gold species were evaluated in gas-only system at temperatures from 300 to 400 °C and pressures up to 265 bar, with hydrogen fugacity constrained by the reaction $H_2+S=H_2S$. Results of the experiments demonstrate that Au can be dissolved in significant concentrations in aqueous vapours. As the fugacity of gold increases with the fugacity of H_2S (in both pure H_2S gas and H_2O-H_2S mixtures), it follows that formation of stable volatile sulphide species and their solvation by H_2S ($AuS(H_2S)_n$) control the solubility of gold in the gas phase. Moreover, as the solubility of Au in the vapour phase increases with the fugacity of H_2O, it also follows that gold solubility is enhanced by formation of species hydrated by H_2O molecules, $AuS(H_2O)_m$. These results provide strong evidence that H_2S plays an important role in the vapour transport of gold.

The relative importance of solvation/hydration of sulphide and chloride complexes was assesed for vapours of composition similar to those of natural low-density magmatic-hydrothermal fluids. As these vapours are mostly water rich, gold will be transported in the vapour dominantly as hydrated gold complexes. The data on the stoichiometry and stability of gold species presented in this study represent an important contribution to our knowledge of the chemical properties of volatile metal species. Equally important, they permit accurate modeling of vapour-related processes involved in the mobilization, transport and deposition of gold in magmatic hydrothermal systems, notably those of epithermal environments.

Water resources issues in the basin of transboundary Selenga river

D.TS.-D. ZHAMYANOV, I.D. ULZETUEVA, V.S. BATOMUNKUEV AND E.D. SANZHEEV

Baikal Institute of Nature Management SB RAS, 8, Sakhyanova Str., Ulan-Ude, 670047, Russia, (*correspondence: dabaj18@yahoo.com)

According to the United Nations, in the world is more than 260 rivers belonging by several states. Within their basins it is formed about 80 % of a world river flow and lives about 40 % of a world's population [1].

The Selenga river basin is located in the centre of the Euroasian continent, in a zone of a world watershed of Arctic and Pacific oceans basins and closed basin of the Central Asia. In the landscape relation the Selenga river basin is situated in contact area of taiga and steppe natural zones that predetermines development in this territory the natural environment, which is characterised by a high level of a biological variety and hypersensibility to external influences.

The intergovernmental border divides the Selenga river basin into 2 inadequate parts: its prevailing top part is situated in the territory of Mongolia, bottom – in the Russian Federation. The river Selenga – the main inflow of lake Baikal, the importance and uniqueness of which natural characteristics are recognised by the world community as object of the World natural heritage of UNESCO and are legislatively fixed only at the Russian level. Now the Russian-Mongolian relations in the field of protection of water resources are regulated on the basis of the intergovernmental Agreement for protection and use of transboundary waters (1995).

In a boundary control point in 1992-2008 years Fe, Cu, Zn, phenols and nitrogen were constantly marked above permitted standard content. The greatest values of concentration of polluting substances are marked in 1997, 2001, 2002, 2004 years. Thus in separate years presence of pesticides and mercury was fixed, which are according to the Russian requirements is inadmissible for lake Baikal basin. In 2010 for the lake Baikal the government of the Russian Federation enters even more rigid acceptable exposure standards.

The basic sources of pollution are treatment facilities of big cities of Mongolia and Republic of Buryatia (Russian federation) (Ulaanbaator, Darkhan, Erdenet, Ulan-Ude, Gusinoozersk, Zakamensk), and also the mining enterprises (especially gold mining) in Selenga river basin.

Whether has platinum group elements (PGE) enriched in sulfide-rich black shale series in Southern Anhui Province?

YONG ZHAN[1,2], HAIJIAO YOU[1,2], YOUFEI GUAN[1,2], GUODONG SHI[2] AND MAOYAN MA[2]

[1]China Gezhouba Group Corporation, P.R.China (787545119@qq.com)
[2]Anhui University of Architecture, P.R. China

The PGE enriched in black shale series can be found in many places in China, such as Yunnan, Guizhou, Hunan, Gansu, as well as in Shanxi Province. In southern Anhui Province, the Early Cambrian black shale series are developed widely. But whether has PGE enriched in sulfide-rich black shale series is unclear.

The black shale series in southern Anhui Province, belonging to Lower Yangtze depression area, located in the Jiangnan deep-fault zone and suffered multi-stage tectonic movements, where magmatic activities show a polycyclic feature. The black shale series of Hetang Formation in southern Anhui is very stable in the whole Yangtze region and it's sequence corresponds with Niutitang Formation in western Hunan and Guizhou. The black shale series in southern Anhui mainly develop carbonaceous chert, carbonaceous shale, Si-bearing carbonaceous mudstone with the horizontal laminar, rhythmic bedding, wavy bedding, striped bedding and water ripple structure and contain star-shaped pyrite and pyrite aggregates in term of laminar distribution locally. The black shale series belongs to marine hydrothermal deposit that represents an abnormal marine sedimentation, and the sediment environment changes from the anoxic reducing environment in early stage to the half-reduction-oxidation environment in late stage [1]. PGE distribute in black shale series in Hunan-Guizhou region, especially in Ni-Mo sulfide ore bed, and spots of PGE can be found in part. The content of Re (Pd) is $1030\sim5550\times10^{-9}$, up to 10280×10^{-9}; Os content is $60\sim150\times10^{-9}$, up to 190×10^{-9}; Pt content is $50\sim580\times10^{-9}$, up to 690×10^{-9}[2].

The black shale series in southern Anhui is the same as Hunan-Guizhou in sequence, geological features, geochemical characteristics and genesis, so there is a great probability for enrichment and metalogeny of PGE in black shale series in southern Anhui. And the black shale series in southern Anhui should be given a systematic study.

This research was financially supported by the Natural Science Foundation of Anhui Provincial Education Department of China (NO.KJ2010A070).

Hydration crystallization process in mafic-felsic mixing magmatic system: A case study from the Dabie orogen (East-central China)

C. ZHANG[1,2]*, F. HOLTZ[1] AND C. MA[2]

[1]Institute of Mineralogy, Leibniz University of Hannover, Callinstr 3, D-30167 Hannover, Germany (*correspondence: c.zhang@mineralogie.uni-hannover.de)
[2]State Key Laboratory of Geological Processes and Mineral Resources, Faculty of Earth Sciences, China University of Geosciences, 430074 Wuhan, China

Hydration crystallization processes, which refer to hydrous minerals-forming reactions in the late stages of magma evolution, have essential influence on the evolution and composition of solid phases and liquids of hydrous magmas as well as on the evolution of water content in residual melts. For quantitatively modeling igneous systems involving hydrous crystllization processes, the knowledge of physico-chemical conditions, i.e. X, T, P, $a\mathrm{H_2O}$, $f\mathrm{O_2}$, prevailing in magmas is a prerequisite.

The Liujiawa intrusion is an igneous complex located at the eastern boundary of the Dabie orogen, consisting of mafic and felsic components of distincitive origins. We identified five lithologically different parts: amphibole-rich cumulate, biotite-pyroxene gabbronorite, diorite, dioritic porphyry and granite. Geochemical data indicate that the gabbronorites ressemble the most primitive basaltic magmas, while the granites represent continental crust-derived magmas. Fractional crystallization and magma mixing processes have generated other lithologies. The low An content (<An60) of plagioclase and the crystallization sequence (opx prior to cpx) indicate a water content lower than 2.8 wt% H_2O in the parental melts. Biotite (16 wt%) is the only hydrous mineral in the gabbronorite, except for trace amounts of amphibole, while biotite is absent in the amphibole-rich cumulate (amphibole 48 wt%). In the diorite, a clear evidence of magma mixing is given by helminthoid clinopyroxene relics in the core of euhedral amphiboles. Textural and chemical data indicate that biotite and amphibole formed from incongruent hydration reactions of orthopyroxene and clinopyroxene, respectively. Continuous formation of amphibole at various T-P-$a\mathrm{H_2O}$ conditions are revealed by systematically varying chlorine and Al concentrations. To summarize, hydrous crystallizations, as part of the vertical evolution of intracontinental magmatism, are responses to various physico-chemical conditions, and the fractionation including hydrous minerals have significant contributions to the petrological and geochemical characteristics of final rocks.

Mineralization features and metallogeny of polymetallic deposit in black shale series in Southwest China

CHENGJIANG ZHANG , ZHENGQI XU AND SHIJUN NI

Chengdu University of Technology, Chengdu, 610059, China (*correspondence: xuzhengq@163.com)

Black shale series is widely distributed in the Late Sinian-Early Cambrian in Southwest China. Its lithologic characters are: carbonaceous shale or slate, carbonaceous dolomite, siliceous dolomite, silicalite and phosphorite. It is accompanied with mineralization and enrichment of Mo, V, U, Hg and P. Its mineralization features and metallogeny are studied through systematic sampling and analysis.

The mineralization features are: (1) Black shale series is the source bed, in which the contents of U and other metal elements are higher. (2) Uranium mineralization is accompanied with the features of multi-elements. At present, the mainly found types include: U-P, U-Hg, U-Mo, U-V and U-Au. (3) Uranium mineralization occurs near the center of submarine hydrothermal venting-flowing of black shale series. At some special geological positions, such as the center of submarine hydrothermal venting-flowing, Mo, Ni and U, as well as platinum group elements, concentrate and mineralize. (4) Uranium mineralization in black shale series is obviously related with the transformation effect in the later period and is the necessity for the forming of large and rich uranium deposit in black shale series in Southwest China. There are apparent proofs for the later transformation effect on uranium mineralization in black shale series. For example, in Baimadong Uranium Deposit and Jinsha Uranium Deposit in Guizhou Province, the stratohorizons with uranium of higher content are all accompanied with fault structure, tectonic breccia and hydrothermal alteration of silicification.

Metallogeny of U-Polymetallic deposit in Black Shale Series in Southwest China mainly undergoes the following stages: 1) Early enrichment: Primary enrichment of Uranium of higher content (uranium anomaly) in the depositing and diagenetic period of black shale series is the prelude of metallization of Uranium deposit in Southwest China. 2) Later transformation effect: Transformation of the shallow fluid causes the re-enrichment of Uranium (uranium ore occurrence, small or middle-scale uranium deposit); 3) Superimposed mineralization: Superimposition and transformation of the deep fluid causes the formation of rich and large ore (large-scale Uranium deposit).

Geochronology and Sr-Nd-Pb-Hf isotopic compositions of gabbroic intrusions adjacent to Southern Shang-Dan Suture Zone in the Qinling orogen, central China

CHENG-LI ZHANG*, LIANG LIU AND LEI LI

State Key Laboratory of Continental Dynamics, Northwest University, Xi'an, 710069, China (*correspondence: clzhang@nwu.edu.cn)

Shang-Dan Suture Zone (SDSZ) is a main tectonic boundary between North and South Qinling belts in Qinling Oregon, central China, and marked by a discontinuous tectonic lens of island-arc volcanic-sedimentary rocks, which were intruded by gabbroic intrusions to south side of SDSZ in east Qinling. The U-Pb zircon age, Hf and whole-rock Sr-Nd-Pb isotopes for the gabbros are reported in order to assess their source signatures and tectonic settings.

The U-Pb ages of 478±11Ma and 434.7±4.4Ma have been obtained from Fushui and Ziyu gabbroic intrusion, respectively. Both of them have quite similar Pb isotopic compositions, of which the initial $^{206}Pb/^{204}Pb$ ratios of Fushui gabbros rang from 18.1154 to 18.3353 and the Ziyu gabrros from 18.0195 to 18.0851. However, the Fushui gabbros has much high initial $^{87}Sr/^{86}Sr$ (0.70785~0.71191) and negative $\varepsilon_{Nd}(t)$ (-5.43~-2.79), showing a relatively enriched mantle reservoir with DMM and EM2 signatures. In contrast, Ziyu gabbros possess low initial $^{87}Sr/^{86}Sr$ (0.70353~0.70426) and positive $\varepsilon_{Nd}(t)$ (+3.98~+4.19), displaying a slightly depleted mantle source. In addition, Ziyu gabbros posses a wide ranges of $\varepsilon_{Hf}(t)$=-39~+10, evidently indicating contamination resulted by the continental materials during transfer through crust. Furthermore, both gabbros are characterized by the island-arc magmas with a relatively enriched LILE, poor HFSE and evident depletion of Nb, Ta and Ti. Thus, we infer that both gabbroic intrusions have resulted from subduction-related processes during early Paleozoic, and the mantle source changes from the Fushui to Ziyu intrusions present subduction of the ancient Qinling oceanic crust during 478Ma and break off of the Qinling oceanic plate around 435Ma due to arc-continent collision.

Geogical significations of Qiatekaer Cu-Ni-Sulfide mineralized occurrence in West Kangguer ductile shear belt, Jueluotage area, Eastern Tianshan, Northwest China

D.Y. ZHANG, T.F. ZHOU*, F. YUAN AND Y. FAN

School of Resources and Environmental Engineering, Hefei University of Technology, Hefei 230009, China (*correspondence: tfzhou@hfut.edu.cn)

Geology and geophysics of the Qiatekaer occurrence

The Qiatekaer Cu-Ni occurrence is located in the east section of Kangguer deductile shear belt, eastern section of Jueluotag tectonic belt, Eastern Tianshan, Xinjiang, China. which have the same geological setting as the Cu- Ni deposits in the east part. The mafic dyke out crops in Qiatekaer area was found sulfides such as pyrite and pentlandite, and Ni concentration of some mineralized gabbros reach more than 400ppm, and Cu-Ni mineralized abnormalities are obviously indentified by geophysical methods such as gravity, magnetism and CSAMT [1].

Discussion

Geological characters indicate that Qiatekaer area has large potential to form Cu-Ni deposits, and there are obvious Cu-Ni sulfide mineralization judged by geochemical and geophysical characters[2, 3]. The identification of Qiatekaer Cu-Ni sulfide mineralized occurrences gives good direction to further explorer Cu-Ni deposits along the Kangguer deductile shear belt, which extends more than 500 kilometers.

Microanalysis of trace element in Fe oxide and sulphides using LA ICP-MS and EMPA

DEXIAN ZHANG[1,2,3]*, BRIAN RUSK[3], NICK OLIVER[3] AND TAGEN DAI[1,2]

[1]School of Geosciences and Info-physics, Central South University, Changsha, Hunan Province, China,410083 (*correspondence: Dxzhang303@gmail.com)

[2] Key Laboratory of Metallogenic Prediction of Nonferrous Metals, Ministry of Education,China,410083

[3]Economic Geology Research Unit, School of Earth and Environmental Sciences, James Cook University, Townsville, QLD, Australia

Our aims are to investingate the trace element concentrations and distributions in natural Fe oxides and sulfides using LA ICP-MS combined with EMPA,which are predominantly important in the study of ore genesis, economic geology of ore deposit.

In our study we analysed 267 individual magnetite and 139 pyrite in 48 samples using a GeoLas 193 nm excimer laser ablation system coupled to a Varian 820-MS series ICP-MS, and conducted elemental maps on 12 magnetite grains and sulphides grains on a Jeol JXA8200 super-probe at the Advanced Analytical Center (AAC) at James Cook University. The laser system parameters are :repetition rate:10 Hz, laser beam energy: 8J/cm^2, analysis time: 65 (30s measurement of background (laser off) and 35s analysis signal), external standard: NIST SRM 610, 612 and Mass -1, the internal standard: Fe.

EMPA trace element maps indicate that magnetite is not zoned with respect to trace element distribution, so we can use analysis limited spot on magnetite to represent the whole concentration of individual grain. The typical detection limits for a 45 micron spot are Li (1.62 ppm), Na (518ppm), Mg (0.58 ppm), Al (0.93 ppm), Si (80 ppm), K (1.41 ppm), Ca (18.39 ppm), Ti (0.17 ppm), V (0.03 ppm), Cr (1.13 ppm), Mn (0.29 ppm), Fe (5.73 ppm), Co (0.03 ppm), Ni (0.89 ppm), Cu (0.28 ppm), Zn(0.96 ppm), Ga (0.55 ppm)), Ge (0.82 ppm), As (0.17ppm), Mo (0.03 ppm), Ag (0.01 ppm), In (0.08 ppm), Sn (0.11 ppm), Sb (0.03 ppm), Ba (0.29 ppm), W (0.005 ppm), Au (0.004 ppm), Pb (0.01 ppm), Bi (0.003 ppm), Th (0.001 ppm)

The results suggests that LA ICP-MS combined with EMPA is a effective and powerful tools to investigate the trace element concentration and distribution in Fe oxides and sulphides.

Simulating foam transport in the vadose zone at the continuum scale

Z. FRED ZHANG[1]*, MARK D. WHITE[1] AND MARTIN W. FOOTE[2]

[1]Energy and Environment Directate, Pacific Northwest National Laboratory, Richland WA 99352 USA (*correpondence: fred.zhang@pnl.gov)
[2]MSE Technology Applications, Inc., Butte, MT 59701 USA

The nuclear wastes residing in the deep vadose zone at the Hanford Site near Richland, WA, USA, threaten the underlying groundwater [1]. To immobilize the contaminants, aqueous and/or gaseous amendments may be carried by foam and injected into the contamination region. Foam is an emulsion-like, two-phase system in which gases are dispersed in a liquid and separated by thin liquid films. Foam has a very low density and a very high apparent viscosity. The transport of foam in the vadose zone is complex in that the number of lamellae present governs foam flow characteristics such as viscosity, relative permeability, and interactions between injected and residential fluids. We have developed a simulation capability into the STOMP numerical simulator [2] to model the transport of foam and the amendments contained in foam. Bench-scale lab experiments were conducted by injecting pre-generated foam into an initially unsaturated system containing one or more types of sediments. Soil water content and foam pressure were measured with time at multiple locations. The Figure below shows the simulated moisture-content distribution during the injection of foam into a two-dimensional flow cell. Further work is warranted for better understanding the foam transport mechanism in the vadose zone and parameterizing the model.

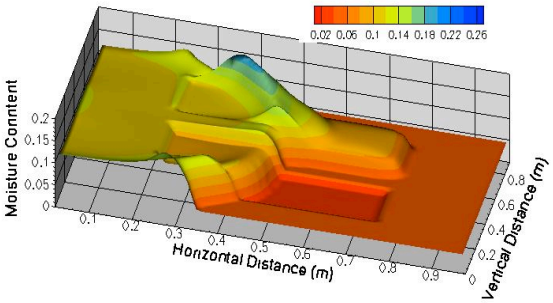

Figure 1: Simulated moisture content distribution during the injection of foam.

The significance of Cenozoic magmatism from the Eastern margin of the Eastern Himalayan syntaxis

HONGFEI ZHANG, FABIN PAN, WANGCHUN XU, LAISHI ZHAO AND YONGHAO YE

State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China (hfzhang@cug.edu.cn)

Previous studies show that the adakitic rocks have magma crystallization ages between 10~18 Ma in central Gangdese belt (west of 92°E) and 22~26 Ma in eastern Gangdese (east of ~ 94°E) [1,2,3,4]. It seems that the magma crystallization ages for the Gangdese adakitic magmatism tend to an increased variation from west to east. However, whether this variational trend extend to far eastern Gangdese is uncertain because previous work on the far eastern Gangdese adakitic magmatism lacks high-precision geochronological data. If the age variational trend for the adakitic magmatism is true, an interesting issue is what continental dynamic process taken place along the Gangdese belt.

We carried out an integrated study of U-Pb zircon dating, geochemistry and Sr-Nd-Hf isotopes for two granitoid intrusions in Motou area, the eastern margin of the eastern Himalayan syntaxis. U-Pb zircon dating shows their magma crystallization ages of ~28 Ma. These granitoids have adakitic geochemical signatures. Our result further confirms the age variation of the adakitic magmatism along the Gangdese belt. We suggest that the adakitic magmatism resulted from break-off of the subducted Indian continental slab and a westward propagation model for the slab break-off can account for the age variation and magma generation.

Modeling of hyporheic zone of surface water - groundwater with 3S technology

JING ZHANG[1]*, HUILI GONG[2] AND XIAOJUAN LI[3]

[1]The Key Laboratory of Resource Environment and GIS of Beijing, Capital Normal University, Beijing 100048, P. R. China (*correspondence: maggie2008zj@yahoo.com)
[2]College of Resource Environment and Tourism, Capital Normal University, Beijing 100048, P.R. China
[3]College of Resource Environment and Tourism, Capital Normal University, Beijing 100048, P.R. China

Hyporheic zone of surface water - groundwater is a mixture of surface water and ground water zone where the biogeochemical activities in the region are very strong. Moreover, this zone is mainly affected by natural factors and human factors. The physical, chemical and biological processes are often occurs within the hyporheic zone, and affect the water movement, solute transport processes and the process of biological activities. Massive algae blooms are one of the biggest problems that rivers/lakes/coasts face today in China. For example, before the Beijing 2008 Olympic Games opening, Qingdao Olympic Sailing Venue, the green algae covers a third of the sea off the city of Qingdao. Algae are often caused from high nitrogen containing components of untreated waste, and nitrogen is a detergent and the main ingredient in plant fertilizer. The hope Green Olympic Games and current situation make so many Chinese people unease. Rapid development of computer technology and geo-information technology provides an objective basis for truly integrated cross-disciplinary. Global Earth Observation System of aerospace, aviation and ground coordination with multi-temporal and spatial resolution has been more and more widely applied in geochemical, hydrological, ecological and environmental studies. With the advanced development of 3S technology (Remote Sensing, Geographic Information System, Global Positioning System), monitoring, measuring and modeling biogeochemical processes and its ecological function in hyporheic zone of groundwater and surface water is more visualized and reliable. This talk will focus on an overview of application of 3S on biogeochemical processes in hyporheic zone of groundwater and surface water in China with some preliminary modeling studies [1].

Recycling subcontinental plagioclase-rich lower crust in the North China craton

JUN-BO ZHANG[1,2], WEN-LI LING[1,2]*, YONG-SHENG LIU[1,2], SHAN GAO [1,2], TIMOTHY KUSKY[1], ZI-WAN CHEN[1,2], XIAO-FEI QIU[1] AND MENG CHE[1]

[1]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China (*correspondence: lingwenli2008@126.com)
[2]Faculty of Earth Sciences, China University of Geosciences, Wuhan 430074, China

Foundering of eclogitic lower crust into the convecting mantle has been proposed to explain the unusually evolved chemical composition of Earth's continental crust. However, whether the granulitic lower crust is also removable remains unclear due to its relatively lower density. Here, we report a geochemical study of distinct phenocrystal clinopyroxene and silicic melt inclusions hosted by early Cretaceous high-Mg andesite (HMAs) from Shandong province, eastern North China craton, which suggests recycling of plagioclase-rich lithologies. Three types of clinopyroxenes are recognized. Type I and II clinopyroxenes show normal- and reverse zonation, respectively, and both are featured by clear negative Eu anomalies in their cores. Type III clinopyroxene occurs in a remnant poikilitic texture with a high-Mg# core, but with no Eu anomaly, and encloses low-Mg# olivine grains. Both olivine and clinopyroxene crystals of the andesite contain high-Si and low-Mg melt inclusions, which are enriched in alkali metals and have low Eu/Eu*, showing a nature akin to their host clinopyroxenes and HMAs. It is thus suggested that the HMAs were derived from lower-degree melting of recycling plagioclase-rich lithologies. These rocks are interpreted as granulitic lower crust returned into the convecting mantle, which then interacted with mantle peridotite via partial melting. If so, our scenario also provides a critical guide for making high-Mg andesite and continental crust and that the granulitic component input could play a key role in the subcontinental mantle heterogeneity.

A LA-ICP-MS study of garnet from the Nihe iron deposit, Anhui Province, China

LEJUN ZHANG*, TAOFA ZHOU, YU FAN, FENG YUAN, LING MA AND BING QIAN

School of Resources and Environment Engineering, Hefei University of Technology, P.R. China (*correspondence: zljzhang@163.com)

The Luzong volcanic basin is located at the central part of the Middle and Lower Yangtze River area and contains numerous important Cu-Au-Fe deposits. The Nihe iron deposit is a newly discovered large scale iron deposit in the western part of the Luzong volcanic basin. In the contact zone of the diorite porphyry intrusion and the trachyandesite of Zhuanqiao Formation occur anumbers of garnet in the Nihe iron deposit. This study presents LA-ICP-MS data for garnets from the Nihe iron deposit, discusses the factors controlling incorporation of trace elements into garnets, and strengthens the potential of garnet trace elements geochemistry as a tool to help understand the evolution of hydrothermal fluids.

Garnets from the Nihe iron deposit range from $Adr_{48}Grs_{52}$ to almost pure andradite (Adr>99). LA-ICP-MS data show that the garnet have detectible Zr, V, U, Sc, Nb, Th, Zn, Ga, Cr, Ge, Hf, Sr, Ta, Pb and REE (∑442~1301ppm, avg. 812ppm). All the garnets are show typical LREE-enriched and HREE-depleted patterns, with a strong positive Eu anomaly. Incorporation of trace element into garnet is in part controlled by its crystal chemistry, with a coupled substitution mechanism(eg. $[X^{2+}]$ VIII -1$[REE^{3+}]$ VIII +1 $[Si^{4+}]$ IV -1 $[Z^{3+}]$ IV +1). Variations in textural, optical features and geochemistry of the garnet are largely controlled by fluid composition. Garnet composition and zonation record the history of the hydrothermal fluid and can be used to identify fluid changes in physicochemical properties.

N3).

Formation mechanism of foliated (garnet-bearing) granites of the Tongbai-Dabie orogenic belt: Evidence from the Mamiao cross section

L. ZHANG[1]*, Z. ZHONG[1], H. ZHANG[1] AND W. SUN[2]

[1]State Key Laboratory of Geological Processes and Mineral Resources, Faculty of Earth Sciences, China University of Geosciences (Wuhan), Wuhan 430074, P. R. China (*correspondence: lizhang@cug.edu.cn)

[2]Key Laboratory of Isotope Geochronology and Geochemistry, Guangzhou Institute of Geochemistry, the Chinese Academy of Sciences, Guangzhou, 510640, China

High pressure (HP) metamorphic rocks are important for understanding the genesis of the foliated (garnet-bearing) (FGB) granites in the Tongbai-Dabie orogenic belt. Based on a study on geochemistry of HP metamorphic rocks and FGB granites from the Mamiao cross section in the Tongbai-Dabie orogenic belt, the relationship between these rocks are discussed. The regular pattern of variation trends of elemental compositions of the HP metamorphic rocks, as well as the similarity in the isotopic compositions suggests the continuous evolutional relationship of retrograde metamorphism between the HP rocks. The changes in elemental compositions between HP gneisses and FGB granites are significantly different from variations of elemental compositions occurred during the retrograde metamorphism of HP eclogites. These differences in geochemistry presented in this study and previous studies suggest that there is no continuous evolutional relationship of retrograde metamorphism between the FGB granites and the HP metamorphic rocks. The magma source of the FGB granites was most likely from retrograded metamorphism and depressional partial melting of the UHP gneisses.

This research was supported by NSFC of China (No. 40873044) and the Chinese National Key Project for Basic Research (No.2006CB403502).

Kinetic experiments of some silicate mineral dissolutions in water from a subcritical to a supercritical state

RONGHUA ZHANG, SHUMIN HU AND XUETONG ZHANG

Institute of Mineral Resources, Chinese Academy of Geological Sciences, Lab.Geochemical Kinetics. Baiwanzhuang road 26, Beijing 100037 (zrhhsm@pku.edu.cn)

Measurements of steady-state dissolution rate of pyroxene, quartz, garnet, albite and actinolite in water were performed using flow through reactor (well mixed) from a subcritical to a supercritical state at temperatures from 25 to 435°C at 23-33 MPa. Minerals used in experiments are collected through microscope, cleaned and analyzed chemically. Usually, all reactive solutions were undersaturated with respect to the mineral. A few secondary product phases were found on the reacted surface. The kinetic experiments indicate that the measured dissolution rates of the minerals at T ≤300°C coincide with previous experiments of quartz, diopside and albite published in literatures. The dissolutions are stoichiometric, when the release ratio of molar concentrations of metal M_i versus molar concentration of Si in outlet solutions $\Delta Mi/\Delta Si$ is identical to the stoichiometric number N_i in solid. The stoichiometric dissolution of pyroxene in water is present at near 200°C, and it for albite in water is at 300°C. Dissolution rates (r_{Si}) for quartz, diopside, hedenbergite, albite, garnet in water were found to increase with increasing T from 25 to 300°C. Experiments indicate that the rates of pyroxene and albite decrease with increasing T from 300 to 400°C. The maximum release rates of Si for those minerals are reached at 300°C. The maximum rates for quartz are at about 374°C. The different metals of the minerals often behave the different release rates. Usually, the release rates of Na, Ca, Mg, Fe, Al of minerals are often higher than Si at T<300°C, and the metal M_i-H^+ exchange reactions are faster at low temperature. The hydrolysis of Si-O-Si bond and metal ion-H^+ exchange reactions at T< 300°C are different from reactions at T ⩾ 300°C. Because, the effects of water solvent properties (lowering density and dielectric constant within the region from a sub-critical to supercritical state, hydrogen networks of water molecules break) affect dissolution rates, e.g., dissolution rates of Si vary with 1/dielectric constant.

Note: This project is supported by the projects of 2010G28, 2008ZX05001-003-006, K1006, SinoProbe-07-02-03, SinoProbe-03-01-2A.

Melting of juvenile lithospheric mantle: Geochemical evidence from Neoproterozoic mafic-ultramafic rocks in South China

SHAO-BING ZHANG*, RONG-XIN WU AND YONG-FEI ZHENG

School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (*correspondence: sbzhang@ustc.edu.cn)

While many studies deal with the fate of ancient SCLM, less attention has been paid to the fate of juvenile lithospheric mantle. We present a geochemical study of a Neoproterozoic mafic-ultramafic complex in the eastern Jiangnan orogen, South China. Harzburgite is significantly depleted in Ca and Al, suggesting significant melt extraction; gabbro and spilite have low contents of TiO_2 and P_2O_5. While all the mafic rocks show the arc-like patterns of REE and trace element distribution, the harzburgite is complementary to the mafic rocks in the spidergrams. Zircon U-Pb dating on the gabbro gave three groups of ages at 891±13 Ma, 824±3 Ma and 764±19 Ma, respectively. The 891±13 Ma zircons are less common and unzoned or weakly zoned in CL images, which are interpreted as residues from magma source. The 824±3 Ma zircons are dominant and show clear magmatic zoning, representing crystallization age of the gabbro. The 764±19 Ma ages result from reworking of the collision orogen in response to supercontinent breakup. The harzburgite, troctolite and gabbro have positive $\varepsilon_{Nd}(t)$ values of 3.29 to 5.69 and lower initial $^{87}Sr/^{86}Sr$ ratios of 0.7033 to 0.7059, whereas the spilites show neutral $\varepsilon_{Nd}(t)$ values of -1.24 to 0.40 and higher initial $^{87}Sr/^{86}Sr$ ratios of 0.7039 to 0.7068. In particular, the gabbro rich in zircons has the highest $\varepsilon_{Nd}(t)$ values of 5.69 and the youngest Nd model age of 1.03 Ga. Lu-Hf isotope analyses on the zircons from the gabbro gave positive $\varepsilon_{Hf}(t)$ values of 10.2 to 12.1 at t = 824 Ma and Hf model ages of 0.90 to 0.98 Ga Ma. The positive $\varepsilon_{Hf}(t)$ and $\varepsilon_{Nd}(t)$ values as well as the small differences between the magma crystallization age and the Hf-Nd model age for the gabbro indicate its derivation from partial melting of an isotopically depleted mantle source. Along with available data in the Jiangnan orogen which suggests the postcollisional tectonic setting, it is concluded that the mafic-ultramafic rocks were derived from partial melting of the juvenile lithospheric mantle that probably formed by arc-continent collision at about 900 Ma, and underwent partial melting at about 820 Ma. Therefore, the gabbro and spilite represent the melts, whereas the harzburgite would be the restites after melt extraction. This provides geochemical evidence for anatexis of juvenile lithospheric mantle in the postcollisional regime.

Phase equilibrium of the Cd-bearing systems at 298 K: $Cd^{2+}//Cl^-$, SO_4^{2-}, NO_3^--H_2O quaternary system

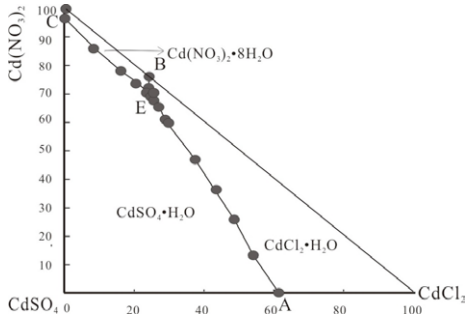
ZHANG SHIPENG[1], HUANG YI[2,3]* AND NI SHIJUN[3]

[1]College of Materials and Chemistry & Chemical Engineering, Sichuan, PRC

[2]Department of Geochemistry, Chengdu University of Technology, Sichuan, PRC (*correspondence: huangyi@cdut.cn)

[3]Applied Nuclear technigues in Groscience Key Laboratory of Sichuan Proviance, PRC

Solid- Liquid Equilibrium of quaternary system $Cd^{2+}//Cl^-$, SO_4^{2-}, NO_3^--H_2O at 298 K were studied by an isothermal solution saturation method. Experimental results indicate that there are three univariant curves BE, AE and CE, one invariant point E and three crystallization fields in the quaternary system. The quaternary system belongs to a simple type, and there're no double salts or solid solution existing. The crystallization zones of equilibrium solid phases are $CdCl_2·H_2O$, $CdSO_4·H_2O$, and $Cd(NO_3)_2·8H_2O$, respectively. The composition of the invariant point is $CdCl_2·H_2O$, $CdSO_4·H_2O$, and $Cd(NO_3)_2·8H_2O$, respectively. The physico-chemical properties of solution in the quaternary system show regular changes along with the increased cadmium concentration. The results indicated that $Cd(NO_3)_2·8H_2O$ possessed the highest solubility among those three salts, which means a strong transfer of Cd ion and a high pollution risk of soil environment. And the solubility of $CdSO_4·H_2O$ would be restrained as the salts existing together.



A simulation study of hydrocarbon gas generation from Fischer–Tropsch synthesis with varying carbon source and hydrogen in a gold tube system

ZHANG SHUICHANG, MI JINGKUI AND HE KUN

Key Laboratory for Petroleum Geochemistry, China National Petroleum Corporation

The Fischer–Tropsch synthesis (FTS) is a widely accepted mechanism for the formation of abiogenic gases, but the experimental results from different laboratories vary considerably and can rarely match the natural occurrence [1-3]. Our FTS experiments were conducted in a sealed gold tube on Fe and Ni catalysts using graphite and CO_2 with distinctive isotopic composition as the starting material by reduction in pure hydrogen at 400 °C and 50 MPa for 2-60 h. Results show that synthesis between gaseous phase carbon (CO_2) and H_2 is easier than solid phase carbon (graphite) counterpart and ^{13}C depleted CO_2 is more reactive than ^{13}C enriched CO_2. After short reaction time carbon isotopic compositions of hydrocarbons from all three FTS experiments decrease in $\delta^{13}C$ values of C_2 to C_4 alkanes with respect to CH_4, showing so-called inverse trend. With increasing reaction time, synthesis was gradually shifted to thermal cracking. ^{13}C depleted gas from thermal cracking mixed with ^{13}C enriched residual gas leads to partial reversal and normal isotopic distribution among C_1-C_4 alkanes. Hydrocarbon gases from the FTS will finally decompose to carbon and hydrogen if reaction time is longer enough.

FTS experiments running under laboratory condition from low to high temperature differs from abiogenic synthesis of hydrocarbons in natural systems, which is a cooling process from high to low temperature either under aqueous hydrothermal or volcanic intrusion condition. Hydrocarbons generated from the FTS experiments may be decomposed via thermal cracking and isotopic composition among gaseous components can show all possible distribution patterns. FTS-type natural reactions occur under certain PT condition and hydrocarbon gases generated have no further decomposition and may hold a fixed "inverse" isotopic distribution. This may explain the controversial isotopic distribution patterns observed from varying FTS experiments.

[3]Earth Sciences Division, Lawrence Berkeley National Laboratory, University of California, Berkeley, CA 94720, USA (Tianfu_Xu@lbl.gov)

Geological storage of carbon dioxide in deep saline formations can decrease the accumulation of CO_2 in the atmosphere, and thus slow down global warming. Most injected CO_2 remains for a long time as either a separate supercritical phase or in solution in brine; both forms constitute increased risk of leakage back to the surface or other environmental impacts. Mineralogical trapping of injected CO_2 is more secure but usually very slow. For standard sandstones (quartzite and arkose) investigated so far, it takes up to 10000 years to achieve 5 percent CO_2 mineralization [1]. Volcanogenic sandstones have relatively high reaction rates and larger amounts of reactive minerals, which means that if they were used for storage, there could be a larger fraction of CO_2 mineralized in a shorter time. However, porosity and permeability tend to decrease with increase of volcanic rock fragments (VRF) in sandstones, which limits the rate of CO_2 injection. We have attempted to quantitatively evaluate these tradeoffs to assess the feasibility of using volcanogenic sandstone to achieve highly secure CO_2 storage. We determined relationships between VRF percent, porosity, permeability and CO_2 injection rate from available geological data, and used TOUGHREACT to evaluate the trade-off between higher reactivity and lower porosity and permeability. Preliminary results show that roughly 5% VRF is optimal, and can result in almost complete CO_2 mineralization, but this depends on the magnitude of reactive surface area (RSA) specified. Varying RSA between 2 cm^2/g and 50 cm^2/g changes the fraction mineralized from 13% to almost 100% at 1000 years. Baseline simulations were done with a 1-D model. A corresponding 2-D radial model shows a slight increase of mineralized CO_2 due to a larger interface between the CO_2 plume and saline water.

Biomethylation potential of mercury depends on the kinetics of HgS precipitation

T. ZHANG, H. HSU-KIM* AND M.A. DESHUSSES

[1]Duke University, Civil & Environmental Engineering, Durham, NC 27708, USA (*correspondance: hsukim@duke.edu)

Monomethylmercury (MeHg) is an extreme neurotoxin that accumulates in food webs and poses a significant risk to human health. In natural aquatic systems, the predominant mechanism of MeHg production is microbial methylation of inorganic mercury (Hg) by sulfate-reducing bacteria (SRB). MeHg production rates are largely controlled by the availability of Hg species for uptake into SRB and the productivity of those microbes. In sediments, sulfide controls Hg speciation due to its high abundance and strong affinity to bind Hg^{2+}. Previous studies have demonstrated that natural organic matter (NOM) interferes with the precipitation of $HgS_{(s)}$ by preventing aggregation of HgS nanoparticles that are formed during the initial stages of precipitation. We hypothesize that bioavailable Hg concentration is related to the kinetics of HgS precipitation, and not necessarily to equilibrium speciation of Hg in sulfidic porewater.

We conducted methylation bioassays using pure cultures of two methylating SRB, *Desulfobulbus propionicus* (1pr3) and *Desulfovibrio desulfuricans* (ND132). The bacterial cultures were exposed to three different forms of Hg-sulfides, including dissolved $Hg(NO_3)_2$ and Na_2S, humic-coated HgS nanoparticles (<30 nm), and metacinnabar particles (>1000 nm), which were formulated to represent three different 'aging' states of mercury in sulfidic sediments. Our results showed that methylation rates were greatest with the dissolved Hg-sulfide treatment. In the treatments with HgS nanoparticles, MeHg production was observed at a rate that was significantly faster than the metacinnabar treatment. These results may be due to: 1) the relatively poor crystallnity of HgS nanoparticles compared to bulk minerals that are inherently less soluble; 2) the larger extent of nanoparticle-bacteria surface contact that allows nanoparticulate Hg to be spatially more accessible for the methylating bacteria than micro-scale metacinnabar. Moreover, methylation potential appeared to decrease as HgS nanoparticles 'aged' (16 hrs~1 week), which may be attributed to the enhanced crystallinity of nanoparticles during aging. Overall, our study points to a new paradigm for modeling aqueous mercury speciation in anaerobic environments and the bioavailability of inorganic mercury to methylating bacteria.

The bioleaching effect of agitation speed on low-grade chalcopyrite ore under the combined catalysis

W. M. ZHANG[1,2] *

[1]State Key LaboratoryBreeding Base of Nuclear Resources and Environment, East China Institute of Technology, Nanchang 330013, China
(*correspondence: wmzhang@ecit.cn)
[2] School of Civil and Environmental Engineering, East China Institute of Technology, Fuzhou 344000, China

Chalcopyrite is the most important copper mineral. It is, however, relatively recalcitrant to chemical and bacterial oxidation because of its special crystal structure and electrochemistry in contrast to many other copper minerals. It is essential to find some desirable methods to enhance chalcopyrite bioleaching. The purpose of this work is to study the bioleaching of agitation speed on low-grade chalcopyrite ore under the combined catalysis

The low-grade chalcopyrite ore used in this study was obtained from Yongping Copper Mine, SE-China. The particle size was less than 5 mm. The chemical composition is as follows: 0.40% Cu, 14.12% Fe, 13% S. The chemical phase analysis showed that chalcopyrite is 0.38% and the other copper minerals 0.02%. The mixed *Acidithiobacillus ferrooxidans* and *Acidithiobacillus thiooxidans* used in this study were isolated from acid mine drainage at Yongping Copper Mine. Leaching experiments were carried out in 10 L plastic drum with 800 ml 9K + S medium without Fe^{2+}, 200 ml inoculation, 25%(W/V) pulp density, 3.0 g/L activated carbon, 2.0 mg/L Ag^{+}, 8.0 g/L Fe^{2+} and 1.20 pH (the pH values were controlled within 1.50 with sulphuric acid during the bioleaching processes). The agitation speeds were 120, 150, 180, 240 and 300 rpm ,respectively.

The results show that the agitation speed has a great effect on the bioleaching of low-grade chalcopyrite ore under combined catalysis of activated carbon, Ag^{+} and Fe^{2+}. The agitating speed of 300 rpm is most beneficial to the dissolution of copper, in this case, the leaching rate of copper reaches 84% after 456 h leaching, which is 37% higher than that at 120 rpm. It is found that it is more favorable to the bioleaching of low-grade chalcopyrite ore if the redox potential is controlled at 580-620 mV.

Variation of hydro-chemistry in lower reaches of the Chinese Golmud-river and its effects on the groundwater

ZHANG WENJIE AND TAN HONGBING

School of Earth Sciences and Engineering, Hohai University, Nanjing, 210098

Major chemical compositions of Golmud-River in Qinghai, China have been measured in order to understand the spatial changeable characteristics and uncover their formation mechanism. In the lower reaches, the river is divided into two dominate tributaries of west river and east river. The principal chemical compositions of Golmud-River change significantly after it flows into alluvial-pluvial fan through Golmud city. With respect to the upper reaches, the chemical composition of west river changes slightly while the TDS of the east river increases greatly with an average of 1566.028 mg/L and reaches to a peak value of 2956.160mg/L in the same geological features. In order to figure out this abnormal variation, hydrological characteristics of the two rivers are researched. TDS of West River varies from 360.061 mg/L in the upper reaches to 552.166 mg/L in the lower reaches. Such characteristic indicates that chemical compositions of West River are principally dominated by dissolution of weathered chemical components along the river course. In contrast, the sharp rise of TDS of east river could arise owing to fluctuations of groundwater table which is about 1~3m and higher than groundwater critical evaporation depth. Moreover, groundwater table has been rising with the ascending of water leakage since the completion of hydropower station in upper reaches. Consequently, a large amount of salts are carried upward to the surface and greatly accumulated under strong evaporation. Hence, a conclusion can be drawn that significant high salinity of East River originates from soil salinization which is due to groundwater table ascending and strong evaporation.

Influence of humic acids on pyrene sorption by carbon nanotubes

XIAORAN ZHANG, MELANIE KAH AND THILO HOFMANN*

Department of Environmental Geosciences, University of Vienna, Althanstrasse 14, 1090 Vienna, Austria (*correspondence: thilo.hofmann@univie.ac.at)

Understanding the interactions between organic contaminants and carbon nanotubes (CNTs) is essential for evaluating the materials' potential environmental impact and their application as sorbent. Although a great deal of work has been published in the past years, data are still limited in terms of compounds, concentrations, and conditions investigated. This can be mainly explained by limitations associated with the generally-applied batch sorption test set ups. The present study focuses on the effects of humic acids (HA) on the sorption of organic contaminants onto CNTs. The presence of HA may have two opposite effects on sorption. On one hand, competition between HA and organic contaminants can result in a decrease in sorption to CNTs. On the other hand, HA are known to disperse CNTs and we showed in a previous study that sorption capacity is directly related to surface area. The presence of HA may thus increase sorption of organic contaminants through an increase in the available surface area. The balance between these phenomena remains unclear as classical separation techniques (e.g. centrifugation or filtration) are not adequate to efficiently separate the CNTs and liquid phase under conditions where CNTs are partially dispersed. We previously validated a passive-sampling method to study sorption of PAHs. The method is applicable to dispersed CNTs and we here use it to investigate the influence of HA on the sorption of pyrene. Sorption isotherms were determined over a wide concentration range. Changes in isotherm shapes were interpreted in terms of sorption mechanisms for a range of HA concentrations (0-200 mg/L).

Changes in the sorbent properties as a function of HA concentration are essential to understand and distinguish the various processes involved. CNTs settling behaviour, size distribution in suspension and particle diameter in the supernatant were determined by UV-vis spectrometer, particle size analyzer (CIS-100) and dynamic light scattering, respectively. Preliminary results confirmed the strong dispersing effect of HA on CNTs. The size range of CNTs decreased from 0-60 μm down to 0-8 μm in suspensions containing 0 and 200 mg/L HA, respectively. The speed of settling also decreased dramatically with increasing HA concentration, but after 2 d, particles remaining in the supernatant had similar diameters for all HA concentrations (200 nm), as compared to the control without HA (650 nm). Together with the isotherm analysis, these results will allow a better understanding of the interactions between organic contaminants and CNTs in complex environmental matrices.

Chemical sensors based on Zr/ZrO_2 electrode for measurement of pH in a subcritical to supercritical aqueous water

XUETONG ZHANG, RONGHUA ZHANG AND SHUMIN HU

Institute of Mineral Resources, Chinese Academy of Geological Sciences, Lab.Geochemical Kinetics. Baiwanzhuang road 26, Beijing 100037 (zrhhsm@pku.edu.cn)

A Zr/ZrO_2 oxidation electrode was fabricated for in situ measurement of pH values in aqueous solutions at elevated temperatures. Combined with an Ag/AgCl reference electrode, the Zr/ZrO_2 sensor responded rapidly and precisely to the pH of the solutions over a wide range of temperatures. The Zr/ZrO_2 electrode was made by oxidizing Zr metal wire with a Na_2CO_3 melt to produce a thin film of ZrO_2 on the Zr wire surface. The nanostructure of the ZrO_2 thin film was characterized using high-resolution transmission electron microscopy (HRTEM) observations. The nature of the nanostructured ZrO_2 thin film on the Zr of the Zr/ZrO_2 electrode plays a vital role in the construction of Zr/ZrO_2 chemical sensors, particularly when the electrode is utilized for in-situ measurement of the electrochemical parameters of aqueous solutions at high temperatures and pressures.

Electric probe analyses of the ZrO_2 thin films revealed that the Zr/ZrO_2 interface is divided into 5 zones from the outermost zone to the center: 1) prismatic and oxygen-rich ZrO_2 zone; 2) ZrO_2; 3) oxygen-rich Zr; 4) oxygen-bearing Zr; 5) Zr metal. Especially, the outermost oxygen-rich ZrO_2 zone of the films is composed of nanometer-sized monoclinic crystals.

The experimental measurements of the Zr/ZrO_2 sensor potential against an Ag/AgCl reference electrode indicate that the sensor potential responds linearly with the pH of NaCl-HCl-H_2O (and NaCl-NaOH-H_2O) over the temperature range from 20 to 200°C. The slope of the potential versus pH plot at 200°C is close to the theoretical value of the Nernstian slope for the test solution at electrochemical equilibrium. The Zr/ZrO_2 sensor is expected to find use for in situ measurement of pH in aqueous fluids in natural processes over a wide temperature range, especially for hydrothermal vent fluids at mid-ocean ridges.

[5]Lab. of Ion Beam Physics, ETH Hönggerberg, Zurich, Switzerland

Carbonaceous aerosols, which comprise the large fractions of elemental carbon (EC) and organic carbon (OC), badly affect climate and human health. However, there is a large uncertainty about detailed apportionment and quantification of its sources due to the large number of origins and chemical compounds associated with the aerosols. Radiocarbon (^{14}C) measurements of EC and OC allow an improvement in carbonaceous aerosol source apportionment, leading to a full and unambiguous distinction and quantification of the contributions from non-fossil and fossil sources (Szidat, 2009). The principle technique of thermal-optical analysis (TOA), which employs laser light absorption to distinguish EC from the pyrolyzed OC, is widely accepted for determination of OC and EC concentrations. However, the challenge of TOA methods lies in physically differentiating the OC and EC. Early removal of EC in the inert phase (He) and the formation of char due to pyrolysis of OC can lead to large errors in ^{14}C measurements of OC and EC, if using the conventional protocols such as IMPROVE, EUSAAR-2 and NIOSH. Here, we present a new protocol including four-stage thermal treatments optimized for isolating OC, mixture of refractory OC and non-refractory EC and refractory EC for ^{14}C measurement. In our protocol, the charring was found to be significantly reduced to less than 5% when analyzing the water-extracted filters under pure O_2 mode (65ml/min) for summer and winter filters from Gothenburg (Sweden), Moleno and Zurich (Switzerland). And both charring carbon and refractory OC could be evolved completely before native EC throughout the analysis. OC and EC together with other carbonaceous fractions could be isolated for ^{14}C measurement by the present TOA method. Furthermore, a new TOA protocol for OC/EC determination including pure O_2 pre-treatment was developed to reduce the uncertainty in EC determination from charring and light-absorbing organic compounds (also called "brown carbon") compared to other protocols.

Degassing history of Earth

YOUXUE ZHANG

Department of Geological Sciences, University of Michigan, Ann Arbor, MI 48109-1005, USA (youxue@umich.edu)

"*Once upon a time, there were few data but many models. Now, there are many data but no models.*"

Noble gas isotopes have provided much of our understanding of Earth's early history [1-3]. Various degassing models have been developed, including degassing of the whole mantle, degassing of all gases at similar relative rate [1], solubility-controlled degassing [2], and steady-state degassing models [4]. This report will evaluate various degassing models with recent data. For example, helium outgassing flux has been lowered by more than a factor of two based on sophisticated ocean general circulation models [5], which also impacts on the estimated degassing flux of carbon. Years of measurements and progress have allowed isotopic ratios of various mantle reservoirs being pieced together [6]. For example, $^{129}Xe/^{130}Xe$ in OIB mantle is found to be lower than that in MORB mantle [7]. Missing Xe has been found to be a non-issue [8]. Nucleogenic ^{21}Ne production rate relative radiogenic ^{4}He has been revised [9-10], which leads to an interesting neon paradox that nucleogenic ^{21}Ne production in the whole silicate Earth is barely enough to supply nucleogenic ^{21}Ne in air. Although non-nucleogenic mantle neon is solar, nonradiogenic mantle argon is atmospheric [11]. Nonradiogenic mantle helium is commonly thought to be similar to Jupiter. For Kr and Xe, the jury is still out. I will address what the new data mean in terms of Earth's degassing, whether the new data can be modeled consistently, or whether we are now suffering from too many data.

Anaerobic cultivation and degradation capability evaluation of microorganisms in petroleum-contaminated groundwater at low temperature

YULING ZHANG, XIAOSI SU*, SHENGYU ZHANG AND HUANCHI JIN

Key Lab of Groundwater Resources and Environment, Ministry of Education, Jilin University (*correspondence: lingling29@126.com),
(State major projects for water pollution control and treatment Technology 2008ZX02707-007)

In this study, water and soil samples were collected from the shallow groundwater in vertical direction of a petroleum contaminated site in the northeast of China. Cultivation research of anaerobic microorganisms and microbial degradation test of TPH were carried out using 0# diesel oil as the sole carbon source. Microorganisms were enriched in the four traditional culture media by anaerobic pyrogallic acid method [1,2].

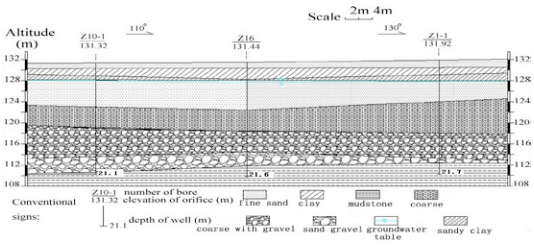

Figure 1: Hydrogeologic profile of petroleum-contaminated site

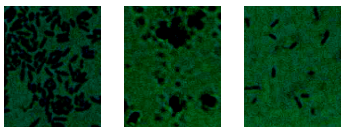

Figure 2: Morphology of three kinds strains which had the most degradation effect on TPH under the microscope

Discussion of results

Species and relative density of microorganisms were heterogeneous in different layers of groundwater after 10 days' cultivation at 10°C. All of these strains had a certain extent of degradation effect on TPH in oxygen limited environments under low temperature, with three kinds of which had a degradation efficiency of more than 60%.

Characteristic and the formation conditions of chlorite in granite-type uranium ore-field, South China

ZHANSHI ZHANG[1,2]*, GUOLIN GUO[1] AND ZHENPING JIANG

[1]Key Laboratory of Radioactive Geology and Exploration Technology Fundamental Science for National Defense, East China Institute of Technology, Fuzhou, Jiangxi, 344000, China (*correspondence: zhszhang@ecit.cn)

[2]Key Laboratory of Nuclear Resources and Environment (East China Institute of Technology), Ministry of Education, Nanchang, 330013, China

Granite-type uranium deposits were the most important uranium mining deposit type in China currently. Chloritization was one of the most developed hydrothermal alterations during the uranium mineralization, and also developed before and after the mineralization. Quarry operation had proven that chloritization-type-ore not only the important supplement of the traditional silicification-type-ore but also a new high-grade type ore. Three representative granite-type uranium ore fields in South China had selected in this study. Based on the field investigation, representative chloritization-uranium-ore had been sampled. Separating of clay minerals, XRD analysis and electron probe microanalyser(EPMA) had been employed to study the characteristic and the formation condition of the chlorite.

It is revealed the assemblage type of clay minerals were chlorite-illite or illite-chlorite types. Chlorite distributed in the rocks either in pseudomorph of biotite or vermiform and flaky conglomeration in veins. Brunsvigite and Ripidolite had been distinguished based on the chemical composition based on EPMA analyze, magnesium and iron chemical composition of chlorite varied greatly, chlorite was mostly derivated from the argillaceous rock based on nAl/n(Al+Mg+Fe) value, escept some from the magnesium-rich fluid which might announce that there were some chlorite and even the chloritezation-type-ore had be contaminated by Mafic-rich fluid. The formation temperature varied in 163□287°C had been calculated. The temperature of chlorite which related to the formation of uranium deposit is higher than the chlorite which formatted before and after the uranium mineralization. And the temperature is closed to the temperature of uranium deposit. The chlorite formed under reduction condition. Dissolve-precipitation and dissolve-transfer-precipitation were the formation mechanism.

Hydrogen isotope fractionation in marine algae: Salinity effect

ZHAOHUI ZHANG[1,*], WEIMING GONG[1] AND KUNSHAN GAO[2]

[1]Department of Earth Sciences, Nanjing University, 22 Hankou Road, Nanjing, 210093, China. (*correspondence: zhaohui@nju.edu.cn)

[2]State Key Laboratory for Marine Environmental Sciences, Xiamen University, Xiamen, 361005, China

With the advance of GC-IRMS technology, compound-specific hydrogen isotopes of algal biomarkers have been widely used in hydrology reconstruction in paleoceanography. However, the salinity effect on hydrogen isotope fractionation in marine algae remains largely unclear. We have cultured five different species of myarine algae, Prymnesiophyceae *Emiliana huxleyi* (CCMP 1516), Prymnesiophyceae *Geophyrocapsa oceanica* (CCMP 2051), Dinophyceae *Prorocentrum minimum* (CCMP 1329), *Navicula climacosphenae bootyh*, Coscinodiscophyceae *Thalassiosina pseudomanh* (CCMP 1335) in artificial sea water with different salinities while keeping other parameters the same. Cell density was measured on a Z2 Coulter® Particle Count and Size Analyzer. Algal biomarkers are analyzed for structure identification on GC-MS and measured for hydrogen isotope ratio on GC-IRMS. Salinity effect in hydrogen isotope fractionation will be discussed.

ID-TIMS zircon U-Pb age of Yulonggou intrusive rocks and its geological significance in South Qilian Mountains, NW China

ZHAO-WEI ZHANG[1,2], WEN-YUAN LI[1], YONG-BAO GAO[1,2] AND ZHOU-PING GUO[1]

[1]Xi'an Center of Geological Survey(Xi'an Institute of Geology and Mineral Resource), CGS, Xi'an, Shaanxi 710054, China

[2]Chang'an University,Xi'an,Shaanxi 710054,China (zhaoweiz@126.com)

Yulonggou intrusive rocks, belongs to Riyueshan-Hualong basic-ultrabasic rocks belt, the belt has developed a number of intrusive rocks related closely with copper-nickel mineralization, it is great significance for the emplacement time and mineralization characteristics of basic-ultrabasic rocks to guide prospecting in Hualong area. The paper reports partial achievements of magmatic type copper-nickel ore resources potential evaluation in Hualong county, Qinghai Province, mainly by fieldsurvey and research on Yulonggou intrusive rocks on the process of the project, and obtained the zircon U-Pb age of 442.4±1.6 Ma(MSWD=0.059) rock formation in Yulonggou by ID-TIMS. Its petrology and geochemistry characteristics analysis and regional comparative research showing Yulonggou intrusive rocks is a ferruginous series ultrabasic-basic complex rocks, and has good magmatic differentiation and high abundance of useful elements that Ni、Cu、Co, so it is a favorable ore formation intrusive rocks; The age of 440 Ma, is conversion period from subduction orogeny to collision orogeny in the whole of Qilian Mountains, and into the stage of orogenic with the closure of Laji Mountain small ocean basin, form Yulonggou basic-ultrabasic intrusive rocks in extensional environment of post-collision. Contacting information of other intrusive rocks in Riyushan-Hualong basic-ultrabasic rocks belt, all the intrusive rocks may be formed in the same period, and have specific dynamic mechanism and evolution process. This extensional rifting event has a very close relationship with the mineralization, so the research has very important practical significance.

Elastic anomalies due to spin state transitions in cobaltate perovskites: Analogue behaviour for Fe^{2+} in $(Mg,Fe)SiO_3$

ZHIYING ZHANG[1]*, JOHANNES KOPPENSTEINER[2], WILFRIED SCHRANZ[2] AND MICHAEL A. CARPENTER[1]

[1]Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge CB2 3EQ (*correspondence: zz254@cam.ac.uk)
[2]Faculty of Physics, University of Vienna, Strudlhofgasse 4, A-1090, Vienna, Austria

$(Mg,Fe)(Si,Al)O_3$ perovskites with orthorhombic *Pnma* structure and (Mg,Fe)O are the principal minerals of the Earth's lower mantle. Fe^{2+} undergoes spin state transitions at high pressure and high temperature, which have important effects on the physical properties of the lower mantle. Fe^{2+} in (Mg,Fe)O changes from high spin state to low spin state with increasing pressure, leading to large changes in the bulk modulus and small changes in the shear modulus. However, the influence of spin state transitions on $(Mg,Fe)(Si,Al)O_3$ are less clear. There are still controversies about the nature of the stable spin configuration at high pressure and high temperature, the extent of the effect of spin state transitions on elastic properties and so on. It is hard to investigate the elastic moduli and acoustic dissipation at high pressure and high temperature. Therefore, analogue materials have been made use of. Co^{3+} is isoelectronic with Fe^{2+}, and undergoes spin state transitions as a function of temperatue at ambient pressure. We have investigated elastic anomalies and acoustic dissipation associated with spin state transitions of Co^{3+} in $NdCoO_3$ and $GdCoO_3$ perovskites (orthorhombic, *Pnma*) using resonant ultrasound spectroscopy at high frequencies (0.1-1.5 MHz) and dynamic mechanical analysis at low frequencies (0.1-50 Hz). Strain analysis based on lattice parameter data from the literature shows that the spin state transitions are accompanied by significant variations in shear strain due to the change in ionic radius of Co^{3+}. Spin state/strain coupling via octahedral tilting leads to the renormalization of shear modulus. In $NdCoO_3$, the shear strain is small, and thus the coupling is weak. The temperature dependence of the shear modulus scales semi-quantitatively with an empirical spin order parameter. On the other hand, large shear strain and strong coupling occurs in $GdCoO_3$, and large softening of the shear modulus by up to ~35% has been observed, accompanied by enhanced acoustic dissipation. The large shear strain associated with octahedral tilting in $(Mg,Fe)SiO_3$ at high pressure suggests similar elastic behaviour as in $GdCoO_3$.

Structure and mineralization characteristics of Kangding gold orefield, Sichuan Province, China

ZHANG ZHIJUN[1 2], DENG JUN[1], GONG QINGJIE[1] AND WANG QINGFEI[1]

[1]China University of Geosciences, Beijing, 100083
[2]Tianjin North China Geological Exploration Bureau, Tianjin, 300170

The Kangding gold orefield, located in the north part of the 'kangding complex' block and Sanjiang ore cluster area, has great potential in mineral resources. Based on the geological settings, the gold deposits in the study area are divided into two series : one series is in Kangding complex and the other is in the Xiaojin area with arc-shaped structures. Orefield structure, ore deposit geochemistry and metallogenic model are studied and compared between the two series. The rocks mainly contain amphibolite, granite, granulite, and basic dikes. The Kangding complex has experienced the formation of the basement from Neoarchean to the Paleoproterozoic, the Neoproterozoic magmatic activities (between 860-750Ma.) with the mountain of the main body, Mesozoic Indo-Chinese - Yanshanian magmatic activity, as well as the Cenozoic Himalayan magmatic activities. Magmatic activities are closely related to the formation of gold mineralization. Kangding complex is characterized by two layers which are crystalline basement and fold basement. It is a mixture of metamorphic and magmatic complex, and is the product of regional metamorphism, deformation and partial melting of magmatic rocks since Proterozoic.

Characteristics of metallogenetic fluids and genesis of Nongping gold-copper deposit in Eastern Yanbian, Northeastern China

H.L.ZHAO, Y. S. REN*, N. JU AND H. WANG

College of Earth Sciences, Jilin University, Changchun 130061, China (*correspondence: renys@ jlu.edu.cn)

Nongping is another porphyry deposit besides Xiaoxinancha large-scale gold-copper deposit in Yanbian area, Northeastern China. It experienced such four stages as sulfides, quartz-sulfides, quartz-sulfides-bismuthinite and quartz-melnikovite-tourmaline stage. And the quartz-sulfide-bismuthinite stage is the main gold mineralizing stage.

The petrographic and microthermometric studies on the fluid inclusions in quartz grains from sulfides-bearing quartz vein formed in the main mineralizing stage show that there are five types of the primary inclusions: (I) gas-liquid, (II) CO_2-bearing three-phase, (III) multiple phases, (IV) pure gas and (V) pure aqueous phase. The metallogenic fluid is of high-moderate temperature (homogenization temperature ranges from 237.8 to 399.4 °C, mainly in the range of 310 ~ 370 °C). The salinity of fluid inclusions is 1.39~12.3wt% and 33.32 ~ 42.03wt%. Different types of inclusions are closely accompanied, with roughly accordant homogenization temperatures and significantly different salinity. These characteristics indicate that the metallogenetic fluids experienced fluid boiling. The laser Raman spectroscopic analysis shows that the main components gas phase of the metallogenetic fluids are H_2O and CO_2, with a small amount of CH_4.

Nongping gold-copper deposit and Xiaoxinancha large-scale gold-copper deposit develop the same kinds of inclusions with similar homogenization temperatures, and they both experienced fluid boiling in the formation of deposits [1,2]. Combined with metallogenic geological conditions and mineralization, a conclusion can be drawn that both two deposits are derived from the same magmatic and mineralization events under alike tectonic settings. At the end of the early Cretaceous, thanks to the subduction of the Pacific Ocean slab to the Eurasia plate, large copper-gold mineralization took place under the background of lithospheric extension.

High-resolution carbon and oxygen isotopic record through the transition from OAE1a to ORB1 in the Mudurnu section, central Turkey

KUI-DONG ZHAO[1], SHAO-YONG JIANG[1]*, XIU-MIAN HU[1], İSMAIL ÖMER YILMAZ[2] AND HONG-FEI LING[1]

[1]State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Jiangsu, 210093, P. R. China (*correspondence: shyjiang@nju.edu.cn)

[2]Department of Geological Engineering, Middle East Technical University, 06531 Ankara, Turkey

Change in oceanic sedimentation from Cretaceous black organic carbon-enriched deposits (Oceanic Anoxic Events) to predominantly oceanic red beds (ORBs) occurred widely in the Tethys. Few attentions have been given to the transition and environmental changes from the Selli Level (OAE1a) to the Oceanic Red Bed 1 (ORB1).

High-resolution carbon and oxygen isotope curves derived from the early Aptian hemipelagic sediments cropping out at Mudurnu, central Turkey, reveals isotopic excursion and recovery through the transition from the OAE1a to ORB1. Comparison with the standard reference $\delta^{13}C$ curve of the Alpine Tethys shows that the overall character of the excursion through OAE1a is clearly reproduced in central Tethys. A sharp negative $\delta^{13}C$ excursion (1.5‰) followed by an abrupt and prolonged positive $\delta^{13}C$ excursion (3.5‰) and black shale deposition through OAE1a. $\delta^{18}O$ values also show sharp negative excursion synchronous with $\delta^{13}C$ before OAE1a, implying that the onset of OAE1a might be related with rapid influx of CO_2 into the atmosphere from volcanogenic and/or methanogenic sources. Aftermath the OAE1a, $\delta^{13}C$ values keep high value and last for a long time (>1.0 myr), then decrease gradually to normal values until the appearance of ORB1. The recovery of carbon isotope last for longer than 1myr. Gradually intensifying of bottom circulation and increasing in dissolved oxygen in bottom waters is the most probable the cause for the transition from OAE1a to ORB1.

Component and structure of manganese dominant mineral of Co-rich crusts from West Pacific

ZHAO LEI[1] YANG HUA[1] AND ZHAO XIAOYI[2]

[1]China University of Geosciences (Beijing), 100083 (zhaolei51yh@yahoo.com.cn)
[2]Hebei Province Geophysics Investigation Institude

West Pacific is one of the most enriched regions of Co-rich crust. This study selected a multilayered-structure crust, and sampled from an enrichment belt of the main manganese mineral. The component of the manganese- dominant mineral is MnO_2 with water and a lot of other element (Fe, Ca, Na, Mg, etc.), its formula can be writing as $MnO_2 \bullet XH_2O$ (with Fe, Ca, Na, Mg, and other elements). As it is completely different from vernadite, but its structure and stability similar with δ -MnO_2 ; for close intergrowth with iron hydroxide, XRD values are larger with the 0.24~0.245 nm and the 0.14~0.143 nm than vernadite. The name is proposed for the marine δ -MnO_2 . Marine δ -MnO_2 has layer-structure even with tunnel structure, and has good structural stability. When heated to 400 °C , its crystal structure remains basically unchanged. Marine δ -MnO_2 changes into Mn_2O_3 (γ -Mn_2O_3) around 550 °C , then changes into Mn_3O_4 around 804 °C . The temperature of 804 °C is lower 146 °C than the temperature of 950 °C reported by a literature, the structural stability may be related to the metal ions contained. The manganese-dominant mineral of Cobalt-rich crusts in this area is δ -MnO_2 , for the three main manganese minerals of todorokite, birnessite and δ -MnO_2 in deep seas, δ -MnO_2 is the most thorough oxidized mineral, the O/Mn are 1.74~1.87,1.87~2.00,1.99. This shows that the crusts underwent the strong oxidative environments and agrees with the enrichment characteristic of the REE.

Identification of marine manganese minerals should use many means, and the peak of XRD should be determined according to the standard of marine manganese minerals. Considering different stabilities and structures between marine manganese minerals and the terrestrial counterparts, we should use a new naming system for marine manganese minerals: marine 1 nm mineral, marine 0.7 nm manganese mineral marine δ -MnO_2.

Fe isotope evidence for mantle metasomatism in the lithospheric mantle of the Eastern China

X.M. ZHAO[1]*, H.F. ZHANG[1] AND X.K. ZHU[2]

[1]State Key Laboratory of Lithopheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China (*correspondence: xinmiao312@mail.iggcas.ac.cn, hfzhang@mail.iggcas.ac.cn)
[2]Institute of Geology, Chinese Academy of Geological Sciences, Beijing 100037, China (xiangkun@cags.net.cn)

To further constrain the iron isotopic composition of the terrestrial mantle and investigate the behavior of iron isotope during mantle processes, we have determined the Fe isotopic composition of Cenozoic alkali basalts and peridotite xenoliths entrained in Mesozoic and Cenozoic basalts from eastern China by high-resolution MC-ICP-MS.

Results from alkali basalts show a limited Fe isotopic variation, with δ^{57}Fe ranging from 0.169‰ to 0.241‰. By contrast, both the mantle peridotites and their mineral separates from the North China Craton exhibit an extremely large Fe isotopic variation with δ^{57}Fe ranging from -1.002‰ to 0.258‰. This may reflect heterogeneous Fe isotopic compositions of the lithospheric mantle beneath the North China Craton. An average δ^{57}Fe (-0.028‰) calculated from all the mantle xenoliths in this study is obviously lower than the average value (0.198‰) of δ^{57}Fe for the Cenozoic alkaline basalts, similar to the previous observation that the basalts generally have heavier Fe isotopes than the mantle peridotites. In individual minerals, δ^{57}Fe of the olivines (-0.968 to 0.154‰) are systematically lighter than those of the coexisting pyroxenes (-0.718 to 0.169‰ for orthopyroxene and -0.642 to 0.304‰ for clinopyroxene, respectively). The phlogopite of apparently metasomatic origin has the heaviest iron isotopic composition amongst the mineral phases with δ^{57}Fe of 0.302 to 0.376‰. This Fe isotope disequilibrium between mineral phases and an extremely Fe isotope variation in these peridotites, in particularly for the wehrlites, were probably produced by the multistage melt-peridotite interactions, consistent with the petrological observation that some of the xenoliths analyzed such as wehrlites were the products of highly mantle metasomatism. Analogous positive correlations between δ^{57}Fe and other major and trace element indicators of metasomatism such as CaO and Rb further support the above suggestion.

These characters suggest that mantle metasomatism or melt-rock interaction can significantly modify Fe isotopes and play an important role in producing Fe isotopic heterogeneity of the lithosphere mantle.

The effect of post-depositional fluids on Edicaran sedimentary carbonate in South China

YAN-YAN ZHAO* AND YONG-FEI ZHENG

School of Earth and space science, University of Science and technology of China, Hefei 230026, China (*correspondence: yyanzhao@ustc.edu.cn)

The post-depositional fluid flow in carbonates can alter the primary geochemical signatures, leaving detectable signatures in the chemical sedimentary rocks. The geochemistry of veins or cements is essential to understanding the origin of post-depositional fluids. We carried out a detailed study that combines the conventional and laser methods of analyzing C-O isotopes and trace elements in Ediacaran carbonates of the Lantian formation at Piyuancun in South China. Different components of carbonates (calcite, dolomite and bulk carbonate) and different microfacies (wallrock and veins) were analyzed, respectively. The results are used to examine the primary geochemical signatures and geometry of post-depositional fluid flow. All carbonate components show $\delta^{18}O$ values of -18.48 to -12.78‰ and $\delta^{13}C$ values of -10.28 to -7.02‰ (both relative to PDB). The $\delta^{18}O$ values for all carbonate components are almost consistent, but dolomites have slightly higher $\delta^{13}C$ values than the calcite and bulk carbonate. The different components of carbonate have preserved their primary geochemical signatures based on isotope fractionations between calcite and dolomite. Thus, the dolomite would probably precipitate from the same water as the calcite. The veins can be divided into Groups A and B based on their $\delta^{18}O$ values of –17.2 to –11.3‰ and –23.7 to –18.1‰, respectively. Nevertheless, $\delta^{13}C$ values for all the veins and wallrock fall in the same range from –10.6 to –8.9‰. Group A veins have different $\delta^{18}O$ values and REE patterns from the corresponding wallrock, indicating that these veins and wallrock are not in equilibrium with each other and vein-forming fluids are of external origin. There is no correlation between $\delta^{18}O$ and $\delta^{13}C$ values for these veins and wallrock, suggesting that the wallrock was not altered by diagenesis. The low $\delta^{18}O$ values for these veins indicate that the vein-forming fluids were derived from continental deglacial meltwater subsequent to the Gaskiers iceage. Group B veins have similar $\delta^{18}O$ and $\delta^{13}C$ values to the corresponding wallrock. Their REE patterns are almost similar to those of the wallrock except a small difference in HREE. These features indicate that vein-forming fluids are similar to those of wallrock and thus of internal origin. The precipitation water for these veins and wallrock is probably related to seawater. Therefore, the post-depositional effects of diagenetic fluids are recorded by the vein-wallrock compositions.

Zinc isotopes in the Southern Ocean – A tracer of biogeochemical cycling?

Y. ZHAO[1]*, D. VANCE[1] AND W. ABOUCHAMI[2]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Wills Memorial Building, Bristol BS8 1RJ, UK (*correspondence: y.zhao@bristol.ac.uk)

[2]Max Planck Institute for Chemistry, P.O. Box 3060, 55020 Mainz, Germany (wafa.abouchami@mpic.de)

Zinc (Zn) is an important trace metal micronutrient in the marine realm. Dissolved Zn concentrations show extreme variation in the ocean, probably due to both biological uptake and regeneration as well as abiotic processes. Zn isotopes may be useful in tracking this biogeochemical cycling. Here we report the first Zn isotopic data for the Southern Ocean, using a newly developed analytical approach. Our samples derive from the IPY/Geotraces ANT-XXIV/III cruise (Atlantic sector, Southern Ocean), whose main objective was to study the biogeochemistry of trace metals in the Fe-limited Southern Ocean. Our study is focused on the distribution and isotopes of dissolved Zn across the major frontal systems along the Greenwich Zero Meridian, including 3 depth profiles and 11 samples across a surface transect.

Much higher Zn concentrations were found at the surface of the southern ACC and the Weddell Gyre (WG) relative to that of Sub-Antarctic Front (SAF). The WG depth profile showed a local Zn (and Si) concentration maximum in the upper 200m. Zn and Si concentrations show tight linear correlations at any one site. Surface waters, however, showed a monotonically poleward decreasing trend of Zn/Si. Heavy $\delta^{66}Zn$ was found in the surface waters of the southern ACC and WG. Anomalously low $\delta^{66}Zn$ at around 50m depth has been noted in two of the three depth profiles in this study. In surface waters $\delta^{66}Zn$ is fairly constant except for a pronounced fall in at the Polar Front Zone (PFZ) co-incident with a drop in concentration.

These Zn isotope variations are consistent with biological uptake of light isotopes in the photic zone. Isotopically light Zn at around 50m is consistent with findings of similarly light Zn in the shallow sub-surface at other locations, and may highlight the role of shallow recycling of cellular Zn as an important process in the oceanic Zn cycle.

Gas accumulation rules of volcanic rocks of deep formations in Songliao Basin, Northeast China

Z.H. ZHAO[1]*, G.H. JIAO[1], P. SUN[1], X.S. JUAN[1], J.X. XIAO[2], X.H. JIANG [1] AND H.Q. BAI[1]

[1]Langfang Branch of Petroleum Exploration and Development Research Institute, Petrochina, Langfang 065007 (*correspondence: zehui_zhao@pku.org.cn)
[2]School of Energy Resources, China University of Geosciences (Beijing), Beijing 100083 (xiaojx@cugb.edu.cn)

Deep formations of Songliao basin are defined as between basement and second member of Quantou formation in lower Cretaceous, including later Jurassic Huoshiling formation, early Cretaceous Shahezi formation, Yincheng formation, Denglouku formation and 1-2 members of Quantou formation. Songliao basin was made up of groups separated fault depressions in Shahezi age of early Cretaceous.

The volcanic rocks in Yincheng formation and Huoshiling formation, are the major reservoirs for deep gas. By the means of systematically analyzing the form conditions, accumulation patterns and exploration prospects of the deep gas, it is suggested that the deep volcanic gas reservoirs are characterized by the short distant migration for gas, locating around main trough and along the fault. The existence of deep volcanic gas pool is controlled by source rocks. High quality volcanic reservoirs controlled by lithology, by lithofacies, by fracture and diagenesis, take controls of the extent of the gas pool. The locations and high production of volcanic gas pools are controlled by faults. Generally, the source rocks, reservoirs and faults all make the contribution to the formation of volcanic gas pool. From the point of view of the forming conditions of deep volcanic gas pools, it is suggested that the beneficial tectonic zone with both development of the source rock and the volcanic reservoir are the favorable exploration zone.

A 4 million year record of paleo-erosion rates from the Qilian Shan, China

ZHIJUN ZHAO[1] AND DARRYL E. GRANGER[2]*

[1]College of Geographical Sciences, Nanjing Normal University, Nanjing 210046, China (zhaozhijun@njnu.edu.cn)
[2]Dept. of Earth and Atmospheric Sciences, Purdue University, West Lafayette, Indiana, 47907 USA (*correspondence: dgranger@purdue.edu)

It has been proposed that mountain erosion rates increased rapidly at 2-4 Ma due to climate change, based partly on sediment accumulation rates in central Asia [1]. This idea has been recently supported by paleo-erosion rates from the Tien Shan determined from ^{10}Be in basin sediments, which suggest that erosion rates in these mountains doubled near 2 Ma [2]. To test the hypothesis that this represents a regional climatic signal, we constructed a 4 Ma record of paleo-erosion rates from the Qilian Shan, at the northeastern topographic boundary of the Tibetan Plateau.

We analyzed 22 samples for ^{10}Be to determine paleo-erosion rates from the Laojunmiao (LJM) section exposed in an anticline near the city of Yumen. A subset were also analyzed for ^{26}Al. The LJM section has previously been dated by magnetostratigraphy [3]. After accounting for changes in sedimentation rates, we observe no clear change in source area erosion rates from 4 Ma to 1.2 Ma; however, erosion rates increase by an order of magnitude during a discrete interval extending from 1.2-0.8 Ma, subsequently returning to near the background rate. The interval of rapid erosion is found immediately above a regional unconformity.

Our erosion rate record indicates that climate change across the Plio-Pleistocene boundary did not strongly influence erosion in the sparsely glaciated Qilian Shan. Although we cannot exclude that climate change near the Middle Pleistocene transition may have driven the rapid erosion we observe, we prefer the explanation that rapid erosion is a transient response to a tectonic uplift and fault activity near the range front, as evidenced by the regional unconformity. Rapid erosion and sedimentation rates observed elsewhere, such as the Tien Shan [2], may therefore be a local response to either glaciation or uplift, rather than indicators of a global response to climate variability.

Origin of postcollisional mafic-ultramafic rocks in the Dabie orogen: Implications for recycling of the deeply subducted continental crust

Z.-F. ZHAO* AND Y.-F. ZHENG

School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (zfzhao@ustc.edu.cn)

Recycling of the deeply subducted continental crust has bearing on crust-mantle interaction during its subduction to mantle depths, which is known to cause ultrahigh-pressure (UHP) metamorphism in the stability fields of coesite and diamond. UHP metamorphic slices are generally considered as an exhumed product from the mantle depths, which provides a reference to the recycled crust. However, it is critical to find petrological and geochemical records that bear the recycling of deeply subducted continental crust and the consequent crust–mantle interaction in continental subduction zones.

The Dabie orogen was built by the Triassic continental collision between the South and North China Blocks, with subduction of the continental crust to mantle depths. It is intriguing whether the recycled continental crust is recorded in postcollisional mafic igneous rocks. Whole-rock major–trace element and Sr-Nd isotopes and zircon Hf isotopes were determined for postcollisional mafic-ultramafic rocks of Early Cretaceous age in the orogen. The results show arc-like patterns of trace element distribution, high initial $^{87}Sr/^{86}Sr$ ratios of 0.7065 to 0.7077 and very negative $\varepsilon_{Nd}(t)$ values of −19.9 to −15.3 for whole-rock. Zircon Hf isotope analyses gave negative $\varepsilon_{Hf}(t)$ values of −26.3±0.6 to −7.0±0.5 with two-stage Hf model ages of 1.62 to 2.83 Ga. These trace element and radiogenic isotope compositions are similar to those in UHP rocks, suggesting that the mafic-ultramafic rocks were derived from an enriched mantle source with incorporation of crustal component. It may be generated by interaction between the subcontinental lithospheric mantle and the felsic melt derived from the subducting continental crust. In other words, there would be melt-peridotite reactions during the continental deep subduction, forming the orogenic lithospheric mantle composed of peridotite, pyroxenite and hornblendite. Partial melting of the orogenic lithospheric mantle gave rise to the postcollisional mafic-ultramafic rocks, recording the recycling of continental crust in the continental subduction zone.

The evolution of the Tarim Craton in Archean and Proterozoic: Zircon U–Pb and Hf isotopic evidence from the Kuruktag area, NW China

B.H. ZHENG[1]*, W.B. ZHU[1], L.S. SHU[1], H.L. WU[1] AND J.W.HE[1],

[1]State Key Laboratory for Mineral Deposits Research, Department of Earth Sciences, Nanjing University, Nanjing 210093, P.R. China (*correspondence: zhengbihai@gmail.com)

The Tarim Craton is one of the three major cratons in China. Compared with Yangtze Craton and North China Craton, only limited age data of the basement rocks in Tarim have been published. Presently, there is still great uncertainty about the formation and crustal growth of the Tarim Craton. Kuluktag Uplift is located in the northeast of Tarim Basin. Basement rocks crop out widely in Kuluktag and are unconformably overlain by Sinian strata. Three Proterozoic detrital zircon samples (F3, F7, F10) and one Neoproterozoic Granite sample (F4) have been collected and LA-ICPMS U-Pb zircon dating as well as Hf isotopic analysis have been carried out. The results show that the granite sample was formed in ca. 832Ma, probably related to the break of Rodinia Supercontinent. The three detrital zircon samples reveal identical age spectra. Two events are recorded: 1) Ca. 2000Ma metamorphism, which caused the reworking of old crustal materials; 2) Tectonic activity between ca. 2350Ma to ca. 2750Ma, which involved both juvenile and old crustal materials. Two stage model ages of all four samples vary from ca. 3.8Ga to ca.2.5Ga, indicating the crustal growth of Tarim Craton lasted from the Paleoarchean to the earliest Palaeoproterozoic, which is comparable with Yangtze and North China Cratons.

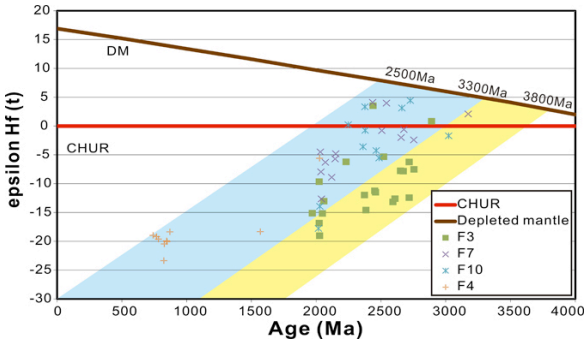

Figure 1: Diagram of εHf(t) values vs. $^{207}Pb/^{206}Pb$ ages for zircons of samples from Kuruktag, NE Tarim in this study.

Influence of major hydraulic projects on saltwater intrusion in the Yangtze River estuary

ZHENG MAOHUI[1*], LIU SHUGUANG[1,2] AND JIANG SIMIN[2]

[1]Shanghai Institute of Disaster Prevention and Relief, Tongji University, Shanghai 200092, China (*correspondence: zmh@tongji.edu.cn)

[2]Department of Hydraulic Engineering, Tongji University, Shanghai 200092, China (jiangsimin@tongji.edu.cn)

To understand the influence of the Three Gorges Project (TGP) and South-to-North Water Diversion Project (SNWDP) on saltwater intrusion in Yangtze River estuary, a depth-averaged 2D numerical model, loosely coupled with geographic information system (GIS), is developed to compute and analyze the hydrodynamics and salinity field about the estuary water. The model is validated through observed data. Then combined simulations under multiple hydrologic conditions considering different regulation schemes of the hydraulic projects as well as varied tidal ranges in the outer sea are carried out. Furthermore, the numerical output is rendered dynamically in GIS environment, and the distribution behaviours and variation trend of salinity are analyzed. The result shows that the salinity of north branch is higher than that of south branch (fig.1), and the change of salnity is mostly affected by river discharge. The maximum water diversion scheme of 1000 m^3/s of SNWDP will aggravate saltwater intrusion, while the increased discharge of TGP in dry season will restrain saltwater intrusion in the estuary.

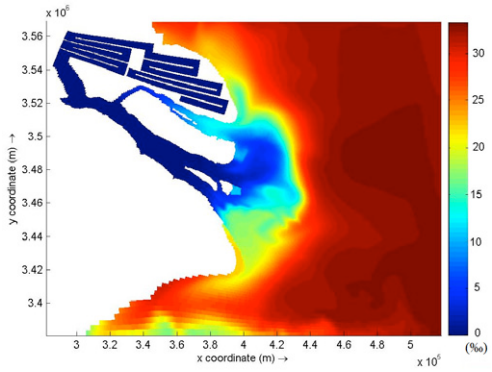

Figure 1: simulated salinity field of Yangtze River estuary in dry season

Methodology and foreground of metalloprotein

PEI-XI ZHENG[1] AND YAN ZHOU[2]

[1]College of EarthSciences, Jilin University, Changchun China 130061

[2]Center of Test Science and Experiment Jilin University Changchun China 130026

Metalloproteins is proposed as a new omics to follow genomics, proteomics and metabolomics. Researchs on metalloproteins not only answer the question of the chemical compose of metals and proteins, but also pioneer a new way for probing into the mechanisms of life substances such as metalloproteins in life activity. In Metalloproteins, metalloenzymes and othe metalcontaining biomolecules are defined as “Metallomes”. Syntheses and metabolic functions of genes and proteins cannot be performed without the aid of various metal ions and metalloproteins. The main research targets of metallomics are to identify the metallomes and elucidate their biological or physiological functions in biosystem. Chemical speciation analysis is a key technology in metalloproteins study.

Some new trends in the study of metalloproteins and metalloenzymes have been described from aspects of metal ions-related diseases (especially the neurodegenerative diseases), the roles of metalions in folding, aggregation and assembly of proteins, the design and reconstruction of metallochaperons and metalloproteins, interactions between metalloproteins and DNA.

Now, metallomics is focused on analytical techniques and methods, particularly the so-called hyphenated techniques which combine a high-resolution separation technique (gel electrophoresis/laser ablation, chromatography or capillary electrophoresis) with a highly sensitive detection method as elemental (inductively coupled plasma, ICP) or molecular (electron spray ionization (ESI) or matrix-assisted laser desorption/ionization (MALDI)) mass spectrometry, or nuclear X-ray fluorescence/absorption spectrometry. The applications of these advanced analytical methods in the identification of metallo-/phosphor-/seleno-proteins, probing of relationships between structure and function of metalloproteins, and study of clinically used metallodrugs will be selectively outlined, along with their advantages and limitations.

[3]School of Earth and Environmental Sciences, University of Portsmouth, Burnaby Road, PO1 3QL, UK

Nd isotopes recovered from Cretaceous fossil fish teeth can promote understanding of ocean circulation during this Period [e.g. 1-2], but this goal is limited by the sparsity of available data. This study presents a new time-series of Nd isotopes obtained from fish teeth collected mainly from the Gault Clay and English Chalk in the UK, spanning ~ 110 – ~ 67 Ma.

ε_{Nd} values range from ~ -8 to ~ -12.5 in the mid- to Late Cretaceous. The data show a clear decreasing trend from ~ -9 to ~ -10.5 from the early Albian to late Albian. Data from the Cenomanian–Turonian range from ~ -8.5 to ~ -11, and then reach the lowest values of ~ -12.5 in the Santonian and early Campanian, and finally recover to ~ -9 in the Maastrichtian.

Comparison with weathering proxies allows this effect to be deconvolved from circulation changes. For example, the parallel increase in the Nd-isotope and Sr-isotope ratios [3] from the early Campanian to Maastrichtian supports the idea that this increasing trend in the Nd-isotope record reflects the reorganization of ocean circulation; otherwise the enhanced global continental weathering, as indicated by Sr isotopes, should have driven the Nd isotopes in the opposite direction.

Interestingly, the low Nd-isotope values found in the Santonian and early Campanian in our record happened coincidently with major changes in Nd isotopes in the South Atlantic [2]. This coincidence in timing might suggest that changes of ocean circulation patterns in the NW European area are caused not only by local processes, but are also related to large-scale reorganization of ocean circulation induced by global tectonic movements.

Growth of zircon and rutile during continental subduction-zone metamorphism: A case study of UHP eclogite in the Dabie orogen

Y.-F. ZHENG*, X.-Y. GAO, R.-X. CHEN AND T.S. GAO

CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (*correspondence: yfzheng@ustc.edu.cn)

Both time and temperature of zircon formation can be directly dated by the U-Pb chronometer and the Ti-in-zircon thermometer, respectively. However, difficulty is encountered for rutile due to the effects of high common Pb on the U-Pb dating and pressure variable on the Zr-in-rutle thermometer. This is particularly so for Dabie-Sulu UHP eclogites of China, which gave consistently lower Zr-in-rutile temperatures than known estimates. Nevertheless, a combined study of zircon and rutile enables tight constraints on P-T-t path of continental subduction-zone UHP eclogites. We measured the Zr content of rutile by both EMP and LA-ICPMS for low-T/UHP eclogit in the Dabie orogen. Zircon U-Pb isotopes and trace elements were analyzed by LA-ICPMS, yielding U-Pb ages of 242±4 Ma and Ti-in zircon temperatures of 713±17°C for Group I zircons, and U-Pb ages of 226±2 Ma and Ti-in-zircon temperatures of 681±12°C for Group II zircons. The Zr-in-rutile temperatures were calculated and interpreted based on possible P-T-t paths for the eclogite. Most inclusion and matrix rutiles yield Zr-in-rutile temperatures of 574 to 658°C at 2.5 GPa and 593 to 680°C at 3.3 GPa. This suggests that these rutiles would grow below and at the peak pressure during continental subduction. A few inclusion rutiles give high temperatures of 719-757°C at 2.0 GPa, consistent with their growth at the peak temperature during HP eclogite-facies recrystallization in response to the "hot" exhumation. Thus, the Zr-in-rutile thermometry is capable of providing metamorphic temperatures for rutile growth provided if petrological and geochronological constraints are available on their P-T-t paths. Although the secondary Zr loss of rutile could be enhanced by fluid-assisted recrystallization, the slow rate of Zr diffusion in rutile makes it impossible as an efficient mechanism for a considerable change in rutile Zr content at the eclogite-facie conditions. Therefore, the remarkable differences in Zr content and thus in temperature between the different occurrences of rutile suggest that many rutiles did not grow at peak P-T conditions. In other words, the Zr-in-rutile temperatures can be used to indicate rutile growth in the different stages of continental subduction-zone metamorphism.

Formation of anhydrous amorphous calcium carbonate and implication for biomineralization

GEN-TAO ZHOU[1]*, YE-BIN GUAN[1] AND QI-ZHI YAO[2]

[1]School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, P. R. China (*correspondence: gtzhou@ustc.edu.cn)

[2]School of Chemstry and Materials, University of Science and Technology of China, Hefei 230026, P. R. China

Amorphous calcium carbonate (ACC) has been found as a transiently stabilized precursor in biomineralization in a variety of organisms, and is thought to play a role in the biological control over the subsequent crystallization. However, transient and stable phases of ACC differ in their structure and composition. Stable ACC contains structural water at a ratio of 1:1, while transient ACC is an anhydrous phase, and usually is in a syncytic membrane-delineated environment. Despite the fact that little is known about the formation and stabilization of biogenic ACC, it has been shown that certain macromolecules and/or other additives, such as magnesium and phosphate, may be determinant factors in the processes. To the best of our knowledge, nevertheless, no anhydrous ACC has been successfully synthesize in vitro even in the presence of the macrobiomolecules extracted from biogenic anhydrous ACC. Herein, a biomimetic mineralization process was applied to synthesize $CaCO_3$ by use of phosphatidylcholine (PC) as a model mineralization modifier. The present results show that PC is capable of inducing formation of the unusual anhydrous ACC, and the anhydrous ACC can transform into calcite with the follow-up mineralization. It implies that membrane lipid can exert significant effect on the formation and transient stabilization of anhydrous ACC bound by the membrane. Moreover, an intriguing phenomenon is that there is a large amount of ACC exclusively overlying on the surface of the secondary calcite during the subsequent mineralization. Therefore, the secondary calcite may function as an "organic-inorganic composition substrate", facilitating ACC deposition to its surface. This finding may indicate that even though the biogenic crystalline $CaCO_3$ and ACC intimately contact each other in organism, it does not means the exclusive origin of the crystalline polymorph from ACC. In contrast, the crystalline polymorph may facilitate the formation of ACC. Our results may provide a new insight into biomineralization mechanism of $CaCO_3$.

Geochemical character and tectonic implication of the Fuling composite pluton in Southern Anhui Province

ZHOU JIE[1,2], JIANG YAOHUI[2] AND XING GUANGFU[1]

[1]Nanjing Institute of Geology and Mineral Resource, Nanjing 210016, China

[2] State Key Laboratory for Mineral Deposits Research, Department of Earth Sciences, Nanjing University, Nanjing 210093, China

The Fuling composite granite located in the South of Anhui Province, is one of a tungsten-bearing granites in the east of Jiangnan orogenic belt. It crops out over an area of approximatedly 145km^2. The complex intruded into Precambrian to Cambrian siliceous shale, siliceous mudstone and limestones, with NE-SW direction. The complex is composed of 4 rock unites, the earliest units consists of spotted feldspar granite, the earlier units of feldspar granite, the later porphyraceous feldspar granite, and the last fine grain feldspar granite, named Jingkanling body, Yulongchuan body, Xiaochangxi body, and Fanzhengjian body respectively. Petrochemical data show that these granites are metaluminous to peraluminous and have high-silica (SiO_2>71%), total alkalis (Na_2O+K_2O = 5.72 to 10.75wt.%), rare elements (total REE = 99.14 to 533.86ppm) and Fe*(FeOt/(FeOt+MgO) = 0.83 to 0.97). In trace elements, they are enriched in Rb, Th, U, Zr, Hf and depleted in Ba, Sr, and Ti. Compared to the Xiaochangxi pluton and Fanzhengjian pluton, the Jingkanling pluton and Yulongchuan plutons are more depleted in Nb,Ta. $(La/Yb)_N$ ratios of the late granite unit lower than the early, average value is 11.93, 7.84, 5.15, 6.92 respectively. New LA-ICPMS zircon U-Pb dating suggests that the crystallization age of the Yulongchuan body is 127Ma, belonging to late Yanshan periods. Isotopically, Fangzhengjian granite has negative $\varepsilon_{Nd}(t)$(-5.5~ -5.91), and T_{2DM} values is between 1.35Ga to 1.4Ga. Petrographic, elemental and Sr-Nd isotopic characteristics indicate that the pluton belongs to an A_2 type granite. Fuling granite intrusion is enlongated in a NE-SW orientation, which is consistant with the distribution of regional Late Yanshanian granites in the coastal area and is parallel to the NE trending Jixi fault. A-type granites generally form in extensional tectonic environments regardless of the origin of the magma source. Combined with other A-type granites in the NE Yangtze Block, it can be concluded that Fuling A-type granite was derived by partial melting of metasediments in the back-arc extension environment, trigged by the subduction of the Pacific plate.

The comparsion of Mo isotope and paleo-oxygenation parameters in black shales from Upper Yangtze marine sediments

LIAN ZHOU, JIE SU, HU ZHAOCHU, HUANG JUNHUA, ZHAO LAISHI

State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

This paper investigates the high-solution of Mo isotopes and uses trace-element analyses for fresh and representative black shales and siliceous shales collected from the transition between the Late Ordovician and the Early Silurian at the Wangjiawan section in Yichang and the Late Permian Dalong Formation in the Shangsi Section of Sichuan. The applicability of different geochemical parameters used as paleo-oxygenation indices are also compared. The preliminary results show that V/(V+ Ni), U_{auth}(auth U), V/Cr, Ce_{anom} and U/Th have a scattered variation range, but most samples plot within the suboxic-anoxic fields. The suboxic-anoxic environment was dominant during the deposition and formation of the two anoxic facies. These redox indicators show little correspondence to the δ^{98}Mo values. The U/Mo ratio can be used as a potential proxy for the paleo-redox conditions due to the possibility that Mo is enriched relative to U at different redox gradients during early diagenesis. This evidence is more significant for the euxinicity condition and corresponds to positive δ^{98}Mo (>1.5‰) values with low U/Mo ratios. This evidence is likely related to the depositional conditions near the boundary between anoxic and euxinic environments, which are characterised by low bioturbation or water circulation. Other samples reveal a wide scatter of U/Mo ratios and δ^{98}Mo <1.5‰. These results are likely due to punctuated improvements in oxygenation with intense bioturbation or water circulation, which led to the redistribution of trace element.

This study has been supported financially by the National Natural Science Foundation of China (Nos. 41073007, 40821061, 90714010) and MOST Special Fund from the State Key Laboratory of Geological Processes and Mineral Resources and the Fundamental Research Funds for the Central Universities.

Study on glaciochemical and microparticle characteristics of three snow pits in East Antarctica

L.Y. ZHOU[1]*, Y.SH. LI[2] AND S. JIANG[2]

[1]The key Laboratory of Coast & Island Development of Ministry of Education, School of Geographic and Oceanographic Sciences, Nanjing University, 210093, China (*correspondence:liyazhou@nju.edu.cn)

[2]Polar Research Institute of China, 200129, China

In the Antarctic summer of 1998/1999, the third Chinese Trans-Antarctic inland glaciological scientific expedition successfully entered Dome A area and extended its research to the site of 79°16'S, 77°00'E, 3,931 m.a.s.l, 1,128km away from Zhongshan station. We present the glaciochemical and microparticle characteristics of three snow pits which were drilled at the 1128km(DAP1), 1000km(DAP2) and 800km(DAP3) site along the investigation route.

From the dating results of the three snow pits, we come to a conclusion that the DAP1 snow pit, which was 3.3m deep, represented the whole sediments from 1987 to 1998; while DAP2 snow pit which was 2.1m deep represented a 7-year long sediment from 1992 to 1998 and DAP3 snow pit of 2.4m deep represented a 8-year long sediment from 1991 to 1998. Comparing the different radius part of the microparticles in the snow pits, we find that they are well linear related which implicates that the main source of the microparticles is the remote continents and the local factors have weak influence on them. The concentration of microparticles also coincides with the accumulation rate, that is, high microparticle concentrations agree with high accumulation.

From the glaciochemical analysis results, we find that the concentration of calcium in the snow pits changes smoothly, which implicates that it is from the deposit of the remote continents and the local influence is not evident. But for DAP3 snow pit, the calcium concentration slightly fluctuates for the unknown local causes. The sulfate in the snow pit exhibits a noticable wave crest for the eruption of Pinatudo volcano in 1991, which verifies the preciseness of the snow pit dating. What's more, the precipitation calculated by the snow pits well agree with the trend of global warming. The snow pit contains instructive information on the sedimentary characteristics and the climate change.

This study was granted by the National Natural Sciences Foundation of China (No.40703019, 40773074, 40906098).

Instantaneous release nuclide diffusion and migration simulation in fracture medium

N.Q. ZHOU[1] S. ZHAO[1] AND Y.Q. TANG[2]

[1] Dept. of Hydraulic Engineering, Tongji University, Shanghai, 200092 China (nq.zhou@tongji.edu.cn)
[2] Nuclear Industry of China Geotechnical Engineering Co. Ltd, Shijiazhuang, 050021 China

Most nuclear power plants are built on the bedrock foundations in China. The safety of nuclear power plant is an important matter. A magnitude 9.0 earthquake hit Japan's northeastern Honshu island on March 11, 2011. Fukushima nuclear power plant was disabled, releasing numerous uranium and radiocative ^{131}I dangerous contaminant into the environment. ^{131}I and ^{137}Ce have been detected in China.

The purpose of this work is to introduce nuclude diffusion and migration in fracture medium. Qian *et al* once studied contaminants migration in fracture medium [1,2]. Nuclide has its characteristics, such as attenuation, absorption, dilution, and so on. The experiment can be only carried out in laboratory. ^{131}I is used to simulate nuclide migration, its radiocative half-life is 8.3 days. According to the geological conditions of Zhejiang Sanmen Nuclear Plant, China, the lithology is tuff sandstone and andesite basalt on Unit 1 and Unit 2 reactor blocks. The fracture distributions are investigated on the field. Based on the statistical results, random fractures are generated using Monte Carlo method [3]. Li *et al* studied ^{85}Sr, ^{134}Se and ^{60}Co absorption equilibrium resperctively [4]. Iodine absorption coefficient is measured, then the diffusion and migration equation is established about include instantaneous release.

The research results show that: Instantaneous release of radionuclides in fracture medium is mainly diffusion and adsorption at the preliminary stage. When the adsorption reaches saturation, diffusion and migration of radionuclides play major roles. With the increase of radionuclide migration distance and the lapse of time, the decay will become more obvious and the impact will gradually disappear beyond a certain distance.

Carbon isotope of residual gas in the source and reservoir rocks in the Northeastern Sichuan Basin

S.X. ZHOU[1], J. LI [1,2], B.Z. WANG [1,2], S.P. LIU[1,2] AND H.K. ZHANG[1,2]

[1]Key Laboratory of Petroleum Resources Research□Institute of Geology and Geophysics, CAS, Lanzhou, 730000 (*correspondence:sxzhou@lzb.ac.cn)
[2]Graduate University of CAS, Beijing, 1000049

There are many large gas fields in the northeastern part of Sichuan Basin, but their origin and source are not clear due to limited information obtained from chemical compositions of accumulated gas. In this study, carbon isotopic signatures of residual hydrocarbon gas and CO_2 in different source rocks, reservoir rocks and solid bitumens have been measured and gas-source correlation have been done in this area.

Our results show that various source rocks in different geological period have different isotopic composition of residual gas. Methane in the Precambrian and Cambrian mudstones range from -34.1‰ to -39.4‰ with ethane -27.1‰ to -37.3‰, while other source rocks isotopic signatures are $\delta^{13}C_{C1}$=-30.2 ~ -32.6‰ for Ordovician , $\delta^{13}C_{C1}$=-30.9 ~ -31.8‰ for Silurian, $\delta^{13}C_{C1}$=-35.5‰ for Permian and $\delta^{13}C_{C1}$= -34.5‰ for Triassic, and ethane isotopic values in these source rocks lighter than -28‰ indicate that gases in various marine source rocks are derived from sapropelic organic matter except Permian source rock.

Residual gas in Precambrian solid bitumens are -30.6 ~ -34.9‰ for methane and -30.1‰ for ethane, while gas in the Lower Triassic and Upper Permian reservoir formations containing solid bitumens display methane $\delta^{13}C$ values between -32.5‰ and -36.1‰ lighter than methane values of gas in the reservoirs, ethane $\delta^{13}C$ values between -20.7‰ and -26‰ heaver than ethane values in natural gas, and $\delta^{13}C$ values of CO_2 between -8.6‰ and -13.6‰. It is conclusion that some natural gases maybe relate to Silurian source rocks, and thermochemical sulfate reduction (TSR) is not obvious in reservoirs.

Analysis of Poyang Lake water body dissolved inorganic carbon isotopic tracing and its carbon source contribution

ZHOU WEN-BIN[1,2], HU CHUN-HUA[1,2]*, JIANG JIAN-HUA[1,2], GUO CHUN-JING [1,2] AND LOU QIAN [1,2]

[1]School of Environmental and Chemical Engineering, Nanchang University, Nanchang, 330031, China (*correspondence: chhu@ncu.edu.cn)

[2]Key Laboratory of Lake Poyang Environment and Resource Utilization, Ministry of Education, Nanchang University, Nanchang, 330029, China

In recent decades, intensifying global climate changes caused by the greenhouse effect have led to recognition of the importance of the global carbon cycle. The key to the research on this phenomenon is the identification of the source of CO_2, its variations, and its response to human activities. Lake is sensitively responding to regional and global climate changes, being a rather considerable carbon source [1-2]. During the high- and low-water periods of 2009 and 2010, water samples from the Poyang Lake region and the estuary of five rivers were collected. We analyzed the correlation of the temporal and spatial distribution of dissolved inorganic carbon (DIC). We also examined the carbon flux in the lake and the contribution of its three major carbon sources to the flux. Results show that the DIC content in the high-water period is higher than that during the low-water period. In contrast, the value of $\delta^{13}C$ DIC is positive in the low-water period and negative in the high-water period; the monthly DIC carbon flux in Poyang Lake is 2.822t–268.428t, and its mean is 135.836t. The largest contributor (73.07% contribution rate) to the carbon flux in Poyang Lake is the CO_2 water vapor exchange. The second largest contribution (15.53% contribution rate) is the river input. Weathering of rocks with dissolved carbonate is the major mechanism controlling the DIC source and the $\delta^{13}C$ DIC composition. The changes in seasonal rainfall runoff are the main factors.

Predicting CO_2 EOR and geological sequestration processes with artificial noble gas tracers

Z. ZHOU[1]*, M.J. BICKLE[2], A. GALY[2], H.J. CHAPMAN[2], N. KAMPMAN[2], B. DUBACQ[2], M. WIGLEY[2], O. WARR[1], T. SIRIKITPUTTISAK[1], P. HANNAH[3] AND C.J. BALLENTINE[1]

[1]University of Manchester, M13 9PL, UK (*correspondence: zheng.zhou@manchester.ac.uk)

[2]Department of Earth Sciences, University of Cambridge, UK

[3]Full-Spectrum Monitoring, LLC, USA

Naturally occurring noble gas isotopes provide one of the best tools to study gas-fluid-mineral interaction [1]. By injecting and studying artificial noble gas tracers in CO_2 EOR or potential sequestration reservoirs, hydrological modelling can be established to quantify the multi-phase flow of fluids and determine the flow path and flow rate of fluids. This will enable further understanding of gas-aqueous fluid-mineral reactions and kinetics.

We present preliminary results from an artificial noble gas tracer study in a commercial CO_2 EOR reservoir located in Wyoming, USA. We constructed a continuous tracer injection system which consisted of two HPLC pumps, three high pressure cylinders and a wireless remote system monitoring temperature, pressure and weight in real time. Over 9 days, we injected 2 STP litres of ^{3}He and ^{129}X each directly into the EOR CO_2 injection stream. Based on the analysis of background $^{3}He/^{4}He$ and $^{129}Xe/^{132}Xe$ (0.07Ra and 0.98 respectively), our predicted spiked $^{3}He/^{4}He$ and $^{129}Xe/^{132}Xe$ ratios for the mass of injected CO_2 are 49.54Ra and 11.64 respectively. The wellhead injector fluid and 4 production wells surrounding the injector were sampled from September 2010 to February 2011.

Preliminary results show that the highest $^{3}He/^{4}He$ and $^{129}Xe/^{132}Xe$ ratios in the injected CO_2 stream reached 49.0Ra and 23.94 respectively and establish the tracer input function. ^{3}He tracer was detected in all producing fluid samples from 4 monitoring wells. Spike breakthrough is consistent with the reservoir geology with the wells updip of the injector seeing tracer arrival earlier than those located downdip of the injector. Spike breakthrough in wells updip of the injector correlated with the well temperature which was an indication of the CO_2 breakthrough, but in the wells downdip of the injector spike came through, most probably, dissolved in the water phase. $^{3}He/^{4}He$ ratio is at a much lower level than the injected ratio and reflect the magnitude of reservoir fluid and CO_2 interaction.

Re-Os geochronology of black shales from the Neoproterozoic Doushantuo Formation, Yangtze platform, South China

BI ZHU[1,2], HARRY BECKER[2], SHAO-YONG JIANG[1]*, DAO-HUI PI[1] AND MARIO FISCHER-GÖDDE[2]

[1]State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Jiangsu, 210093, P. R. China (*correspondence: shyjiang@nju.edu.cn)

[2]Freie Universität Berlin,Institut für Geologische Wissenschaften, Malteserstr. 74-100, D-12249 Berlin, Germany

Re-Os geochronometer is a useful tool in dating organic-rich sedimentary rocks like black shale. Precise Re-Os chronology also provides constraints on temporal variation in Os isotopic composition of seawater, which reflects the relative dominance of radiogenic Os from weathering of upper continental crust and unradiogenic Os from alteration of oceanic crust or dissolution of cosmic dust.

In this study, we carried out Re-Os isotopic analysis of black shale samples from the fossil-bearing Miaohe member (Doushantuo Formation IV) at Jiulongwan section and from Doushantuo Formation II at Baiguoyuan section in Three Gorge area, South China. A Re-Os isochron age of 593±17 Ma (MSWD=1.0) with initial Os ratio of 0.88±0.13 for the basal Miaohe Member was obtained by using a CrO_3-H_2SO_4 dissolution technique. This age falls in the range of precise U-Pb zircon ages of 551 Ma from the top and 635 Ma near the base of the Doushantuo Formation, respectively. The minimum age difference of ~25 Ma between the base of the Miaohe member and the 551 Ma old tuff on the top of the Miaohe member means very low sedimentation rates during black shale deposition (< 0.5 m/Ma). By the same technique, samples from Doushantuo Formation II at Baiguoyuan section only gave an imprecise age of 582±58 Ma (MSWD=1.8) with an initial Os of 0.54±0.05, which is comparable to the initial Os (0.62±0.03) for the 608 Ma Ediacaran Old Fort Point Formation in western Canada (Kendall *et al*. 2004). The increase in initial Os ratio from 0.54 for the lower Doushantuo Formation to 0.88 for the upper Doushantuo Formation is consistent with the secular increase of $^{87}Sr/^{86}Sr$ in the late Neoproterozoic ocean, and may result from enhanced continental weathering rates during the Ediacaran due to continental convergence of East and West Gondwana and subsequently the formation of a Transgondwana Supermountain.

Recent advances in kinetics of water-rock interaction and applications to geological carbon sequestration

CHEN ZHU[1]*, FAYE LIU[1] AND PENG LU[1,2]

[1]Department of Geological Sciences, Indiana Univeristy, Bloomington, IN 474705, USA (*correspondence: chenzhu@indiana.edu)

[2]Now at the Carela Corporation

Recent laboratory experiments, field, and modelling studies on the kinetics of water-rock interactions have shown that the rates of dissolution and precipitation reactions are strongly inter-dependent or coupled [e.g., 1, 2, 3]. Numerous laboratory experiments have measured the dissolution rates at conditions far from equilibrium. However, reactions in batch and column experiments and in the field proceed in the near equilibrium region because of the low solubility of aluminosilicates. In the near equilibrium region, the Gibbs free energy term in the rate equations reduce the overall reaction rates. In the case of feldspar dissolution, slow clay precipitation effectively reduces feldspar dissolution rates by orders of magnitude. The implication is that a reaction network is operating, and a system geochemistry approach is necessary for studies of kinetics in geological systems.

When water-rock interaction theories are applied to geological carbon sequestration, the rate of fluid flow also plays a significant role on reaction rates. Recently, we conducted multi-phase reactive flow and transport modelling to simulate large scale CO_2 injection (a million tons per year for 100 years) into Mt. Simon sandstone, a major deep saline reservoir in the Midwest of USA [4]. The results indicate that most of the injected CO_2 remains within a radius of 2500 m lateral distribution. Four major trapping mechanisms and their spatial and temporal variations are evaluated in our simulations: hydrodynamic, solubility, residual, and mineral trapping. In our model, the replenishing water continues to dissolve CO_2 long after the injection, which results in total dissolution of hydrodynamically trapped CO_2 at the end of 10,000 years. In contrast, most previous models neglected the regional flow after injection and hence artificially limited the extent of geochemical reactions as if in a batch system. Consequently, a supercritical CO_2 plume (hydrodynamic trapping) would persist after 10,000 years.

Kinetic study of brucite carbonation

CHEN ZHU[1], LIANG ZHAO[1]*, XIONG GAO[1], JUNFENG JI[1], JUN CHEN[1] AND H. HENRY TENG[1,2]

[1]Department of Earth Sciences, Nanjing University, Nanjing, Jiangsu, 210093, PRC (*correspondence:zhaoliang@nju.edu.cn)
[2]Department of Chemistry, the George Washington University, Washington, DC, 20052, USA

Increasing evidence suggests that the widespread used of fossil fuels has led to a rapid increase in carbon dioxide concentration in atmosphere. One method to prevent CO_2 in the atmosphere from rising to unacceptable levels is carbon dioxide sequestration. Of all the options proposed so far, mineral carbonation is the one that offers advantages in the stablity of the final products and hence the elemination of legacy issues. However, this approach faces the problem of slow reaction kinetics and the difficulty of recycling leaching agents used to extract cations [1].

We present an experimental study of mineral carboation using NH_4Cl solution as leaching agent and brucite as raw material. The acidic environment resultant from caused by NH_4^+ hydrolysis facilitates mineral dissolution and the release of NH_3, which will be collected as a base agent for pH adjustment during the carbonate process and form NH_4Cl again. Recycle use of the leaching agent lowers the total cost and increases the commercial potential of the process. Furthermore, most magnesium-rich layer silicon minerals have similar structures and brucite-like magnesium-oxygen octahedral layers exist between silicon-oxgen tetrahedrons, it is reasonable to believe that brucite and magnesium-rich layer silicon minerals have similar dissolution mechanism.

Kinetic experiments show that the convertion-time followed the Avrami model, and that the reaction rate increased with increasing temperature and ammonium chloride concentration, decreasing solid/liquid ratio, and particle size. The following mathematical equation is found to fit the relationship between the reaction constant(k) and various experimental parameters:

$$k=5.22\times10^{5}C^{0.12}(S/L)^{-0.22}D^{-0.31}e^{-5710/T}.$$

The reaction activiation energy calculated by the Arrhenius equation 47.47kJ/mol, in agreement with the reported value for surface controlled brucite dissolution [2].

Large area multi-stage quasi-layer petroleum accumulation in carbonate reservoirs in Tazhong area, Tarim Basin

ZHU GUANGYOU[1,2], ZHANG SHUICHANG[1,2], WANG YU[1,2] AND SU JIN[1,2]

[1]Research Institute of Petroleum Exploration and Development, PetroChina, Beijing 100083, China
[2]State Key Lab of Oil Recovery Elevation, Research Institute of Petroleum Exploration and Development, PetroChina, Beijing 100083, China

Tazhong area is an important exploration domain in the Tarim basin with abundant petroleum. Ordovician carbonate reservoir is the major exploration target. The formation and distribution of those reservoirs were major controlled by high energy sedimentary facies, dissolution and faults. Reef-shoal complex in the Lianglitage Formation in Upper Ordovician and karst weathering crust reservoir in the Yingshan Formation in Lower Ordovician were both distributed quasi-layered in large area. The Hydrocarbons were complex accumulated in multi-layer. Those reservoirs were composed of carbonate rocks with low porosity and low permeability, and buried in 4500~6500m depth with intensive heterogeneity. The spatial distribution of effective reservoirs controlled the occurrence of hydrocarbon and accumulated in large area, which showed an integral enrichment characters.

Detailed oil-source rock correlation indicates that the crude oils were mix-oils originated from both Cambrian source rocks and Ordovician source rocks, nevertheless, the natural gases were major oil-crack gases from Middle-Lower Cambrian sources. The analysis of accumulating process shows that the Tazhong area experienced three stages of hydrocarbon accumulation. The first stage occurred in the Late Caledonian tectonic cycle and the hydrocarbons originated from Cambrian-lower Ordovician source rocks, and were severely degraded in the Early Hercynian tectonic movements in large areas. The second stage occurred in the Late Hercynian tectonic cycle which was the most important hydrocarbon charging stage, the oils and gases were from Middle-Upper Ordovician source rocks. The third stage occurred in the late Himalayan tectonic cycle, Cambrian oil-crack gases began to generated in depth, charged into Ordovician reservoirs along faults, gas-washed the oil pools and then formed condensate gas reservoirs which is now extensively occurred in Tazhong area.

Geochronology, geochemistry and ore-forming fluid characteristics of the Shijinpo gold deposit in Beishan belt, NW China

JIANG ZHU, XINBIAO LV*, CHAO CHEN AND YALONG MO

Faculty of Earth Resources, China University of Geosciences, Wuhan, 430074, China
(*correspondence: Lvxb_01@163.com)

The Shijinpo gold deposit is one of numerous lode gold deposits in the Beishan orogenic belt, southern margin of the Altaids, northwestern China. Gold mineralization is hosted in the early Devonian granite and consists primarily of auriferous quartz veins that confined to the EW-trending faults. Ore-related hydrothermal alteration is dominated by sericite + quartz + sulfide assemblages in close proximity of gold veins. Pyrite is the predominant sulfide mineral, variably coexisting with minor amounts of chalcopyrite, sphalerite, and galena. Gold occurs mostly as free gold enclosed in or filling microfractures of pyrite and quartz. Native gold is present coexisting with Au-bearing tellurides consisting mainly of petzite.

Measured $\delta^{34}S$ values for sulfide minerals range from 8.32‰ to 10.33‰, indicating a deep-seated sulfur source most likely of magmatic origin. Calculated $\delta^{18}O$ values for the ore fluid range from +2.7‰ to +3.3‰ and the corresponding δD values range from -95‰ to -99 ‰, compatible with mixing of magmatic and meteoric components. Fluid inclusion studies suggest that gold veins were deposited at intermediate temperature conditions (150 to 320°C) from aqueous or aqueous-carbonic fluids with moderate salinity (4.65 to 12.16 wt% NaCl equiv). The ore-forming fluid is assumed to undergo boiling at high temperature triggered by fracturing and then mixed with the ground water. Laser incremental heating $^{40}Ar/^{39}Ar$ analysis of hydrothermal sericite yield an plateau age at 364.6 ± 3 Ma (2σ), suggesting that the gold veining took place in the late Devonian.

Combining these observations with the regional geology we propose that the Shijinpo gold deposit was formed during compressional to transpressional processes in a subduction-related setting.

Mechanisms of nitrogen dissipation in an N-saturated subtropical forest in Southwest China

J. ZHU*, P. DÖRSCH, H. SILVENNOINEN AND J. MULDER

Norwegian University of Life Sciences, 1432 Ås, Norway
(*correspondence: jing.zhu@umb.no)

Published N budgets for N-saturated watersheds in subtropical SW China suggest significant N retention, despite low forest growth, P deficiency and high soil acidity [1]. To characterize mechanisms of N dissipation in these systems, we applied state-of-the-art field and laboratory methodologies to a headwater catchment at Tieshanping (TSP), SW China, (4.04 g N m^{-2} a^{-1} atmogenic deposition, 61% of which in form of NH_4^+ and 0.57 g N m^{-2} a^{-1} effusion in stream water mostly as NO_3^-). We explored spatiotemporal patterns of N_2O emission and ^{15}N and ^{18}O natural abundances of NO_3^- *in situ* and characterized nitrification and denitrification and their gaseous product stoichiometries by laboratory incubation.

Highest N cycling rates and N_2O emissions were found during the wet season (summer), with marked variations between wet and dry years. N_2O emissions during summer were driven mainly by rain episodes. Soils on the hillslopes showed higher denitrification and N_2O emission rates than a perturbed groundwater discharge zone (GDZ) which had less organic carbon. The spatial pattern of denitrification was consistent with NO_3^- concentration profiles and natural abundance signatures. Laboratory experiments confirmed that organic carbon is the limiting factor for N-removal by denitrification in this ecosystem and that the different landscape elements harbour denitrifier communities with distinct N_2O product stoichiometries, explaining part of the variation in observed N_2O emissions. Nitrification in the hillslopes was found to be unbalanced, producing significant amounts of nitrite which decomposed rapidly to NO and N_2O at low native pH (4.0), indicating chemodenitrification from incomplete NH_4^+ oxidation as a potentially important additional source for N_2O. Estimated annual N_2O emission for 2009 and 2010 was 0.29 g N m^{-2}, equivalent to appr. 8.5% of the annual N input. To close the N budget of the watershed, a field ^{15}N labelling experiment was conducted to assess total gaseous losses including N_2.

[3]National Central University, Jhongli, Taiwan

Gamma-ray measurement coming from the lunar surface is a powerful method to infer its composition of material in the top several tens of centimeters. While gamma ray lines are remotely measured in orbit, chemical elements can be identified in light of the energies from which they were emitted, and concentrations can be estimated based on their fluxes.

Chang'E-2 spacecraft was launched to the Moon (100 km, circle polar orbit) at 1st, Oct., 2011, with a gamma-ray spectrometer (CE2-GRS) as one of its scientific payloads. CE2-GRS using a large $LaBr_3$ (Ce) crystal as its main detector is expected to provide global elemental maps of the lunar surface (e.g., Th, K; Mg, O, Al, Ca, Si, Fe, Ti). It employs a big cup-shape CsI (Tl) crystal to suppress the Compton effects and reduce the background gamma rays from the spacecraft materials interacted with GCRs. Gamma-rays are recorded as 512 channel-spectrum every 3 seconds in the range of 0.3 to 10 MeV with the energy resolution of ~ 4% fwhm@662 keV.

CE2-GRS has about 4-days background measurements in its cruise period. The spectrum shows higher quality than that from past scintillation detectors for the lunar gamma-ray remote measurement. From the background spectra, self-activity peaks of $LaBr_3$ crystal (from ^{138}La and ^{227}Ac decay chain generation) can be found clearly. Elements (O, K, Mg, Al, and Ti) from the spacecraft body, the fuels, and instruments were also identified. Potassium map (cps, 5°×5°) was obtained using first three-month measurements. Since the higher spatial resolution (~ 150 km × 150 km), the derived map can show the potassium distribution on the Moon clearly.

Absolute calibration will be carried out based on the spatial response function. Comparisons with that of Lunar Prospector, Kaguya, and Chang'E-1 will be investigated to see if the new potassium could indicate some interesting, new science.

A Paleoproterozoic tectonothermal event recorded in Precambrian basement rocks of the Kuluketage uplift, Northeastern Tarim, China

W.B. ZHU, H.L. WU, L.S. SHU AND D.S. MA

State Key Laboratory for Mineral Deposits Research, Department of Earth Sciences, Nanjing University, Nanjing 210093, People's Republic of China, (zwb@nju.edu.cn)

The Kuruktag uplift is located to the north of the Tarim Block. The Neoarchaean to early Neoproterozoic basement rocks are unconformably overlain by the middle Neoproterozoic to Phanerozoic sedimentary cover. The Precambrian basement rocks also crop out in the Korla region, at the western end of the Kuruktag uplift, whose ages are uncertain because of the paucity of reliable isotopic data. These basement rocks, including gneisses, amphibolites, marbles and schists, were subjected strongly deformed and metamorphosed to amphibolite facies.

Four garnet-bearing schists were collected for zircon U–Pb dating and Hf-isotope analyses. CL images display that most zircon grains occur as relatively dark and rounded crystals and are homogeneous in texture, indicative of metamorphic origin. The samples give four metamorphic zircon ages of 1844Ma, 1847Ma, 1850Ma and 1867Ma, respectively. The metamorphic zircon age of ~1.85 Ga obtained in this study indicate that an important tectonothermal event occurred at the end of the Paleoproterozoic in the Tarim Block. Lu–Hf isotopic analysis on these zircons gives Hf model ages ranging from 2.9 to 3.5Ma, indicating that the late Paleoproterozoic metamorphism and tectonism of the Tarim Block represent an overprint on an Archaean basement. These data imply a Paleoproterozoic orogeny in the northern Tarim.

This episode of Precambrian tectonothermal event is broadly coeval with those seen in many continents around the world such as Baltica, Laurentia, Northern Finland, Northern Fennoscandian Shield, Amazonia, North China and India, etc., which is coincident with the timing of the orogeny associated with the amalgamation of the Columbia super-continent, suggesting that the Tarim Block was the part of this supercontinent.

Origin and fractionation of heavy metals of sediments in the drinking water source of Beijing

ZHU XIANFANG[1] AND JI HONGBING[1,2]*

[1]The Key Laboratory of Metropolitan Eco-Environmental Processes, College of Resource Environment and Tourism, Capital Normal University, Beijing 100048 China (xf_zhu@126.com, *correspondence: hongbing.ji@yahoo.com)

[2]State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China

The Miyun Reservoir, the only one surface drinking water source of Beijing, incepted kinds of pollutants from rivers, agricultural production, mining activity, tailing and so on. Four sediment cores (35cm per core) were collected from Miyun Reservoir and cut into slices of 5 cm each core. Samples were subjected to a total digestion technique and analyzed by ICP-OES for Cr, Pb, Cd, Co, Cu, Mn, Ni, Ti, V and Zn, and by AFS for As and Hg. The seven-step sequential extraction technique was determined the distribution of speciation for heavy metals (except As and Hg). The results revealed the contents of heavy metals were not apparent enrichment compared with the shale standard. Most of heavy metals decreased while the depth increased. The results showed that the main fraction for most of heavy metals was residual phase. Additionally, the extractive phase of Cd was higher and reached 60%, the following was Ni, Co, Zn and Pb.

The origin of heavy metals was identified by multivariate analysis with total content. The results of correlation analysis revealed obvious correlation between heavy metals. Cu, Mn and V were highly correlated among them ($r>0.800$; $p<0.01$), Cr and Ni were also identified, whereas As and Ti were less correlated with Cu, Mn and V ($r>0.500$; $p<0.01$). The correlation coefficients were not as high as among Hg, Co and other heavy metals. PCA showed there were five principal components. PC1 included Ti, Cd, Cu, Mn and V, PC2 were Cr and Ni, PC3 were As and Zn, PC4 was Hg, and PC5 was Co. Therefore, the five principal components represented five primary origins of heavy metals, which were erosion of rocks, industrial and mining, agricultural production and domestic sewage, atmospheric deposition and secondary pollution of water environment, respectively. The results provided scientific basis for protection of drinking water source of Beijing.

Isotope fractionation of transition metals by higher plants

X.K. ZHU[1], S.Z. LI[1], Y.M. LUO[2] AND L.H. WU[2]

[1]Lab Isotope Geol., MLR, Inst. Geol., CAGS, Beijing, China (xiangkun@cags.ac.cn; blueoceain@yahoo.com.cn)

[2]Inst. Soil Sci., CAS, Nanjing, China

Transition metals such as Fe, Cu and Zn are present as trace elements in organisms, but are essential for life. Thus variations in transition metal isotope composition may be important in tracing the interaction between geosphere and biosphere, to trace the pathways of these elements into and within biological system. A prerequest for these applications is an adequate undersdanding of the the mass fractionation of these isotopes during steps of biological uptake and translocation . Here we report the result of a case study for sotope fractionations of Fe, Cu, Fe and Zn by higher plant using a Cu accumulator *Elsholtzia splendens*.

Elsholtzia splendens growth-experiments were carried out in green house and in soils with different chemical properties, namely: copper contaminated soil collected from natural envirioment □denoted as CK□, CK with addition of sulphur powder, CK with addition of EDDS, and CK with addition of both EDDS and sulhpur. Soils, roots, stems and leaves were measured for Cu, Fe and Zn isotope ratios using Nu Plasma HR MC-ICPMS after digestion and chemical purification. The results display some prominant features, taking Cu isotopes as an example: 1) relative to soils, the plants show overall lighter isotope enrichment, implying significant isotope fractionation occurred during Cu uptaking of the root from the soil and light Cu isotope were taking preferentially; 2) from soil to root to stem, Cu isotope composition become progressively lighter, indicating stepwise mass fractionation during Cu uptaking and translocating; 3) relative to stems, leaves enrich heavy Cu isotope by *ca*.0.3‰, suggesting a change in Cu transport mechanism from stems to leaves, and showing that heavy Cu isotope can be preferentially taken at some stage during biological processes; 4) the extent of light isotope enrichment of the plant relative to soil varies with the chemical property of the soil, and the light Cu isotope enrichment is enhanced by the addition of EDDS.

The results presented above enhance our knowledge about mass fractionation proccesses of transition metal isotopes in higher plants significantle.

Mining-induced groundwater environmental impact assessment at Shuyang county, Jiangsu Province, China

X.B. ZHU, J.C. WU, J.F. WU AND X. YUAN

Dept. of Hydrosciences, School of Earth Science and Engineering, Nanjing University (zxb@nju.edu.cn)

The phosphorite was found at Tangzhuang village, Shuyang county, Jiangsu province. It is about 2.2km^2. It's can be used and planned to be exploited in the future. Groundwater environment would be impacted heavily by exploiting phosphorite because the phosphorite is deep below the subsurface. The groundwater level should be reduced to the bottom elevation of the phosphorite. So, the huge cone of depression, which result in the subsidence, would be developed.

There is the phreatic aquifer and the confined aquifer in the study area. The hydrogeologic conceptual model was generalized and the numerical model of groundwater flow was built with the MODFLOW module in GMS software. The dewatering of deposit was caculated, 4100m^3/d for the upright well used for workers to get inside the exploitation platform and 13054^3/d for the exploitation channel. The drawdown is computed at the same time. The maximum drawdown is 60m for the confined auqifer and 4m for the phreatic aquifer.

The effect of phosphorite exploitation on the groundwater environment is obvious. Some engineering measures are suggested to be implemented to reduce the effect. Pumping well planned to be built to supply drinking water for people around the study area. Grouting convrete boreholes are suggested to be constructed to cut off the water exchange between the phreatic and the confined aqufer. The effect of exploitation and the subsidence due to dewatering of deposit can be controlled with these engineering measures.

Zircon ages and Hf isotopic feature of Neoproterozoic metamorphosed sedimentary rocks in the South Qinling terrain, China

X.-Y. ZHU [1,2], F. CHEN [2], S.-Q. LI [2] AND L. YANG [1]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029, China

[2]School of Earth and Space Sciences, University of Science and Technology of China, Hefei, 230026, China

The Qinling orogenic belt, being part of the central orogenic belt in China, was resulted from the North China and South China blocks in early Mesozoic. The Shangnan-Danfeng tectonic zone is an inner suture, which separates this belt into the North and South Qinling terrains. Neoproterozoic sedimentary-volcanic sequences widely distributed in South Qinling have been considered to be basement rocks. Characteristic Neoproterozoic magmatic events (~750 Ma) were recorded in zircons from magmatic and low-grade metamorphic rocks in the South Qinling terrain and the South China block, interpreted as an indicator for close tectonic connection of both terrains in Neoproterozoic [1, 2].

This study presents results of zircon situ Lu-Hf and U-Pb isotopic analysis of low-grade metamorphic sedimentary-volcanic sequences in the South Qinling terrain. Most detrital zircons are euhedral to subhedral, implying a short transportation of material after weathering. Detrital zircon populations with oscillatory zonation of magmatic origin yield U-Pb ages mainly clustering at ~850 Ma and ~1890 Ma. Two zircon groups are characterized by distinguishable Hf isotopic feature, having negative initial εHf values of around -8.4 and positive initial εHf values of around +3.6, respectively. The atypical Neoproterozoic magmatic activity of ~850 Ma in the South Qinling terrain basement, similar to those along the northwestern and south eastern margins of South China block, are probably related to an earlier stage of the break-up of Rodinia supercontinent [3, 4].

Abnormal positive $\delta^{13}C$ values of carbonate in Lake Caohai, Southwest China and their possible paleoenvironmental significances

Z. ZHU [1,2,3], J. CHEN [1]*, S. REN [2] AND Y. LI [2]

[1]The State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (*correspondence: chenjingan@vip.skleg.cn)

[2]Chongqing Key Laboratory of Exogenic Minerallization and Mine Environment, Chongqing Institute of Geology and Mineral Resources, Chongqing 400042, China

[3]Chongqing Research Center of State Key Laboratory of Coal Resources and Safe Mining 400042, China

Carbon source inputs, CO_2 exchanges between atmosphere and lake water, as well as lacustrine productivity are commonly considered as the main controls on the $\delta^{13}C$ values of lake authigenic carbonates. Generally, $\delta^{13}C$ values of carbonates in most lakes are lower than +5‰, few are up to +13‰ [1]. Here, stable carbon isotopes were measured on bulk carbonates from a short sedimentary core in Lake Caohai, Guizhou Province, southwest China. The results showed that $\delta^{13}C$ values vary between -14.25‰ and +23.10‰, which is the largest carbon isotope variations discovered so far in carbonates from lacusrine sediments, and some $\delta^{13}C$ values are the most positive values up to +23.10‰, more positive than previously reported values. On the basis of combination with oxygen isotope and carbonate contents proxies, we suggested that the carbon isotope composition of carbonate from Lake Caohai was controlled by photosynthesis/ respiration of aquatic plants, and the input of bacteria to carbon isotope fractionation of organic matter may be responsible for the abnormal positive $\delta^{13}C$ values in Lake Caohai [2,3]. Therefore, more attention should be paid on the carbon isotope composition of carbonates in Lake Caohai in future research.

Al diffusion in olivine: An experimental study

IRINA ZHUKOVA*, HUGH O'NEILL AND IAN CAMPBELL

Research School of Earth Scuance, National Australian University, ACT 2000 (*correspondence: irina.zhukova@anu.edu.au)

Al content in olivine is temperature dependent [1] and diffusion is thought to be very slow [e.g. 2].

We performed a series of experiments of Al diffusion in San Carlos olivine and synthetic forsterite at 1300ºC and log fO2 = -0.7; -5.7 and atmosphere pressure. In order to provide an inside into mechanism of alumina substitution into olivine, activities of SiO_2, MgO and Al_2O_3 were buffered in all runs. Four mineral associations were used: (a) forsterite – periclase – spinel; (b) forsterite – spinel – sapphirine; (c) forsterite – sapphirine – cordierite; (d) forsterite – cordierite – enstatite and the results analysed by LAICPMS. Each profile was fitted to a one – dimensional diffusion model in a semi-infinite medium with a source reservoir maintained at constant concentration.

The concentration of Al at the interface in equilibrium with the high silica activity buffer (d) is 5 times higher than in case of the low silica activity buffer (a), changing from 50 ± 12 ppm to 220 ± 30 ppm. The solubility of Al in S.C.O. is 2 - 4 times higher than in forsterite (430 ± 50 ppm). These concentrations are 2-4 times lower then those calculated from olivine-spinel geothermometer (940 ± 170 ppm) [1] and obtained by partitioning experiments (755 ± 25 ppm) [3] at temperature of interest.

High rate diffusion of Al in S.C.O. and forsterite was obtained: $\log D_{Al/Fo} = -15.6 \div -13.2$ (m^2/s) and $\log D_{Al/Ol} = -15.1 \div -14.4$ (m^2/s). No dependence of Al diffusion rate on oxygen fugacity has been observed. The rate of Al diffusion was strongly controlled by activity of major cations (Si, Mg): there are 2 order of magnitude difference between diffusion coefficients of Al in forsterite in low and high silica activity experiments: $\log D_{Al/Fo(a)} = -15.5 \pm 0.1$ (σ) (buffer *a* with activities of $a_{SiO2} = 0.01$ and $a_{MgO} = 1.00$) compare to $\log D_{Al/Fo(c)} = -13.3 \pm 0.1$ (σ) (buffer *d* with activities of $a_{SiO2} = 0.58$ and $a_{MgO} = 0.14$). This difference suggests that the mechanism of Al substitution into the olivine lattice requires an ochtohidral site vacansy.

The characteristic of lithology and facies and reservoir of volcanic rock in Songliao Basin, China

ZHUO SHENGGUANG[1]*, WANG XIANBIN[2] AND YANG GUIFANG[3]

[1] Zhuo Shengguang,Northeast University at Qinhuangdao, China (*correspondence: zoe200200@163.com)
[2]Key Lab of Petrol Resources Research, CAS, Lanzhou (xbwang@lzb.ac.cn)
[3]Northeast Petroleum University at, Qinhuangdao, China (sgzhuo@sina.com)

Yingcheng formation is rich in volcanic rock.in Songliao Basin,China.Volcanic lithofacies consists of eight types; such as fallout facies, effusion facies, base surges facies, pyroclastics flow facies, lahar facies, eruption-sedimentary facies,sub-volcanic rock facis and sub-explosive breccia facies. Volcanic apparatus make up of layered volcano, micro-shield volcano and cone volcano. Lithology of volcanic rock is mainly middle acid volcanic rock (dacite, rhyolite, middle acid brecciated tuff and tuff), belonging to the calc-alka-line series of subalkaline series. The eruptive and overflow facies have better reservoir capacity, the reservoir capacity of volcanic rocks has largely been affected by volcanic condensation diagenesis, tectonism, solution and fluid activity.the volcanic rocks reservoir commonly with the porosity of 6.3% ~ 10.8 % and permeability of about $0.55\times10^{-3}\mu m^2$ ~ $122.0\times10^{-3}\mu m^2$.The most of effective reservoir are the upper phase or external phase of volcanic facies belts, usually being layers or thin layers of 10-20m.The pores of volcanic reservoir could be classified into four types: 1) primary pores of original rocks, 2) diagenetic pores, 3) diagenetic fractures, 4) secondary tectoclases and weathered fractures. Types 2) and 3) are the most effective reservoir space which were formed in volcanic eruption process of cooling and aftercooling.

U-Pb age, geochemical and Hf-O isotopic constraints on magma source of the I-type calc-alkaline Baimaxueshan Batholith (SW China): Implications for crustal recycling at a convergent margin

J.-W. ZI[1,2]*, P.A. CAWOOD[1,3], W.-M. FAN[2], E. TOHVER[1], Y.-J. WANG[2] AND T.C. MCCUAIG[1]

[1]School of Earth and Environment, University of Western Australia, Crawley, WA 6009 Australia (*correspondence: zijianw@gmail.com)
[2]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China
[3]Department of Earth Sciences, University of St. Andrews, KY169AL, Fife, Scotland, UK

The late Permian to Tiassic is a critical period of the development of the eastern Paleo-Tethys, and corresponds with ocean closure and arc accretion onto the margin of Asia. Mafic enclaves and host granitoids from the Baimaxueshan batholith within the Sanjiang Orogen, SW China, document the tectonomagmatic history of accretion. SHRIMP U-Pb analyses on zircons from the mafic enclaves and host granitoids bracket their crystallization ages into the range of ca. 253-248 Ma, and establish that the mafic and felsic magmas were coeval. The granitoids have calc-alkaline, metaluminous I-type character, and show features of magma mixing between mafic and felsic melts. Whole-rock elemental and Sr-Nd isotopic systematics are compatible with an infracrustal origin for the felsic melt, whereas the mafic enclaves may represent relicts of magmas derived from partial melting of subduction-modified ancient lithospheric mantle triggered by fluids/melts released from the descending slab. The elevated *in situ* zircon $\delta^{18}O$ values shown by both the mafic enclaves (9.23 ± 0.2‰ (VSMOW)) and host rocks (8.70 ± 0.09‰) require a considerable input of high-$\delta^{18}O$ supracrustal components through subduction or underthrusting to the sub-arc mantle wedge, which also explains the enriched Sr-Nd and zircon Hf isotopic ratios ($\varepsilon_{Hf}(t)$ = -10 ± 1) displayed by the enclave samples. This together with zircon Hf depleted mantle model ages (T_{DM}^{C}= 1.53 to 2.52 Ga) peaked in the Mesoproterozoic imply that crustal growth processes largely involved reworking of pre-existing lithosphere rather than accretion of juvenile asthenosphere-derived materials.

Application of lithogeochemistry for regional scale mapping of geothermal prospectivity in Sabalan volcano, North West of Iran

M. ZIAEI, M.ZIAII, A.KAMKAR AND M. ASGHARI

Faculty of Mining and Geophysics, Shahrood University of Technology; Shahrood, Iran, (mziaii@shahroodhut.ac.ir)

Many different techniques are suggested for geothermal (convective systems) exploration including geological mapping, magnetic, gravity, hot spring, geochemical sampling, seismic and well logging methods. Geothermal systems are usually characterized by indicative geological features that may not be implied or easily be described by only one analytical method. The methodology presented here provides combined applications of several different methods in order to generate regional scale mapping of geothermal prospectivity in Sabalan volcano located in North West of Iran. The relation of the geothermal occurrences (18 geothermal occurrences used as training points) to evidential maps is assessed by means of the logistic regression as a data driven method. Six evidential maps were used derived from maps of (1) gravity, (2) magnetic, (3) geology, (4) zone proximal to hydrothermal alteration, (5) zones proximal to faults, (6) geochemical multiplicative zonality (V_z). The first five evidential maps are selected based on previous research works. Sixed evidential map is selected based on geochemical zonality anomaly.

According to geochemical studies As, Sb, Hg, Bi and B are typically enriched in geothermal areas. Thus V_z can be introduced as a geochemical evidential map for geothermal exploration.

At least seven sub-areas (in which two areas have been explored and exploited) can be recommended for follow up exploration work based on favorability map. The results indicated that, integration of V_z evidential map with other maps used as spatial evidence is important in filtering-out false selected areas.

The Zagadochnaya kimberlite is a barren type-II kimberlite, which contains Cr-diopside, pyrope garnet (Grt) and spinel xenocrysts, as well as eclogite and grospydite xenoliths [1], but no discrete peridotite xenoliths. We have investigated Grt grains and associated minerals. Some Grts (groups A, B) and associated Cr-diopsides (similar to subgroups IIa, IIb of [2]) show evidence of an early metasomatic event and variations in LHREE/HREE ratios compatible with a model of percolative fractional crystallization of kimberlite melts [3]. Other Grts (group C) exhibit strongly sinusoidal CI-normalized REE patterns, typical for cratonic Grt-peridotites produced by metasomatism of strongly refractory harzburgites. Most of group B and C Grts show secondary domains rich in Cr-diopside + Cr-spinel ± phlogopite. In these domains the Grts are (Ca, Cr)-depleted, are enriched in almost all incompatible elements, and show humped CI-normalized REE patterns (max at Eu). Low Ti/Zr ratios (~ 10) and presence of phlogopite in these domains suggest an origin by reaction with a melt of type-II kimberlite affinity. Based on Ca concentration profiles across Grt zoning, this late-stage event took place less than 10^4 years before the Zagadochnaya kimberlite eruption, i.e. it was probably related to the same magmatic stage of the host kimberlite.

Silicon and oxygen isotopes: The maturation of lacustrine diatoms

K. ZIEGLER[1]*, J.P. DODD[2], Z. D. SHARP[2], A.J. BREARLEY[2] AND E.D. YOUNG[1]

[1]Department of Earth and Space Sciences & Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA 90095, USA. (*correspondence: kziegler@ess.ucla.edu).

[2]Department of Earth and Planetary Sciences, University of New Mexico, Albuquerque, NM 87131, USA.

Oxygen and silicon isotope values of recent (antemortem, post-mortem) and Pleistocene lacustrine diatoms from the Valles Caldera (New Mexico) provide the opportunity to study 420 ka of opal maturation at the same location.

The $\delta^{18}O$ (SMOW) values, obtained by laser-fluorination [1], indicate significant reequilibration, with an increase in $\delta^{18}O$ value from <22‰ to >29‰ within 0.5 yrs after death. This is consistent with growth under oxygen isotopic disequilibrium followed by post-mortem equilibration with lake water. While no structural changes go with the alteration, differences in element compositions also imply exchange between water and diatom. Wholesale reequilibration of $\delta^{18}O$ ratios requires Si-O bond breaking. We measured the $\delta^{30}Si$ values of the same diatoms to see if Si also undergoes isotope exchange. $\delta^{30}Si$ values were obtained by MC-ICPMS [2].

The $\delta^{30}Si$ values (NBS-28) of all ante-mortem and post-mortem diatoms range from -1.0 to -2.6‰, and -0.4 to -1.9‰, respectively. A specific subset of diatoms was collected in spring, and the same population sampled 0.5 and 1.5 years post-mortem. The $\delta^{30}Si$ values increase from -2.4 to -1.9 to -0.4‰, indicating a possible maturation trend. The large ante-mortem range can also be explained by variable relative inputs from processes affecting the $\delta^{30}Si$ values of lake water (diatom [3] and clay [4] formation removes ^{28}Si from water).

Middle Pleistocene (interglacial) lacustrine diatoms from the Valles Caldera have even higher $\delta^{30}Si$ values of +0.3 to +0.7‰. The trend from low to high $\delta^{30}Si$ ratios mimics the $\delta^{18}O$ changes (at a smaller scale). Interglacials correlate with more positive $\delta^{30}Si$ values in marine diatoms [5]. We infer that Pleistocene Valles Caldera diatoms had higher initial $\delta^{30}Si$ values than modern ones, and additionally that exchange processes during burial caused further opal maturation.

The combined silicon and oxygen isotope study of such a system improves our understanding of the potential for using Si isotopes as paleoclimate proxies.

Silicon and oxygen isotope values of cherts and their precursors

K. ZIEGLER[1,2]*, J. MARIN-CARBONNE[1], K.D. MCKEEGAN[1] AND E.D. YOUNG[1,2]

[1]Department of Earth and Space Sciences, University of California, Los Angeles, CA 90095, USA. (*correspondence: kziegler@ess.ucla.edu).

[2]Institute of Geophysics and Planetary Physics, University of California, Los Angeles, CA 90095, USA.

We measured $\delta^{30}Si$ and $\delta^{18}O$ ratios in two sets of recent cherts and their precursors in order to evaluate the use of cherts as proxies for environmental conditions at their formation, and to constrain diagenetic transitions. This work has implications for models for Archean cherts formation.

In a handsample from the Miocene Monterey Formation [1, 2], both cristobalitic chert and biogenic, marine opal-A precursor are present. Magadi chert is modern, inorganic, quartzose chert formed from chemically precipitated magadiite [3, 4]. Both precursor-to-chert transitions are due to dissolution-precipitation processes. Monterey chertification is due to later diagenetic water [1, 2], and Magadi chertification occurs at the surface in the same system as magadiite [3, 4].

$\delta^{30}Si$ values were analyzed by MC-ICPMS (Neptune™), $\delta^{18}O$ values of cherts by ion microprobe (Cameca 1270), and precursor $\delta^{18}O$ values were taken from literature [1, 3].

The $\delta^{18}O$ values of the Monterey opal (37‰) and chert (28-34‰) suggest temperatures of 15°C and 48±8°C, respectively [1]. The $\delta^{30}Si$ values of the chert and opal are 0.0‰ and 1.4‰, respectively. Diatom formation increases the $^{30}Si/^{28}Si$ of the aqueous phase [5], and high diatom $\delta^{30}Si$ values are expected in highly productive oceans. Later chert-forming diagenetic water, equilibrated with Monterey Shale [1], is expected to have more negative $\delta^{30}Si$ values [6], and explains the lower $\delta^{30}Si$ value of the chert.

In contrast, the inorganic magadiite and magadi chert have similar $\delta^{18}O$ (33-38‰ [3, 4] and 38‰, respectively) and $\delta^{30}Si$ values (-0.2 and -0.5‰, respectively). The isotopic similarity demonstrates that no fractionation attends this chertification, as both phases form from the same silicon and oxygen source (hot springs [3, 4]).

$\delta^{30}Si$ ratios of cherts record the last chertification event, which can imprint different $\delta^{30}Si$ values onto its precursor. This needs to be considered for paleoclimate reconstructions.

We thank Jim Boles (UCSB) for providing the samples.

On the multitude of niches for bacteria and archaea in an acidic biofilm

S. ZIEGLER[1], K. DOLCH[1], J. MAJZLAN[2] AND J. GESCHER[1]*

[1]Department of Microbiolgy, Albert-Ludwigs University Freiburg, Germany (*correspondence: johannes.gescher@biologie.uni-freiburg.de)
[2]Department of Mineralogy, Friedrich Schiller University Jena, Germany

We studied a microbial snottite biofilm in an abandoned pyrite mine. The organisms that build up the biofilm grow at pH about 2.3 and sulphate concentrations of up to 200 mM. The microorganisms are dependent on the oxidative dissolution of pyrite as the primary energy source and on CO_2 as the primary carbon source. We assessed the microbial diversity in the consortium using restriction fragment length polymorphism and subsequent sequencing. As expected, organisms belonging to the genera *Leptospirillum* represented the majority of bacterial species. Interestingly, we could furthermore identify archaeal sequences that are most closely related to the ARMAN (Archaeal Richmond Mine Acidophilic Nanoorganisms) group [1] as well as to so far uncultured members of the Thermoplasmatales. Using oxygen profiling we determined that the high oxygen demand of the microorganisms lead to a drop from 100% to 0% oxygen within 700 μm. Hence the internal part of the biofilm seems to be anoxic. Interestingly, we could show that bacteria populated the biofilm mostly at the oxygenated vicinity. MAR FISH experiments, using $^{14}CO_2$ revealed that this is also the center of primary production. However, archaea populated the anoxic core only. Currently, we investigate the archaeal niche in the biofilm.

Developing a comprehensive approach to chamber studies of secondary organic aerosol formation

P. J. ZIEMANN*, A. MATSUNAGA, S. AIMANANT, G. YEH AND Y. B. LIM

Air Pollution Research Center, University of California, Riverside, CA 92521, USA (*correspondence: paul.ziemann@ucr.edu)

Much of what is currently understood about the chemical and physical processes involved in the atmospheric oxidation of organic gases and particles and the formation of secondary organic aerosol (SOA) has been obtained from experiments carried out in environmental (smog) chambers. Achieving a level of understanding from such studies that is sufficient for extrapolating results to the atmosphere (with confidence) and the development of accurate models of SOA formation requires the acquisition of detailed information on a variety of gas and particle properties and processes, such as gas and particle-phase reaction kinetics, gas and particle composition, particle phase, compound vapor pressures, and gas-particle-wall interactions. Obtaining such data is a challenge, but in this talk I will show examples of studies carried out in our laboratory on selected aerosol-oxidant and VOC-oxidant systems in which this goal is close to being achieved. I will demonstrate that by using a diverse array of measurement techniques including mass spectrometry, nuclear magnetic resonance spectroscopy, gas and liquid chromatography, spectrophotometry (with and without compound derivatization), traditional elemental analysis, pycnometry, temperature-programmed thermal desorption, and scanning mobility particle sizing it is possible to develop full, quantitative mechanisms of organic gas and aerosol chemical reactions and models of SOA formation. Doing so, however, requires a more comprehensive approach to chamber studies that acknowledges the obvious: “The atmosphere does not have walls.”

The hafnium and neodymium isotopic composition of seawater in the tropical Atlantic Ocean

M. ZIERINGER[1]*, T. STICHEL[1,2] AND M. FRANK[1]

[1]IFM-GEOMAR, Wischhofstrasse 1-3, 24148 Kiel, Germany (*correspondence: mzieringer@ifm-geomar.de)
[2]SOEST, University of Hawaii 1680 East-West Rd, Honolulu, HI 96822, USA

The combination of radiogenic isotopes of hafnium (Hf) and neodymium (Nd) has been used to investigate present and past changes of ocean circulation patterns and continental weathering regimes. We present the first combined full water column Hf and Nd isotopic compositions and concentrations in seawater of the western Atlantic Ocean, as well as Hf and Nd isotopic and concentration data in surface waters of the tropical Atlantic Ocean between the Canary Islands and the northeastern coast of Brazil. Samples were collected during GEOTRACES cruise A11 (Meteor M81/1) from Las Palmas (Canary Islands) to Port of Spain (Trinidad and Tobago) in spring 2010.

Hf concentrations in surface waters range between a maximum of 0.67 pmol/kg north of 20°N off the coast of NW Africa and in the area of the Canary Islands and a minimum of 0.20 pmol/kg off the northeastern coast of Brazil. Surface waters with reduced salinities (< 33.6 psu) due to freshwater input by the Amazon river also show low Hf concentrations. Nd concentrations show a similar distribution pattern with a maximum off the coast of Mauritania (27 pmol/kg) and a minimum in the Amazon plume (14 pmol/kg). Elevated concentrations provide evidence of inputs from partial dissolution of dust from the Sahara region and from ocean island wheathering, which is also reflected in more radiogenic Hf and Nd isotope compositions [1]. Low concentrations of Hf and Nd in the Amazonas plume are most likely caused by particle scavenging induced by high productivity.

Deep-water samples show the highest Hf concentrations in UNADW in the area of the Canary Islands (0.93 pmol/kg), as well as in UNADW in the western basin. Nd concentrations range between a minimum of 12 pmol/kg in SACW and a maximum of 34 pmol/kg in AABW. Lower Hf concentrations in LNADW and AABW indicate an oceanic residence time of Hf shorter than that of Nd.

The isotopic distribution of Hf and Nd in the same samples reflect inputs via dust, the Amazon river, and weathering inputs from the volcanic Canary islands, as well as intermediate and deep water mass mixing.

Connection of atmospheric stability and aerosol and gaseous polutants concentration

N. ZIKOVA[1,2]* AND V. ZDIMAL[1]

[1]Department of Aerosols and Laser Studies, Institute of Chemical Process Fundamentals of the ASCR, Prague, Czech Republic (*correspondence: zikova@icpf.cas.cz)
[2]Department of Meteorology and Environment Protection, MFF UK, Prague, Czech Republic

Our aim is to find suitable criteria to asses an atmospheric stability without direct measurements in order to estimate relationships between meteorological conditions and concentration of aerosol particles (measured by SMPS) and gaseous pollutants (O_3, NO_2 and SO_2). An aerological method, a synoptical method and NWP models' CAPE values are applied.

Aerological method and CAPE were found to be suitable methods for description of atmosperic stability. Synoptical method shows mainly origin of air masses.

The strongest relationships between aerosol particles and stability was found for acumulation mode particles, weaker for particles under 50 nm in diameter.

A negative correlation for acumulation mode particles shows "dilution" of atmosphere during unstable conditions, whereas during stable conditions the aerosol acumulates.

Similar relatioship is between gaseous polutants and stability (apart from concentrations of NO_2).

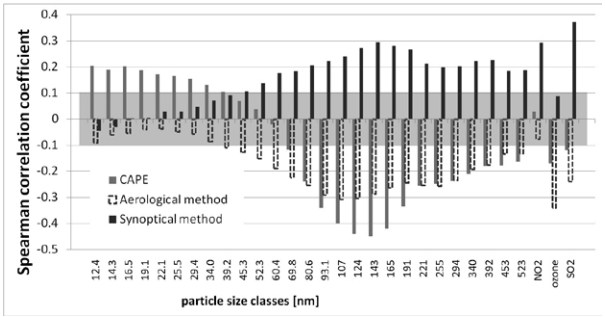

Figure 1: Dependencies between aerosol concentration in different sizes, gaseous pollutants concentrations and atmospheric stability described by the three tested methods.

Possible rhenium fractionation during standard Re-Os dissolution and chemical separation procedures

A. ZIMMERMAN[1], S. GEORGIEV[1,2], G. YANG[1], H. STEIN[1,2] AND J. HANNAH[1,2]

[1]AIRIE Program, Colorado State University, USA
[2]Geological Survey of Norway, 7491 Trondheim

A recent curiosity-driven experiment revealed surprising apparent fractionation of rhenium isotopes during standard Re-Os chemical procedures for Carius tube digestion and elemental separation. A non-standard $^{185}Re/^{187}Re$ ratio of ~0.602 was measured from a standard Re solution after Carius tube digestion and anion exchange chromotography. A replicate produced a similar, though not identical ratio. These surprising results led to a series of quantitative tests to identify procedure(s) that may have led to Re fractionation.

In the original experiments, Re standard solution, Os standard solution, and inverse *aqua regia* were digested in Carius tubes at 250 ºC for 12 hours. The Os was extracted using chloroform-HBr solvent extraction. The isolated Os underwent microdistillation and was measured for its isotopic composition (IC). Os IC ratios matched expected values. After solvent extraction, the Re was collected via anion exchange chromotography and purified using a single bead clean-up. The final measured $^{185}Re/^{187}Re$ was 0.601608 versus the expected value of 0.597393. The replicate yielded an IC of 0.599062. Additional tests of Re standard solution loaded directly onto exchange columns and directly onto single beads yielded similarly elevated ratios.

Given such results, a more detailed experiment excluded the Carius tube digestion and loaded diluted Re standard solution directly on the anion exchange columns. One mL fractions were collected as the Re eluted from the column. Half of each 1 mL aliquot was loaded directly onto Pt filaments for IC measurements whereas the second half underwent single bead cleaning prior to IC measurement. Re was only found in the first three of seven 1 mL splits. Only the third 1 mL fraction produced ratios significantly different than the expected ratio. In all cases, the single bead-treated and straight-off-the-column Re IC ratios matched, thereby showing that Re fractionation does not occur during the single bead clean-up procedure.

Given the apparent lack of Re fractionation in the most recent experiment, which bypassed the Carius tube step, a final experiment utilizing the Carius tube digestion along with step-wise column collection is being conducted. This experment should replicate the orignal inquiry and also help identify if and when Re fractionation occurs.

Risk element sorption in soil amended by urban particulate matter

D. ZIMMERMANNOVÁ[1], J. SZÁKOVÁ[1]*, M. KOMÁREK[1] AND J. SYSALOVÁ[2]

[1]Czech University of Life Sciences, CZ-165 21 Prague 6, Czech Republic (*correspondence: szakova@af.czu.cz)
[2]Institute of Chemical Technology, CZ-166 28 Prague 6, Czech Republic (Jirina.Sysalova@vscht.cz)

Introduction

Our previous experiment showed that although the element contents in dust samples exceeded significantly those in soil, the element contents in plants were not affected by single-rate soil amendment with the rural dust sample [1]. Therefore, we tested the potential effect of urban particulate matter (PM) amendment to two soils differring in their physicochemical parameters (rate: 0.6 g of PM per 1 kg of the soil) on sorption characteristics described by Freundlich and Langmuir isotherms.

Soil	E	K_L	S_{max} (mmol/kg)
Chernozem	0.978	15.6	86.1
Chernozem+PM	0.959	13.6	81.4
Fluvisol	0.963	1.93	137
Fluvisol+PM	0.939	1.09	165

Table 1. Parameters derived from the fitting of the sorption isotherms of Cd with the Langmuir equation

Discussion of the results

Whereas the Freundlich isotherms did not indicate any effect of PM addition to the soils, the Langmuír isotherm allowed us to estimate the potential behavior of the PM in the soil. The results for Cd are summarized in Table 1. The PM added to the Chernozem did not lead to substantial changes in sorption characteristics. On the contrary, the presence of PM in the Fluvisol increased the number of potential sorption sites in the soil. However, the results of the approximation showed a lower affinity of Cd for the Fluvisol and a better stability and a lower bioavailability of Cd in the Chernozem. The results are supported by the decreasing Cd contents in both lettuce and chard biomass growing in PM amended Fluvisol compared to the unamended one.

From Archean to Cambrian: Isotopic crustal evolution of the Borborema Province, NE Brazil

S.A. ZINCONE[1]*, E. WERNICK[2] AND T.J.S. SANTOS[1]

[1] Instituto de Geociências, UNICAMP, Campinas, SP, Brazil (*correspondence: teozincone@gmail.com)
[2] Instituto de Geociências, UNESP, Rio Claro, SP, Brazil

Crustal accretion occurs mainly by the input of calc-alkaline granitoids in the cores of pericontinental and intraoceanic orogens. The added magmas are mainly hybrid, a mixture of a mantle derived component with older crustal rocks as the result of the underplating of major amounts of mafic magma beneath the continental crust. The Santa Quitéria Batholith, Borborema Province, is a good example of the mixing of a juvenile Brasiliano component with older, mainly Paleo-proterozoic, crustal material [1]. One consequence of this growth process must be a systematic change in the crustal isotopic composition through time. This assumption is confirmed by 307 Sm-Nd data for Archean, Paleo- and Neoproterozoic rocks from the northern Borborema Province [1-7] which show a systematic change of the $^{144}Nd/^{143}Nd_{(t)}$ values with time.

Plastic deformations in zircon and their influence on its chemical composition

T.F. ZINGER[1], N.S. BORTNIKOV[2] AND E.V. SHARKOV[2]

[1]IPGG RAS, St-Petersburg, Russia (tzinger@mail.ru)
[2]IGEM RAS, Moscow, Russia (bns@igem.ru; sharkov@igem.ru)

We studied 150 grains of zircon from 8 gabbro samples, dragged at 4 sites in axial part of the MAR, Markov Deep, 6ºN, during 10th cruise of R/V "Academic Ioffe" (2001-2002) and 22nd cruise of R/V "Professor Logachev" (2003). This part of the MAR represents typical oceanic core complex (OCC), where altered lower crustal gabbros and serpentinized mantle peridotites expose on seafloor. These rocks were undergone by different tectonic deformations, including plastic flowage. The zircon in gabbros along with host rocks were undergone by plastic creep at 815 to 680ºC (Ti-in-zircon thermometry).

During deformations zircon was enriched by diversity of rare elements (U, Th, Hf, Pb, P and Y) and REE. We suggest that it was linked both with appearance of deformation-related crustal-plastic microstructures in zircon, which enhanced diffusion of these components, and circulation of intergranular fluid as demonstrated processes of delution and redeposition of the zircon material with appearance of secondary small pyramidal zircons on another side of the crystal. Nature of this high-temperature fluid is not clear yet: it can be residual fluid, formed under solidification of host-gabbros, or result of involving of fluids, circulated in upper oceanic lithosphere, under it heating by these intrusions; most likely both factors were setting in motion. Introducing U, Th and Hf into zircon crystals can change their original isotopic systematics and influence on results of their isotopic dating.

Chemical models for formation of clay-rich layered rocks in the Mawrth Vallis region, Mars

M.YU.ZOLOTOV[1]* AND M.V.MIRONENKO[2]

[1]School of Earth and Space Exploration, Arizona State University, Tempe, AZ 85287, USA (*correspondence: zolotov@asu.edu)

[2]Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, 19 Kosygin Str., Moscow 119991, Russia

Clay minerals have been detected in ancient martian terrains with the near-infrared orbital spectroscopy [1,2]. In the Mawrth Vallis region, a prospective landing site for the MSL rover in 2012, minerals are observed within the following stratified sequence of layered rocks (from the top): silica and kaolinite, montmorillonite-like Al-rich clays, a Fe^{2+} phyllosilicate, Mg/Fe smectites, and sulfates [2-6]. We use three numerical models to explore a formation of these rocks through alteration of a fragmented basaltic material by a downward percolation of H_2SO_4-rich fluids. One model assumes a decrease in the solution to rock ratio with depth. In another model, the downward fluid migration is considered. In both models, fluids reach chemical equilibrium with rocks. In the third model, kinetics of mineral dissolution is considered along with fluid percolation. The modeling is performed for 0 ºC and pressure from 0.006 to 1 bar. The system was either open or closed with respect to CO_2 and O_2.

The modeling reproduces the observed silica-kaolinite-montmorillonite-smectite sequence of dominated minerals. In the models, the sequence reflects neutralization of fluids with depth. Open system models also lead to formation of goethite and/or hematite, and carbonates form in association with smectites (saponite). In closed systems, zeolites and Fe^{2+}-chlorites occur with smectites, and Fe^{2+}-chlorite rich rocks form between layers rich in montmorillonite and smectites. The latter result is consistent with observations, though the upper part of the martian profile also agrees with an open-system acid alteration. Modeled Ca sulfates coexist with clay minerals, and more soluble sulfates could form through evaporation of neutralized fluids accumulated in the lower part of the stratigraphic sequence.

Study on the phase equilibrium of the quaternary system Cd^{2+}, K^+, $Na^+//SO_4^{2-}$-H_2O at 298 K

FANG ZOU[1], HUANG YI[1,2]*, NI SHIJUN[2] AND ZENG YING[3]

[1]Department of Geochemistry, Chengdu University of Technology, Sichuan, PRC (*correspondence: huangyi@cdut.cn)

[2]Applied Nuclear technigues in Groscience Key Laboratory of Sichuan Proviance, PRC

[3] College of Materials and Chemistry & Chemical Engineering, Sichuan, PRC

Solid- Liquid Equilibrium of quaternary system Cd^{2+}, K^+, $Na^+//$ SO_4^{2-}-H_2O at 298 K were studied by an isothermal solution saturation method. Experimental results indicate that there are five univariant curves E_1F_1, E_1F_4, E_1E_2, E_2F_2 and E_2F_3, two invariant points E_1, E_2 and four crystallization fields in the quaternary system. The system belongs to a quaternary system, and there is a double salt ($Na_2SO_4{\cdot}3K_2SO_4$) existing. The crystallization zones of equilibrium solid phases are K_2SO_4 ($E_1F_1MF_4$ field), $Na_2SO_4{\cdot}3K_2SO_4$ ($E_1E_2F_3F_4$ field), $Na_2SO_4{\cdot}10H_2O$ ($E_2F_2AF_3$ field), and $CdSO_4{\cdot}H_2O$ ($E_2F_1BF_2$ field), respectively. The composition of the invariant point E_1 is K_2SO_4, $Na_2SO_4{\cdot}3K_2SO_4$ and $CdSO_4{\cdot}H_2O$, respectively. The composition of the invariant point E_2 is $Na_2SO_4{\cdot}3K_2SO_4$, $Na_2SO_4{\cdot}10H_2O$ and $CdSO_4{\cdot}H_2O$, respectively. The physico-chemical properties of solution in the quaternary system show regular changes along with the increased cadmium concentration. $CdSO_4$ possessed the highest solubility among those three salts, which means a strong transfer of Cd ion and a high pollution risk of soil environment.

[3]Yunnan Architecture Engineering Design Institute, Kunming ,China P.R.China, 650041

11 typical samples are purple or bleached sandstone and ores, from K_2ml_1 (main orebody hosting bed), K_2ml_2, K_2md and K_1p in Liuju Sandstone-bound Copper Deposit, Dayao, Yunnan, China. Quartz and minor calcite were used for making fluid inclusion tests.

The original inclusions mainly are in vapor-liquid phase. Their generation period features are apparent. The original and secondary inclusions in bleached sandstone respectively represent main metallization stage (forming stratiform chalcocite orebody) and reforming stage. The ones in quartz veins respectively represent minor metallization stage (forming veiny chalcopyrite orebody) and later reforming stage. The ore-forming fluid could be two medium-low salinity fluid of organic material-bearing, medium-temperature to medium-low- temperature, reducing fluid and a little organic material-bearing, oxidizing fluid. 70% uniform temperature numbers of fluid inclusions assemble between 200°C and 100°C. The fluid belongs to NaCl-H_2O system, in which, beside agglutinates, the salinity is less than 12%. The component test results of the original quartz inclusions by La-ICP-MS show the fluid in main metallization stage is of H_2O-SO_2-CO_2-CH_4 (C_3H_8-C_2H_6) - HSO_4^- - HCO_3^- type, and the fluid in secondary metallization stage is of H_2O-SO_2-CO_2-N_2-CO-CH_4- HSO_4^- type.

Research results indicate the fluid metallogenesis mode may be described as: the forming and reforming movements of the Daxueshan Anticline provided power and energy (heat energy) for metallization, which drove deep-seated organic matter-bearing and reducing fluid to go up and cycle, with superficial oxidizing infiltrating fluid, to extract ore-forming material from the source beds. Because of the physical-chemical conditions changing in the high permeability and porosity of sandstone beds at the gently inclined wing of the Anticline, oxidation-reduction reactions occurred in the fluids which led to form the deposit.

Robust aerosol indirect effects inferred from remotely-sensed cloud properties acquired during VOCALS

PAQUITA ZUIDEMA[1], DAVID LEON[2] AND DAVID PAINEMAL[3]

[1]U. of Miami/RSMAS, 600 Rickenbacker Cswy, Miami, FL 33149, USA, (pzuidema@rsmas.miami.edu)
[2] U of Wyoming, Laramie, WY, 82071, USA (leon@uwyo.edu)
[3] U. of Miami/RSMAS, 600 Rickenbacker Cswy, Miami, FL 33149, USA, (dpainemal@rsmas.miami.edu)

One wealth of the VOCALS field experiment in the southeast Pacific stratocumulus region is a unique dataset on cloud properties acquired through a suite of airborne remote sensors. This includes a lidar, a cloud radar and a radiometer providing cloud liquid water paths. All are valuable individually, but in combination form a powerful suite capable of extending aircraft assessments of aerosol-cloud-precipitation impacts beyond what can be done with in-situ measurements. The cloud liquid water path dataset also allows for the statistically-robust examination of thin clouds, which cloud radars and satellites have difficulty characterizing. For this presentation the new cloud liquid water path dataset is described, compared to adiabatically-derived values, and aerosol indirect effects — co-variations with cloud liquid water path, precipitation, and cloud albedos — are assessed. In keeping with the theme session, comparisons to similarly-derived satellite properties will be made to opine on satellite assessments but done on larger spatial scales.

Effects of grid size in interpolating of geochemical data

RENGUANG ZUO[1,2]

[1]State Key laboratory of Geological Process and Mineral Resources, China University of Geosciences, Wuhan, 430074, China (zrguang@cug.edu.cn)
[2]State Key laboratory of Geological Process and Mineral Resources, China University of Geosciences, Wuhan, Beijing, 100083, China

Grid size is one of important uncertainty sources in interpolating of geochemical data. We explore the grid size how to influence geochemical mapping using a case study located in the western Gangdese belt, Tibet (China). This study area measures about 19,375 km^2 and comprises of 921 stream sediment samples with a density 0.05 sample point per km^2 corresponds to the scale of about 1:500, 000. The selection of grid size is influenced by the density of samples or mapping scale(i.e., The denser the sample points, the larger the scale of mapping, and the smaller the grid size), and the structure of point patterns (i.e., distance between the sampled points, and the range of spatial dependence). Generally, the gird size should be smaller than a given size which makes >95% of the closest point pairs not fall into the same grid. The grid size is also larger than a given grid size because finer grid cell do not make sense as it will be hard to visualize or print them at this scale of work [1]. The resulting of neighbour nearest distance between point pairs shows that the average spacing between the closest point pairs is 2.18 km, and 5% probability smallest distance is 1.09 km, which makes >95% point not fall into the same grid. The original dataset is divided into two parts namely testing dataset and training dataset. The testing dataset contains randomly selected samples, which are 5% of the total number of samples, and the remaining 95% samples are used for interpolating data. Six grid sizes namely 1.1 km, 1.3 km, 1.5 km, 1.7 km, 1.9 km, 2.1 km are selected to interpolate Cu data using inverse distance weighted method (IDW) with the same parameters. The results indicate that 1.7 km is the optimal grid cell size in this study because the interpolating Cu map has the maximum value of standard deviation, and the difference between Cu true value and interpolated value has the lower mean and relative lower standard deviation.

Technical methods of barriers of near-surface disposal of very low level radioactive waste

RUI ZUO, JINSHENG WANG AND YANGUO TENG

College of Water Sciences, Beijing Normal University, Beijing 100875, China, (zr@bnu.edu.cn)

The caused environmental pollution problems by nuclear are very urgent, any country treats it with caution. Under existed technologies, geological disposal is recognized as the most effective method. For security and efficient, the very low level radioactive waste (VLLW) is separated from the medium-low-level radioactive waste, and the design of the repository could meet the environmental requirements without very strict geological condition, however, the barrier material of the VLLW repository still is key to radioactive waste disposal. A candidate site, which was for the disposal of VLLW in Southwestern China, was built in the terraces of alluvial valley. We focused on the multiple geological barrier system on the near-surface geological disposal. The multiple barrier technology is reflected at natural barriers (natural geological body) and engineering barriers (material). For the absorption of the barrier, batch tests and column experiments methods were applied for the influencing factors and mechanism of adsorption.

The disposal site was on a narrow but long river terraces at the interchange of two rivers, the groundwater table in the site was generally 5-6m. ^{90}Sr were selected as the typical nuclides. The barriers in the wall and bottom of repository (basin-shaped) were selected. The fine particle (d<1mm), which is from the site, was used for the barrier material in the wall, attapulgite mixed with gravel was used for the bottom barriers. The sorption characteristics and influencing fators of ^{90}Sr in the two barrier material were measured by batch tests, results show that the selected fine particle (d<1mm) for ^{90}Sr have a certain adsorption, the orders of distribution coefficient in the 10^2. And from the results, the K_d value of the fine particle and the attapulgite was 40-80 and 100-120, respectively, and there was a great influence of pH value, content of CO_3^{2-}, and initial concentration on sorption. In addition, modified (acid treated, sonicated and baked) attapulgite was researched for the sorption capacity, the concentration of hydrochloric acid at 1M, or ultrasonic time of 10min, or the temperature at 600°C, the adsorption of nuclear improved significantly.

This study is supported by “the Fundamental Research Funds for the Central Universities”.

Luminescent properties of natural copper and silver iodide

L.A. ZYRYANOVA, N.N. BOROZNOVSKAYA AND K.V. TOLOCHKO

Tomsk State University, Tomsk, Russia

Studies have been performed on the structural characteristics and roentgenoluminescence spectra (RL) of copper and silver iodides from the zone of oxidation of the Rubtsovsk polymetallic deposit (Rudnyi Altai). The investigation on the RL characteristics of the natural Cu and Ag iodides has demonstrated their dependence on the Cu/Ag-ratio and the structural type of a mineral. It has been established that the RL spectra of the cubic marshite (Cu, Ag)I, miersite (Ag, Cu)I and hexagonal iodargyrite (AgI) differ in the intensity and spectral composition of the emission in the wave length range of 400-800 nm. The correlation has been discovered between the silver content entering the minerals of the (Cu, Ag)I - (Ag, Cu)I series and the RL intensity in the range of 600-800 nm. The shift of emission bands in the range of 600-800 nm from iodargyrite to miersite and farther to marshite into the long-wave zone has been established. In the iodargyrite RL spectra, the short-wave RL band (420-450 nm) has been found, the emission character of which coincides with the excitonic luminescence of 2*H* and 4*H* polytypes of AgI.

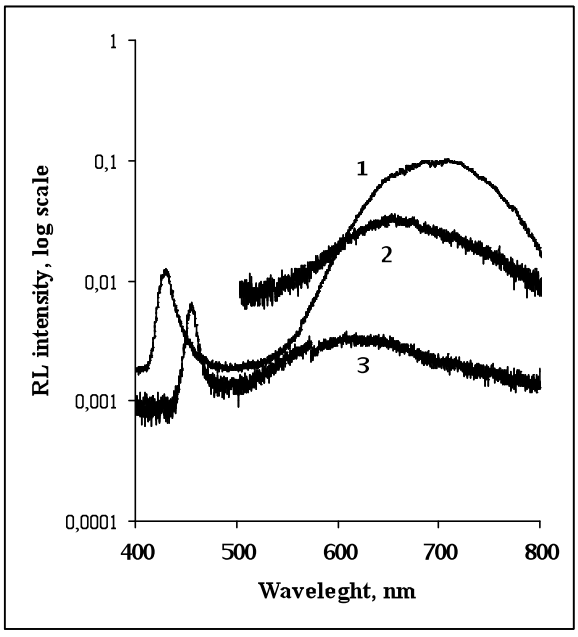

Fig. 1: Roentgenoluminescence spectra (RL) of copper and silver iodides: 1 – marshite, 2 – miersite, 3 – iodargyrite

These researches have been supported by the Ministry of Education and Science of Russia.

Deconstructing the nuclear accident at the Fukushima-Daiichi Plant: What went wrong and what are the prospects for recovery?

EDWARD BLANDFORD

Center for International Security and Cooperation Stanford University, (edb3@stanford.edu)

The recent large-scale industrial accident at the Fukushima-Daiichi Nuclear Power Plant was the culmination of three inter-related factors: external natural hazard assessment and site preparation, the utility's approach to risk management, and the fundamental reactor design. The reactor accident was initiated by a magnitude 9 earthquake followed by an even more damaging tsunami. However, it was othe inability to remove the decay heat in the reactor core that led to core meltdown and radioactive release. A review of the timeline of the major Fukushima accident sequences will be given. The plant first experienced a station blackout (i.e. loss of all offsite and onsite power) due to flooding of backup critical emergency cooling equipment. The lack of an ultimate heat sink led to the fuel overheating. Subsequently, the generation of hydrogen through steam oxidation of the fuel cladding led to chemical explosions causing significant structural damage.

The focus of this talk is on the engineering aspects of the reactor accident and the prospects for local environmental recovery. Radionuclide measurements in space and time provide important evidence for the exact evolution of fuel damage leading to partial core melting in multiple units. A review of the spent nuclear fuel pools is given where isotopic water composition and visual inspection images provide important evidence for the condition of the spent nuclear fuel.

While it will be several months to a year before we will be in a position to learn most of the lessons from this tragedy, several conclusions about preventative design, mitigation actions, and emergency response have been drawn by international organizations

While the public health impact appears to have been low, the economic and nearby environmental consequences are severe, There is no doubt that land restoration will take over a decade and perhaps much longer. A review is given of actions taken by the Japanese government for land recovery in areas such as decontaminating top soil and local farmland as well as highly radioactive water used during 'feed and bleed' cooling of the core.

The role of the Geochemical Society of Japan for mitigating the Fukushima accident and its aftermath

MITSURU EBIHARA

Department of Chemistry, Graduate School of Science and Engineering Tokyo Metropoolitan University, (ebihara-mitsuru@tmu.ac.jp)

A huge earthquake (M 9.0) and coupled tsunami on March 11, 2011 yielded enormous damage in the area from north Kanto to whole Tohoku district. Besides direct disaster caused by earthquake and tsunami, equally serious accident happened at Fukushima Daiichi nuclear power plant of Tokyo Electric Power Company. By this accident, nuclear power reactors couldn't been controlled properly, and eventually radioactive materials were released from the nuclear power reactors and dispersed over rather wide area. Consequently, agricultural materials, drinking water and food were contaminated with radioactive nuclides. It was urgent to figure out how radioactive materials were spread not only in the area close to the nuclear reactors but also over surrounding, rather wide district. Such information must release the uneasiness for public people and objectively predict the possible influence caused by radioactive material over agricultural products for people engaging in agriculture.

To grapple with this task promptly as well as effectively, scientists belonging to the Geochemical Society of Japan, the atmospheric and oceanic section of the Japan Geoscience Union and the Japan Society for Nuclear and Radiochemical Sciences were allied and presented a proposal for comprehensive and systematic survey of radioactive materials in the environment to the ministry of Education, Science, Culture and Technology (MEXT). In this proposal, aerosol, rain, soils and underground water samples are to be collected as systematically as possible and as wide as possible for the sampling area. Besides such an action, we discussed with nuclear physicists to work together in collecting soil samples in Fukushima prefecture systematically and measuring radioactivity precisely under controlled counting protocol, making contour maps of individual radionuclides. Such a collaborative project was eventually supported by the government and officially started in early June, being continued for three months. The data thus obtained are to be opened to the governmental sector as well as to the public including scientific communities in due course so that national and international academic societies can utilize these data for scientific discussion.

Geochemistry of the long term evolution of the used nuclear fuel/water interaction

BERND GRAMBOW

SUBATECH, Ecole des Mines, Université de Nantes, CNRS-IN2P3, 4, r Alfred Kastler, 44307 Nantes, France

Options for stabilizing the failed reactors in Fukushima are to create a sarcophage or to remove the fuel debris for safe geological disposal. In either case interaction of the molten and re-solidified damaged fuel (corium =UO_2-ZrO_2-Zr-Fe_2O_3..) will occur with natural waters leading to certain radionuclide release. Very little is known on the interaction of this material under natural geochemical conditions. In the absence of more pertinent data, and since in corium the UO_2/ZrO_2 seems to be a tetragonal solid solution, one may use the large knowledge from used fuel/water interaction to obtain some insight in potential radionuclide release controls.

A very large experimental and theoretical database has been collected since 30 years on used nuclear fuel/water interaction in the context of deep geological disposal options in clay rock, granite and salt. Current understanding and model uncertainties were recently assessed in the just finished European MICADO project. Detailed parametric studies of dissolution and radionuclide release behavior have allowed identifying key dissolution mechanism. The comparison of spent fuel behavior to that of natural uraninite as well as to pure UO_2 and Pu doped UO_2 gave important insight into radiation effects on fuel behavior over geological time. Two radionuclide release terms can be distinguished: a rapid release of a few percent of the inventories of volatile fission products such as Cs-135, Cs-137, I-131 and I-129 from fracture surfaces and grain boundaries in the fuel and a much slower release governed by the dissolution of the fuel matrix. The latter process concerns the release characteristics of matrix bound radionuclides, mainly the actinides, Sr and the rare earth elements. Fuel surface oxidation states are of fundamental importance for fuel matrix dissolution. The gamma and alpha radiation fields may create local oxidizing conditions at the fuel surface, accelerating fuel dissolution. The radiolytical enhancement of fuel dissolution is counteracted in geological disposal by the presence of hydrogen. Estimated times needed under natural water conditions for complete fuel matrix dissolution are in the range of 10000 yr under oxic conditions and in the range of millions of years under reducing conditions.

The fraction of matrix bound radionuclides will be lower and the labile fraction will be higher in the fuel debris of Fukushima than in ordinary spent fuel since high temperatures lead to stronger volatilization. Even though reducing conditions might have prevailed in the initial stages of fuel melt-down in the accident (large oxygen potential buffer capacity of melted metal Zirconium and presence of hydrogen) the beneficial long-term effect of hydrogen is unlikely to occur in Fukushima debris since hydrogen is expected to escape and oxidizing conditions will prevail.

Atmospheric dispersion of the Fukushima effluents

A. MATHIEU[1*], J.P.BENOIT[1], D.DIDIER[1], J.GROELL[1], I.KORSAKISSOK[1], D.QUÉLO[1], E.QUENTRIC[1], O.SAUNIER[1], M.TOMBETTE[1], V.WINIAREK[2], M.BOCQUET[2]

[1] Institute of Radiation Protection and Nuclear Safety, BP 17, 92262, Fontenay-aux-Roses, France, (*correspondance: anne.mathieu@irsn.fr)

[2] Université Paris-Est, CEREA, joint laboratory Ecole des Ponts ParisTech and EDF R&D, Champs-sur-Marne, France

In case of an accidental situation involving radioactive material, government agencies have to provide, in support of the public authorities, a scientific estimation of the emission and of its consequences for human health and environment. The technical crisis centre of IRSN has a special focus on atmospheric dispersion since it's the first contribution to radiation exposure. IRSN operates a complete modelling platform which links a release of radioactive material to its consequences. The evolution of atmospheric and ground activity is computed by using an estimation of the source term and the state of the atmosphere. Atmospheric dispersion is modelled using a Gaussian puff model at small scale, and a Eulerian long-range transport model at large scale.

Following the earthquake and tsunami that hit Japan on March 11, 2011, IRSN has monitored in real time, the state of the Dai-ichi nuclear power plant as well as simulated the atmospheric dispersion of estimated releases. The talk will present the atmospheric dispersion of the plume simulated through the Japanese territory as well as the American and European continents. The relevance of the simulations will be assessed by comparisons with measurements. Uncertainties about the source term and the meteorological conditions will be discussed. Finally, the use of atmospheric dispersion model, inverse modelling and data assimilation techniques to narrow uncertainties on the source term will be illustrated.

Measurement of radioactivity of aerosol at a few sites in Japan after the Fukushima Daiichi Accident

S. NAGAO[1*], M. KANAMORI[2], T. TOKUNARI[2], K. HAYAKAWA[3], A. TORIBA[3], T. KAMEDA[3], Y. HAMAJIMA[1], M. INOUE[1] AND M. YAMAMOTO[1]

[1]Low Level Radioactivity Laboratory, Inst. of Nature and Environ. Technol., Kanazawa Univ., Nomi, Ishikawa 923-1224, Japan,
(*correspondance: nagao37@staff.kanazawa-u.ac.jp)
[2]Graduate School of Natural Sci. and Technol., Kanazawa Univ., Kakuma, Ishikawa 920-1192, Japan
[3]Inst. of Medical, Pharmaseutical and Health Sciences, Kanazawa Univ., Kakuma, Ishikawa 920-1192, Japan

Nuclear accident at the Fukushima Daiichi Nuclear Power Plant (NPP) was occurred after the 2011 Tohoku Earthquake and Tsunami. About 370-630 PBq of radionuclides was released from the Fukushima Daiichi NPP, according to the estimation by Nuclear Safety Commission (NSC) of Japan and Nuclear and Industrial Safety Agency (NISA). To understand migration behaviour of radionuclides in atmosphere, we have to monitor radioactivities of ^{131}I, ^{134}Cs and ^{137}Cs of aerosol samples in Japan temporally and spatially.

We have been collected aerosol samples using a high volume air sampler at Wajima and Nomi in Ishikawa Prefecture, Japan before the Fukushima Daiichi NPP accident. To realize transport processes of radionuclides from the Fukushima Daiichi, the filter samples collected at above sites, about 400 km far from the Fukushima Daiichi NPP, were measured for radioactivities of ^{131}I, ^{134}Cs and ^{137}Cs using ultra-low background Ge detection system at the Ogoya Underground Laboratory of Kanazawa University.

The presentation will be reported for the radioactivities of ^{131}I, ^{134}Cs and ^{137}Cs at the Ishikawa sites from March to May in 2011, before and after the Fukushima accident. We also show temporal variations in radioactivities of these radionuclides at a few sites in Japan, reported by Japanese scientists as preliminary data, and discuss the migration of these radionuclides in atmosphere on the basis of the spatial variations.

Seismological investigations of the March 11, M9, Tohoku-oki earthquake

JEROEN RITSEMA

Department of Geological Sciences, University of Michigan

On March 11, 2011, a shallow, M9 earthquake with an epicenter roughly 160 km offshore struck the Fukushima prefecture in Japan. The ensuing tsunami was responsible for 20,000 fatalities, widespread damage along the Honshu coast, and the flooding of the Fukushima Dai-ichi nuclear power station, a crisis that is still unfolding. Yet, from a seismological point of view, the response to the earthquake has been a success. Thanks to the enormous investment in seismological and geodetic infrastructure by scientists from Japan and around the world, the earthquake magnitude, faulting mechanism, depth, extent along the Japan Trench, and, hence, its tsunami-generation potential was fully understood within 30 minutes after the earthquake occurred.

The Tohoku-oki earthquake was a classic mega-thrust (i.e. reverse) earthquake. It ruptured a fault plane on the plate interface that is dipping 14 degrees to the west. The largest slip was concentrated at shallow depth near the trench which explains the exceptionally large tsunami. Every large earthquake holds surprises and Tohoku-oki was not an exception. Before March 11, the seismic record suggested that M7.5 to M8.2 earthquakes break small patches of the plate interface along the Japan Trench south of Sendai. Given this experience, the magnitude of the Tohoku-oki earthquake was unexpectedly high. Moreover, the Tohoku-oki earthquake was spatially compact. It ruptured only a 200x100 square km area of the plate interface. Just west of the trench, slip on the fault plane exceeded 60 m. This is the largest fault offset ever reported.

The Tohoku-oki earthquake has been analyzed by a large number of scientists around the world. An open-access special issue of the journal “Earth, Planets, and Space” appeared in June. Articles in this issue are already providing a detailed and remarkably consistent picture of the many complex facets of the Tohoku-oki earthquake. In this presentation, I will summarize these investigations and place the earthquake in a historical context.

[2]Hiroshima Univ., Hiroshima, Japan
[3]Osaka Univ., Osaka, Japan
[4]Dokkyo Medical Univ., Tokyo, Japan

On 11 March 2011, A Great East Japan Earthquake of magnitude 9.0 happened, and generated a series of large tsunami waves in the east coast of Japan. By these events, Tokyo Electric Power Company (TEPCO) Fukushima Dai-ichi Nuclear Power Plants (units 1, 2, 3 and 4) suffered major damage, and significant amounts of radionuclides were released into the environment. Monitoring efforts performed so far have shown that dangerous contamination is mostly localized in a narrow band within 40 km of the plant, stretching to the northwest. The Japanese Government announced that the serious accident of TEPCO's Fukushima Daiichi Nuclear Power Plant was ranked up to Level 7, the most serious accident according to INES, the same level as that in the case of Chernobyl Nuclear Power Plant in the Soviet Union on April 26, 1986.

To understand the components of radionuclides released, their levels and distributions, some soil core samples up to a depth of 30 cm were taken at the zone within 20-30 km from the plant in the end of March. The samples were cutted every 5 cm in depth. Another one soil sample (0-5 cm in depth) was also collected at the ca. 1.7 km point (outside the premises) west from of the plant in April. These samples were subjected to the measurements of γ-ray emitting radionuclides and Pu isotopes

As a result, volatile radionuclides such as ^{131}I,^{134,137}Cs and so on were mainly detected with various levels, showing serious contamination in the NW from the plant. The distribution reflected the role of wind pattern and rainfall in washing out radionuclides to the ground. Small amounts of Pu isotopes (^{239,240}Pu and ^{238}Pu) were detected for all of the surface soil (0-5 cm) from zone within 20-30km, but their activity ratios of ^{238}Pu/^{239,240}Pu were around 0.03, indicating the origin of global fallout Pu. Only one sample collected from 1.7 km close the plant showed a little higher ratio of ca 0.06. Thus, currently, Pu release was negligibly small and volatile nuclides ^{131}I,^{134,137}Cs, etc. were responsible for a large share of released radioactivity. There are some spots of higher contamination called "Hot Spot".

A preliminary overview of studies on dispersals of radionuclides from Fukushima nuclear power plants

NAOHIRO YOSHIDA

Department of Environmental Chemistry and Engineering, Tokyo Institute of Technology, Japan

The Tohoku Japan earthquake occurred on 11th March, 2011, accompanied by huge tsunami which attacked all coastal areas in northeastern Japan and caused the accdidents of Fukushima Daiichi nuclear power plant. Some nuclear reactors lost their control almost entirely or partly, and the fission products and feasible neutron activated nuclides in the reactors have been dispersing in environment.

To promote a study on disperse of the radionuclides in order to prevent further unnecessary dose for people, many scientists have gathered and started monitoring, mapping, and model simulation of disperse of radionuclides in local and large covering areas as well. This is a preliminary overview of studies on dispersals by many motivated collaborators.

Radionuclides are found to be strong tracers of atmospheric and oceanic movement with time stamps of some with their different half-lives to distinguish different emission phenomena, direct and/or rebound transport, and dry and/or wet deposition. The distribution of radionuclides in time and space is highly localized, which may be determined by their accumulation and diffusion because of distance, topography, wind direction, precipitation, surface runoff, marine gires and currents. Their occurrences, however, are sometimes difficult to be explained straightforward because of the unknown source processes and their strength, their physical and chemical forms in the atmosphere and the oceans, their transformation through chemistry, the size distribution of dusts on which they are absorbed, dry and/or wet deposition on the surface soil, and their chemistry and transport after deposition.

Some scientific programs have started and will continue before and even after the cease of the nuclear plant crisis, to obtain knowledge on the ongoing radioactive pollution, to understand and to predict their distributions, and for the unexpected similar future accidents. This is a great challenge for the scientists in this research field, geochemistry and not necessarily limited to isotope geochemists nor any scientists, but to human beings. Further international collaborations would be much appreciated in any fields of study with different time and space scales.
