Potential for mineral trapping during CO_2 storage in sedimentary basins

PER AAGAARD*, HELGE HELLEVANG, BINYAM L. ALEMU, VAN T.H. PHAM AND ANJA SUNDAL

Department of Geosciences, Univ. Oslo, Norway (*correspondence: per.aagaard@geo.uio.no)

A system perturbated by CO_2 injection reacts by dissolving primary minerals and form new secondary phases, and is also accompanied by an increase in solution trapping. The importance of such mineral reactions for safe long-term storage is highly system dependent.

Based on mineralogical and sedimentological information from siliciclastic reservoirs suitable for CO_2 storage (Sleipner (Utsira fm), Snöhvit (Tubåen fm), Johansen fm, Skagerrak (Gassum- & Haldager fm), a.o.), we performed numerical simulations on geochemical reactions induced by the CO_2 injection. The Norwegian offshore clastic reservoirs considered, represent a wide range in mineralogical composition, burial history and present day P, T, and salinity conditions. The sensitivity of dissolution and secondary mineral growth were analysed with respect to temperature, pressure, salinity and initial mineral assemblage.

In low-temperature quartz rich reservoirs, such as the Utsira fm. (Northern North Sea), we see that the potential for secondary carbonate growth is both limited by slow nucleation and growth rates of the carbonates, and on the limited amount of divalent metal cations present in primary phases such as glauconite, smectite, and chlorite. At higher temperature, the rate of carbonate growth is higher with faster response to the release of divalent metal cations. Aluminum released by feldspars and micas is preferentially precipitated out in non-carbonate secondary minerals, as dawsonite ($NaAl(OH)_2CO_3$) is not likely to form as it is only thermodynamic stable relative to other NaAl-phases at low temperatures [2].

Variable radiogenic isotopic compositions in Saharan dust across the Atlantic

S. AARONS*, S. ACIEGO AND J. GLEASON

University of Michigan, Ann Arbor, MI 48109-1005, USA (*correspondence: smaarons@umich.edu)

Isotopic characterization of aerosol mineral particles (dust) of varying sizes is essential in classifying potential source areas and determining the correct source of dust deposited over oceans and icesheets. The Sahara is considered a dominant source of aerosol dust in the Northern Hemisphere. Weathering, size, and mineral sorting can have an effect on radiogenic isotope compositions [1]. In order to investigate the isotopic variability of Hf, Nd and Sr we analyzed ten airborne dust samples in 2 size fractions collected during cruise M55 that intersected a cross-Atlantic dust storm originating in the Sahara in late 2002.

Past measurements of the isotopic composition of Hf, Nd and Sr of dust has focused primarily on coarse sized particles (1-30μm), whereas far-reaching deposition is primarily of a smaller size fractions (~2μm). Studies have shown that $^{87}Sr/^{86}Sr$ varies with grain size [2], but no systematic work has been done to show if there is a fallout distance effect on the isotopic composition. Weathering and sorting of minerals has a negligible effect upon the Nd isotopic composition [3]. The Hf isotopic composition however has been hypothesized to be highly variable due to a depleted "zircon effect" in the dust over time and distance [4].

$^{87}Sr/^{86}Sr$ measurements were performed on a Finnigan MAT 262 TIMS ($^{143}Nd/^{144}Nd$ measurements pending), and measurement of $^{176}Hf/^{177}Hf$ was performed on a Nu Instruments MC-ICPMS. Hf isotopic compositions show an east to west trend toward more radiogenic compositions across the Atlantic. While no Sr isotopic sorting trend based on distance from the dust storm is evident, the fine grained samples are consistently more radiogenic than the coarse grained samples from each site. A shift of >400 ppm in the $^{87}Sr/^{86}Sr$ ratio between coarse and fine fractions is found, with an average $^{87}Sr/^{86}Sr$ ratio of 0.7159, consistent with a Saharan dust source. The silicate versus water soluble fractions show a shift in $^{87}Sr/^{86}Sr$ ratios with ~70% of the Sr in the water soluble fraction attributable to seasalt and ~30% from dust.

Geochemistry and mineralogy of the arid region, Hormozgan province (southern Iran), in relation with geo-pedological factors of soil evolution

HAKIME ABBASLOU[1], FRANCISCO MARTÍN[2]*, ALI ABTAHI[1] AND MOHAMMAD JAVAD POORGOHARDI[3]

[1]Soil Science Department, College of Agriculture, Shiraz University, Iran
[2]Soil Science Department, University of Granada, Spain (correspondence: fjmartin@ugr.es)
[3]BSc. In oil and petroleum engineering

The concentrations of trace elements in soils depend mainly upon the bedrock type, from which the soil parent material is derived, and pedogenic processes acting upon it [1]. Geochemistry of trace elements, mineralogical characteristics of soil diagnostic horizons and relevant parent rocks were measured with regard to determining amount and distribution of elements concentration in soils developed from different parent materials in Hormozgan province (southern Iran) to assess distribution, evolution and influential processes of the elements behavior in soils. The studied area has an arid climate with predominant sedimentary and basic igneous parent rocks. Elements concentration in soil and parent material are higher than the proposed range of world's soil average and relevant parent material by different references; however, Se and Pb concentrations are much lower than arid world's soil average. Statistical analysis of elements with soil properties and mineralogical characteristics suggest that different elements are classified in three cluster: i) samples with the highest amount of trace element concentration coinciding with highly developed soils and phyllosilicate minerals dominant; ii) soils with high percentage of quartz and sand; and iii) with partially lower amounts of elements coinciding with gypsiferous soils containing gypsum and dolomite minerals. No significant difference between horizons A and B in relation to C horizons were found representing early stages of weathering and pedogenic processes, and indicating that trace elements composition of the soil will be inherited from the parent material. Enrichment factor results show that lithogenic origin is the dominant source of elements, especially Mn, Fe, Sb, Bi, Sr, Sn and Co, and pedogenic origin is more notable for elements like As, Pb and Cu.

Investigation of geochemical properties of Khonj bentonite mine (East of Iran)

H. ABBASNIA[1]* AND TORSHIZIAN[2]

[1]Iranian Mining Engineering Organization, Mashhad, Iran
[2]Islamic Azad University, Mashhad Branch, Mashhad, Iran (*correspondence: Abbasnia.hosein@gmail.com)

Bentonite usually forms from weathering of volcanic ash, most often in the presence of water. However, the term bentonite, as well as a similar clay called tonstoin, has been used for clay beds of uncertain origin. Konj Bentonite mine with area about 15 km2 locate in South Korassan province in the east of Iran. Lithology exposes of the rocks is consisting of Shale and Sandstones (Jurassic), Limestone and Marl (Cretaceous), Andesite and Dacite (Oligomiocene), green sandstone, Andesite, Tuff, Argillite and Conglomerete (Eocene). Form geological viewpoint, a Bentonite horizon with 10 m and more thickness have been extended in mine area and have been formed more than 1800000 ton Bentonite. Forming of this Bentonite horizon is because of acidic submarine colcanism activities and part of silicate rocks, Montmorillonite, Tuff and volcanic ash with Eocene age. These complexs in diagenes level undergo mineralogy changes and after that have been affected by surface weathering. Bentonite horizon divides to 4 classification super quality, high, normal and low quality. Mineralogy studies by XRD analysis show that main former mineral phase of Bentonite is consist of Montmorillonite, crystobalithe, and Calcite and secondary phase is consist Quartz, Albite and Gypsum. Chemical analysis result by XRF show that Khonj Bentonite is Soda type as maximum amount of Na20 is about 3.29 % while maximum amount of K2O is less than 1.5 %. According to chemical and physical test result like acidity (ph-9-10) and absorption index (597-705), best application for this Bentonite is using in sinker and found industrials.

Recycled halogen signature preserved in the Tristan hotspot

L.D. ABBOTT[1]*, R. BURGESS[1], D. MURPHY[2] AND C. BALLENTINE[1]

[1]SEAES, University of Manchester, Oxford Road, Manchester, M13 9PL, UK (*correspondence:lisa.abbott@postgrad.manchester.ac.uk)
[2]School of Natural Resource Sciences, Queensland Institute of Technology, G.P.O. Box 2434, Brisbane, Qld. 4001, Australia

The halogens (Cl, Br, I) are moderately volatile elements which exhibit incompatible behaviour during melting, and are fractionated by biological processes. Although the halgoens share similar geochemical properties to the noble gases in many systems, the heavy halogens have been underutilised as tracers because of the analytical difficulties related to determining their low abundances in geological materials.

Halogen compositions have been determined in a suite of ocean island basalts, including samples from the Tristan group of islands (Tristan and Inaccessible Is.). Analyses were completed on fluid and melt inclusions in olivine separates, using an extension of the Ar-Ar technique.

The Tristan and Inaccessible Island basalts exhibit a subducted halogen signature, showing a strong overlap in Br/Cl and I/Cl with marine pore fluids (fig. 1). Intergrated Br/Cl and I/Cl values extend up to 3.4 x 10^{-3} (molar ratio) and 4.1 x 10^{-3}, with mixing trend between MORB and marine pore fluid end-members observed. Higher ratios are obsevered in the Inaccessible Island samples, suggesting that the composition of the Tristan hotspot source has changed over time.

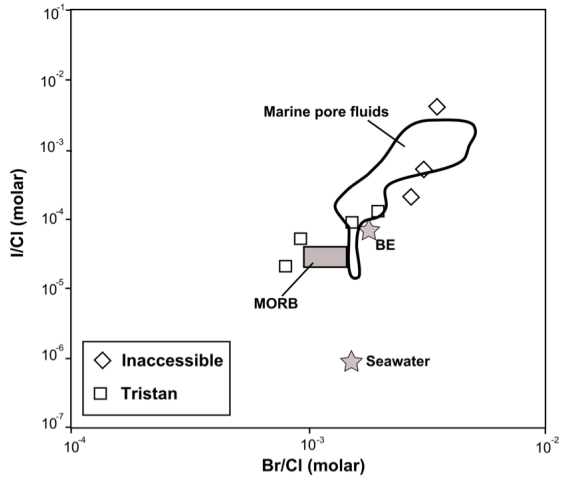

Figure 1: Observed overlap with marine pore fluids

Calc-alkaline lamprophyre from Lusatia (Germany) derived from a multiply enriched mantle source

KH.M. ABDELFADIL[1], R.L. ROMER[1], TH. SEIFERT[2] AND R. LOBST[3].

[1]Deutsches GeoForschungZentrum, Potsdam, Germany (khaled@gfz-potsdam.de, romer@gfz-potsdam.de)
[2]TU Bergakademie Freiberg, Freiberg, Germany (seifert@mailserver.tu-freiberg.de)
[3]Sächsisches Landsamt für Umwelt (LfULG), Dresden, Germany (Reiner.Lobst@smul.sachsen.de)

Lusatia represents part of a 570-545 Ma old Cadomian magmatic arc that – in contrast to the adjacent areas of the Sudetes and the Erzgebirge – largely escaped metamorphism during the 350-340 Ma old Variscan orogeny. The post-Cadomian mantle beneath Lusatia was sampled by c. 400 Ma old tholeiitic gabbros and c. 230 Ma old calc-alkaline lamprophyre (spessartite), which allows to characterize the effect of the Variscan orogeny on the mantle beneath Lusatia and to compare it with the metasomatized mantle beneath the Erzgebirge and the Sudetes.

The tholeiitic gabbros originated from a mantle source that had been metasomatized during subduction beneath the Cadomian magmatic arc, which led to enrichment of LREE, Ba/Nb, and LILE relative to primitive mantle. The post-Variscan spessartites have the same trace-element pattern and Zr/Nb, Ce/Pb, and Y/Nb as the gabbros, indicating derivation from the same mantle source. The distinctly higher Rb, Ba, Pb, Sr, Th and Cs contents, higher La/Yb $^{87}Sr/^{86}Sr$, and $^{206}Pb/^{204}Pb$ ratios, and lower $^{143}Nd/^{144}Nd$ ratios in the spessartites, however, indicate a second, Variscan event of mantle enrichment. In addition, the spessartites have trace element ratios (i.e., Ba/Nb, Nb/U, Th/U, and Th/Nb) that resemble continental crust and the Sr, Nd and Pb isotope systematics demonstrate involvement of crustal material.

The trace-element signatures and Sr and Nd isotopic composition of Lusatian spessartites differ from post-Variscan calc-alkaline lamprophyres from the adjacent areas of the Sudetes and the Erzgebirge. This implies that the subduction during the Variscan orogeny resulted in geochemically and isotopically heterogenous mantle on the regional scale, possibly reflecting the contrasting nature of the subducted rocks.

Application of advanced nuclear magnetic resonance (NMR) spectroscopy and ultrahigh resolution mass spectrometry (MS) to studies of organic matter transformations

H. ABDULLA, P. CARICASOLE, H. CHEN, A. W. KAMGA, G. A. MCKEE, R. MESFIOUI, E. SALMON, R. L. SLEIGHTER AND P. G. HATCHER*

Department of Chemistry and Biochemistry, Old Dominion University, Norfolk, VA 23529. (habdulla@odu.edu, pcaricas@odu.edu, hxchen@odu.edu, akamga@odu.edu, gmckee@odu.edu, rmesfiou@odu.edu, esalmon@odu.edu, rsleight@odu.edu, *correspondence: phatcher@odu.edu)

The recent introduction of advanced NMR and MS methods has changed the landscape in our ability to discern the changes that natural organic matter (NOM) undergoes during processing in the environment. We can now identify molecular-scale transformations associated with both biotic reactions (biodegradation) and abiotic reactions (photodegradation, oxidation, physical separations, and thermal alteration). The strategy we have adopted for the examination of these various processes is to employ both NMR and MS together because of their complementarity in identifying molecular-level changes. Moreover, we have established ways to examine both dissolved and sedimentary OM in such a manner.

Results of our studies on biodegradation of NOM, in microcosm studies, in following terrestrial organic matter as it is exported to the oceans, have made it possible to identify suites of molecules that are recalcitrant, readily degraded, and newly produced. The MS data allow us to assign elemental formulas to these molecules, and the NMR data allow us to propose structural motifs. Our photochemical studies of DOM show that oxygenated and terrestrially-derived molecules are rapidly consumed while more aliphatic autochthonous molecules remain intact. Studies of sedimentary OM transformations have lead to the discovery of some important abiotic pathways for the reorganization of OM during diagenesis. For example, we have identified amidation reactions as important for N-sequestration in sediments. In the realm of thermal transformations, we can recognize decarboxylation as being part of a dominant process acting on kerogen.

The geochemical variation of volcanic rocks from Papandayan and Cikuray volcanoes, West Java: An existence of Gondwana continental fragment as crustal contaminant

M. ABDURRACHMAN[1,2]* M. YAMAMOTO[1] AND E. SUPARKA[2]

[1]Akita University, Akita-shi 010-8502, Japan (*correspondence: mirzam@gc.itb.ac.id)
[2]Bandung Institute of Technology, Bandung 40132, Indonesia

The Papandayan and the adjacent Cikuray Volcanoes are part of the active volcanoes in the Triangular Volcanic Complex, West Java [1]. Papandayan volcano consists of basaltic andesite (Early Stage), andesite (Middle Stage) and dacite (Late Stage); all of them belong to to medium-K series, with high $^{87}Sr/^{86}Sr$ (0.705243-0.705907) and low $^{143}Nd/^{144}Nd$ (0.512504-0.512650) ratios. In contrast to the Papandayan volcano, the Cikuray volcanic rocks exhibits a low-K series, with low $^{87}Sr/^{86}Sr$ (0.704172-0.704257) and high $^{143}Nd/^{144}Nd$ (0.512823-0.512858) ratios. Detailed petrological and geochemical studies indicate that the diversities in K_2O as well as isotopic ratios are mainly due to the influence of the Gondwana continental fragment (Fig 1a) [2] which is contaminating the Cikuray type magma to produce the Papandayan magma (Fig 1b).

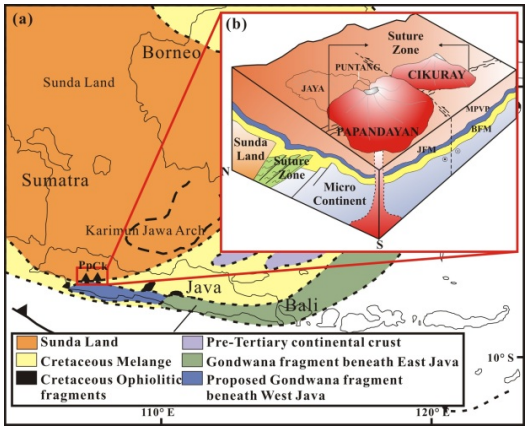

Figure 1: (a) A map showing the proposed Gondwana fragment beneath West Java [2,3,4, this study], (b) A schematic model of Papandayan-Cikuray volcanoes.

Rutile included in the podiform chromitite from ocean floor at MAR 15°20'N FZ, Site 1271, ODP Leg 209

NATSUE ABE

IFREE, JAMSTEC, 2-15 Natsushima-cho, Yokosuka 237-0061, JAPAN, (abenatsu@jamstec.go.jp)

Several podiform chromitites includes rutile grains in abyssal peridotite are recovered from Site 1271 at Mid-Atlantic Ridge (MAR) 15°20' N fracture zone (FZ) during an ocean drilling cruise, ODP Leg 209 [1]. Only chromian spinel is preserved as the primary mantle mineral and all other primary minerals in the chromitite samples are completely altered. The primary chromian spinel has comparable Cr# (0.5) with it in the chromitite "minipod" sampled from Hess Deep [2]. The samples associated with chromitites from the drilling site consist of mainly dunite, some amphibole-bearing gabbros and troctolite, and rare in harzburgite. Therefore, the chromitites from this site are included in the rock series that composes the Moho transition zone as same in the ophiolites. It implies that a mass of melt existed, but was consumed in the uppermost mantle beneath the area. This means that the area is not magma-starved, although it is unclear when and where did interaction occurred. Some grains of the chromian spinel in the samples have thick rims of Cr-magnetite or completely replaced by magnetites. Cr content increases in the Cr-magnetite rim accompanied with Fe-enrichment. The chemical modification of the chromian spinel suggests that the chromitite from Site 1271 were metamorphosed at high temperature condition up to the upper greenschist facies because significant Al-missing from spinel cores is taken place at high temperature as a result equilibration with fluids in equilibrium with chlorite.

Geological, mineralogical and geochemical characteristics of Saheb Skarn (west of Iran)

NASIM ABEDI [1], MOHAMMAD YAZDI [2] AND KAMAL DANA [3]

[1](abedi42@yahoo.com)
[2](m-yazdi@sbu.ac.ir)
[3](Kamaldana@yahoo.com)

Saheb Iron Deposite is located in the northeast of Saghez in Sanandaj-Sirjan geotectonic zone, NW of Iran. Saheb Fe-skarn was developed along the contact of Saheb intrusive body with carbonatic rocks. Both endoskarn and exoskarn zone have been formed along the contact. Endoskarn is narrow while exoskarn is relatively wide and includes calc-silicates, silicates, sulphide, oxides, and carbonates minerals. Skarnification processes occurred in two separate stages (1) prograde (2) retrograde.

According to field and lab studies on Saheb intrusive body is granite to granodiorit I-type, metalumious and calk-alkalin. Calcareous host rocks have been recrystallized by this intrusive body. Also several forms of fine-grained garnet and amphibole have been formed close to skran contact while fine-grained epidote formed relatively farther from the contact. Anhydrous calc-silicates has been formed during early prograde stages at temperature range of 420-550°C. The retrograde stage began as the temperature of hydrothermal fluids decreased up to 400-420°C. During this stage, the anhydrous calc-silicate minerals were changed to a series of relatively low-temperature minerals.

Geochemical trend of major, minor and rare earth elements shows that considerable amounts of elements such as Fe, Si, Cu, K, Th, and Nb were added to the skarn system by the hydrothermal fluids derived from the pluton. In contrast, notable quantities of Ca and Mg were leached from the skarn system. It seems that garnets are the most principal host minerals for REEs, U, Y, and Th in this skarn. The main ore mineral are magnetite and hematite with up to 10 thick with Fe: 51.72%, Cu: 0.35%, Au: 0.038ppm.

Molecular characterisation of soil organic matter by laser-desorption ionization Fourier-transform ion cyclotron resonance mass spectrometry (LDI-FT-ICR-MS)

SAMUEL ABIVEN[1]*, JENS FUCHSER[2], MICHAEL W. I. SCHMIDT[1] AND THORSTEN DITTMAR[3]

[1]University of Zurich, Soil Science and Biogeography, Switzerland, (*correspondence: samuel.abiven@geo.uzh.ch)
[2]Bruker Daltonics, Bremen, Germany (Jens.Fuchser@bdal.de)
[3]Max Planck Research Group for Marine Geochemie, Oldenburg, Germany (tdittmar@mpi-bremen.de)

Soil organic matter (SOM) characterisation has been an analytical challenge for decades. On one hand, methods like humic substances extraction describe large pools of molecules, but these extractions target operationnally- rather than chemically-defined pools. On the other hand, specific compound analysis provides a more precise overview on the molecules present in the soil, but the sum of these molecules represents only a minor portion of the soil organic matter. Despite these shortcomings, soil organic matter characterisation is used in many concepts of soil science. For example, the soil aggregation hierarchical model describes the physical organisation of soils into fractions bound together by organic matter of different quality for each size fraction. Due to the method inadequation, most of these concepts still need to be validated.

We took advantage of a unique analytical set-up coupling laser-desorption ionization (LDI) to ultrahigh-resolution mass spectrometry via the Fourier-transform ion cyclotron resonance technique (FT-ICR-MS) to further characterise soil organic matter and to validate the soil aggregation hierarchical model. Soil aggregates (3-5 mm) were collected from two soils, a cambisol (32 % clay, 4.2 %C), and a loess-derived soil (15% clay, 1.6 %C). Aggregates were fractionated by fast wetting into <63, 63-125, 125-250 and > 250 µm fractions. These fractions were air-dried and ground to powder prior to analysis. LDI-FT-ICR-MS analyses were performed on otherwise untreated samples. Thousands of molecular formulae were identified in each samples, many of them could be associated with polyphenolic structures. The combination of LDI with ultrahigh-resolution FT-ICR-MS offers fundmentally new insights into soil organic matter, one of the largest organic matter pools on Earth.

Cadmium isotopes in Banded Iron Formations and early life in the Precambrian ocean

W. ABOUCHAMI[1,3]*, K. MEZGER[2], S.J.G. GALER[3] AND R. FREI[4]

[1]Institut für Mineralogie, Corrensstr. 24, 48149 Münster, Germany (*correspondence:wafa.abouchami@mpic.de)
[2]Institut für Geologie, Universität Bern, CH-3012 Bern, Switzerland (klaus.mezger@geo.unibe.ch)
[3]MPI f. Chemie, Postfach 3060, D-55020 Mainz, Germany (steve.galer@mpic.de)
[4]Institute of Geography and Geology, University of Copenhagen, DK-1350 Copenhagen, Denmark (robertf@geo.ku.dk)

The exact genesis of Banded Iron Formations (BIFs) is not fully understood, yet there is a consensus that they are seawater precipitates and as such provide valuable archives of Precambrian ocean chemistry, its oxygenation and perhaps clues to early life. Here we explore Cd stable isotope fractionation in BIFs to try to assess the degree of biological activity in the ancient oceans. Cadmium isotopes are particularly suited since (1) they trace differences in biological productivity between biogeochemical provinces in the modern oceans [1], (2) in contrast to Cr and Fe isotopes, Cd isotopes are not redox sensitive, and (3) they are not fractionated by Fe-Mn oxide precipitation.

Two suites of BIFs from Isua (3.8 Ga) and South Africa (2.2 Ga) were analysed using a Cd double-spike technique at MPI. Exceedingly low Cd concentrations (20-60 ng/g) are found in all BIFs, except one Isua sulfidic facies sample, independent of their provenance and age. Such concentrations are two orders of magnitude lower than found in modern Fe-Mn deposits, supporting extreme trace metal depletion in the early oceans. The Cd isotope ratios, expressed as $\varepsilon^{112/110}$Cd, are varied but systematic, ranging from essentially negative values (-3.7 to -0.3) in the 3.8 Ga-old Isua samples, except for the single sulfidic facies sample, to exclusively positive values (+0.9 to +5.5) in the 2.2 Ga-old South African samples.

The Cd isotope range of the Isua BIFs is consistent with that of modern seafloor hydrothermal systems and contrasts markedly with that of the Proterozoic. The isotope effect during the Proterozoic is similar in magnitude to that observed in the present-day oceans and seems to mark the onset of biological productivity following the Great Oxidation Event. Additional data will be crucial for constraining the timing of oxygenic photosynthesis in the early Earth.

Sorption of engineered silver nanoparticles to environmental and model surfaces

P.M. ABRAHAM AND G.E. SCHAUMANN *

University Koblenz-Landau, Institute of Environmental Sciences, Germany
(*correspondence: schaumann@uni-landau.de)

The fate of engineered nanoparticles in the environment is strongly determined not only by their tendency to form homo- or heteroaggregates but also by their interaction with environmental surfaces like plant leaves, soil particles, sediments or biofilms.

In this study we are investigating the deposition behavior of silver nanoparticles to model and environmental surfaces and to understand the role of particle-surface interaction forces for the quality and quanity of nanoparticle deposition.

Surface-nanoparticle interactions were investigated in batch experiments via equillibrium sorption isotherms to various natural and model surfaces. The model surfaces were chosen to cover a wide range of intermolecular interactions considering van-der Waals interactions as well as proton donor and acceptor interactions.

All the sorption isotherms for sorption of silver nanoparticles to different model surfaces were described best by Langmuir sorption. The Langmuir adsorption coefficient is controlled by the chemical nature of the model surfaces used.

The sorption study was accompanied by atomic force microscopy (AFM) on a qualitative and a quantitative basis for assessment of morphology and nanomechanical parameters of the covered surfaces.

In this contribution, we will discuss the physicochemical aspects of sorption and deposition of silver nanoparticles on environmental surfaces and the resulting environmental effects with special respect to quantitative aspects of sorption and interaction.

The geoengineering possibilities and impact of enhanced silicate weathering in the ocean

J. ABRAMS[1,2]*, C. VÖLKER[1], D. WOLF- GLADROW[1] AND P. KÖHLER[1]

[1]Alfred Wegener Institute for Polar and Marine Research, PO Box 12 01 61, D-27515 Bremerhaven, Germany (*correspondence: Jesse.Abrams@awi.de)
[2]Institute of Environmental Physics (IUP), University of Bremen, Otto-Hahn-Allee 1, 28359 Bremen, Germany

Geoengineering methods are being explored to counteract global warming effects on Earth's climate. The use of enhanced silicate weathering has been proposed as a method that could speed up the consumption of CO_2 by enhancing naturally occurring chemical weathering. This study investigates that method, which involves grinding, dispersing and dissolving olivine, a magnesium silicate mineral, in river catchments and over the open ocean in order to absorb excess CO_2 and oppose ocean acidification. Previous research shows that if olivine is distributed over land areas of the tropics, it has the potential to sequester as much as 1 Pg C yr^{-1} leading to a reduction of global warming by 1 K and a rise in sea surface pH by 0.1 by the year 2100 [1]. Here, different olivine distribution scenarios over the ocean are examined using the REcoM-2 biogeochemical model coupled to the MITgcm ocean general circulation model. The additional distribution of finely ground olivine over the open ocean could increase the amount of carbon sequestered. Extra input of silicate could create better growing conditions for large silicon dependant diatoms, which contribute largely to the export of organic matter. In this study, we calculate the additional contribution and consequences of olivine distribution. As one of the least expensive geoengineering methods, enhanced weathering is a promising option to help contribute to the efforts to reduce the effects of climate change. However, this can cause both intentional and unintentional changes to the climate that may have potentially important consequences on the Earth's ecosystems.

Cenozoic intraplate volcanism in Central Europe determined by LAB topography

MICHAEL ABRATIS AND LOTHAR VIERECK-GOETTE

Institute of Geosciences, Friedrich-Schiller-Universitaet Jena, Germany

Several intraplate volcanic fields between the Eifel (Germany) and Silesia (Poland) form the northern E – W oriented zone of the Central European Cenozoic Igneous Province (CECIP). The mafic magmas show systematic regional trends in geochemistry and mineralogy that require variations of the melting processes in the upper mantle. From the Eifel to NW Bohemia the magmas exhibit increasing Si-saturation and decreasing $(La/Yb)_N$ ratios approaching the volcanic field of the Vogelsberg from both sides. The chemical variations require (1) an increasing degree of partial melting and (2) shallower equilibration depths of melt segregation indicated by increasing melt proportions from the spinel instead of garnet lherzolite mantle. A correlation of the geochemical and mineralogical data is rather obvious with the decreasing depth of the lithosphere-asthenosphere boundary (LAB) from 100 to 60 km towards the Vogelsberg. Both characteristics can thus be explained by assuming (1) a background potential for (melilite) nephelinitic melt formation along the volcanic zone due to slight buckling of the European lithosphere induced by the alpine deformation front and (2) an overprint of increasing energy supply due to increasing amounts of lithospheric uplift and rifting (or more unlikely temperature supply) towards the Vogelsberg, which marks the crossing of the northern extension of the Rhine Graben with the E-W running buckled zone.

Within the Bohemian Massif towards Silesia the chemical variations indicate an additional overprint by lithosphere penetrating NNW-running tectonic structures paralleling the Tornquist-Teisseyre-Lineament, the Elbe zone as well as the zone of earthquake swarms crossing the Cheb Basin). Approaching these structures from both sides the necessary amount of partial mantle melting decreases as well as the volumes of erupted magma, an observation similar to oceanic fracture zones. This may be explained by the cooling effect of these tectonic elements on the melting zone at the LAB or by metasomatically induced linear lithospheric mantle heterogeneities.

From the present data we propose a genetic model where the LAB topography strongly determines the composition of the Cenozoic intraplate volcanics in Central Europe.

Sources of chemical elements in fumarols of active volcanic regions (Ebeco volcano, Paramushir Island)

N.A. ABROSIMOVA* AND S.B. BORTNIKOVA

Trofimuk Institute of Petroleum Geology and Geophysics, SB of the RAS, 3, Koptuga pr., 630090 Novosibirsk, Russia (*correspondence: geonat86@mail.ru)

Volcanic fumaroles are important objects for study gas transport of chemical elements. We can directly observe chemical elements transported in gas phase in depositions of fumarole domes such as native sulfur, incrustations, and condensates.

This study presents results of geochemical analyses of native sulfur from the fumarolic fields at the volcano Ebeco, Paramushir Island. It was carried out in order to:

(1) evaluate mechanisms of trace elements transport in gas-hydrothermal discharges at the volcano;

(2) determine possible sources of elements in fumaroles.

A wide spectrum of elements was detected in the samples of native sulfur using Synchrotron XRF method, in water extracts from the samples, and in thermal solutions at the volcano by ICP-AES analysis.

Based on the obtained data, statistic analyses together with detailed comparative analyses of native sulfur composition with host andesites and metasomatites compositions the following sources of elements and mechanisms of transport ones in fumaroles can be educed:

1. Host andesites and metasomatites: Ga, Ge, Zr, Nb, Th, U, Cu, Zn which are transported by volcanic gas as aerosol particles.

2. Magmatic fluids: As, Sb, I, Se, Te, Br, Sn, Cs which are transported in a gas phase, such as pure elements, hydrides, sulphides, and halides.

3. Solutions rising throughout the volcanic edifice, interacting with wall rocks, gas phase and are enriched in geochemical barriers: V, Sr, Rb, K, Ca, Y, Fe, Cr, Mn.

Hydrogeological and geochemical characterisation of a mantled evaporite karst based on hydrogeochemical data

P. ACERO[1,*], F. GUTIÉRREZ[1], J.P. GALVE[1,2], M.J. GIMENO[1], L.F. AUQUÉ[1], AND P. LUCHA[1]

[1]Earth Sciences Dept., University of Zaragoza, Spain (*correspondence: patriace@unizar.es, fgutier@unizar.es, jpgalve@unizar.es, mjgimeno@unizar.es, lauque@unizar.es, plucha@unizar.es)

[2]Earth Sciences Dept., University of Modena e Reggio Emilia, Italy

The dissolution of soluble minerals present in sediments and rocks due to the action of groundwater flow may cause the subsidence of the overlying material and eventually the settlement of the ground surface with the formation of sinkholes. Very frequently the anthropogenic activities (mainly irrigation and agricultural practices) activate or accelerate the processes involved in the generation of sinkholes, favouring its development.

In this study, the hydrochemical features of the Ebro valley mantled evaporite karst in Zaragoza city area (NE Spain) are investigated in order to shed light on the functioning of the interconneted karst and alluvial aquifers and to identify the hydrogeological and hydrochemical processes and factors involved in sinkhole genesis. The surroundings of Zaragoza city are probably the area in Europe where subsidence due to evaporite karstification has a greater socio-economic impact.

With these aims, a review of the hydrochemical information contained in the public database maintained by the Ebro Waters Authority was done. Moreover, several hydrochemical field sampling campaigns were carried out and their results were interpreted with the assistance of classical ion-ion plots, statistical calculations and geochemical modelling.

The preliminary results obtained in the study suggest that the main feature controlling the hydrology and hydrochemistry in the studied area is the fluctuation of water levels and compositions seasonally caused by irrigation. Other important factors are: (1) halite and calcium sulfate dissolution, (2) differences in the chemical composition of the irrigation waters upstream and downstream Zaragoza, as clearly observed in small sinkhole lakes, and (3) local focused discharge of more saline waters from the evaporite aquifer into the overlying alluvial aquifer.

Pyroxenite xenoliths from Cenozoic alkaline basalts, Bohemian Massif

L. ACKERMAN[1]*, P. ŠPAČEK[2] AND M. SVOJTKA[1]

[1]Institute of Geology v.v.i., Academy of Sciences of the Czech Republic, Rozvojová 269, 165 00 Praha 6, Czech Republic (*correspondence: ackerman@gli.cas.cz)

[2]Institute of Geophysics v.v.i., Academy of Sciences of the Czech Republic, Boční II, 141 34, Praha 4, Czech Republic

The Cenozoic alkaline basalts from the Bohemian Massif contain abundant mantle xenoliths. They predominantly spinel lherzolites and harzburgites, but also rare wehrlites, olivine-bearing clinopyroxenites and websterites. Mantle peridotite (lherzolite-harzburgite) from Kozákov volcano (Lusatian fault, NE Bohemia) and Lutynia (SW Poland) show similar evolution – melt extraction followed by basaltic melt cryptic metasomatism [1,2]. Nevertheless, position of pyroxenites in these scenarios remains unknown.

We studied pyroxenites from Dobkovičky, Kuzov (both in Ohře/Eger graben), Kozákov and Lutynia. The studied xenoliths have different textures. While olivine/spinel-bearing clinopyroxenite from Kozákov has equigranular texture with common orthopyroxene exsolution lamellae within clinopyroxene grains, Dobkovičky clinopyroxenite show cumulate texture with large clinopyroxene grains and orthopyroxene present only on their grain boundaries. Olivine-bearing websterite from Kuzov has equigranular texture while Lutynia spinel-bearing clinopyroxenite-websterite has cumulate (clinopyroxene with orthopyroxene lamellae) texture with spinel symplectite. The pyroxenites from Kozákov, Dobkovičky and Lutynia yield a range of two-pyroxene equilibration temperatures from 820 to 900° C. In contrast, Kuzov websterite has higher equilibrium temperature of 1050° C. The #Mg numbers of clinopyroxene and orthopyroxene from Kozákov and Lutynia vary from 91.3 to 92.8 and 90.0 to 90.7, respectively and therefore fall within the same range as reported for peridotite [1,2]. Clinopyroxene from Kozákov pyroxenite show LREE enrichment suggesting its formation from basaltic melt derived in spinel-bearing peridotite stability field. Dobkovičky clinopyroxenite show lower #Mg (89.4 and 86.4, respectively). Taking into the account this low value and its texture, it is likely that represents cumulate from the host basalt.

Hadean greenstones and the origin of the Earth's early continental crust

JOHN ADAM[1], TRACY RUSHMER[1], JONATHON O'NEIL[2] AND DON FRANCIS[3]

[1]GEMOC, Earth and Planetary Sciences, Macquarie University, 2109, Australia
[2]Department of Terrestrial Magmatism, Carnegie Institution of Washington, 5241 Broad Branch Road, N.W., Washington, DC 20015, U.S.A.
[3]Earth and Planetary Sciences Department, McGill University, 3450 University Street, Montreal, Quebec, H3A 2A7, Canada

Partial-melting experiments, at 1.0–3.0 GPa and 900–1100 ºC, were conducted on two greenstones of Early Archaean (Hadean) age from the Nuvvuagittuq Complex of northern Quebec. For comparison, similar experiments were also conducted on a modern boninite (from the North Tongan Arc) with compositional similarities to the Nuvvuagittuq greenstones. Partial-melts produced by these experiments are compositionally similar to some TTGs, including a 3.66 billion year old tonalite that encloses the Nuvvuagitttuq Complex. Because the degree of melting needed to produce the tonalitic melts is comparatively high (> 30 %), the relative concentrations of most incompatible elements in the melts are similar to those in their greenstone and bonninite parent rocks. Thus many of the incompatible element characteristics of TTGs may have been inherited from previously fractionated source rocks that already possessed similar characteristics. If this was true, early continental crust production may have been closely associated with some form of crustal re-cycling that duplicated many of the magmatic consequences of modern plate tectonics.

Evaluating new particle formation, growth, and CCN formation in global models

P.J. ADAMS*[1], D.M. WESTERVELT[1], I. RIIPINEN[1], J.R. PIERCE[2] AND W. TRIVITAYANURAK[3]

[1]Center for Atmospheric Particle Studies, Carnegie Mellon University, Pittsburgh, PA 15213, USA (*correspondence: peter.adams@cmu.edu)
[2]Department of Physics and Atmospheric Science, Dalhousie University, Halifax, NS B3H 3J5, Canada
[3]Highway Department, Transportation Ministry of Thailand, Bangkok, Thailand

Although observations of nucleation events often show rapid growth to CCN sizes, global aerosol models have typically shown modest sensitivities of CCN concentrations to uncertainties in nucleation rates. This may be because models lack good nucleation parameterizations, or they underestimate particle growth (e.g. by condensation of SOA). Alternatively, observations of strong growth events may be rare and play a minor role in the overall global CCN budget.

The ability of a global aerosol microphysics model to predict accurately the formation and growth of new particles is tested against observations for several locations: Atlanta, Hyytiälä, Pittsburgh, Saint Louis, and San Pietro Capofiume. Full-year model simulations are compared against size-distribution measurements for corresponding years. Metrics for comparison are nucleation frequency as well as daily nucleation rates, growth rates, condensation sink, sulfuric acid concentrations (where available), CCN formation rates and nuclei survival probability. The global model used is the TwO-Moment Aerosol Sectional (TOMAS) microphysics algorithm incorporated into the GEOS-CHEM global model. Separate model runs were performed using two nucleation schemes: ternary nucleation with a 10^{-5} tuning factor and activation nucleation.

In general, comparison results show that TOMAS does not understate the importance of nucleation to CCN concentrations, as most metrics show less than a 50% bias compared to ambient measurements. Averaged across all five sites, nucleation frequency is overpredicted in the model by 18% and 32% in the ternary and activation simulations, respectively. Growth rates are typically slightly overpredicted in both the ternary and activation model cases, with median growth rates of 2.9 nm h^{-1} and 3.4 nm h^{-1} compared to 2.3 nm h^{-1} in the measurements at Hyytiälä. At Hyytiälä, nuclei survival to 100 nm in the ternary case is found to be roughly 12% higher than observed, although the median survival probabilites approximately agree at 1.8%.

Hydrogenase enzyme assay for the quantification of microbial activity in subsurface environments

R.R. ADHIKARI* AND J. KALLMEYER

Institute of Earth and Environmental Sciences, University of Potsdam, 14476 Potsdam, Germany
(*correspondence: adhikari@geo.uni-potsdam.de)

The subsurface biosphere is the largest microbial ecosystem but very little is known about the microbially mediated processes that drive early diagenesis. Hydrogenase is an ubiquitous enzyme that catalyzes the interconversion of molecular hydrogen and/or water into protons and electrons. The protons are used for the synthesis of ATP, thereby coupling energy-generating metabolic processes to electron acceptors such as carbon dioxide or sulfate. It can therefore be used as a measure for total microbial activity as it targets a key metabolic compound rather than a specific turnover process.

Using a highly sensitive tritium assay we measured hydrogenase enzyme activity in the rather oligotrophic marine subsurface sediments of the Equatorial Pacific (EQP) and the organic-rich sedimens of Lake Van, a saline, alkaline lake in eastern Turkey.

At the EQP sites Hydrogenase activity could be detected throughout the most of the entire length of the cores down to depths of 15 to 35 meters below seafloor (mbsf). In contrary, the rather organic matter-rich Lake Van sediments exhibit measurable Hydrogenase activity only down to around 75 cm. Concomitant with the difference in organic matter content, hydrogen consumption rates are usually below 0.5 nmol H_2/g/min in EQP sediments, whereas they are around to 2 to 5 nmol H_2/g/min in Lake Van Sediments. At several EQP sites there appear to be small horizons of elevated Hydrogenase activity, indicating the location of redox fronts.

Additionally, we present enumerated microbial cell abundance in all samples in order to obtain per-cell turnover rates which allows a deeper insight into the energetics of subsurface ecosystems.

The effect of deep ocean stratification on pCO_2 and $\Delta^{14}C$

JESS F. ADKINS

MS100-23, Dept of GPS, Caltech, Pasadena, CA, 91001

Recently we have used the distribution of $\delta^{18}O$ in the deep Atlantic Ocean at the Last Glacial Maximum (LGM) to constrain the ratio of transport (psi) to vertical diffusion (kappa) in abyssal waters that flowed from around Antarctica (Lund, *et al*. 2011). This conservative tracer balance implies that psi/kappa was 8 times larger at the LGM as compared to today. As it is highly unlikely that the ocean overturning was eight times more vigorous at anytime in the past, we look to variations in kappa in the past to change this ratio. This large reduction in vertical mixing is akin to increased stratification in the LGM deep ocean.

In this work we use a 7-box ocean model to explore the consequences of deep stratification on the carbon budget of the ocean-atmosphere system. Toggweiler's 7-box model (Paleo, 1999) is modified slightly to allow explicit isolation of southern source water relative to a northern source overturning circulation. Mixing between these so called 'blue' and 'red' circulations is allowed at both the deep interface and in the Sub-Antarctic surface waters. Simulated increases in the ratio of psi/kappa lead to pCO_2 draw down, though this effect is largely due to the budget of preformed nutrients in the deep. An important sensitivity to the vertical rain ratio of organic to inorganic carbon arises in cases with deep stratification (lower kappa). Because organic matter is remineralized more in the shallow water column and carbonate in the deep, there is an important vertical stratification in the effect on pH. Preferential deposition of alkalinity in an isolated southern source water mass lowers pCO_2 in both closed and open system simulations. We will present the effects of deep stratification on both pCO_2 and the radiocarbon distribution in the past ocean.

Hydrothermal processes beneath the Merensky Reef and UG2 Chromitite, Bushveld Complex, RSA

E.E. ADLAKHA[1], J.J. HANLEY[1] AND C.A. HEINRICH[2]

[1]Saint Mary's University, Dept. Geology, Halifax, Canada (correspondence: erinadlakha@gmail.com)
[2]ETH Zurich, Institute of Geochemistry and Petrology, CH-8092 Zürich, Switzerland

Pegmatites in the Bushveld Complex occur as veins/pipes comprised of quartz-andesine-biotite intergrowth. Mineral thermometry indicates minimum equilibration temperatures of 610-740ºC. Mossbauer spectroscopy of biotite Fe^{3+}/Fe^{2+} ratios constrain fO_2 within 1 log unit of FMQ. The Cl isotope composition of biotite is consistent with a mantle source ($\partial^{37}Cl$ = -0.15‰ to 0.84‰). $^{40}Ar/^{39}Ar$ dating of biotite indicates pegmatite crystallization ages ranging from 2044 (±23) to 2023 (±12) Ma; therefore, late stage volatile activity persisted well beyond the accepted crystallization age of the layered rocks (2054.4±1.3 Ma[1]).

Quartz and andesine contain primary inclusions of magmatic origin, varying from early low salinity two-phase aqueous to late, nearly anhydrous NaCl-CaCl2-dominant halide melt inclusions. Silicate melt inclusions (high K-rhyodacitic) are also present, and are unambiguously coeval with the halide melt inclusions, demonstrating that the late stage felsic liquid was saturated in this salt melt. Trace element modelling shows formation of these pegmatites by low degrees of fractional crystallization (~1 vol%) of the melt composition trapped in the inclusions.

Pegmatite cores contain base metal sulfides hosting primary inclusions of Pd-bearing melonite [(Ni, Pd)Te_2]. Normative abundance patterns are most similar to those from the Platreef, showing a marked enrichment in Pd relative to Pt (Pd/Pt > 8), Cu relative to Ni (Cu/Ni > 20) and significant depletion in Ir. Analyses of melt inclusions by LA-ICP-MS indicate high concentrations of precious metals such as Pd and Au (0.2-0.6 ppm range) at the time of their entrapment.

We show direct evidence that relatively oxidizing, halide melt-saturated silicate residues were ore metal-bearing at the time of entrapment. Ore/accessory metal ratios in the melt inclusions and sulfide assemblages in the pegmatites are consistent with the bulk rock metal ratios of the pyroxenite cumulates below the Merensky Reef, suggesting that metals were scavenged from those cumulates. Quantitative modelling suggests that the residues significantly impacted metal tenor and ratios in the Upper Critical Zone magma.

Electron and proton transfer equilibria of reducible moieties in humic substances

MICHAEL AESCHBACHER, RENÉ P. SCHWARZENBACH, AND MICHAEL SANDER*

Institute of Biogeochemistry and Pollutant Dynamics (IBP) Swiss Federal Institute of Technology, ETH Zurich (*correspondence: michael.sander@env.ethz.ch)

Humic substances (HS) can act as electron acceptors and electron transfer mediators and play an important role in biogochemical redox processes and in reductive pollutant transformations. Yet, key redox properties of HS remain poorly characterized. Using a novel electrochemical approach, we previously demonstrated largely reversible electron transfer to HS in reduction-O_2 reoxidation cycles and a linear correlation of electron accepting capacities with aromaticities for different HS [1]. These findings suggested quinones as major redox active moieties. The aim of this work was to characterize the electron and proton transfer equilibria of reducible moieties in HS by extending on the electrochemical methods presented in [1].

In a first step, we determined the effect of pH on the coupling of protons to electrons (molar ratios m_{H+}/n_{e-}) transferred to selected humic acids during electrochemical reduction. m_{H+}/n_{e-} gradually decreased from 1.1 to 1.0 at pH 6 to 7 to values < 0.8 at pH 10. The trend in m_{H+}/n_{e-} was consistent with increasing deprotonation of formed hydroquinones with pH, supported by the pH dependence of m_{H+}/n_{e-} during the reduction of selected model quinones. Consistent with the m_{H+}/n_{e-} ratios, potentiometric E_h-pH titration curves for HS reduced to different extents had slopes of $\Delta E_h/\Delta pH \approx -60$ mV.

In a second step, we determined the distribution in standard reduction potentials (E_h^{0}' at pH 7) of reducible moieties in HS by fitting the decrease in E_h with increasing number of electrochemically transferred electrons, n_{e-}, using a model assuming i types of redox active sites with $E_h^{0}(i)$. Attainment of redox equilibria was facilitated by addition of small amounts of radical electron transfer mediators (e.g. diquat). The E_h-n_{e-} curves showed pronounced redox buffering over a wide E_h range. The fitted $E_h^{0}(i)$ distributions were in good agreement with the standard reduction potentials of naphthoquinones and anthraquinones, suggesting that benzoquinone moieties were already present as reduced hydroquinones in the non-pretreated HS.

The proton and electron transfer equilibria of the studied HS support quinones as major reducible moieties in HS and allow, for the first time, estimating free energies of electron transfer reactions involving HS and placing HA on the redox ladder of biogeochemical redox couples and of organic and inorganic pollutants.

Noble gas paleotemperature records: Recent developments in dating, archives, and interpretation

WERNER AESCHBACH-HERTIG, MARTIN WIESER AND THOMAS MARX

Institute of Environmental Physics, University of Heidelberg, D-69120 Heidelberg, Germany (*correspondence: aeschbach@iup.uni-heidelberg.de)

Noble gases in combination with ^{14}C dating provide the classical tools to derive paleotemperature records from groundwater. This contribution focuses on recent developments that expand the range of archives and dating methods that can be combined with the noble gas thermometer. It also addresses the interpretation of noble gas data, in particular with regard to the formation of excess air and its significance as a climate proxy.

It has been demonstrated that under certain conditions noble gas temperatures can be derived from fluid inclusions in speleothems [1]. While this method holds great potential, the difficulties imposed by disturbing gas components in stalagmites are still very challenging. On the other hand, the increasing importance of the speleothem climate archive raises the interest for applications of groundwater dating techniques such as ^{3}H-^{3}He to cave drip waters [2].

In the groundwater archive, dating remains problematic. Recent studies have tried to use all available information, including the noble gas temperatures, to constrain recharge conditions and thereby improve the dead-carbon correction in the calculation of ^{14}C ages [3]. Another promising approach to broaden the range of dating tools is the development of atom trap trace analysis for Kr and Ar radioisotopes [4]. Here too, however, big challenges remain to be solved.

It becomess increasingly evident that the excess air component in groundwater is not only a disturbance but holds paleoclimatic information. This is for example demonstrated by a recent study from the Indian monsoon region, where the neon excess correlates with stable isotopes, as both indicate changes in monsoon strength. Nevertheless, the processes of excess air formation and the corresponding models for this component are still under discussion. New field experiments to address these questions are currently conducted.

Kinetic isotopes effects in speleothems: Insight from clumped isotopes and fluid inclusions

H.P. AFFEK[1], S. ZAARUR[1], T. KLUGE[1], A. MATTHEWS[2], Y. BURSTEIN[2,3], A. AYALON[3] AND M. BAR-MATTHEWS[3]

[1]Dept. of Geology and Geophysics, Yale University, USA
[2]Inst. of Earth Sciences, Hebrew University, Jerusalem, Israel
[3]Geological Survey of Israel, Jerusalem, Israel

Carbonate clumped isotopes (Δ_{47}) is a new paleothermometer, based on ^{13}C-^{18}O abundance, providing temperature estimates that are independent of $\delta^{18}O$ of the water in which the carbonate was formed. As such it is most relevant for paleoclimate on land, where the complexity of $\delta^{18}O$ in the hydrological cycle makes temperature reconstruction difficult. A variety of biogenic carbonates adhere to one Δ_{47}-T calibration, developed by inorganic precipitation, which is assumed to reflect isotope equilibrium. Speleothems are a notable exception, with an offset to lower Δ_{47} values, yielding erroneously high temperatures. This offset, due to kinetic isotope effects in CO_2 degassing, is consistent with the offset from nominal ^{18}O equilibrium typically observed in speleothems. We hypothesize that these kinetic effects are related to speleothems forming from thin films of solution, where fast degassing leads to an isotopic offset in DIC, that is recorded in the $CaCO_3$ forming soon thereafter, due to the long time required to regain isotopic equilibrium. To gain further insight we synthesized $CaCO_3$ by surface precipitation, mimicking thin film carbonate formation. The resulting Δ_{47}-T is less steep than in biogenic carbonates, and is consistent with Δ_{47} in modern stalagmites from several caves. Such calibration may enable extraction of drip water $\delta^{18}O$, while accounting for ^{18}O kinetic offset, using a theory based assumption of a constant $\delta^{18}O$-Δ_{47} kinetic trajectory. We will explore this assumption using laboratory experiments of $\delta^{18}O$ in surface calcite precipitation, and by comparison with fluid inclusions water isotopic composition in Soreq cave.

Geochemical heterogeneity of the clinoform sequence by the example of neocomian sediments of the West Siberian plate

I.V. AFONIN, G.M. TATYANIN AND P.A. TISHIN

Tomsk State University, Russia, (if_w@sibmail.com)

In recent years two models of clinoform sequence forming are developing: cross-stratification and avalanche-stratification models. Potential oil content and foulness of these complexes and necessity in their fractional partition indicate the urgency about solving this problem. The conventional methods for seismic facies analysis and the biostratigraphy can't always give a necessary result. Therefore we have tried to typify different units of clinoform sequence of the achimovskaya slice (West Siberia).

Within these researches 52 argillite samples from the units AC_3-BU_{12}, AC_1-BU_{12}, AC-BU_{12}, AC_2-BU_{11}, AC-BU_{10}, AC-BU_9 were analyzed by XFA and ICP-MS. Based on the researches studied rocks were classified in two geochemical groups. The first group includes argillites of the units AC-BU_{12}, AC_2-BU_{11} which characterized by low REE accumulation (102-204 ppm) at La/Yb varied from 10 to 14, high Eu/Eu* content (0,58-0,66), and low Ce/Ce* content (0,9-1,07). These values indicate a deep-sea regime of the sedimentation. The second group consists of the units AC_3-BU_{12}, AC_1-BU_{12}, AC-BU_{10}, and AC-BU_9 with higher REE concentration (154-262 ppm), increased Ce/Ce* (1,08-1,58) and La/Yb (10,1-24,07) ratios, and decreased Eu/Eu* content (0,48-0,59). At the same time Mn/Fe, Sr/Ba variations in successions of the units AC_3-BU_{12}, AC1-BU_{12} record increasing parameters of the basin paleosalinity (Sr/Ba 0,44-0,56) and indicators of chemogeinc accumulation of sediments (Mn/Fe 0,007-0,01) on the upper levels. It shows trasgressive regime of sedimentation. For the units AC-BU_{10}, AC-BU_9 an inverse relationship was established where the Sr/Ba (0,3-0,44) and Mn/Fe (0,0076-0,011) values are decreasing up in the succession (Sr/Ba=0,33-0,35 и Mn/Fe=0,77-0,92), thus indicating their regression regime.

Thereby accomplished researches allow defining polygenetic sedimentation regime of the clinoform sequence of achimovskaya slice. It is established a consistent change of the northwest transregression (AC-BU_{12}, AC_2-BU_{11}), deep-sea sedimentation (AC-BU_{12}, AC_2-BU_{11}) and following southeast sea basin regression (AC-BU_{10}, AC-BU_9). These facies reconstructions can be used at the correlation of the units in succession.

The study was funded by the Russian Ministry of Education and Science.

Experimental compressibility of molten hedenbergite at high pressure

C.B. AGEE[1], R.G. BARNETT[1], C.M. WALLER[2], P.D. ASIMOW[2], X. GUO[3] AND R.A. LANGE[3]

[1]Inst. of Meteoritics, Univ. New Mexico, Abuquerque, NM
[2]Geological and Planetary Sciences, Caltech, Pasadena, CA
[3]Geological Sciences, Univ. Michigan, Ann Arbor, MI

The compressibility and density of molten hedenbergite ($CaFeSi_2O_6$) has been determined through a multi-lab collaborative effort to establish a new database for a range of silicate melt compositions. The database will contribute to development of an empirically based predictive model of silicate liquid density and compressibility over a wide range of P-T-X conditions where melting could occur in the Earth. Experimental methods include (i) double-bob Archimedean method for melt density and thermal expansion at 1 bar, (ii) frequency-sweep ultrasonic sound speed measurements on liquids for adiabatic melt compressibility at 1 bar, (iii) sink/float technique for melt density to 11 GPa, and (iv) preheated shock wave measurements of P-V-E equation of state to 150 GPa. The combined data from ultrasonics and shock waves yield an isentropic bulk modulus (K_s=19.81 GPa) and its pressure derivative (K'=5.19). Static compression sink/float measurements carried out in piston-cylinder and multi-anvil devices using olivine and garnet buoyancy markers are in good agreement with these elastic constants. We also determined the fusion curve for hedenbergite well beyond the pressures of earlier work [1] and observed a significant decrease in slope with pressure consistent with a temperature maximum of ~1900 °C at 10-12 GPa. This change in sign of the liquidus Clapeyron slope is also supported by our data that predict a density crossover between hedenbergite crystals and melt at approximately 10.5 GPa.

Crystallization kinetics: A probe of magmatic and eruptive processes in volcanic systems

C. AGOSTINI[1]*, M.R. CARROLL[1] AND P. LANDI[2]

[1]University of Camerino, Geology Division, via Gentile III da Varano, Camerino, (MC) Italy (*correspondence: claudia.agostini@unicam.it; michael.carroll@unicam.it)
[2]INGV Pisa Division, via della Faggiola 32, Pisa, (PI) Italy

The main objective of this experimental study is to constrain and quantitatively model the complex solidification process that transforms a magma in a solid material. During this research there will be studied nucleation and growth of crystalline phases induced by both decrease in temperature and by decrease in $P(H_2O)$ at constant temperature.

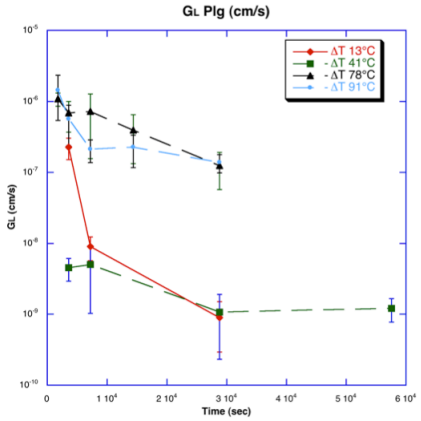

Figure 1: Figure showing Plg growth rate (GL) vs duration of decompression experiments for different ΔT, for Stromboli case.

Discussion of Results

This research concerns two different volcanic systems, Pantelleria and Stromboli, to better understand how crystallization kinetics can affect different magma compositions (in this case peralkaline rhyolites and basalts).

The study of crystallization kinetics through phases growth rates [1] (Couch *et al.*), together with the calculation of nucleation density and nucleation rates [2] (Hammer *et al.*) represent a step toward the estimation of the time scales of magmatic processes in volcanic systems and the interpretation of shallow magmatic processes such as time and velocity of magma ascent.

Subduction-related or subdution-modified source? The case of Central-Eastern Anatolia volcanism

SAMUELE AGOSTINI[1], M. YILMAZ SAVAŞÇIN[2] AND PIERO MANETTI[3]

[1]Istituto di Geoscienze e Georisorse-CNR, Pisa – Italy (s.agostini@igg.cnr.it)
[2]Tunceli Universitesi, Tunceli – Turkey (yilmaz.savascin@deu.edu.tr)
[3]Dipartimento di Scienze della Terra, Università di Firenze, Firenze – Italy (piero.manetti@unifi.it)

Neogene volcanic rocks are widespread in Central Anatolia, between Konya and Kayseri, and Eastern Anatolia, in the region enclosed among Adana, Sivas and Diyarbakır. They occur as large ignimbrite sheets, lava plateaus, monogenetic cones as well as big stratovolcanoes. Some of these rocks are calc-alkaline, from basalts to rhyolites, while others are basanites, tephrites, alkali basalts and trachy-basalts, characterized by alkaline, mostly sodic, affinity.

No clear time and/or space separation between calc-alkaline and alkaline rocks, and no sharp chemical and/or isotopic boundary may be traced. Rather there is a gentle transition, with many samples characterized by intermediate features. As an example, alkaline rocks have Mg# varying from 72 to 45, $^{87}Sr/^{86}Sr$ from 0.7034 to 0.7055 and Ba/Nb from 5.0 to 11, whereas the same parameters span in the ranges of 71-45, 0.7039-0.7056 and 11-163, respectively, in the calc-alkaline basaltic samples. Thus, all the observed data point out for the involvement of two different mantle sources in the genesis of this magmatism, and most samples seem to be derived from interactions of these different sources.

Furthermore, the distribution of calc-alkaline rocks is not strictly linked with respect to subduction dynamics. Large volumes of very young (<2 Ma) calc-alkaline rocks are found in Kapadokyan region, in Central Anatolia, even if current subduction is very slow, or stopped at all. More to the east, some calc-alkaline rocks, are found both predating and postdating the 15 Ma Arabia-Eurasia collision, either in the upper turkish plate or the Arabian foreland.

The Miocene to Pliocene calc-alkaline rocks of Central and Central-Eastern Anatolia are sourced in a subduction-modified mantle wedge. Anyway, the occurrence of calc-alkaline magmas intimately connected with intraplate-type magmas, the presence of transitional samples, the lacking of strict connections with the subduction dynamics and geometry in the calc-alkaline rocks indicate that the metasomatizing event of the mantle wedge is in this case decoupled from the event responsible for the partial melting.

A review of the analytical accuracy of Cl isotope measurements in rocks by various techniques: A way to explain inconsistency between results

PIERRE AGRINIER[1]*, MAX COLEMAN[2] AND MAGALI BONIFACIE[1]

[1]Institut de Physique du Globe de Paris (IPGP), France (*correspondence: bonifaci@ipgp.fr)
[2]Jet Propulsion Laboratory, Pasadena, CA, USA

There are large inconsistencies between various Cl isotope values found for silicate rocks. Notably, mantle $\delta^{37}Cl$ is +4.7‰ [1] to near ~ 0‰ [2] and ≤ -1.6‰ [3,4], implying very different conclusions about the Earth's Cl budget and geodynamics. Each value was obtained with different analytical methods (TIMS, dual-inlet IRMS, continuous flow IRMS, SIMS). Although all use the same reference for waters (SMOC), silicate measurements require Cl extraction from the rock and only one study checked the validity of the whole analytical procedure [5]. In the absence of international rock reference materials, we analysed at IPGP two rocks 15 and 7 times in different sample sizes as well as GSJ materials provided for possible inter-lab calibrations [5]. Although less sensitive than the continuous flow technique used at University of New Mexico (UNM), the IPGP dual-inlet IRMS method is more precise and gives 100 ± 8% overall Cl yields and ± 0.12‰ $\delta^{37}Cl$ reproducibility for Cl extracted from 39 to 9042 ppm Cl rocks [5] (ie., the range of mantle-derived samples analysed [3]). Large analytical Cl isotope fractionations result from non-quantitative Cl yields (Fig. 1 in [5]). There is now a global agreement that some TIMS data in [1] are unreliable [5,6]. It is hard to evaluate discrepancies between IPGP and UNM data, as there are only few details reported for UNM method validation. The only yields reported are too high: 124 ± 17% for >1000ppm Cl samples [7]. More importantly, a new lab using an independent extraction method [8] recently reproduced the IPGP values on 3 rock samples (JB1, JB2 & Allende) – while UNM produced a 2‰ more positive value for Allende. Thus, the observed discrepancies possibly might arise from analytical artifacts in the UNM method and therefore the mantle is depleted in ^{37}Cl.

Neoproterozoic to Mesozoic history of Sanandaj-Sirjan Zone, West Iran

VAHID AHADNEJAD

Geology Department, Payame Noor University, Tehran 19395-4697, I. R. Iran. (v.ahadnejad@gmail.com)

Neoproterozoic tectonics is documented by U-Pb inherited zircons of Sanandaj-Sirjan Zone (SSZ) granitoids, West Iran. The 0.989 Ga inherited zircon of Malayer Syenogranite [1], Northern SSZ, is in accordance with combination of the supercontinent Rodinia at ca. 1.0 Ga. The collision between East and West Gondwana between 0.6 and 0.5 Ga is also could be pursuit by other granitoids of the SSZ which are implied a ca. 0.55 Ga. for Bubaktan biotite granite and Sheikh Chupan granodiorite [2] and ca. 0.59 Ga for Nagadeh monzogranite [3]. The magmatism at Late Neoproterozoic-Early Cambrian in SSZ [2, 3, 4] which is consistent with Pan-African orogenic event, implies that this zone was a part of Gondwana at that time.

Subsequent extension regime in Paleozoic caused rifting of Iranian microplates including SSZ away from Gondwana. Closure of Paleotethys due to its northward subduction and the synchronous opening of the Neotethys in the Late Triassic move Iranian microplates northeastward and accrete them to the Laurasia. Closure of Neotethyan oceanic crust re-amalgamated Iranian blocks at the late Mezosoic. The immense Paleozoic-Mezosoic plutonism in SSZ is the result of this opening and closure of Pale- and Neotethys.

Polyphase deformation in Golpaygan metamorphic complex, Sanandaj-Sirjan Zone, Iran

G.A. AHMADI

Padidab Consultig Engineers, Northern Ordibehesht St., P.O.Box 81358-53164, Isfahan, Iran (ahmadi.gh1354@gmail.com)

Geological Setting

The Golpaygan metamorphic complex in north of Golpayegan city is a part of Sanandaj-Sirjan zone [1]. This zone is the metamorphic belt of the Zagros Orogen in the western Iran that formed by Neo-Tethys initiation and closure events between Arabian plate and Iranian microcontinent [2, 3]. This complex lithologically consists of phyllite, mica schist, garnet mica schist, marble, quartzite, amphibolite, metavolcanics and gneiss [4].

Deformations and related structures

Three stages of deformations can be recognized in this area. First deformation (D1) was associated with a regional metamorphism from lower greenschist to amphibolite facies that has developed during NE subduction of Neo-Tethys oceanic crust under Iranian microcontinent in late Jurassic. First foliation (S1) has developed during this deformation that has folded intensely by late deformations and doesn't show distinct direction. Second deformation (D2) is the most important deformation in the area and it can be recognized by isoclinals and recumbent folds with NW- SE axes, axial plane foliation (S2) and shear zones. It is considered as a progressive deformation with ductile shortening and thrusting from NE to SW. The deformation has formed during collision between Arabian plate and Iranian microcontinent in late Cretaceous to Palaeocene age [5]. Third deformation (D3) consists of en echelon gentle folds and strike - slip faults that have developed during continuous deformation with ductile- brittle condition. This deformation has developed during regional dextral transpression after collision.

Survey of Aeolian airborne dust over Iran from the point of view geochemistry and mineralogy (case study: Western Iran and North of Persian Gulf and Sea of Mokran)

H. AHMADY BIRGANI[1]*, S. FEIZNIA[2] AND N. CHAREHSAZ[1]

[1]Faculty of Natural Resources, University of Tehran, Iran (*correspondence: hesamahmady@ut.ac.ir)
[2]Faculty of Natural Resources, University of Tehran, Iran (sfeiznia@ut.ac.ir)

Introduction and Methods

This research aims to show the characteristics and particle-related pollution of dust storms reaching Iran and North of Persian Gulf and Sea of Mokran. Satellite images have shown that these Aeolian dust storms originate in Arabian countries in Middle East and North of Africa continent. We have conducted numbers of analysis to reveal the MMD, SEM, XRD and ICP-MS to detection of the most important source areas with regard to radioactive, heavy and toxic trace elements [1,2].

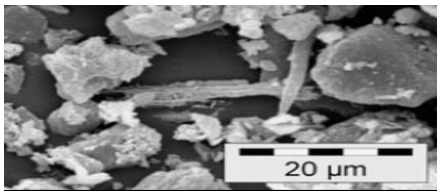

Figure 1: a sample of SEM image of Aeolian dust reaching Iran

Elements / Countries	o	c	Si	Al	Ca	Mg	k	Na	Radioactive & Toxic Traces
Iraq	47	23	13	5	2	3	3	2	2
Saudi Arabia	45	21	16	3	4	5	2	3	1
Syria	46	22	15	4	2	3	3	3.3	0.7
Kuwait	48	16	20	2	3.5	3	3	3	1.5
Occupied Palestine	52	23	16	1	2	1.6	2	1	0.4
Egypt	49	17	19	2	4	3	3	2.7	0.3

Table 1: elements compositions from the countries nearby Iran

Result has revealed that the most dangerous source areas of dust storms reaching Iran are located in Iraq country and war implications by turns have the worst effect on Iraqi environment. Soon after dust storm, Iran country be affected by Toxic, Radioactive Elements and new Microorganism (Bacteria, fungus, viruses) and make all kinds of Human disease and soil pollution and lead to decreasing of forest and plant communities.

Investigation of platinum group minerals (PGM) from Falcondo Ni-laterite deposit (Dominican Republic) using hydro-separation concentrates

T. AIGLSPERGER[1]*, J. A. PROENZA[1], F. ZACCARINI[2], G. GARUTI[2], F. LONGO[3]

[1]University of Barcelona, Dept. Crystal. Mineral. Ore Deposits, Barcelona, Spain (*thomas.aiglsperger@ub.edu)
[2]University of Leoben, Dept. Appl. Geol. Sci. Geophysics, Leoben, Austria
[3]Falcondo Xstrata Nickel, Santo Domingo, Dominican Republic

Two samples, one saprolite and one limonite, with total platinum group elements (PGE) contents of 62 and 212 (ppb) respectively, were processed by the innovative hydro-separation (HS) technique, with the aim to determine the presence of PGM and to understand their origin.

The studied samples were collected in the Falcondo Ni-laterite deposit, developed over the Cordillera Central serpentinized peridotite, located in the central part of Dominican Republic.

Two different types (I and II) of PGM were recognized. Type I PGM form grains less than 10 μm, occurring enclosed in fresh chromite (laurite and an unnamed [$(Rh,Ir_3)S_4$]) or included in altered awaruite (Os-Ru-Ni-Fe compound). PGM of type II consist of free grains, bigger than 10 μm. They comprise laurite and compounds of Pt-Ir-Fe-Ni, Ru-Os-Ir-Rh and Ru-Os-Ir-Fe-O characterized by porosity, irregular shape and complex chemical zoning. Type II PGM have been found only in the saprolite sample.

Composition and shape of both types I and II laurite and the an unnamed [$(Rh,Ir_3)S_4$] suggest a magmatic origin. Other type II PGM may represent the alteration product of pre-existing PGM formed at high temperature. The process that altered the magmatic PGM probably started with the serpentinization and continued during weathering and lateritization.

Our results, although preliminary, indicate that the HS technique can be successfully applied to concentrate PGM also from relatively PGE poor samples, thus providing useful information regarding their distribution and genesis.

Interpreting CO_2 measurements in volcanic gas plumes: The need for integration with geophysical data

ALESSANDRO AIUPPA[1,2]

[1]Dipartimento DiSTeM, Università di Palermo, Italy, (aiuppa@unipa.it)
[2]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Palermo, Italy

Measuring CO_2 concentrations and fluxes in volcanic gas plumes has long remained a challenge for volcanologists. Because CO_2 is the second most abundant gas species in volcanic emissions, and among the first to exsolve and separate from ascending magmas in the crust, the paucity of CO_2 plume data has prevented us from obtaining more in-depth information on magmatic degassing processes. The recent advent of new techniques, and more particularly of the MultiGAS (Multi-component Gas Analyser System), has given new impulse to CO_2 plume measurements, however, and has allowed the acquisition of unprecedented long and robust CO2 flux datasets. Observations made over the last 6 years at Etna and Stromboli (in Italy) have, in particular, demonstrated an unexpectedly large time variability of composition (e.g., CO_2/SO_2 plume ratios) and CO_2 fluxes, which interpretation still remains open and somewhat controversial. Here, I show that integrated analysis with geophysical data (volcanic tremor, deformation data) is key to interpret the dynamic processes operating in volcano's plumbing systems, which produce the observed large variations in plume composition and flux. At Etna, in particular, I demonstrate that the cyclic variations in plume CO_2/SO_2 ratios, systematically observed in 2007-2009, were paralleled by variations in tremor amplitude and location, and by inflation-deflation cycles captured by the GPS network [1]. These combined (multidisciplinary) observations have offered a more robust understanding of processes operating at depth inside Etna, which I here review. Since permanent networks for semi-continuous gas plume observations are becoming more and more in use at volcano observatory worldwide, integrated geochemical-geophysical observations will likely represent a key target of volcanic gas studies in the years to come.

A possible model of accelerated dehydration by fluid migration in deformed amphibolite associated with Oeyama Ophiolite

RIICHI AKAI

Graduate school of Systems and Information Engineering, University of Tsukuba, Tsukuba, Ibaraki,305-8573, Japan (r1.akai@gmail.com)

In subduction zones, miscible fluids commonly would act as metasomatism agent [1]. A petrographic metasomatic model [2] for deformed amphibolite along 50m in the melange of Oeyama Ophiolite member shows continuous compositional change for parent's amphibole grains. For this model, fluid interaction was investigated in order to explain to the crystallization of secondary minerals and alterations of amphibole. The block (mono-mineralic amphibolite together with zoisite vein) that is prospected as the protolith [2] was newly found at the edge of outcrops. This field and petrographic study for vein which are assumed to have precipitated in the surroundings of porphyroclastic parent's minerals would contribute to show the whole process of metasomatism as a case of the evolution of crustal fluid.

In the petrography, some clino-zoisite and zoisite at the initial deformation stage in the vein may be the products of replacement amphibole as those size and shape are similar with fractured amphibole grain and those distributions are mostly connected. The most oligoclase precipitated at later stage doesn't have chemical heterogeneity, and some oligoclase are associated with hydro-fracturing amphibole and zoisite. Some textures seem to show the dissolving of the parent minerals.

Considering these crystallization by some fluid migration during the deformation process, the compositional evolution of the fluid must be required. The huge infiltration of Al (at early stage) and Na (at later stage) during deformation must have been changed by some coupled dissolution and precipitation process together with the reaction of amphibole along the vein.

If dissolution and replacement are key processes, and associated with this major crystallization of anhydrous-minerals during this metasomatism, the chemical system of initial amphibolite would be dehydrated.

This model for fluid interaction is concordant with the last metasomatic model based on spatial compositional trend of amphibole[2].

Geocehmical and genetic features of polymetallic Pb-Zn-Cu-Au-Ag deposits of Gümüşhane, Turkey

M. AKÇAY[1] AND R. YAŞAR[2]

[1]Dept. of Geology, Karadeniz Technical University, 61080 Trabzon. (akcay@ktu.edu.tr)

[2]Dept. of Geology, Karadeniz Technical University, 61080 Trabzon

The deposits occur as veins and lenses within dolomitic limestones nearer mainly to its upper contact with the overlying flysh. The main ore zone is 400 m long along E-W direction, 100 to 150 m wide along N-S direction and has a thichness of 1 to 17 m. The recent exploration activities and feasibility studies indicate an estimated reserve of 1,815,000 tons at 1.81 g/ton Au, 77.11 g /ton Ag, 0.6 %Cu, 5% Zn and 3% Pb. The ore zones are mainly in the form of massive shoots with sporadic pockets of sphalerite and galena, and to alesser extent, as Cu enriched lenses with chalcopyrite, Bi and Te-enriched sulphosalts, and luzonite as well as rare altaite. These minerals are also enriched in Au and Ag.

The deposition of ore occurs within voids in monolithic carbonate breccias, which is, in turn, probably related to rifting. The preferential occurence of the ore in brecciated zones, the presence of ore lenses nearer the upper contact of the Berdiga Limestone with the Upper Cretaceous flysch and along the lower contact of the flysch, as well as the weak mineralisation within units underlying the limestone point towards an epigenetic origin, despite the widespread mode of occurrence in the form of massive lenses. The presence of similar deposits in the vicinity may indicate a joint origin connected with the Eocene magmatic activity, widespread in the region, denoting that the overlying flysch unit may have behaved as a cover unit. Fluid inclusion research suggests epithermal conditions with low salinities (<8,5wt%NaCl eq.) and low to moderate temperatures (130-370 ºC; X=240 ºC). The sulphur contents of sphalerite, galena, pyrite and chalcopyrite were determined to be magmatic in origin, with near $\delta^{34}S$ values ranging from -2‰ to +3‰. Mineral pairs found to be in isotopic equilibrium support epithermal conditions. The Eocene magmatics in the close vicinity of the mineralised areas are likley to be responsible for the formation of such epithermal systems.

Growth-zoned chromian spinel in rodingite: Evidence for Cr mobility in hydrothermal solution

N. AKIZAWA[1]*, S. ARAI[1], A. TAMURA[2] AND J. UESUGI[1]

[1]Department of Earth Sciences, Kanazawa Univ., Ishikawa 920-1192, Japan

[2]Frontier Science Organization, Kanazawa Univ., Ishikawa 920-1192, Japan

We found growth-zoned chromian spinel in a rodingite within the layered gabbro section of the northern Oman ophiolite (Wadi Fizh). The chromian spinel coexists with Ca-rich plagioclase (An; 97-100), diopside (Mg#; 0.87-0.97), uvarovite, titanite, gismondite and chlorite (Cr_2O_3; up to 2.3 wt%). It shows a high Cr# (= Cr/(Cr+Al) atomic ratio), around 0.8, and is different from mantle spinels (in chromitites and peridotites) in the Oman ophiolite (Cr#<0.75). The procursory gabbro is rather wvolved in chemistry, and free from chromian spinel. The rodingite spinel increases Fe3+ from the core to the rim (up to >YFe=0.3). The spinel characteristically shows euhedral and skeltal shapes (Fig. 1). The spinel and uvarovite mostly occur as independent grains, which means the former does not serve as the source of Cr for the latter. The spinel and uvarovite, which enclose euhedral grains of plagioclase, chlorite and pumpellyite, show concentric and oscillatory chemical zoning (Fig. 1).

The petrological characteristics strongly indicate that the spinel and uvarovite in the Wadi Fizh rodingite were independently precipitated from hydrothermal solutions involved in rodingitization of gabbros at low pressure condition (near Moho). This suggest that the Cr was mobile in the aqueous solution at low pressure condition (<0.3 GPa). Chromium was possibly supplied from the underlying mantle via high-temperature solution, which was possibly involved in precipitation of diopsidites (Python *et al*., 2007).

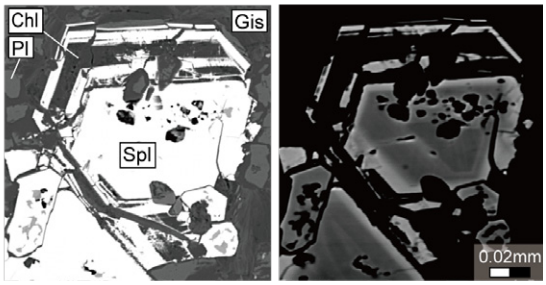

Figure 1: Composite images of spinels. Abbrreviations: spl=spinel, pl=plagioclase, chl=chlorite, gis=gismondite.

Biogenic Mn oxide formation at pH 5.5 and 7 by new Mn-oxidizing bacteria from a former U mining site

D. M. AKOB*, A. BEYER, F. SCHÄFFNER, M. HÄNDEL, D. MERTEN, G. BÜCHEL, K.U. TOTSCHE AND K. KÜSEL

Friedrich Schiller University Jena, 07743 Jena, Germany (*correspondence: denise.akob@uni-jena.de)

Uranium mining near Ronneburg, Germany resulted in widespread environmental contamination with acid mine drainage (AMD) and high concentrations of heavy metals and radionuclides. Natural attenuation of heavy metals is occurring at this site in Mn oxide rich soils and sediments ranging in pH from 5 to 7. While microorganisms readily oxidize Mn(II) and precipitate Mn oxides at pH ~7 under oxic conditions, few studies describe Mn(II)-oxidizing bacteria (MOB) at pH ~5 and/or in the presence of heavy metals. In this study we (1) isolated MOB from the contaminated Ronneburg area at pH 5.5 and 7 and (2) evaluated the biological formation of Mn oxides. We isolated nine MOB strains at pH 7 (members of the *Proteobacteria*, *Actinobacteria*, *Bacteroidetes*, and *Firmicutes* phyla) and a single isolate at pH 5.5 (Oxalobacteraceae isolate AB_14, within the *β-Proteobacteria*). While LA-ICP-MS showed that all isolates accumulated Mn and Fe in their biomass, the Oxalobacteraceae isolate AB_14 had higher intensities of Mn and Fe peaks. Preliminary FTIR analysis indicated that all isolates formed precipitates, which showed absorption bands that were characteristic for birnessite. This, the first known report of any organism capable of Mn oxidation at low pH, demonstrated that MOB can be involved in the natural attenuation of both moderately acidic and neutral pH soils and sediments via the formation of biogenic Mn oxides. Future work will fully evaluate the minerals formed in this process as well as their interactions with contaminating heavy metals and radionuclides.

Geothermal energy development in Turkey

A. AKPINAR[1]*, E. AKARYALI[2] AND M.I. KÖMÜRCÜ[3]

[1]Dept Civil Engn, Gümüşhane Univ, TR-29100, Gümüşhane, Turkey (*correspondence: aakpinar@ktu.edu.tr)
[2]Dept Geol Engn, Gümüşhane Univ, TR-29100, Gümüşhane, Turkey (eakaryali@gmail.com)
[3]Dept Civil Engn, Karadeniz Tech. Univ, TR-61080, Trabzon, Turkey (mkomurcu@ktu.edu.tr)

Geothermal energy is a clean and environmentally friendly energy source, as well as it is renewable and sustainable. It can be used in buildings, agriculture, industry, greenhouse heating etc. This energy source is independent of meteorological events such as wind and sun and more economic and reliable than some of the other energy sources.

In this study, historical development of geothermal energy in Turkey and balance of between geothermal potential and consumption are investigated. With this objective, the studies which have been started by General Directorate of Mineral Research & Exploration (MTA) in 1960's are examined. At the result of these studies, it was determined that, 170 numbers geothermal areas which have low and middle heat were discovered by MTA until 2000. The performed studies have shown that probable geothermal energy potential in Turkey is 31500 MWt for direct use and 4500 MWe for electric production [1]. However, the present use of geothermal energy is a very small fraction of the identified geothermal potential. Only 7% of the geothermal source potential of Turkey was used so far [2]. When Turkey uses the entire total geothermal potential, it can meet 14% of the total energy needs (head and electricity) [3]. This implies a very thought-provoking figure for Turkey which depends greatly on foreign thermal resources. For sustainable development in Turkey, it is very important to increase this percentage to upper values.

Assessing organic carbon distribution in the Koiliaris critical zone catchment (Greece) by using geostatistical techniques

E. AKSOY[1]*, P. PANAGOS[1], N. NIKOLAIDIS[2] AND L. MONTANARELLA[1]

[1]Joint Research Center of the European Commission Institute for Environment and Sustainability, Via E.Fermi, 2749, 21027 Ispra, VA, Italy (*correspondence: ece.aksoy@jrc.ec.europa.eu, panos.panagos@jrc.ec.europa.eu luca.montanarella@jrc.ec.europa.eu)
[3]Department of Environmental Engineering, Technical University of Crete, 73100 Chania, Greece (nikolaos.nikolaidis@enveng.tuc.gr)

Organic carbon amount of the soil is one of the most important geochemical parameters for defining soil characterization. It affects directly to the soil functions (biomass production, C sequestration, biodiversity, etc.) and problems about it may finalize as soil threats. Because of these reasons accuracy of the distribution assessment is an important topic.

This study implemented in Koiliaris Catchment Critical Zone, in Greece with an aim of accurate and detailed assessment of organic carbon distribution. Slope and aspect from DEM; CORINE landcover classification; geological formations and WRB soil classification information were used as covariates in this study. All layers were in the raster format with 100m resolution and the sample points has measured organic carbon values from Crete University field work. Regression – Kriging geostatistical technique was used to be able to find the distribution of the organic carbon through the catchment. As a conclusion, significant correlation between the covariates and the organic carbon dependent variable was found and organic carbon distribution map of Koiliaris CZ was produced in the digital soil mapping perspective.

Sampling technology of deep groundwater with Diffusive Gradient in Thin Film (DGT)

L. ALAKANGAS[1]*, M. ÅSTRÖM[2] AND B. KALINOWSKI[3]

[1]Swedish Nuclear Fuel and Waste Management Co, Box 929, SE-57229 Oskarshamn, Sweden (linda.alakangas@skb.se)
[2]Geochemistry Research Group, Linnaeus Univ., SE-39182 Kalmar, Sweden
[3]Swedish Nuclear Fuel and Waste Management Co, Box 250, SE-10124 Stockholm, Sweden

The Äspö Hard Rock Laboratory (HRL), SE Sweden, is a unique underground facility where the Swedish concept for storage of nuclear fuel waste is tested at natural repository conditions [1]. It also offers an environment for researchers interested in conducting experiments as well as testing equipment in situ at the deep subsurface.

In order to obtain as little disturbance of the sample as possible during sampling, a special designed container where the conditions in the bedrock is mimicked has been developed to be able to collect deep groundwater maintaining the pressure and the reduced state in cored boreholes. This is crucial for pH which is one of the main parameters in reaction modelling, but also for volatile species and redox sensitive elements.

In addition, the container makes it possible to sample trace elements by the new in-situ technique called Diffusive Gradients in Thin films (DGT) [2]. In the deep groundwaters at the Swedish canditate sites most trace elements such as lanthanides and actinides generally occur at concentrations below the detection limit using standard sampling methods. The DGT technique makes it possible to determine dissolved labile trace elements in-situ by trapping species in binding agents for a longer period of time, accumulating the trace elements. The container in which the DGT samplers are established is constructed in stainless steel and can maintain a high pressure of 50 bar. The PEEK material inside prevents the water to have contact with the metal. During the sampling period a constant agiation and flow through the container will be regulated.

The outcome will contribute to a better understanding the trace metal dynamics in deep groundwaters. Measurements of sensitive parameters at in situ conditions will increase the quality of the hydrogeochemical models that will be used in the safety assessment for the final respository.

Distribution of potentially toxic elements around Dolly Au-Cu Mine, Central Iran

FATEMEH ALAVI TABAEE[1], DR SOROUSH MODABBERI[2] AND DR HOOSHANG ASADI HAROONI[3]

[1]School of Geology, University of Tehran, Enghelab St. Tehran, Iran, (n.alavi63@yahoo.com)
[2]School of Geology, University of Tehran,,Enghelab St. Tehran, Iran, (modabberi@ut.ac.ir)
[3]School of Mining Engineering, Technical University of Isfahan, (hooshang_asadi@yahoo.com)

"Dolly Deposit" is the first porphyry Au-Cu deposit recognized in the Urmia-Dokhtar volcanic arc of Iran with an extent of about 9 km^2 in 40 km northwest of Delijan city in Central Iran.

Mineralization in the Dolly region is associated with a set of altered porphyry Quartzdiorite stocks and dikes intruded within a fault zone of 1-2km width at the center of a stratovolcano consisting of andesite lava and pyroclastics. Intrusive and locally volcanic rocks have been altered to potassic, fillic, argilic, propylitic and silica alteration assemblages by hydrothermal solutions. It is estimated that approximately 10 percent of Dolly deposit has an oxide and 90 percent sulfide ore mineralogy.

Copper ores are composed of chalcopyrite, bornite, chalcosite and malachite.

In order to study trace element distribution around the Dolly deposit from en environmental point of view, soil and rock samples have been taken from the areas affected by mineralization.

Concentration of As, Sb and Bi show higher values than the mean standard values, i.e. 7.2-328 ppm for As, 1.7-160 ppm for Sb, and 0.5-13.9 ppm for Bi.

Calculation of enrichment factor and also geoaccumulation index indicate that the area is naturally contaminated with these elements, for some parts it is considered to be highly contaminated requiring remediation. Noting that the deposit is supposed to be extracted in the coming years it is suggested that geochemical environmental considerations should be considered in order to delineate or restrict the contamination. On the other hand, the data obtained is a valuable piece of information from forensic geochemical views against or for possible future claims.

The great volatile delivery to Earth

F. ALBAREDE[1]*, C. BALLHAUS[2], C.-T. A. LEE[3], Q-Z. YIN[4] AND J. BLICHERT-TOFT[1]

[1]Ecole Normale Supérieure de Lyon, France (*correspondence: albarede@ens-lyon.fr)
[2]Steinmann Institut, Universität Bonn, Germany
[3]Dept. of Earth Sciences, Rice University, Houston, Texas
[4]University of California, Davis, California

The $^{206}Pb/^{204}Pb$ and $^{207}Pb/^{204}Pb$ ratios of the BSE indicate that Pb has been *depleted* with respect to U at some time T_1 after the beginning of the Solar System and raises the question of where the missing unradiogenic Pb resides. The Earth's gravity field is too strong for heavy Pb vapor to escape thermally. Pb has been either lost to space upon hit-and-run impacts or buried into the core, with the effect that the U/Pb ratio of the BSE has increased over time. The present Pb composition of the BSE requires that the U/Pb fractionation *increased* at T_1 >140 Ma after the formation of the Solar System. This age postdates the oldest lunar rocks [1] and also any Pb burial into the core during the lunar Giant Lunar Impact [2]. We suggest that both the proto-Earth and the Moon were extremely depleted in volatile elements, whether siderophile or not, because accretion ended while temperature was still high.

Chondritic impactors ('late veneer') dislodged from their orbits in the outer Solar System account for the strongly siderophile inventory of the BSE [3] and also explain well the late delivery of Pb and other volatiles, notably water [4]. The issue of how the impactors' U and Pb became fractionated from each other nevertheless still is outstanding. High-velocity impacts of asteroids on the Earth lead to total melting and partial vaporization of the impactors [5]. The vapor produced by impacts eventually rains back onto the Earth upon cooling, whereas molten metal separates from silicates either as diapirs or as metal rain [6]. The siderophile content of the BSE hence is accounted for by the vaporized fraction of the veneer, while the bulk of the impactor's non-siderophile volatiles adds up to the volatile content of the Earth. Using Ballhaus *et al*.'s (this meeting) metal/silicate partition coefficients, we find that 8% volatilization of a late veneer equivalent of up to 5% of the Earth's mass with metal/liquid segregation at 1600 K reproduces well the trace element concentrations in BSE. We find that 70% of Pb and Cd, 80% of Sn, 50% of W, and 7% of Cr in BSE come from the impactors. A late veneer with a rather unremarkable mean water content of ~1% adequately accounts for the terrestrial water inventory.

Behavior of mercury in thermal sources of Kamchatka

YURY V. ALEKHIN, SERGEY A. LAPITSKY AND RENATA V. MUKHAMADIYAROVA*

Lomonosov Moscow State University, 119991 Moscow, Russian Federation (*correspondence: rinutiya@mail.ru)

For the first time for a deep-seated source of thermal waters (Kamchatka, operational holes of the Mutnovsky Geoelectric power station) are analysed compositions co-existing steam-and-gas and liquid phases and for temperatures 180 – 200 °C, the molal distribution coefficient of mercury in system a steam-liquid is defined. Results have shown, that in samples of deep-seated fluids (the borehole bottom on depth 1600) dominates the elementary mercury enriching steam-and-gas phase with the big distribution coefficient (8,17) in favour of vapour phase. Analogous results are gained on a considerable quantity of samples of other thermal sources at simultaneous selection of a liquid phase and a condensate of steam-and-gas. Results on mercury compared with distribution coefficients of other microelements.

By data in paper [2, 3] the highest content of mercury in a gas phase is fixed on an exit of Apapelsky sources 75000 ng/m^3 this result is in the contradiction with the size of a Henry's coefficient defined in paper [4] and with our data. For check and the coordination of results of these works direct measurements of mercury contents in steam-and-gas phase by the instrumentality of field atomic absorber UCM-1MC (ECON, Moscow) was realized and the thermal waters of Apapelsky sources and condensates was collected. High values of contents of mercury in condensates are in the obvious contradiction with concentration of mercury in a water phase of thermal sources and can be explained only considerable enrichment of condensates of water steam by mercury of a gas phase, i.e. its carrying over in the aerosol form.

By our results and by results described in work [1] for system of a caldera of Uzon high concentration of mercury (up to 11 ppb in Cloride Lake) not only in a steam-and-gas phase, but also in sodium chloride waters are characteristic.

Experimental research of metal mercury solubility in water

YURY V. ALEKHIN, NAIL R. ZAGRTDENOV* AND RENATA V. MUKHAMADIYAROVA

Lomonosov Moscow State University, 119991 Moscow, Russian Federation
(*correspondence: nailzag@yandex.ru)

The experimental works [3, 4] was devoted to solubility of elementary mercury in water in the range of temperatures 120-500 ^{0}C. The great number of papers [1, 2, 5] for an interval 20-120 ^{0}C is in the obvious contradiction with the reliable high-temperature data. Unusual nonlinearity of dependence lg m – 1/T for simple reaction Hg^0_{liquid} - Hg^0_{aq} forces to assume change of the dominating form in a solution in the field of low temperatures.

We had been suggested the version about complete dominance of form Hg^0_{aq} (dissolved) at high temperatures when solubility of elementary mercury is high also prevalence of the oxidized forms of mercury at the low. Position of mercury in a standard electrochemical voltage range of metals isn't an obstacle for occurrence of analytically significant concentration of the oxidized forms against the lowest solubility Hg^0_{aq} at small volatility of steams Hg^0_{liquid} in the field of low temperatures. The made experiments on solubility of mercury in an interval 20-80 ^{0}C in various oxidation-reduction conditions have confirmed our version. The good concordance of our data on solubility of mercury in reductive conditions with data [4] which extrapolated on 20-80 ^{0}C is obtained. For 20 ^{0}C linear extrapolation from area of high temperatures for Hg^0_{aq} gives quantity of solubility 1,99 ppb. We experimentally receive value 1,95 ppb. This value on two order more low, than usual total solubility in oxidizing conditions. Results of research allow to offer the simple version of temperature dependence of Hg^0 solubility and Henry's coefficients for equilibrium with liquid mercury in absence of the oxidized forms.

Effect of temperature and mineralogical composition on the reactivity of shale: A comparison study of potential caprock from two potential CO_2 storage sites

B.L. ALEMU*, P. AAGAARD AND H. HELLEVANG

Department of Geosciences, University of Oslo, P.O.Box 1047 Blindern, N-0312 Olso, Norway
(*correspondence: b.l.alemu@geo.uio.no)

Two caprock shales, one from a proposed CO_2 storage site in Longyearbyen, Svalbard, and the other from a potential CO_2 storage site off-shore Norway, close to the Troll field, were used in this study. The shale from Svalbard was cored from the De Geerdalen formation close to the town of Lonyearbyen from a depth of around ~ 800m. On the other hand the shale from Troll field was cored from Upper Jurassic Draupne Formation from a depth ~ 1000m below see floor. Both samples have different mineralogical composition which is partly influenced by their respective diagentic history. The two samples were reacted in batch reactors under different temperature and constant pressure conditions. Crushed samples from both samples were reacted with a mixture of CO_2 and brine at a temperature of 250 °C, 100 °C and a constant total pressure of 110 bars. The experiment from 250 °C lasted 35 days each while the experiment from 100 °C lasted 70 days. In addition, control reactions using brine solution without CO_2 were run for high temperature experiments to discern effect of temperature-driven reactions from CO_2-enhanced reactions.

The results indicate different reactivity for both samples. The release rate of cations was affected both due to mineralogy and experimental condition. For example, K appeared to be maximum in samples reacted with brine only whereas Ca, Fe and SiO_2 were higher in samples reacted with mixture of brine and CO_2. More Ca was released from the De Geerdalen shale as it had more carbonate. On the other hand the solution from the Draupne shale released more Mg, K, Fe and SiO_2. Dissolution of carbonates was significant on the reacted solids from both samples as evidenced by the decrease in total inorganic carbon content. Compared to high temperature reactions, lower temperature reactions dissolved more carbonates. In addition, dissolution of carbonate was much more pronounced in the Draupne shale. XRD analysis of the samples also revealed some alterations of minerals in both samples.

Origin of N isotopic anomalies in meteoritic and cometary organic matter

JÉRÔME ALÉON

CSNSM, CNRS/IN2P3/U. Paris Sud. Bat. 104, 91405 Orsay Campus, France. (Jerome.Aleon@csnsm.in2p3.fr)

Organic molecules in meteorites and comets display a large range of nitrogen isotopic variations of unclear origin. It is widely assumed that ^{15}N excesses trace an interstellar-like chemistry in a cold dense medium, mostly by analogy with deuterium chemistry [e.g. 1]. However, chemical models face difficulties in achieving the level of ^{15}N enrichment relative to the ambient interstellar/protosolar gas observed in meteorites and the relationship between ^{15}N and D excesses remains osbcure [2,3]. Here I present isotopic fractionation calculations coupled with mixing calculations aiming at reproducing the observed distribution of ^{15}N and D excesses in acid insoluble organic matter from carbonaceous and ordinary chondrites, in subgrains nicknamed hotspots and nanoglobules, as well as in interplanetary dust particles, samples from comet Wild 2 returned by the Stardust mission and in HCN from comet Hale-Bopp. I show that the N-H isotopic compositions in these samples can be explained by a mixture of three components : (1) a late isotopic exchange with a ^{15}N-D-rich gas produced by ion-molecule reactions, possibly in the solar protoplanetary disk (PPD), (2) a D-poor, ^{15}N-rich component best preserved in the Isheyevo chondrite of abundance anti-correlated with meteoritic age, indicating a late origin in the solar PPD and (3) a minor D-rich ^{15}N-poor component of likely presolar origin, best preserved in ordinary chondrites. The anti-correlation between ^{15}N excesses and meteoritic age extends to bulk isotopic composition and differentiated objects suggesting a general trend of increasing $^{15}N/^{14}N$ ratio in organic molecules as the solar PPD ages and clears.

Uranium contamination in the subsurface is an enduring problem throughout Europe and North America. Current strategies for the remediation of uranium aim at transforming the soluble and mobile oxidized form of uranium, U(VI), to the reduced and relatively immobile form, U(IV). Until recently, reduction of U(VI) to U(IV) was assumed to produce solely the sparingly soluble mineral uraninite, $UO_{2(s)}$. However, recent research reveals that other species of U(IV), referred to here as 'monomeric U(IV),' can form as the product of microbial U(VI) reduction. Because monomeric U(IV) lacks the crystalline structure of uraninite, it is likely to be more labile and susceptible to reoxidation. For this reason, geochemical models that assume $UO_{2(s)}$ as the sole product of U(VI) reduction may not capture the true system behavior.

Here we use infrared spectroscopy (IR), uranium L_{III}-edge X-ray absorption spectroscopy (XAS), and phosphorus K-edge XAS analyses to determine the binding environment of monomeric U(IV) associated with *Shewanella oneidensis* MR-1 bacterial cells. Several systems were tested as a function of pH, including: cells without uranium, cells with adsorbed U(VI), cells that produced monomeric U(IV) and cells that produced uraninite as a product of U(VI) reduction. Uranium XAS analyses confirmed the reduction of U(VI) to U(IV) in U(IV)-containing systems, and the presence of either monomeric U(IV) or $UO_{2(s)}$ was confirmed by extended X-ray absorption fine structure (EXAFS). IR analyses revealed a strong coordination of U(IV) with phosphate groups in the monomeric U(IV) systems -coordination not seen in the other systems. The P EXAFS results provide further evidence of U(IV)-phosphate coordination in monomeric U(IV) when compared to an abiotic U(IV)-phosphate reference. The results of this study provide valuable insights into the binding environment of the monomeric U(IV) species associated with microbial biomass and reaffirm the conjecture that phosphate coordination is critical in the formation of the species.

Insights into biogenic secondary organic aerosols produced from five structurally different precursors

M.R. ALFARRA[1,2]*, N. GOOD[2], J.F. HAMILTON[3], K.P. WYCHE[4], P. MONKS[4], A. LEWIS[3] AND G.B. MCFIGGANS[2]

[1]National Centre for Atmospheric Science (NCAS), The University of Manchester, Manchester, M13 9PL, UK (*rami.alfarra@manchester.ac.uk)
[2]The University of Manchester, Manchester, M13 9PL, UK,
[3]University of York, York, YO10 5DD, UK
[4] University of Leicester, Leicester, LE1 7RH, UK

A series of novel experiments were carried out at the Manchester Aerosol Chamber in order to investigate the chemistry and microphysics of the formation and transformation of biogenic secondary aerosols. A selection of compounds covering a wide range of reactivity including monoterpenes, sesquiterpenes and oxygenated VOCs has been studied in detail. The chemical composition of the formed SOA was measured on-line using an Aerodyne Time-of-Flight Aerosol Mass Spectrometer (cToF-AMS). A hygroscopicity tandem differential mobility analyser (HTDMA) and a cloud condensation nuclei (CCN) counter were used to probe the hygroscopic properties and of the aerosols in the sub- and super-saturated regimes, respectively. A proton transfer mass spectrometer was used to study the evolution of the gas phase oxidation products.

We presents an overview and synthesis of results covering the chemical composition, hygroscopicity and cloud condensation nuclei (CCN) properties of secondary organic aerosols formed from five structurally different biogenic VOCs (β-caryophyllene, limonene, myrcene, linalool, α-pinene). The effect of the use of organic [1] and inorganic seed on the limonene SOA will be presented. Results showed that the formed SOA have a wide range of chemical properties, and that the effect of photochemical ageing on their properties was not uniform across all five precursors. A link of these results to the corresponding findings of the hygroscopic properties of the SOA particles and their CCN behaviour will be presented and discussed.

Release rate of pollutants, nutrients and protons from pristine Eyjafjallajökull ash

H.A. ALFREDSSON[1], S.R. GISLASON[1], S.L.S. STIPP[2] AND K.W. BURTON[3]

[1]Institute of Earth Sciences, University of Iceland, Reykjavík, Iceland (haa4@hi.is)
[2]Nano-Science Centre, Department of Chemistry, University of Copenhagen, Denmark
[3]Department of Earth Sciences, University of Oxford, South Parks Road, Oxford, UK

On 14 April 2010, when magma from the Eyjafjallajökull volcano intruded glacier-meltwater, an explosive phreato-magmatic eruption sent unusually fine-grained ash into the jet stream and flood waters all the way to the ocean. Later, when meltwater did not have access to the magma, the eruption produced a larger grained magmatic ash. We were able to sample dry ash, from both these eruption phases. Both ashes were coated with salts during the eruption, and the surface area of the phreato-magmatic ash was an order of magnitude larger than the one of the magmatic ash [1]. Single pass plug flow experiments were carried out at 22 °C using DI-water and North Atlantic seawater. The outlet was connected directly to an ion chromatograph to determine release rate of anions with time without exposure to the atmosphere. The rest of the dissolved elements were measured by various ICP methods.

Magmatic ash released protons, resulting in initial pH drop in the DI-water to 3.2, and initial proton release of $10^{-6.5}$ moles/m^2/s. The surface of phreato-magmatic ash, however consumed protons, a minimum of -$10^{-7.8}$ moles/m^2/s, resulting in an initial pH of 10.3. Initial release rates, normalized to the BET-surface area, were 2-4 orders of magnitude faster than bulk dissolution rate of volcanic glasses and olivine. The rates dropped by orders of magnitude over a few hours. Surface area normalized rates from the magmatic ash was in general faster than the phreato-magmatic rates, and it is only the magmatic ash that releases Fe and Al at elevated rates, $10^{-6.6}$ and $10^{-6.4}$ moles/m^2/s, respectively. These experiments show fundamental difference in the potential environmental impact of volcanic ash of the same bulk composition, but produced by different eruption mechanism. Acid producing gases and salts dissolve in meltwaters and are transported to the ocean via flood waters. Furthermore, phreato-magmatic ash will not fertilize surface waters with water soluble iron, like the magmatic ash.

Magmatic variety through tectonic modulation of the 27 ka Oruanui eruption, Taupo, New Zealand

A.S.R. ALLAN[1]*, C.J.N. WILSON[1], M.-A. MILLET[1] AND R.J. WYSOCZANSKI[2]

[1]SGEES, Victoria of Wellington, PO Box 600, Wellington 6140, New Zealand (*aidan.allan@vuw.ac.nz)
[2]NIWA, Private Bag 14901, Wellington, New Zealand.

Deposits of the earliest three phases (of 10) in the 530 km^3 magma, 27 ka Oruanui eruption reflect shifting vent positions and accompanying variations in compositional diversity [1, 2]. New data reveal close connections between changing vent positions and magma chemistries, involving a tectonic modulation of the eruption dynamics, thus.

1) Start of phase 1 of the eruption. Through all of the phase 1 deposits, pumice clasts from a crystal richer, biotite-bearing rhyolite magma are found that encountered the main (biotite-free) Oruanui magma in the conduit. Biotite-bearing pumices occur at 2-4% abundance, increasing to 16-17% in the uppermost phase 1 deposits. Thermobarometric constraints in combination with glass chemistry and *in situ* trace element fingerprinting of amphibole and plagioclase source this magma to an adjacent system which erupted at ~28 ka from vents ~15 km northeast of the Oruanui phase 1 vent area. This adjacent system operated entirely independent of the Oruanui magmatic system for >20 kyr prior to the 27 ka eruption and no connection was previously inferred. Lateral transport of the biotite magma is indicated, implying that a rifting event accompanied/controlled the start of the Oruanui eruption.

2) Shutdown of the phase 1 vent. After <0.1% of the Oruanui magma volume had been discharged, activity ceased for several weeks to months, despite the underlying presence of ~530 km^3 of gas-saturated rhyolite magma.

3) Renewal of explosive activity (phase 2) from the same vent site, with a renewed influx of biotite-bearing rhyolite from the adjacent independent magma system, indicating that another rifting event and dike emplacement occurred.

4) Rifting-related unzipping of new vents aligned down the E side of modern Lake Taupo in phase 3, coincident with the first appearances of high-silica (roof cupola) rhyolite and low-silica rhyolite dredged from the magma chamber roots, a spike in the abundance of juvenile mafic material and a marked increase in the tempo of the eruption.

Nd isotopes vs magnetic susceptibility as a double proxy for paleoclimate and paleoweathering: The Kerguelen Case

C.J. ALLEGRE[1], L. MEYNADIER[1] AND D.V. KENT[2]

[1]IPGP (Sorbonne Paris Cité, Université Paris Diderot, UMR7154 CNRS), 1 rue Jussieu, 75238 Paris Cedex 05, France (allegre@ipgp.fr, meynadier@ipgp.fr)
[2]Rutgers University, Department of Earth and Planetary Sciences, 610 Taylor Road, Piscataway, NJ 008854-8066 U.S.A. (dvk@rci.rutgers.edu)

In a seminal paper, Kent (1982) has shown that the magnetic susceptibility (MS) measured in a sediment core near the Kerguelen Island, fluctuated coherently with $\partial^{18}0$. Those variations translate the climatic change between glacial and interglacial periods. Since MS variations also fluctuate with $CaCO_3$ content (high carbonate correlates with low MS), Kent interpreted the MS variations as a dilution effect induced by $CaCO_3$. However, when we corrected MS from carbonate dilution, the fluctuations persisted and still correlated with $\partial^{18}0$. Thus, if indeed the carbonate dilution plays a role, it is not the ultimate reason for the climatic variation of MS.

We also measured both the Nd isotopic composition (ε_{Nd}) of ancient seawater and of the detrital fraction of the sediment, which is related to the local erosion. Interestingly, in this region, ε_{Nd} of ancient seawater varies with climate in coherence with MS and $\partial^{18}0$, whereas very small variations are seen on the detrital ε_{Nd}. This difference will be discussed in detail.

We will show that oceanic currents were much more active during Interglacials than Glacials and that in the region mechanical erosion and chemical erosions were also more active during Interglacials.

To evaluate continental crustal growth through time we have compiled an isotope data base for ~1400 zircons from Australian sand dunes and the world's major rivers. The data base comprises zircons that show no age zoning as shown by drilling 25 microns into zircons mounted on tape by LA-Q-ICP-MS. These selected dated zircons are mounted in epoxy and polished, cathodoluminescence imaged, analysed for oxygen isotopes using SHRIMP and analysed for Lu-Hf isotopes using LA-MC-ICP-MS. The premise behind this work is that zircon Hf model ages date the formation of continental crust. Primitive continental crust melts to form granitoid magmas from which the zircons crystallize and we can calculate this "incubation time". The Hf model ages have two major sources of uncertainty: 1. the growth curve for $^{176}Hf/^{177}Hf$ for the depleted mantle, 2. the $^{176}Lu/^{177}Hf$ used in the model age calculation. Using only those zircons with $\delta^{18}O$ of that of the mantle (5.3±1‰) reduces the uncertainty in the $^{176}Lu/^{177}Hf$ used in the calculation principally by excluding those grains that have a mixed supracrustal component indicated by $\delta^{18}O > 6.3‰$. We define juvenile zircons as those grains with incubation times <250 Ma and they are rare leading us to important model refinements and re-evaluation of when major additions to the continental crust occurred. Our data indicate that the major crustal growth periods were 3.4-2.9 Ga, 2.2-1.8 Ga, and 1.0-0.6 Ga.

Volatile solubility in phonolites from Erebus volcano: Towards a multi-component degassing model

M. ALLETTI*, A. BURGISSER, B. SCAILLET AND C. OPPENHEIMER

ISTO/CNRS, 45000, Orléans, France (*correspondence: marina.alletti@cnrs-orleans.fr, burgisse@cnrs-orleans.fr, bruno.scaillet@cnrs-orleans.fr, co200@cam.ac.uk)

The interpretation of the chemistry of volcanic gas emissions demands a firm understanding of the deep processes that control partition of volatile species between melt and gas. Volatile solubility in silicate melts is greatly affected, among other factors, by the composition of magma. Erebus volcano (Antarctica) hosts one of the few persistent active lava lakes on Earth, and the only one of anorthoclase-phonolite composition. Despite its remoteness, the lake is closely studied and its gas emissions measured during the austral summer field season using infrared spectroscopic methods. Melt inclusions (MI) in anorthoclase and pyroxene crystals have H_2O concentrations similar to or lower than those of halogens (i.e. Cl and F), indicating extensive degassing. The first studies [1] attempting to link MI data to gas composition used degassing models that neglected the multi-component fluid phase, and which did not account for experimentally-determined solubilities for Na-phonolitic melts.

In order to model the degassing path at Erebus in *f-X* space, we performed experiments of (i) H_2O solubility and (ii) partitioning of Cl between a hydrous fluid phase and the melt (expressed as $D^{fl/melt}_{Cl}$). The starting material was anorthoclase phonolitic lava from Erebus (ERE 13-29 Dec 05). Experiments were carried out in the pressure range of 250-10 MPa and at a temperature of 1000 °C. Our results for H_2O solubility are in good agreement with previous studies on similar melt composition [2] and can be interpolated by the following law:

$$H_2O\ (wt\%) = 0.182 * f_{H2O}\ (MPa)^{0.677}$$

Our results for Cl partitioning indicate a more complex behavior. We found that $D^{fl/melt}_{Cl}$ varies between 6.0 and 1.7 from 250 to 100 MPa, and increases again from 50 MPa up 10.2 at 10 MPa. This variable trend with ascent supports the idea proposed by Shinohara [3] of a heterogeneous chloride system with respect to decompression, with NaCl stable at high pressure and HCl stable from 100-50 MPa and to lower pressures still. Separating our experimental data into low and high pressure ranges, we propose a fugacity-based model of equilibrium degassing for Cl [4] and discuss our preliminary results.

High temporal resolution $\delta^{18}O$ and $\delta^{13}C$ heterogeneity in a *Porites lobata* coral skeleton

N. ALLISON[1], A.A. FINCH[1]* AND EIMF[2]

[1]Department of Earth Sciences, University of St. Andrews, Fife KY16 9AL, UK (*correspondence: aaf1@st-and.ac.uk)
[2]NERC Ion Microprobe Facility, University of Edinburgh, Edinburgh EH9 3JW, UK

$\delta^{18}O$ and $\delta^{13}C$ were determined at high spatial resolution (beam diameter ~ 30μm) by secondary ion mass spectrometry (SIMS) across ~1 year of a modern *Porites lobata* coral skeleton from Hawaii. All analyses were made on coral fasciculi (which make up the bulk of the skeleton) and not centres of calcification. Our data indicate that skeletal $\delta^{18}O$ and $\delta^{13}C$ are dominated by weekly-monthly oscillations (of >2‰ and >5‰ respectively) which far exceed the annual seasonal signal. These variations do not reflect seawater temperature or composition.

The dissolved inorganic carbon (DIC) pool available for calcification is derived from seawater or from molecular CO_2, which can diffuse from the coral tissue into the calcification site. Variations in the $\delta^{18}O$ of the DIC pool may reflect the source of DIC (seawater or molecular CO_2), calcification site pH (affecting the proportions of DIC formed via hydration and hydroxylation of molecular CO_2 and the proportion of HCO_3^- derived from seawater DIC that is converted to CO_3^{2-}) and DIC residence time at the calcification site (influencing the extent to which oxygen isotopic equilibrium with the surrounding water is obtained). DIC pool $\delta^{13}C$ is also affected by DIC source and calcification site pH (affecting DIC speciation). However carbon isotopic equilibrium at the calcification site is reached in < 20s, before any significant uncatalysed oxygen isotopic equilibration has occurred. The $\delta^{13}C$ of the molecular CO_2 component of the DIC pool is affected by the balance of photosynthesis and respiration and the amounts, types and $\delta^{13}C$ of material respired in the coral tissues.

We do not observe significant correlations between skeletal $\delta^{18}O$ and $\delta^{13}C$ in either the original or detrended datasets. Furthermore, neither $\delta^{18}O$ or $\delta^{13}C$ correlates with calcification site pH, estimated from previous SIMS measurements of skeletal $\delta^{11}B$. Our data suggest that the $\delta^{18}O$ and $\delta^{13}C$ composition of the DIC pool is affected by multiple independent influences at this time scale.

Highly depleted melt inclusions in olivine from Shatsky Rise

R.ALMEEV[1]*, M. PORTNYAGIN[2], T. WENGORSCH[1], T. SANO[3], J.H. NATLAND[4] AND D. GARBE-SCHÖNBERG[5]

[1]Institut of Mineralogy, Leibniz University of Hannover, Germany, (r.almeev@mineralogie.uni-hannover.de)

[4]Rosenstiel School of Marine and Atmospheric Science University of Miami, USA
[5]Institute of Earth Sciences, Kiel University, Germany

Shatsky Rise east of Japan is a unique oceanic plateau with characteristics of both “plume head” and non-plume origin [1-3] which was cored during IODP Expedition 324 in 2009. Igneous rocks sampled at four sites are variably altered pillows and massive lava flows of olivine phyric and plagioclase-clinopyroxene microphyric basalts. On-board geochemical data [4] show that the basalts are broadly MORB-like, similar to those from the Ontong Java Plateau (OJP) and likely originating from a slightly enriched MORB-like source.

We report here the first results of geochemical study of olivine-hosted melt inclusions from moderately altered olivine-phyric basalts cored at the Site U1349 (Ori massif, Sample 324U1349-12R4/37-39). Melt inclusions and olivines were analyzed for major elements by electron microprobe and for trace elements by LA-ICPMS. Olivine phenocrysts range in composition from Fo81 to Fo87 (NiO up to 0.4 wt%) and contain small glassy (<20 μm in size) and relatively large partly crystallized (30-60 μm) inclusions. Before analyses, partly crystallized inclusions were homogenized in internally heated pressure vessel at 200 MPa and 1210 °C and 1280 °C and subsequently quenched after 5 and 20 minutes, respectively. Melt inclusions obtained after both heating treatments and corrected for post-entrapment re-equilibration with host olivine have primitive, broadly MORB-like compositions and highly depleted trace element patterns compared to NMORB and the Kroenke-type basalts (OJP) with respect to Ba, Th, Nb, Ta, LREE, Sr, Zr and Hf (e.g., La_N/Yb_N = 0.2-0.4 in inclusions vs. ~0.7 in NMORB). The presence of highly depleted melts trapped in olivine suggests strong geochemical heterogeneity of the Shatsky Rise mantle sources ranged from less to significantly more depleted than average DMM.

Recent cessation of Nile discharge affecting the geochemistry of SE Mediterranean inner shelf sediments

A. ALMOGI-LABIN[1]*, A. SANDLER[1] AND B. HERUT[2]

[1]Geological Survey of Israel, 30 Malkhe Israel, Jerusalem 95501, Israel (*correspondence: almogi@gsi.gov.il)
[2]Israel Oceanographic & Limnolological Research, Tel Shikmona, Haifa 31080, Israel

Climatic-control variations of Nile River discharge to the SE Mediterranean were suggested to play a major role in changing the geochemical characteristics of deep water sediments [1]. During the last century a series of dams were built on the Nile and since the operation of the Aswan High Dam (AHD), in the mid 60th of the last century, late summer floods carrying fine sediments and nutrients stopped entering the Mediterranean. This affected directly the 30 to 50 m silt belt off the Israeli coast, an integral part of the Nile littoral cell. Grain-size, major and trace elements and Sr isotopes were used for assessing the effect of the shut down of Nile discharge on a series of short cores taken along a S-N transect at ~40 m water depth. Chronology was based on ^{210}Pb dating. Grain size sharply increased since the operation of the AHD together with a two fold increase in $CaCO_3$ content accompanied by a distinct increase in Ba/Al ratio. TOC content decreased from ~1.0 wt.% to less than 0.3 wt.% at core tops and δ^{13}Corg decreased by ~3.5‰ (from -19.5 to -23‰) reflecting apparently a distinct drop in nutrient input and major reduction in primary productivity. ^{87}Sr/^{86}Sr value, around 0.7065, determined in the <63μm size fraction of the insoluble material, indicate mainly a basaltic lithological source originating apparently from the Ethiopian highlands and transported by the Blue Nile and Atbara via the Nile River towards the Mediterranean.

The sediments of the Israeli inner shelf, located distally within the Nile littoral cell, responded directly and rapidly to Nile River discharge cessation. This may indicate that distal inner shelf parts of large deltaic systems document faithfully extreme aridity episodes that might occur at the headwaters of large river systems, including that of the Nile River.

The FeS/H_2S system - A model for a primitive DMSO reductase

T. ALPERMANN[1,2], Z. QI[1], W. POPPITZ[1] AND W. WEIGAND[1]*

[1]Institute for Inorganic and Analytical Chemistry, FSU Jena, August-Bebel-Str.2, 07743 Jena, Germany (*correspondence: wolfgang.weigand@uni-jena.de);
[2]now at: Federal Institute for Geosciences and Natural Resources, Stilleweg 2, 30655 Hannover, Germany (Theodor.Alpermann@bgr.de)

Within the Iron-Sulfur-World hypothesis, the development of an autotrophic surface metabolism based on the reduction of CO_2 and catalytic action at iron sulphide surfaces is proposed. The required redox energy for the metabolic reaction pathways is provided by the thermodynamically favoured but kinetically inhibited reaction

$FeS + H_2S \rightarrow FeS_2 + H_2$ ($\Delta_R G°$= -38 kJ/mol, pH 6.5) [1].

The reducing power accompanied by catalytic activity of the FeS/H_2S system could be demonstrated in several studies, e.g. dinitrogen N_2 could be reduced to NH_3 [2]. Another intriguing model compound for the investigation of the reducing power of the FeS/H_2S system is DMSO. In nature, the reduction of DMSO by the enzyme *DMSO reductase* in marine phytoplankton is relevant to the global climate due to the release of major amounts of DMS into the oceanic atmosphere. There, DMS acts as an important source of cloud condensation nuclei.

Our study aimed at investigating the capability of the FeS/H_2S system to reduce dimethyl sulfoxide (DMSO) to dimethyl sulphide (DMS) under geologically mild conditions (1 bar, 90°C). Experiments were carried out under strictly anaerobic conditions in glass vessels and the amount of produced DMS was quantified *via* gas chromatography. The FeS/H_2S system indeed reduces equimolar amounts of DMSO selectively to DMS with yields of up to 60% within seven days. Hence, the FeS/H_2S system can be regarded as a model of a primordial *DMSO reductase* supporting the idea of its relevance for the origin of a first metabolism.

Numerical simulation of alteration patterns induced by sequestration of CO_2 in a carbonate-hosted saline aquifer

P. ALT-EPPING AND L.W. DIAMOND

Institute of Geological Sciences, RWI-Group, University of Bern, Baltzerstrasse 3, CH-3012 Bern, Switzerland, (alt-epping@geo.unibe.ch)

We run reactive transport simulations to understand the transient chemical processes that occur in a carbonate-dominated aquifer during and after the injection of CO_2. The model, its design and its initial and bounding physico-chemical conditions, are patterned after the Upper Muschelkalk-Gipskeuper aquifer-seal pair in the Molasse Basin in Northern Switzerland. Chemical processes are controlled by the dynamics of the CO_2 plume. Supercritical CO_2 is more buoyant than the brine. Consequently, the CO_2 plume tends to rise and spread laterally when it encounters the overlying Gipskeuper seal. Over time $CO_{2,sc}$ dissolves into the brine, causing the density of the brine to increase. The denser brine tends to sink, initiating density driven convection. Depending on the permeability of the aquifer, sinking of the CO_2-enriched brine may occur in a complex finger-like pattern. The dissolution of CO_2 into the brine entails a lowering of the *pH* and hence the dissolution of the primary carbonate mineralogy. Because the brine remains buffered at local equilibrium with the carbonates, the dynamics of the CO_2 plume and the CO_2-enriched brine is reflected by the mineral alteration pattern. Although the drop in *pH* is associated with carbonate dissolution, the *pH* recovers in certain regions of the aquifer faster than in others, thus leading to a complex pattern of carbonate dissolution and reprecipitation. This evolving pattern of carbonate dissolution/reprecipitation implies that chemical constituents that are initially incorporated in or that coexist with primary carbonate minerals may be released into the fluid, then later removed from the fluid by reprecipitation when conditions have changed. Our simulations allow us to assess the release of solid constitutents from the primary mineralogy into the brine as CO_2 injection procedes.

The increase in reservoir pressure during injection, the dynamics of the CO_2 plume and the perturbation of chemical conditions in the reservoir will initiate mass transfer across the aquifer-seal interface and initiate chemical reactions on either side of the interface. We explore the extent of species mobilization and transfer across the reservoir/seal interface, identify the type of reactions that occur as well as their implications for the tightness of the caprock.

Sensitivity to deliberate seeding of marine clouds – Observations and modeling

K. ALTERSKJÆR AND J.E. KRISTJÁNSSON*

Department of Geosciences, University of Oslo, Norway (*correspondence: jegill@geo.uio.no)

Sea salt seeding of marine clouds to increase their albedo is a proposed technique to counteract or slow global warming [1]. In this study, we first investigate the susceptibility of marine clouds to sea salt injections, using observational data of cloud droplet number concentration (CDNC), cloud optical depth, and liquid cloud fraction from the MODIS (Moderate Resolution Imaging Spectroradiometer) instruments on board the Aqua and Terra satellites. We then compare the derived susceptibility function to a corresponding estimate from the Norwegian Earth System Model (NorESM). Results compare well between simulations and observations, showing that stratocumulus regions off the west coast of the major continents along with large regions in the Pacific and the Indian oceans are sensitive.

We then carry out sensitivity experiments with a uniform increase of 10^{-9} kg m^{-2} s^{-1} of 0.13 μm radius sea salt over ocean, in alignment with earlier studies [2]. The increased sea salt concentrations and the resulting change in marine cloud properties lead to a globally averaged forcing of -5.9 Wm^{-2} at the top of the atmosphere, more than cancelling a doubling of CO_2. The forcing is large in areas found to be sensitive by using the susceptibility function, confirming its usefulness as an indicator of where to inject sea salt. When the same sea salt mass is injected in the form of much smaller sea salt particles of 0.022 μm radius, a quite different result is found. These particles are too small to activate as CCN, but they provide a large surface area for sulphuric acid gas to condense on, thereby greatly suppressing the formation of sulphate particles. Therefore the overall CCN concentration is reduced, and the globally averaged forcing is positive.

Abiotic synthesis of methane from biomolecules under ambient conditions

FREDERIK ALTHOFF[1] AND FRANK KEPPLER[2]

[1]Max-Planck-Institute for Chemistry, Joh.-Joachim-Becher-Weg 27, 55128 Mainz; (Frederik.althoff@mpic.de)
[2]Max-Planck-Institute for Chemistry, Joh.-Joachim-Becher-Weg 27, 55128 Mainz; (frank.keppler@mpic.de)

The formation of methane can be classified in biotic and abiotic reactions. While biotic methanogenesis is related to anaerobic microorganisms, abiotic methane formation requires high pressure and/or temperature. Such conditions can be found for instance during biomass burning or serpentinisation of olivine, under hydrothermal conditions in the deep ocean or below tectonic plates [1].

The bio available substances ascorbic acid, iron and hydrogen peroxide were used in aqueous solution to perform an abiotic methane formation under ambient conditions [2]. In a further step to this reaction other important biomolecules were added which are known from methylation reaction in biosystems, e.g. methionine, or expose a possible methane precursor methyl groups, such as choline or leucine.

Furthermore, the reaction was carried out using different iron species, such as Fe^{2+}, Fe^{3+}, ferrihydrite and other iron hydroxides.

Methionine was found to produce the highest amount of methane. Stable isotope analysis in combination with ^{13}C labelling of methionine confirmed the assumption of sulphur bond methyl group as methane precursor. Moreover, a linear increase of the generated methane with the amount of added methionine could be found.

The investigation of the iron species basically showed a conversion to methane, however, methane formation is significantly higher using iron minerals in comparison to free Fe ions. By analysing the remaining products within the solution a reaction scheme was created.

The results of these experiments show the possibility of an abiotic aerobe methane formation using biomolecules under ambient conditions.

The correlation between iodide sorption capacity and microbial enzyme activity in soils

S. AMACHI[1]* AND Y. MURAMATSU[2]

[1]Chiba Univ., 648 Matsudo, Matsudo-shi, Chiba 271-8510, Japan (*corespondence: amachi@faculty.chiba-u.jp)
[2]Gakushuin Univ. Mejiro 1-5-1, Toshima-ku, Tokyo 171-8588, Japan (yasuyuki.muramatsu@gakushuin.ac.jp)

Iodide (I^-) sorption on soils is strongly inhibited by autoclaving, reducing agents, common enzyme inhibitors (NaN_3 and KCN), and anaerobic incubation of soils. These suggest that the sorption of iodide is influenced by the soil redox potentials, and that microbial oxidation of iodide might play a role in the process. Recently, we found that bacterial iodide-oxidizing enzyme is a laccase-like enzyme, since it oxidized not only iodide but also phenolic compounds such as ABTS, syringaldazine and 2,6-dimethoxy phenol. Laccases are copper-containing enzymes that are secreted into soils by soil fungi and bacteria.

To understand possible participation of microbial enzymes in iodide sorption, we examined the correlation of iodide sorption rate with laccase activity in several soils. Laccase activity was assayed colorimetrically with ABTS as a substrate. As have been observed in iodide sorption, laccase activity in soils was also inhibited by autoclaving, reducing agents, enzyme inhibitors, and anaerobic incubation. The calculated iodide sorption rate [$(1-C/C_0)$/h/g dry soils]and laccase activity (Unit/g dry soils) showed significant positive correlation. Furthermore, addition of bacterial iodide-oxidizing enzyme to autoclaved soil allowed it to adsorb iodide again. From these results, it is possible that iodide in soils is oxidized by laccase (or laccase-like enzyme) to I_2 or HIO, and that these oxidized iodine species are incorporated into soil organic matters.

[3]LPTL, CNRS-Université de Paris 6, 4 place Jussieu, 75005 Paris

Understanding Earth degassing is fundamental in global studies of our planet history, as well as in studies of its recent climate. Degassing occurs mainly at Mean Ocean Ridges via exsolution of CO2 vesicles in ascending tholeiite magma, and probably begins at some 30 km under the ridge. Therefore, a precise knowledge of how carbon solubility varies during ascent from the source region is mandatory, a process for which the effect of pressure remains poorly known. A pressure increase induces melt compression, known to diminish argon dissolution with respect to Henry's law at pressures above ~10 kbar, but this effect is poorly documented for carbon where things are complicated by the transformation of CO_2 into carbonate ion, CO_3^{2-}. Early experimental investigations on carbon solubility in various silicate melts up to ~20-30kbar have shown that Henry's law is not followed at high pressures.

We have performed an experimental study of C dissolution in basaltic melts using high-pressure facility in Clermont-Ferrand (France). Analysis of dissolved C was performed using a micro-Raman spectroscopy. Dissolved carbon appears as clear bands due to carbonate ions (an intense peak at ~ 1100 cm^{-1} and a doublet in the 1350-1600 cm^{-1} region), molecular CO_2 being not detectable. Calibration of Raman spectroscopy for quantitative analysis was done by preparing standards at atmospheric pressure and analyzing them using a stable isotope mass spectrometer. The results show that carbon concentration increases steadily with increasing pressure, a behavior consistent with (rare) previous studies on basaltic melts. We also have performed molecular dynamics simulations to investigate the dissolution of CO_2 in a silicate melt. The calculated solubility is consistent with the data, which help understanding how pressure acts on fluid and melt, and yield insight into the details of how CO_2 and CO_3^{2-} interact with the melt network. However, the fact that the carbon solubility in a MORB is continuously increasing with pressure is somewhat surprising, and will be discussed.

This work has shown that

- Raman spectroscopy can be used to quantify C content in natural samples
- The C solubility measured in basaltic melt exhibits a behavior with pressure different from that exhibited by rare gases.
- Our results have important implications concerning the history of the atmosphere degassing and structure of the mantle.

Microbial community structures in shallow-sea, deep-sea, and terrestrial hydrothermal systems

JAN P. AMEND[1], D'ARCY R. MEYER-DOMBARD[2] AND MATT SCHRENK[3]

[1]Washingon University in St. Louis, (amend@wustl.edu)
[2]University of Illinois at Chicago, (drmd@uic.edu)
[3]East Carolina University, (schrenkm@ecu.edu)

The shallow-sea vent fluids and beach sediments at Vulcano Island (Italy) have yielded more culturable hyperthermophiles than any other hydrothermal system—marine or terrestrial. A seemingly insignificant hot spring in Yellowstone National Park (USA) was touted as harboring "remarkable" archaeal and bacterial diversity [1,2]. But how similar are the microbial community structures between sites? And can we quantitatively link the variability between sites to geographical isolation or geochemical parameters such as pH; temperature; pressure; salinity; or oxygen, sulfide, hydrogen, and organic carbon concentrations. In addition, do shallow-sea, deep-sea, and terrestrial hydrothermal systems share a significant number of taxa? And how do the microbial community compositions in these three fundamentally different types of high temperature ecosystems correlate with a wide range of geographical and geochemical parameters?

Our preliminary data analysis of ~1200 archaeal 16S rRNA gene sequences (assigned to ~300 operational taxonomic units (OTUs) with >90% similarity) from 5 terrestrial, 6 shallow-sea, and 17 deep-sea hydrothermal systems shows that ~85% of the OTUs are unique to one of the three types of hydrothermal systems. Only 2% are shared between 'terrestrial' and 'deep-sea' and between 'terrestrial' and 'shallow-sea'; 11% are shared between 'deep-sea' and shallow-sea'. Only 1 OTU (or 0.3%) of those investigated was found in all three types of systems—this was a sequence related to the Thermoproteales, an order of obligately or facultatively anaerobic hyperthermophiles known for carrying out sulfur respiration both chemolithotrophically (with H_2) or heterotrophically. A dendogram of sequences binned by sample showed a clear clustering of the terrestrial, the shallow-sea, and the deep-sea systems. Within the deep-sea systems, the samples from sediments, chimneys, vent fluids, and in situ colonization systems clustered separately. We hypothesize that multivariate analyses of geochemical and microbiological datasets can be used to identify major geobiological patterns and putative environmental causes.

Ferrous iron diffusion in ferro-periclase across the spin transition – A DFT study

M. W. AMMANN*, J. P. BRODHOLT AND D. P. DOBSON

Earth Sciences, University College London, Gower Street, London, WC1E 6BT, UK
(*correspondence: m.ammann@ucl.ac.uk)

Diffusion is believed to control the viscosity of lower mantle minerals. While diffusion-experiments are limited to conditions of the shallow lower mantle, *ab initio* methods allow us to calculate absolute diffusion rates at any pressure and temperature [1,2]. The effect of the spin-transition in ferro-periclase on rheology is currently unknown.

We here present results of density-functional-theory calculations on absolute diffusion rates of high- and low-spin ferrous iron in ferro-periclase. The diffusivity of high- and low-spin iron depends on the physical conditions (pressure and temperature), iron concentration and the value of the chosen Hubbard U. We find that low-spin iron swaps back to high-spin during migration, such that the difference between high- and low-spin migration enthalpies only depends on the energy-difference of the ground-states.

We compared our absolute diffusion rates with experimental data of magnesium-iron interdiffusion in ferro-periclase at temperatures between 1873 K and 2273 K and at pressures ranging from 7 GPa to 35 GPa. All our diffusion rates are in excellent agreement with all the available experimental data.

Our results show that throughout the Earth's lower mantle, iron diffuses at a similar rate as magnesium. Thus, the spin transition of ferrous iron has no significant impact on the rheology of ferro-periclase in the Earth's lower mantle, and ferro-periclase remains much weaker than perovskite throughout. We conclude, therefore, that ferro-periclase can only control the viscosity of the mantle in regions where it becomes interconnected, such as areas of high strain around slabs or near plumes. At much higher pressures, such as in Super-Earths, low-spin iron diffusion is expected to become much slower than magnesium, making ferro-periclase more viscous than pure periclase.

We have developed a method for extracting and separating chromium (Cr) from a seawater matrix for isotope analysis using TIMS. We investigated a variety of ion exchange resins and co-precipitators to determine the optimal extraction method. Reported abundances of total Cr in seawater range from ~70 – 500ng/kg, depending upon seawater oxicity, water depth and proximity to continental land masses. A 500ml sample size permits ~10 duplicate analyses on TIMS which requires a minimum of 10ng of Cr. The reagent blanks are <2ng Cr and yields are high. Cr has four naturally occurring stable isotopes and therefore lends itself to double spiking for improved precision. We use a well constrained and optimized double spike of ^{50}Cr and ^{54}Cr [1].

Data will be presented on the distribution of Cr in major ocean basins, and the extent of isotope fractionation will be compared in oxic/anoxic waters, deep waters, and shelves. Building a global map of marine, Cr isotopes will facilitate a better understanding of the global geochemical and biogeochemical chromium cycle. Speciation analysis of seawater Cr is at odds with theoretical models and thermodynamic data. Both the trivalent and hexavalent ions ($Cr(H_2O)_4(OH)_2^+$ and CrO_4^{2-}) should be present in seawater in solubility equilibrium with the atmosphere, with a predominance of the +6 species. Observational analysis suggests that the system is in disequilibrium suggesting active cycling of Cr species [2]. The two naturally occurring oxidation states of chromium, +3 and +6, have distinct chemical properties and behaviour, with the potential for partitioning and isotopic fractionation between different reservoirs. Cr isotope fractionation in groundwater, of up to 6‰, have been attributed to redox changes [3].

Halite (NaCl) is a water soluble mineral found in soils of the driest regions of Earth, and only modest attention has been given to the hydrological processes that distribute this salt vertically in soil profiles. The recent application of stable Cl isotope analyses to soils (Bao *et al*., 2008) set in motion the opportunity to use Cl isotopes to examine these processes. Here, we compare previously published depth profiles of Cl and Cl isotopes in Antarctica to new data on soils from the Atacama Desert in Chile. We first show, using previously published S and O isotope data for sulfates in both deserts, that downward migration of water and sulfate is the primary mechanism responsible for the depth profiles of these salts, and the S and O isotopes within them. In contrast, we found quite different Cl and Cl isotope profiles between the two deserts. For Antarctic soils with an ice layer near the soil surface, the Cl concentrations increase with decreasing soil depth, while the ratio of $^{37}Cl/^{35}Cl$ increases. Based on previous field observations by others, we found that thermally driven upward movement of brine during the winter, described by an advection/diffusion model, at least qualitatively mimics the observed profiles. In contrast, in the Atacama Desert where rare but relatively large rains drive Cl downward through the profiles, Cl concentrations increased with depth while $^{37}Cl/^{35}Cl$ ratios declined. The depth trends in Cl isotopes were more closely explained by a Rayleigh-like model of downward fluid flow. The isotope profiles, and our modeling, reveal the similarities and differences between these two very arid regions on Earth, and provide additional tools to interpret the direction of fluid flow from Cl profiles on Mars.

[2]Department of Earth Science, Sun Yat-sen University, 510275 China

Nanhe W-Mo-Cu Deposit, lying in the zone between granite rock and layer, located at southwest limb of Zhongdong-Liangjiang Synclinorium southwest, southwest section of Qingzhou-Hangzhou Metallogenic Belt [1-3]. Its tectonic evolution experienced two stages: Continent-island arc collision and amalgamation in Caledonian and platform cracking in yanshanian [4-6]. Ore bodies occur in the zone of Caledonian mix granite, N-E shovel fault [7]. Ore analysis of W-Mo-Cu-Pb element demonstrated that: primary tungsten enriched in amphibolite. Either tungsten or molybdenum ore is mainly enriched in the weathering zone of basic volcanic rocks and Surrounding strata. It also tell us that the content of tungsten and molybdenum elements in layer is as 4-8 times high as rock mass; while the scale in granite mass is higher than the other rock mass. In addition, the content of Cu from the layer to mass present M-type and has a certain correlation with W.

1. Ore bodies are located in the volcanic layers of Cambrian and may be mineralized Paleozoic 2. W-Mo deposit must be Sedimento-Reformed Deposits and its Distribution under strict control of the basic volcanic rocks.3. Cu deposit should be porphyry copper deposits and copper comes mainly from the melting process of granitic rocks.4. Fault activity provide access for the mineralization and magmatic action provide energy and drive。

Linking geochemistry and texture of mine tailings and soils to the evolution of plant community in a contaminated copper-sulphide mining area

HOSSAIN M. ANAWAR* AND M. C. FREITAS

Instituto Tecnológico e Nuclear, URSN, E.N. 10, 2686-953 Sacavém, Portugal (*anawar4@hotmail.com)

The adverse physicochemical properties and toxic elemental contamination of mine tailings generally inhibit the plant growth in the mining area. Some other adverse factors like absence of topsoil, drought, surface mobility, compaction, absence of soil-forming fine materials, soil acidity and shortage of organic matter as well as its associated essential nutrients dwarf the spontaneous growth of the diversified plant species in mining affected lands. Therefore, this study made a survey on plant community development at the abandoned São Domingos copper-sulfide mining area in order to understand the relationship of geochemistry and texture of tailings and soils with development of plant community. The results found several communities of plant species dominating in the area depending on geochemistry, mining contamination, soil texture, soil development and distance from the mining activities. The succession of plant communities shows that the plant communities of low height and biomass and bush-type (shrub), mainly *Erica australis*, *Lavandula stoechas*, *Cistus* genus, *Rumex induratus*, *Daphne gnidium*, *Juncus scirpoides*, and *Genista hirsuta* are grown in the mine waste dumps, slags, colluvium, gossan waste, and tailings contaminated lands with thin soil cover, slopes, ditches and acid mine drainage (landscape one). The poor vegetation coverage is clearly noticeable in the severely affected areas that are vulnerable to degradation and aerial dispersion. By contrast, the upland, contaminated to variable degrees (landscape two) just adjacent to the landscape one has good alluvial soil development like loam, and higher vegetation cover. The plant communities are taller, tree-type, and of higher biomass, namely *Eucalyptus globulus*, *Pinus pinaster*, *Pistacia terebinthus*, and *Pteridium aquilinum* etc. The *Erica australis*, *Lavandula stoechas or luisieri*, and *Cistus ladanifer* are found to variable extents in both landscapes. The *Erica australis* is spontaneously grown in the acidic sulfide mining soils; and this species is very specific plant in São Domingos mining area (Anawar *et al*., 2011). The overall results indicate that the geochemistry and contamination levels of mining activities, soil texture, soil development and landscapes are the species-limiting factors for plant community development and vegetation coverage in the mining area. Although the high concentrations of toxic trace elements (e.g., As, Sb, Cr, Hg, Pb and Zn) and low pH values (soil acidity) are important factors for limiting the plant growth, however, soil texture and good soil development with enriched nutrients can present the high vegetation coverage in the mining contaminated lands and pave a biotechnology-based solution of land reclamation.

Whither the whiff?

Improved understanding of the rock record indicates that the Great Oxidation Event was the culmination of an extended period of complex redox evolution and biogeochemical change rather than a singular event. We review data emerging from the sedimentary rock record about the timing and tempo of this transition and preview frontiers of investigation.

Attention has focused in particular on high-resolution, multi-proxy analyses of latest Archean black shales in drill cores from the Hamersley Basin in Western Australia, and from the Griqualand West Basin in South Africa. These analyses yielded multiple lines of evidence suggestive of photosynthetic O_2 production at 2.6 – 2.5 Ga, including: (1) patterns of Mo and Re enrichment and Mo and U isotope variations indicating the presence of these redox-sensitive metals in mildly-oxygenated contemporaneous water columns; (2) a shift in S isotopes interpreted as revealing the onset of an oxidative S cycle; (3) ^{15}N enrichments that record the operation of an aerobic N cycle, including nitrification and denitrification; (4) sedimentary Fe speciation and $\delta^{56}Fe$ data documenting anoxic and sulfidic (euxinic) conditions at mid-depths, most likely arising from enhanced oxidative weathering of sulfides, and a redox-stratified water column; and (5) a shift in sterane/hopane ratios suggestive of a transition in microbial ecology to greater participation by O_2-dependent eukaryotes. Alternative interpretations are possible for some of these observations, but collectively, consistent with other studies, they indicate a "whiff" of O_2 in the late Archean environment.

The data prompt new questions. How high did pO_2 rise? Was O_2 persistent in the environment, or do the data represent a transient event? If transient, was this one of many such episodes? Can similar evidence be found in the earlier Archean record? These questions are the focus of ongoing investigations.

A magma plumbing system probed by the Grænavatn Porphyritic Group, East Iceland

CHRISTINA B. ANDERSEN[1,2]*, MORTEN S. RIISHUUS[1] AND CHRISTIAN TEGNER[2]

[1]Nordic Volcanological Center, Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavik, Iceland (*correspondence: bomberg@hi.is)
[2]Department of Earth Sciences, University of Aarhus, 8000 Aarhus, Denmark

Neogene plagioclase ultraphyric basalts (PUBs) from East Iceland hold up to 45% macrocrysts that may lend clues to a fossil crustal plumbing system. The ~10 Ma old Grænavatn Porphyritic Group consists of 3-10 PUB lava flows and attain maximum thickness (~90m) west of Reyðarfjörður. It is a regional marker horizon, traceable for >50km along strike, but tapers out to the north, south and up-dip to the east. Modal proportions of plagioclase macrocrysts vary both vertically and laterally within single lava flows. Petrographic observations and crystal size distribution have identified three plagioclase populations; (1) single, zoned euhedral macrocrysts (~5mm) with overgrowth rims, (2) unzoned, anhedral glomerophyric macrocrysts (4-10mm) in clusters up to 3cm, and (3) lath-shaped microlites in the groundmass. Macrocryst cores (An75-85) are more primitive than groundmass microliths (An55-65), and therefore in disequilibrium with the host melt. Detailed textural and chemical mapping of zoned macrocrysts reveals complex histories with resorption, overgrowth and stages with entrapment of melt inclusions. Chemical traverses display oscillatory, continuous normal and reverse zoning. Further, we observe discontinuous reverse zoning (ΔAn4-5) that could suggest decompression of ~10km. These PUBs may enable us to examine the structure of a crustal plumbing system potentially involving events of magma ponding, rapid decompression, mixing, recharge and assimilation.

U-series disequilibria during soil weathering

M.B. ANDERSEN[1]*, D. VANCE[1], A.R. KEECH[1], J. RICKLI[1] AND G. HUDSON[2]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Wills Memorial Building, BS8 1RJ, UK (*correspondence: morten.andersen@bris.ac.uk)
[2]Macaulay Institute, Aberdeen, AB15 8QH, Scotland

The weathering of continental rocks influences long-term atmospheric CO_2 and thus climate. In addition, the riverine transport of weathering products to the ocean partially controls marine geochemical budgets. U-series isotopes have long been recognised for their capability to provide time-scales of weathering processes, as well as the nature of the linkage between chemical weathering and physical denuation. However, to fully exploit the potential of the U-series chronometer in weathering studies, an improved understanding of the chemical behaviour and properties of the U-series nuclides in the weathering regime is required.

We have analysed a Scottish soil chronosequence (soil ages from 0.1-13 ka) [1] for ($^{234}U/^{238}U$), ($^{230}Th/^{238}U$) ($^{238}U/^{232}Th$) and ($^{230}Th/^{232}Th$) activity ratios to investigate the behaviour of the U-series nuclides during progressive weathering. All the bulk soil profiles studied show U-series isotopic disequilibrium, including the C-horizons. In the bulk soil samples a clear trend in ($^{234}U/^{238}U$) is observed, with values above unity for the younger soils (up to 1.3), declining towards unity with time. A corresponding trend is observed in the ($^{230}Th/^{238}U$), with values below unity (down to 0.7) for the younger soils, and increasing with older ages (up to 1.3). These observations suggest that there are two competing processes that dominate: (1) U addition to the bulk soil and; (2) soil leaching. The U added is characterised by a high ($^{234}U/^{238}U$), corresponding to the composition measured in local streams (1.3-2.0). This added U is likely to be from perculating groundwaters that adsorbs to soil surfaces. However, with time this U pool declines, likely to be related to changes in the chemical adsorption properties of the soils. The decline in ($^{234}U/^{238}U$) is combined with leaching of the soil, preferentially releasing more U than Th, due to the higher mobility of U than Th.

The U-series data from the soil chronosequences shows the importance of physio-chemical processes during weathering, which affects element and isotope redristibution during weathering. These have to be quantified in studies using the U-series chronometer to constrain time-scales of weathering.

Monitoring beam-induced radiolysis effects on transition metal complexes in hydrothermal fluids

A.J. ANDERSON[1], R.A. MAYANOVIC[2], M.R. FRANK[3] AND S. PASCARELLI[4]

[1]Department of Earth Sciences, St. Francis Xavier University, Antigonish, Nova Scotia, Canada (aanderso@stfx.ca)
[2]Department of Physics, Astronomy & Material Science, Missouri State University, Springfield, Missouri, USA (RobertMayanovic@missouristate.edu)
[3]Department of Geology and Environmental Geosciences, Northern Illinois University, DeKalb, Illinois, USA (mfrank@niu.edu)
[4]European Synchrotron Radiation Facility, Grenoble, France (sakura@esrf.fr)

The irradiation of aqueous solutions with high brilliance synchrotron x-rays causes the decomposition of water molecules and the formation of transient species such as $H^{\bullet}$, $^{\bullet}OH$, H^{+}, OH^{-} and hydrated electrons, e_{aq}^{-}. These radiolysis products may react rapidly with solutes to modify aqueous speciation. In order to study the effects of beam-induced radiolysis on transition metal-bearing hydrothermal fluids, the structure of Cu and Fe chlorocomplexes was monitored using time-resolved x-ray absorption spectra.

XANES data were obtained at beamline ID-20-C at the Advanced Photon Source, Argonne National Laboratory, from synthetic fluid inclusions of known composition, and from solutions in hydrothermal diamond anvil cells (HDAC) up to 600 ºC. *In situ* energy-dispersive x-ray absorption spectroscopic (ED-XAS) measurements were also made on Fe^{2+} chloride solutions at beam line ID24 at the European Synchrotron Radiation Facility. The ED-XAS spectra were measured at 100 intervals with 1 s time resolution followed by 30 or 60 intervals with 60 s time resolution. Our results indicate that Fe^{2+} ions are oxidized or reduced, depending upon the pressure – temperature conditions of the aqueous fluid. Extended irradiation at 500 ºC resulted in the formation of Fe and Cu nanoparticles.

A single x-ray absorption spectrum acquired over a period of several minutes using a scanning monochromator may measure beam-induced modifications produced during the scan. Such artefacts of radiolysis may be minimized or eliminated by analyzing hydrothermal fluids in a flow-through system or by using ED-XAS to reduce the exposure time to synchrotron x-rays.

Portable Rb-Sr geochronology

F.S. ANDERSON*, K. NOWICKI AND T. WHITAKER

Southwest Research Institute, 1050 Walnut, Suite 300, Boulder, CO 80302 (anderson@boulder.swri.edu, knowicki@ boulder.swri.edu, whitaker@boulder.swri.edu)

We have produced a preliminary, low precision, 12-point Rubidium-Strontium (Rb-Sr) geochronology measurement of the Boulder Creek Granite using a laser desorption resonance ionization mass spectrometer (LDRIMS) capable of being miniaturized into a portable unit. Our current prototype can measure the isotope ratio of lab standards with 10 ppm net Sr or Rb to a precision of ±0.1% (1σ), with a sensitivity of $1{:}10^{10}$ in <15 minutes/point. Using the 1) known Rb-Sr ratios and modal mineralogy from Martian and lunar samples, and 2) LDRIMS precision & accuracy, we have numerically modeled the age error for 100-1000 points and determined that uncertainties <±50 Ma are possible [1]. The ability to make in-situ lunar and Martian radiometric measurements with uncertainties <±50 Ma would significantly improve geologic interpretation of these complex surfaces and potentially constrain impactor flux throughout the solar system.

Preliminary results from the Elephant Butte Boulder Creek Granite (BCG_EB) are compared with TIMS Rb-Sr dates of 1700±40 m.y. from 19 whole rock samples [2]. With careful choice of the statistical binning technique, an identifiable isochron, with an MSWD of 2, can be produced (Fig. 1). The age error of ±870 m.y. is consistent with our analytical models for 12 measurements at ±0.4% precision. If expanded to 100-1000 measurements, our statistical models show that this will improve to <50-100 m.y. values [1]. We have also identified and corrected a resonance effect causing the ~15% fractionation offset of $^{87}Sr/^{86}Sr$ observed in Fig. 1.

Ongoing work will improve precision, increase the number of spot measurements, and produce a portable demonstration instrument.

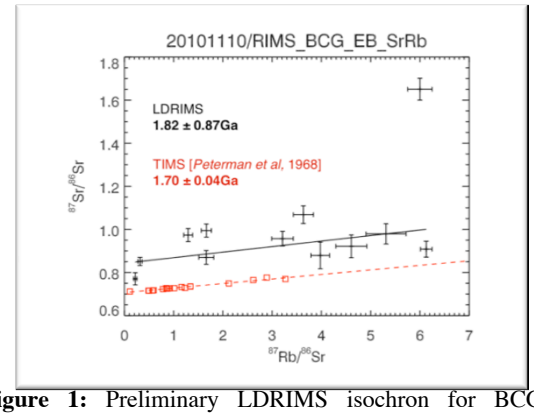

Figure 1: Preliminary LDRIMS isochron for BCG_EB (MSWD 2) is consistent with TIMS results. The age error can be reduced further by making hundreds to thousands of measurements.

Trace element geochemistry of micas by laser ablation ICP-MS in the Moose II lithium-tantalum pegmatite deposit, NWT

M.O. ANDERSON[1]*, D. LENTZ[1], C. MCFARLANE[1] AND H. FALCK[2]

[1]Department of Geology, University of New Brunswick, Fredericton, NB, Canada, E3B 5A3 (*correspondence: m5r5u@unb.ca; dlentz@unb.ca, crmm@unb.ca)

[2]Northwest Territories Geoscience Office, PO Box 1500, 4601-B 52 Avenue, Yellowknife, NT, Canada, X1A 2R3 (hendrik_falck@gov.nt.ca)

The Moose II zoned LCT-type pegmatite is located ~115 km east-southeast of Yellowknife, NWT, Canada, and measures 430 m long and up to 61 m wide. This deposit is a historical producer of lithium and tantalum (1946 – 1954).

Fractionation trends of micas have often been studied as petrogenetic indicators of pegmatite evolution. This study uses laser ablation ICP-MS to explore the fractionation patterns, mechanisms for emplacement, and processes leading to mineralization (e.g., Van Lichtervelde *et al*. [2]). Preliminary results indicate that the Moose II pegmatite has highly evolved compositions, typical of advanced fractionation. This is complemented by analyses of 24 muscovite mineral separates by ICP-MS and XRF, and is comparable to regional studies of muscovite in the Faulkner Lake pegmatites series [2].

Was Atlantic deepwater flow reversed during the Last Glacial Maximum?

ROBERT F. ANDERSON[1]*, MARTIN Q. FLEISHER [1], RAINER GERSONDE[2] AND GERHARD KUHN[2]

[1]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, 10964 USA (*correspondence: boba@ldeo.columbia.edu)

[2]Alfred Wegener Institue for Polar and Marine Research, Bremerhaven, Germany (Rainer.Gersonde@awi.de)

Negre *et al*. [1] inferred northward flow of deep water in the Atlantic Ocean during the Last Glacial Maximum (LGM) based on the north-south gradient in sedimentary $^{231}Pa/^{230}Th$ ratios. The southern end member record of Negre *et al*. was derived from core MD02-2594 in the SE Atlantic (34° 43' S, 17° 20' E; 2,440 m).

New results will be presented from core PS2498-1 in the SW Atlantic (44.1533°S, 14.2283°W; 3783m) that exibit a pattern of sedimentary $^{231}Pa/^{230}Th$ ratios opposite of that in MD02-2594. Whereas $^{231}Pa/^{230}Th$ ratios increase from ~0.045 in the LGM to ~0.07 in the Holocene in MD02-2594, they decrease from ~0.10 in the LGM to ~0.055 during the Holocene in PS2498-1.

Sedimentary $^{231}Pa/^{230}Th$ ratios in PS2498-1 are highly correlated with the opal content of the sediments. Furthermore, the relationship between sedimentary $^{231}Pa/^{230}Th$ ratios and opal content (and with opal flux) in PS2498-1 is continuous with the relationship exhibited in TN057-13-PC4, from a site south of the Antarctic Polar Front in a region of greater average opal abundance.

Based on the observed uniform relationship between sedimentary $^{231}Pa/^{230}Th$ ratios and opal, we conclude that the abundance of opal is the master variable regulating sedimentary $^{231}Pa/^{230}Th$ ratios in the South Atlantic. This is consistent with the global data from sediment traps showing a strong correlation between particulate $^{231}Pa/^{230}Th$ ratios and the opal content of particles [2], reflecting the high affinity of Pa for sorption to opal. Finally, we further conclude that sedimentary $^{231}Pa/^{230}Th$ ratios cannot be used to infer the direction of deepwater flow in the past without a level of control on the spatial and temporal variability of opal flux that is beyond the present capabilities of the field of paleoceanography.

Deep ocean carbonate chemistry on millennial to Milankovitch time scales

ROBERT F. ANDERSON* AND MARTIN Q. FLEISHER

Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, 10964 USA
(*correspondence: boba@ldeo.columbia.edu)

Deep ocean carbonate ion concentration is intimately linked to ocean processes that regulate atmospheric CO_2 over glacial time scales. Well dated records of $CaCO_3$ preservation in deep-sea sediments provide valuable clues about these processes.

Building upon previous studies of $CaCO_3$ preservation in Cape Basin sediments [1, 2], we find that ^{230}Th-normalized fluxes of $CaCO_3$ are well correlated with the abundance of $CaCO_3$ during the last glacial period (LGP), alowing us to use the entire record of ODP-1089 $CaCO_3$ content [1] to infer changes in deep water carbonate ion concentration.

During the LGP, peaks in $CaCO_3$ preservation exhibit features that are reminescant of warm intervals in Antarctic ice cores. Initially we linked increased $CaCO_3$ preservation to ventilation of deep waters via the Southern Ocean, which increased during Antarctic warm periods [3]. However, precise dating of Cape Basin sediments revealed that $CaCO_3$ preservation peaks are associated with vigorous North Atlantic Deep Water (NADW) formation following the Antarctic warm periods rather than by ventilation from the Southern Ocean during these warm periods [2]. Thus, the link between deepwater formation and atmspheric CO_2 is complicated by the complementary impacts of ventilation at opposeite ends of the earth.

Millennial scale features in the $CaCO_3$ record of the Cape Basin are also observed in North Pacific sediments during the LGP, indicating the widespread impact of NADW formation on deepwater carbonate ion concentration.

Finally, we also find an intriguing correlation over longer time scales to suggest that precession forcing [4] and millennial events share some common impacts on deep water carbonate ion via NADW formation.

How acidic is water on calcite?

M.P. ANDERSSON AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark
(*correspondence ma@nano.ku.dk)

Mineral dissolution and precipitation take place primarily on undercoordinated sites on the solid surface, in particular kink sites. Most theoretical studies are performed using molecular mechanics assuming that only water is present at the surface. We have used density functional theory in combination with the COSMO-RS implicit solvent model to calculate pK_a values of water on various sites on a calcite surface. The mineral surfaces were modelled by 80 atom clusters and we have checked convergence of the pK_a values with respect to both cluster size and number of relaxed surface atoms. For kink sites, we found that water is acidic with a pK_a value as low as 3.5. At equilibrium, kink sites are thus covered with hydroxyl ion and water. Our results are relevant for future theoretical studies of dissolution and precipitation of minerals, where the correct equilibrium structure should be modelled.

We also calculated the pKa values for ethanol adsorbed on terrace, step and kink sites on calcite and compared the free energies of adsorption of ethanol and water. Ethanol was found to bind stronger than water on the {10.4} terrace and on the obtuse step, equally strongly on the acute step, whereas on kink sites, water (in the form of hydroxyl ions) binds more strongly than ethanol (in the form of ethoxide). This is consistent with recent experimental data using atomic force microscopy showing that ethanol hinders recrystallization on the {10.4} terrace.

Relationship between palaeoclimate and diagenesis intensity in sediments from transitional environments: The Galician Rías (NW Spain)

A. ANDRADE, B. RUBIO*, D. REY, P. ÁLVAREZ-IGLESIAS, A.M. BERNABEU AND F. VILAS

Research group GEOMA. Departamento de Geociencias Marinas y Ordenación del Territorio, Universidad de Vigo, Vigo Spain (*correspondence: brubio@uvigo.es)

Sediments of coastal areas such as the Galician Rías Baixas (NW Iberian Peninsula), where land and sea interdigitate, are a valuable source of information, since their high sedimentation rates (3-6 mm yr^{-1}) [1] facilitate studies of high resolution. In addition, their position under the influence of both land and sea leads to their exhibiting patterns of interaction between both environments that can help discriminate among local, regional and global climate processes. The Galician coast is one of the regions of the world with most intense coastal upwelling. This, together with continental inputs makes the organic matter contents of sediments from the Rias Baixas to be very high [2], which favour intense diagenetic processes. The intensity of these processes is not only controlled by the organic matter concentrations but also by the relative proportion of oceanic (labile) and terrestrial (refractory) organic matter. Changes in early diagenesis can throw light on the degree of oceanic influence in the Ría, and hence on changes in the circulation and ventilation of its water masses and/or the climate on shore.

In this study on sediment cores taken in the outer Ría de Muros, the combined use of textural analysis, magnetic properties ($\varkappa$, ARM/SIRM, MDF) and geochemical parameters (total concentrations of diagenetically stable and mobile elements in sediment and pore water) allowed the identification of a current redox front and two palaeosedimentary redox fronts. These fronts originated during periods of high marine/terrestrial organic matter ratio (as inferred from the TOC/TN ratio and $\delta^{13}C$). The chronological framework established by ^{14}C dating allowed correlating these fronts to known periods of increased upwelling and reduced continental input due to colder, drier climates in the northwestern Iberian Peninsula, namely the Little Ice Age, the Dark Ages, and the first cold period of the Upper Holocene.

Melting properties of chondritic mantle to the core-mantle boundary

D. ANDRAULT[1], G. LO NIGRO[1], N. BOLFAN-CASANOVA[1], M.A. BOUHIFD[1], G. GARBARINO[2], M. MEZOUAR[2]

[1]Université Blaise Pascal, Clermont-Ferrand, France
[2]European Synchrotron Radiation Facility, Grenoble, France

A large proportion of our planet has experienced melting in the course of its accretion history. In the modern Earth, partial melting in the lowermost mantle is also suggested based on seismic observations of ultra-low velocity zones. The melting properties of the deep mantle thus has major consequences for the existence and survival of chemical heterogeneities in the Earth mantle and, more generally, for our knowledge of mantle dynamics.

Melting curves and Fe partition coefficient have been investigated in a chondritic-mantle material using the laser-heated diamond anvil cell (LH-DAC) at P-T conditions corresponding to the entire Earth's lower mantle. Two different *in situ* synchrotron radiation techniques have been used to infer melting properties *in situ*; X-ray diffraction and X-ray fluorescence spectroscopy.

At core-mantle boundary pressure (135 GPa), the chondritic-mantle solidus and liquidus reach 4150 (±150) K and 4725 (±150) K, respectively. These temperatures are significantly higher than most of estimations of the mantle geotherm. Therefore, partial melting in the D"-layer most certainly indicates chemical heterogeneities with high concentration of fusible elements.

Our observations of a high liquidus as well as a large temperature gap between solidus and liquidus temperatures have important implications for the properties of the magma ocean during accretion. Not only complete melting of the lower mantle would require excessively high temperatures, but also, partial melting should take place over a much larger depth interval than previously thought.

Finally, we provide distribution maps of elements (Ca and Fe) and phases (Mg-Pv, liquid) in our samples which have encountered partially molten at the lower mantle P-T conditions. The Fe partitioning coefficients extracted from these maps show a large preference of Fe for the liquid phase. This behavior is compatible with the production of high density liquids, which can be related to sinking down of liquid phases.

Aerosol-cloud-precipitation interactions in the climate system

M.O. ANDREAE

Max Planck Institute for Chemistry, Mainz, Germany

Aerosols serve as cloud condensation nuclei (CCN) and thus have a substantial effect on cloud properties. Increased aerosol concentrations resulting from anthropogenic pollution lead to higher cloud droplet concentrations, but smaller droplet sizes. This in turn affects the physical processes inside clouds that lead to the initiation of precipitation. Depending on a number of factors, including aerosol composition, atmospheric stability and cloud water content, increasing CCN concentrations may either decrease or increase rainfall. In convective clouds, early rain formation is suppressed, which makes more water and energy available to rise higher in the atmosphere and form ice particles. This may invigorate the dynamics of convection, encourage the formation of hail and lightning, and enhance the transport of materials to the upper troposphere. In order to understand and quantify the effects of air pollution on climate, and precipitation in particular, knowledge of natural abundance and characteristics of aerosols is as essential as the observation of perturbed conditions. I will present recent advances in the conceptual understanding of aerosol-precipitation interactions, as well as measurements on pristine and polluted aerosol characteristics.

Iron speciation in serpentine during oceanic-type serpentinization

MURIEL ANDREANI[1], MANUEL MUNOZ[2], C. MARCAILLOU[2] AND A. DELACOUR[3]

[1]Laboratoire de Géologie de Lyon, ENS - Université Lyon 1, (*correspondance: muriel.andreani@univ-lyon1.fr)
[2]Institut des Sciences de la Terre, Université Grenoble 1, France. (manuel.munoz@ujf-grenoble.fr)
[3]Géosciences Environnement Toulouse, Université Toulouse 3, France. (adelie.delacour@get.obs-mip.fr)

Serpentinisation of ultramafic rocks at mid-ocean ridges is now well known to generate high amounts of H_2, CH_4 and to support novel biological communities. The abiotic production of hydrogen is attributed to the reduction of H_2O during oxidation of the ferrous component of primary minerals. The amount of hydrogen and hydrocarbons formed abiotically is thus directly linked to the amount and state of iron incorporated into product minerals, mainly magnetite and serpentine. However, magnetite is classically the only Fe^{3+}-carrier considered for estimating bulk H_2 fluxes. This is mainly due to the scarce and scattered data on the iron redox state in serpentine minerals and its unknown relationship with both magnetite abundance and serpentinization degree.

To address these questions, we have realized punctual μ-XANES analyses at the iron K-edge (ID24, ESRF) of serpentine minerals in thin sections. Rock samples from 4 different localities (Mid-Atlantic Ridge and Pindos ophiolite) have been selected for their various degrees of serpentinisation and magnetite content.

The results show that Fe^{3+} is abundant in oceanic-type serpentine: it can represent up to 100% of the total iron in the structure but typically tends to 60-65% for sample showing more that 60% of serpentinization. Whole rock chemical analyses and petrographic characterization of the samples allowed us to establish that the Fe^{3+}/Fe^{Tot} in serpentine evolve non-linearly with the local degree of serpentinization. The Fe^{3+} is more rapidly incorporated in serpentine during the first half of reaction, especially if magnetite is rare. This demonstrates the involvement of serpentine formation on natural H_2 production. We have estimated that at least 10% of the H_2 produced is related to serpentine (MARK) and that this value easily attain 30% (Pindos) or even 70% locally in some samples from Logatchev. Thus, evaluation of the raw H_2 production during serpentinization must take into account the Fe^{3+} incorporated in serpentine which is site-dependent. This also opens new perspective on the role of serpentine minerals on the redox state in subduction zones where the oceanic crust is recycled into the earth mantle.

Magama composition and crystallization conditions of the rare-metal granites from Khaldzan-Buregtei massif of peralkaline rare-metal igneous rocks

I.A. ANDREEVA*

Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry Ras, Staromonetny, 35, 119017, Moscow, Russia (*correspondence: andreeva@igem.ru)

New data are obtained on the mineralogical and chemical (major, trace, and volatile components) composition of melt inclusions in quartz from rare-metal granitoids in the Khaldzan-Buregtei Massif, Mongolia. The composition of melt inclusions was estimated with the use of an electron microprobe and ion probe.

The phases identified in the crystalline inclusions are tuhualite, albite, potassic feldspar, sphene, fluorite, zircon, gittinsite, pyrochlore, parisite and yttrocerite, and fluorite.

Melt inclusions in quartz are fully recrystallized, and their daughter minerals compose fine-grained aggregate of quartz, potassic feldspar, riebeckite, polylithionite, fluorite, zirconosilicate, and REE fluorcarbonate. We homogenized the melt inclusions in an autoclave at temperatures of 850 and 950ºC and a pressure of 3 kbar. The chemical composition of the homogeneous glasses was proved to be generally close to the composition of the rare-metal granites, including the concentrations of such components as SiO_2, FeO, MgO, Na_2O, and K_2O. The melts were characterized by high ZrO_2 concentrations (2-3 wt %). The F, H_2O, and CO_2 concentrations in the melts are 1.3-4 wt %, 1-3.4 wt %, and 1.56 wt %, respectively. The glasses of the melt inclusions are depleted in Ba and Sr and enriched in Be, Rb, Y, Nb, Hf, Th, and REE.

Our data indicate that the rare-metal granites were produced by a melt saturated with several trace elements and REE, which is consistent with the geochemical specifics of the rocks themselves. The melts were residual liquids that accumulated in the upper parts of the magma chamber after the fractionation of the alkaline granite magma, reached saturation with many ore components, first of all, Zr, Nb, and REE, and thus became ore-bearing magmas. The specifics of the rare-metal mineralization was predetermined by the high alkalinity of the melt (the agpaitic coefficient = 1.4) and the effects of fluorine and carbon dioxide, which resulted in the crystallization of such rare-metal phases as zircon, zirconosilicates, and REE fluorcarbonates.

Detrital monazite dating and trace-element compositions analysis by XRF-MilliProbe: Implication to provenance study within Ukrainian terrain

A.A. ANDREIEV [1], A.V. ANDREIEV [2], O.V. ZINCHENKO [2]

[1]Ukrainian State Geological Research Institute (UkrSGRI), Kyiv, Avtozavoskaya, 78 (*correspondence:geotech@ukr.net)

[2]Faculty of Geology, Taras Shevchenko National University of Kyiv, Ukraine (andreev@univ.kiev.ua)

Over 2000 detrital monazite grains from Devonian, Paleogene, Neogene, Quaternary sediments of Ukraine have been analysed by XRF Milliprobe for Th, U, Pb, Sr, Y, that as well has been used for Th-U total Pb dating of the monazites.

To apply these analytical and evaluated data for provenance investigation the distribution of above elements in monazites from the set of crystalline rocks of Ukrainian Shield (East European Craton) and Eastern Carpathians has been inferred using XRF measurements. Statistically proved analytical data have allowed distinguishing specific compositional features of monazite derived from (A) alkaline igneous rocks and carbonatites (low contents of Th, U, Y.); (B) granulites and charnockites (increased Th, Sr); (C) metamorphic rocks of amphibolite grade, granites and pegmatites (increased U, Y). The diagram in U/Th*Y/Th – Sr/Y coordinates represents above discrimination in graphic plot. In particular such regularities show systematic sensibility of monazite composition to P-T condition of host rock formation.

The generalized sources of detrital monazites seperated from the sediments within Ukrainian terrain were suggested by implication of the both geochemical and age criteria. Evidently the source of Archean-Proterozoic detrital monazite (>1500 Ma) are crystalline rocks of Ukrainian Shield. For these detrital “old” monazites the rock sources of (B) group prevail (≈2/3 of total amount) whereas ≈1/3 derived from the rocks of (C) group. The Precambrian rocks of (A) group yield insignificant part of the “old” detrital monazites in the studied sediments. Neoproterozoic-Palaeozoic ‘young’ (1100-400 Ma) population of detrital monazite apparently represents product of erosion of acid metamorphic rocks of relatively low grade, which have no direct analogues within Ukrainian Shields. Source area for this population could be Neoproterozoic terrains of EEC margin including ancient rocks of Marmarosh massive (Eastern Carpathians).

The effect of diffusion on P-T conditions inferred by cation-exchange thermobarometry

A.L. ANDREWS*, Z.R. WANG, E.W. BOLTON, AND J.O. ECKERT JR

Yale University, New Haven, CT, 06520, USA
(*correspondence: alexandra.l.andrews@gmail.com)

Mantle xenoliths are used to infer geothermal gradients of the sub-continental lithospheric mantle through cation exchange thermobarometry. This method assumes that cations reach thermodynamic equilibrium at depth and maintain this state during their ascent to Earth's surface. Analyses of the chemical compositions of coexisting minerals suggest that this assumption is not always valid due to diffusion and re-equilibration. Our observations include: 1) element diffusion profiles in minerals; 2) hotter and deeper P-T conditions calculated for the rims of some mineral assemblages than P-T calculations for the cores; 3) more scattered P-T conditions at higher pressures and temperatures. We examined a suite of garnet peridotites from the Kaapvaal craton (Kimberley, South Africa). Rock sections containing garnet, cpx, opx, and olivine were mounted and measured for their major element compositions at Yale University using the JEOL JXA-8530F field emission gun electron microprobe. P-T conditions calculated for these samples using BKN [1] thermobarometry vary from 930–1240°C, 39–52 kbar. More interestingly, zoning is evident in garnet grains with radii varying from 400–1550 μm. This zoning produces P-T differences of 22–144°C and 1.5–6.3 kbar between rims and cores. A multi-component diffusion model was formulated for $Ca^{2+}/Mg^{2+}/Fe^{2+}$ exchange across garnet, cpx, opx, and olivine assemblages as well as Cr^{3+}/Al^{3+} exchange between garnet and cpx. Modeling results are checked against the observed diffusion profiles. Our model suggests that P-T conditions recorded in these mantle minerals depend on the cooling rate, crystal grain size, and geothermal gradient, which might not be the same as the linear regressed line through all calculated P-T conditions.

Insight into effects of elevated CO_2 and soil nutrient levels on biological weathering at the mesocosm scale

M.Y. ANDREWS[1]*, J.R. LEAKE[1], S.A. BANWART[2] AND D.J. BEERLING[1]

[1]Department of Animal and Plant Sciences, University of Sheffield, Western Bank, Sheffield, S10 2TN, UK
(*correspondence: m.y.andrews@sheffield.ac.uk)
[2]Cell-Mineral Research Centre, Kroto Research Institute, North Campus, University of Sheffield, Broad Lane, Sheffield, S3 7HQ, UK

The evolutionary development of large vascular land plants in the Paleozoic is hypothesized to have enhanced weathering of Ca and Mg silicate minerals. This plant-centric view overlooks the fact that plants and their associated mycorrhizal fungi co-evolved. Many weathering processes usually ascribed to plants may actually be driven by the combined activities of roots and mycorrhizal fungi. Here we present initial results from a novel mesocosm-scale laboratory experiment designed to allow investigation of plant-driven carbon flux and mineral weathering at different soil depths, and under ambient (400 ppm) and elevated (1500 ppm) atmospheric CO_2.

Sequoia sempervirens (arbuscular mycorrhizal, AM) and *Pinus sylvestris* (ectomycorrhizal, EM) were studied in two experiments as part of the larger biological weathering project. Each long term (7-13 months) experiment was conducted under similar environmental conditions with the exception of the "soil" substrate in which the trees were grown. One experiment used an organic-poor, low nutrient sand:perlite 50:50 (vol:vol) mix whilst the other used an organic-rich sand:compost (50:50 vol:vol) mixture.

Both species responded differently to elevated CO_2 conditions when grown in organic-poor or -rich substrates. After $^{14}CO_2$ pulse-labeling, the observed carbon flux timing and magnitude were significantly different for both species in the sand:compost study relative to the sand:perlite study. Additionally, the peak carbon flux under elevated CO_2 in the sand:compost system lagged by several hours relative to plants grown under ambient CO_2. Total root biomass was increased under elevated CO_2 in the nutrient poor substrate, but much less so under higher nutrient conditions. Ongoing analyses will elucidate how these disparate responses to elevated CO_2 may affect mycorrhizal biomass and mineral weathering in the mesocosm systems.

Tilts without tears – Structure and elasticity of feldspars

R.J. ANGEL

Virginia Tech Crystallography Laboratory, Department of Geosciences, Virginia Tech, Blacksburg, VA 24060, USA. (rangel@vt.edu)

Framework structures such as feldspars and perovskites typically respond to changes in pressure, temperature and the extra-framework cations by the tilting of the strongly-bonded polyhedra, with little change in the geometry of the individual polyhedra. In the perovskites, the complex tilt patterns can be decomposed in to a combination of six fundamental tilts [1] that have been shown to act as the order parameters that relate the structural evolution of perovskites to their thermodynamic and elastic properties [2]. Tilts are therefore the appropriate fundamental description for the evolution of framework structures.

By contrast, structural variation in feldspars has only briefly been described in terms of tilts [3], and instead work for the last 3.5 decades has focussed on the variation of the T-O-T angles despite these showing very few or no systematic correlations with thermodynamic properties. The complexity and low-symmetry of the feldspar framework, which means that the tilts are not symmetry-breaking and are also difficult to model, is probably the reason for this neglect of tilting. In this contribution I will describe the decomposition of the variation of the feldspar structure in to the four fundamental tilts that were previously defined by Megaw [3], and the construction of an exact rigid-body model of the framework that can be used to show how the various tilts change the unit-cell parameters. This model explains the unit-cell parameter variations seen in real feldspars, and the extreme anisotropy of the response of the feldspar structure to changes in temperature, pressure and extra-framework cation. The success of this analysis offers the opportunity to develop a structure-based model for the thermodynamic and geochemical properties of feldspars in general.

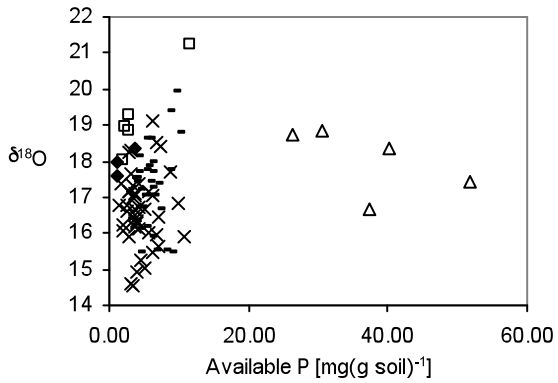
Available-phosphate oxygen isotopes point to extracellular equilibration

ALON ANGERT*, SHUNIT MAZEH, AND TAL WEINER

The Institute of Earth Sciences, The Hebrew University of Jerusalem, Israel (*correspondence: angert@huji.ac.il)

The oxygen stable isotopes in phosphate which is rapidly available for biological uptake can be used as a tracer for phosphorus cycling. Using this tracer in the ocean and in soils requires good understanding of the processes that control it. Here we present the first survey of available (resin-extractable) inorganic δ^{18}Op, based on a method we have recently developed [1]. This survey took place across natural and experimental rainfall gradients, and across soil formed on sedimentary and igneous rocks. In addition, we also analyzed the soil total (HCl-extractable) inorganic δ^{18}Op. The available-P values were in the range of 14.5-21.2‰ (Fig. 1).

Figure 1: Range of concentrations and $\delta^{18}O_P$ at five sites, with annual rain fall varying between 90-780mm/y. A site with igneous bedrock is marked by triangles.



The observed available-P δ^{18}Op values are considerably higher than the values we calculated (based on [2]) for extracellular mineralization of organic phosphate. However, these values are close to the value expected for enzymatic mediated phosphate equilibration with soil water. Evidence for equilibration was also reported in ocean studies, and was usually attributed to fast microbial recycling. However, we argue that microbial recycling can explain equilibration only if inorganic-phosphate excretion overwhelms other fluxes in the system. As a result, we conclude that the equilibration can be better explained by activity of extracellular pyrophosphatase.

Magma emplacement durations and rates and the dynamics of magmatism and volcanism

C. ANNEN[1]*, J. BLUNDY[1], L. CARICCHI[1], T. MENAND[2], M. DE SAINT-BLANQUAT[3], A. SCHÖPA[1] AND R.S.J. SPARKS[1]

[1]University of Bristol, Queen's Rd, Bristol BS8 1RJ, UK (*corrrespondence: catherine.annen@bristol.ac.uk) (jon.blundy@bristol.ac.uk, l.caricchi @bristol.ac.uk, anne.schopa@bristol.ac.uk, steve.sparks@bristol.ac.uk)

[2]LMV, 5 rue Kessler, 63038 Clermont-Ferrand Cedex, France (t.menand@opgc.univ-bpclermont.fr)

[3]Observatoire Midi-Pyrénées, 14 av. Edouard-Belin, 31400 Toulouse, France (michel.desaintblanquat@get.obs-mip.fr)

Protracted emplacement durations for large laccoliths, plutons and batholiths have been infered from radiometric dating. Analysis of conduit fluxes, short crystal residence times inferred from diffusion chronometry and field evidences all support a model of incremental emplacement of igneous bodies where discrete pulses are interrupted by periods of inactivity. According to this model, at least two rates of magma intrusion can be defined: the short-term emplacement rate of an individual pulse and the long-term emplacement rate of the entire igneous body.

Long-term emplacement rates, which may vary over time, control the thermal state of the igneous body and crust. The mechanical ability of the crust to accommodate pulses of magma depends on its thermal state and on short-term emplacement rates. Magma emplacement at high rates and frequency in a thermally imature and thus rheologicaly brittle crust results in fracturing and eruption, whereas magma storage is favoured on longer timescales in a thermally mature crust[1]. Intrusive/eruptive ratios depend on both short and long-term rates and vary over time in a given magmatic system. The growth of large magma chambers where large-scale convection and magma mixing can happen is only possible for a restricted range of emplacement rates.

At deep crustal levels, incremental magma emplacement implies that different timescales control differentiation. Cooling of rapidly emplaced pulses results in the generation of silicic melts on a short timescale, but the magma reservoir as a whole heats up, remelts and possibly assimilates crust on a much longer timescale.

A global understanding of magma dynamics requires dating tools that can discriminate between different processes and identify the different timescales involved.

The reaction products during the preparation of granites for the trace elements analysis by ICP-MS

J. ANOSHKINA AND O. BUHAROVA

Tomsk State University, Lenin avenu 36, 634050 Tomsk, Russia, (*correspondence: julia-seversk@mail.ru)

At present time an essential part of geochemical researches is detection of accompanying elements in different rock and mineral types and analysis of their distribution mechanisms. Last years the main analytical technique for that is ICP-MS. The main problem is sample preparation of geological matrixes. Today there are quite many schemes decomposing of these samples, but most of them are multistep, labor- and time-consuming. Microwave decomposition systems are usually used for intensification of the sample preparation. A serious difficulty for acid revelation is provoked by high-Si magmatic rocks, particularly granites. For the ICP-MS method it is necessary to transform sample to the solution completely, but the granite decomposing can't be always done integrally by using mentioned above schemes. Therefore we've been tried to detect undecomposed fraction at each stage of chemical sample preparation. For that purpose generated sediments were selected, dried and analyzed using scaning electron microscopy with energy dispersive and wave dispersive X-ray microanalysis methods after each revelation step. Sample SG-3 was used for the experiment. Samples decomposed in 3 stages: HF:HNO_3 (5:1) – HCl - HNO_3.

Supernatant liquid was analyzed by ICP-MS method. During the experiment it was revealed that a full decomposing of matrix was accompanied by generation of insoluble residue of Al, Ca, REE fluoride at the first stage. Then fluoride of REE transform to the solution on next stages. But at that on the surface of new growth residue ($0{,}01Na_2O \times 0{,}05(Mg,Fe)O \times 0{,}05Al_2O_3 \times 0{,}09SiO_2 \times 0{,}13K_2O \times 1{,}17F$; $0.03Na_2O \times 0.1MgO \times 0.13Al_2O_3 \cdot \times 1.4F$) take place fractional sorption and defective inclusions of Ta, Nb, Zr, Y, La, Ce,.

The scheme of chemical preparation of rock samples was change on the base of our recently received data. In this case the main aim of more careful methodics was a reduction of part of modified solid phases on the first stage of resolution. The sample with weight about 0.1 gram was dissolved in the complex HF – HCl – HNO_3 for three stages of acid solutions and was controlled in the open system. As the result of this scheme of sample preparation, the content of initial potassium-bearing solid phase was altered to that of ($0{,}01K_2O \times 0.08(Mg,Fe)O \times 0.08Al_2O_3 \times 1.01F$). The following resolution was defined an increase of trace element concentrations in the supernatant liquid.

The study was funded by the Russian Ministry of Education and Science.

Nanometer to centimeter scale analysis and modeling of pore structures in geologic CO_2 storage formations and caprocks

LAWRENCE M. ANOVITZ[1], LUKAS VLCEK[1], GERNOT ROTHER[1] AND DAVID R. COLE[2]*

[1]Oak Ridge National Lab., Oak Ridge, TN, USA 37831
[2]The Ohio State University, Columbus, OH, USA 43210
(*correspondence - cole.618@osu.edu)

The microstructure and evolution of pore space in rocks is a critically important factor controlling fluid flow. The size, distribution and connectivity of these confined geometries dictate how fluids migrate into and through these micro- and nano-environments, wet and react with the solid. (Ultra)small-angle neutron scattering and autocorrelations derived from BSE imaging provide a method of quantifying pore structures in a statistically significant manner from the nanometer to the centimeter scale. These methods were used to characterize the pore features of a variety of potential CO_2 geological storage formations such as the shallow buried quartz arenites from the St. Peter Sandstone and the deeper Mt. Simon quartz arenite in Ohio as well as the Eau Claire shale and mudrocks from the Cranfield MS CO_2 injection test. For example, analyses of experimental and natural samples of St. Peter sandstone show total porosity correlates with changes in pores structure including pore size ratios, surface fractal dimensions, and lacunarity. These new data suggest that microporosity is more prevalent in nominally coarse-grained sandstone and may play a much more important role than previously thought in fluid/rock interactions. The preliminary results from shale and mudrocks indicate there are dramatic differences not only in terms of total micro- to nano-porosity, but also in terms of pore surface fractal (roughness) and mass fractal (pore distributions) dimensions as well as size distributions. Information from imaging and scattering data can also be used to constrain computer-generated, random, three-dimensional porous structures. The results integrate various sources of experimental information and are statistically compatible with the real rock. This allows a more detailed multiscale analysis of structural correlations in the material.

Iron oxides in copper mining environments: Transformation and reactivity

J. ANTELO[1]*, S. FIOL[2], R. LOPEZ[2], D. GONDAR[2] AND F. ARCE[2]

[1]Dept. Soil Science and Agricultural Chemistry. University of Santiago de Compostela. 15782 Santiago de Compostela. Spain (*correspondence: juan.antelo@usc.es)
[2]Dept. Physical Chemistry. University of Santiago de Compostela. 15782 Santiago de Compostela. Spain

The formation, transformation and surface chemistry of iron mineral oxides is of geological significance in surface waters polluted with acid mine drainage (AMD). Geochemical behaviour of these iron oxides controls the availability and mobility of contaminants in these highly polluted systems. The acidic pH values, together with the presence of high amounts of sulphate, will favour the formation of schwertmannite which is a metastable iron oxide that will be transformed to goethite under oxic conditions [1]. However, in copper mining environments co-precipitation of iron and copper ions is expected and therefore the surface chemistry of the iron oxides present in these systems may be different. AMD precipitates have been found to be very effective scavengers of contaminants, although changes in the AMD conditions may result in the release of metals or other contaminants to surface waters.

Several iron oxide samples have been prepared in the presence of high concentrations of sulphate and different copper concentrations ir order to simulate copper-rich mining environments. Long-term transformation experiments were conducted in order to study the mineral oxide stability and surface chemical changes produced over a fitteen months period. Schwertmannite particles are found to be formed initially, but throughout the experiment a release of sulphate, iron and copper ions was observed at the more acidic pH values, which lead to the formation of goethite-like particles. Reactivity of the different mineral phases against arsenate shows that the major adsorption capacity is found in the initial schwertmannite-like particles and arsenate mobility increases in the more stable iron mineral phases that are formed during the transformation experiment.

Bacterial sulfate reduction (BSR) is responsible for the majority of organic matter oxidation in marine sediments and therefore is a key player in the global carbon cycle. The biochemical pathway of sulfate reduction occurs in several reversible steps; each of these steps has an associated isotope fractionation. The ratio between the forward and backward fluxes at each step, the relationship of the individual fluxes to the overall rate of BSR and the resultant expressed sulfur and oxygen isotope fractionation during BSR in natural environments remains enigmatic. The aim of this study is to further our understanding of BSR through analysis and subsequent modelling of sulfur and oxygen isotopes in pore fluid sulfate from ODP-acquired deep sea sediments, the shallow Eastern Mediterranean, and the Yarqon estuary (Israel). Our data demonstrates a correlation between the net rate of BSR and the slope of the relative evolution of oxygen and sulfur isotopes ($\delta^{18}O_{(SO4)}$ vs. $\delta^{34}S_{(SO4)}$) in the residual sulfate pool. We combine these results with literature data to show that this correlation scales over many orders of magnitude (for rate of BSR). Our model, combined with previously published pure culture data [1], suggests that the critical parameter for the relative evolution of oxygen and sulfur isotopes during BSR in natural environments is the rate of intracellular sulfite oxidation. We find that the lower the net rate of BSR, the steeper the slope ($\delta^{18}O_{(SO4)}$ vs. $\delta^{34}S_{(SO4)}$) and the more intense sulfite oxidation.

Geochemical constrains on Lower Ordovician magmatism at the Central Iberian Zone (Central Portugal)

I.M.H.R. ANTUNES[1]*, A.M.R. NEIVA[2]* AND M.M.V.G. SILVA[2]*

[1]Polytechnic Institute of Castelo Branco, 6001-919 Castelo Branco, Portugal (imantunes@ipcb.pt) * Geoscience Centre, University of Coimbra
[2]Department of Earth Sciences, Univ. Coimbra, 3000-272 Coimbra, Portugal (neiva@dct.uc.pt; mmvsilva@dct.uc.pt)

The Central Iberian Zone (CIZ) of the Iberian Massif contains important magmatic bodies, most of them of Variscan age, emplaced during and after the ductile deformation Variscan phases. Ordovician magmatism has been considered rare in the CIZ, however recent geochronological data indicate a Lower Ordovician emplacement age for granitic rocks.

The Oledo pluton has an Early Ordovician emplacement age of 479 - 480 Ma, obtained by ID-TIMS U-Pb ages, on zircon and monazite crystals. This pluton is exposed over an area of about 260 km^2 and intruded the Cambrian schist-metagreywacke complex, which consists of alternating metapelites and metagraywackes with metaconglomerate and marble intercalations. It contains four distinct and contemporaneous granodioritic to granitic phases (GrA-GrD) derived from different magmatic sources.

The pluton shows local deformation and magmatic flow structures probably related to the Caledonian and Variscan deformation events. Granodiorite GrA is the most deformed granitic rock with shear zones and deformation at the border. Granodiorites GrA and GrC contain fine-grained biotite tonalite (TME) and granodiorite microgranular enclaves (GME), which are darker and richer in mafic minerals than the host granodiorites. The geological, mineralogical, geochemical and isotopic (Nd, Sr and O) data indicate that TME and GME and host GrA are of I- type and were related by fractional crystallization process. Least-square analysis of major elements and modelling of trace elements support that GME and host GrA are derived from the TME magma by fractional crystallization of plagioclase, grunerite, biotite and ilmenite from the TME magma. Granodiorite GrB is of hybrid origin. Most variation diagrams for whole-rocks and biotites from GME and host granodiorite GrC show linear trends. Major and trace elements modelling suggest that they result from mixing of relatively primitive granodiorite magma with a magma derived from crustal melting. TME corresponds to globules of a more mafic relatively primitive magma. Granite GrD is of S-type and represents another pulse of magma.

Shale to soil: Geochemistry and clay mineral transformations

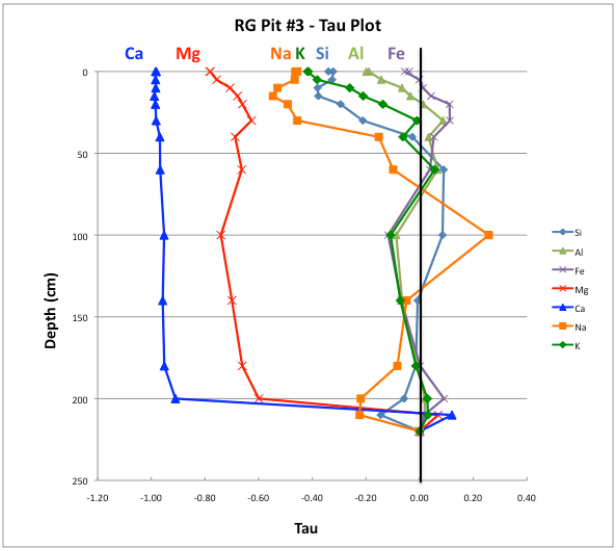
R.H. APRIL*, S. LEMON AND D. KELLER

Geology Department, Colgate Univ., Hamilton, NY 13346, USA (*correspondence: rapril@colgate.edu)

We are studying the weathering characteristics of Clinton group (middle Silurian) shales as part of a larger climate transect study to better understand chemical weathering and soil formation in the Critical Zone. Our research site (Roger's Glen, NY) is the northernmost of six satellite sites - extending from Puerto Rico to New York State – tied to a larger ongoing study of shale weathering at the Shale Hills Critical Zone Observatory in Pennsylvania, USA.

The shales at our site comprise the Sauquoit and Willowvale Formations, green-gray calcareous shales and mudstones containing the clay minerals illite and chlorite. The area was glaciated and soils have developed over the past ~14,000 years on till rich in shale fragments. Illite is resistant to weathering and persists in the soil profile, but chlorite weathers to vermiculite, likely through a mixed-layer chlorite-vermiculite intermediate. Vermiculite in the upper part of the soil profile contains hydroxy-aluminum interlayers, as determined by the gradual collapse of the clay interlayer structure with K-saturation and heat treatments.

Both exchangeable cations and bulk soil chemistry show interesting trends down profile suggesting that a weathering front has developed. Exchangeable Ca and Mg, especially, show sharp increases in the uppermost and lowermost soil horizons where the influence of organic matter decay in the former and shale decomposition in the latter account for these trends. Similar increases in Ca and Mg at depth are apparent in the bulk chemistry (see figure below). Soil pH increases from 4.3 at the top of the profile to 8.1 at depth near where the soil-bedrock interface occurs. Tau plots show depletion of base cations and accumulation of Fe and Al in B-horizons as weathering proceeds down-profile.



An empirical approach to estimate melting temperature and its pressure dependence of some rocks of Oman ophiolite suite

SAYYADUL ARAFIN*, RAM N. SINGH AND ABRAHAM K. GEORGE

Physics Department, College of Science, Sultan Qaboos University, Box:36, Al – Khoudh 123, Oman (*correspondence: sayfin@squ.edu.om)

Pressure Dependence of Melting temperature

We have derived an empirical relation to determine melting temperature, T_m and its pressure dependence. Seismic p- and s-wave velocities and density data [1] were used as inputs to compute Debye temperature, Θ_D which forms the important ingredient of the empirical relation. We have applied the formalism to estimate T_m and its pressure dependence for harzburgite and gabbro rocks of Oman ophiolite suite respectively.

Discussion of Results

At room temperature and atmospheric pressure, the computed values of Θ_D are found to be 694K and 547K, and those of T_m are 1532K and 1132K for harzburgite and gabbro, respectively. A comparison of the pressure dependence of T_m obtained from the empirical approach with those from Lindemann and Simon's formula will be made after we complete the full analysis.

Ultrahigh-pressure podiform chromitites as a possible deep recycled material

S. ARAI [1]*, A.H. AHMED[2] AND M. MIURA[1]

[1]Department of Earth Sciences, Kanazawa Univ., Kanazawa 920-1192, Japan (* correspondence: ultrasa@kenroku.kanazawa-u.ac.jp, mimk1214@stu.kanazawa-u.ac.jp)

Ultrahigh-Pressure (UHP) Chromitites

Podiform chromitites, which appear in the Moho transition zone to upper mantle of ophiolites, have been considerd to be of origin of low-pressure almost *in-situ* magmatic cumulates [1]. The dicoveries of diamond and other UHP minerals (e.g., Robinson *et al*., 2004) from chromitites of Tibet seriously requires us to reconsider the origin(s) of podiform chromitites. Various features of the UHP chromities can be explained by recycling of the ordinary low-P chromitites (Fig. 1).

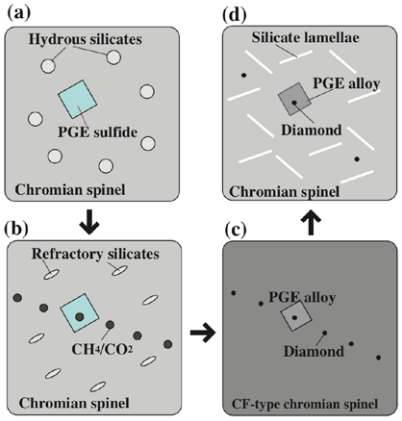

Figure 1: UHP signatures formed by deep recycling of low-P chromitites (Arai, 2010).

Chromitites from the Oman Ophiolite

Only concordant chromities, which we examined at Wadi Hilti, the Oman ophiolite, have some UHP-like signatures, e.g., pyroxene lamellae in spinel (Fig. 1d). Discordant ones show features of low-P magmatic generation (Fig. 1a). The former possibly have a deep recycling origin.

Time variation of He and Ar isotopic compositions in the Earth's atmosphere

YUKO ARAKAWA AND JUN-ICHI MATSUDA

Departmen of Earth and Speace Science, Graduate School of Science, Osaka University, Toyonaka, Osaka 560-0043, Japan

It is very important to study the origin and evolution of the Earth's atmosphere. Noble gas isotopes could be useful tools to trace the degassing history of the Earth. In this study, we have examined the time variation of helium and argon isotopic ratios in the Earth's atmospehere using our previous models on matnle degassing [1, 2, 3].

We thought that the Earth was initially uniform in isotopic compostions of noble gases but was divided into three separate reservoris and that individual elements were carried by mass flow between reservoirs. The mass flow has decreased exponetially as a function of time. The details of the calculation and the isotopic ratios of He and Ar in the mantel are given in our previous papers [2, 3].

Our calculation for the terrestrial air shows that the $^{40}Ar/^{36}Ar$ ratio increased rapidly after the formation of the Earth and has been almost identical to the present value of 295.5 for the last 1 b.y. For the $^{3}He/^{4}He$ ratio calculation, we need to consider the escape of helium into the space. We put the escape terms for ^{3}He and ^{4}He amounts in air estimated from the present atmopheric He budget. In this case, we get a good agreement for the ^{3}He amount in the present air, but can not calculate the present ^{4}He content without a very low escape rate of ^{4}He. In our previous models [2, 3], we assumed that al the noble gases transferred into the continental crust remained there. However, if we assume that all the helium in the continental crust is released to the air as the helium is a tiny element, our calculation shows that both ^{3}He and ^{4}He concentrations (and, therefore, $^{3}He/^{4}He$ ratio) agree very well with the modern-day observed values. The calculated time variation of the $^{3}He/^{4}He$ ratio shows that the $^{3}He/^{4}He$ ratio in air is also constant since 0.1 b.y.

Thus we conclude that the detection of modern-day atmospheric ratio of He and Ar in the ancient terrestrial samples younger than 0.1 b.y. is not always due to the contamination by the modern-day atmosphere.

Acid-base fractionation in the model Cl-bearing granite

L.Y. ARANOVICH[1,2]*AND M.A. NOVIKOVA[1,2]

[1]Institute of Geology of Ore Deposits RAS, 119017 Moscow, Russia (*correspondence: lyaranov@igem.ru)
[2]Institute of Experimental Mineralogy RAS, 142432 Cherogolovka, Russia (nov@iem.ac.ru)

Existing experimental data indicate rather limited chlorine solubility in felsic melts [1]. On the other hand, melting temperature of the model haplogranite in presence of concentrated alkali halide solutions is significantly higher than in pure water, and, for a constant salt concentration increases with increasing pressure [2]. Taken together, these data show that any granite melts containing even small amount of dissolved Cl (of about n*10-1 wt.%) should liberate a very concentrated brine at the early, high-temperature stages of decompression/cooling induced crystallization. With continuing crystallization fluid in equilibrium with granite melt must evolve towards pure water. We have made melting experiments at 800oC and 2 kbar total pressure on the model granite composition Ab69Qtz31 in presence of aqueous NaCl solutions ranging in concentration from XNaCl = 0.2-0.02. The experiments have shown that quench pH of the solution equilibrated with the melt depends strongly on the solution salinity: the quench pH of the most concentrated solution was about 9, while that of the least concentrated one-about 2. Acidic nature of the dilute salt solutions in equilibrium with granite melt was discovered some 40 years ago [3], whereas the very high pH values of the concentrated solutions are reported for the first time. The nature of the acid solutions is well understood as being due to hydrolysis reaction of the type: 2NaCl(fl) + H2O(fl) = Na2O(m) + 2HCl(fl) (1), where fl and m denote fluid and melt phase, correspondingly. The exact reason for the high quench pH observed in concentrated solutions remains as yet unknown, we suggest it results from dissolution of Al2O3 in the course of schematic reaction: 0.5Al2O3(m) + 3NaCl(fl) + 1.5H2O (fl) = AlCl3(fl) + 3NaOH(fl). In any event, the pH variations in alkali solutions liberated from an evolving granite melt must cause significant changes in the magmatic fluid transport properties in respect to various ore metals. This effect is demonstrated in the experiments on partitioning of W and Pb between the model melt and solutions of variable NaCl concentration.

Trace metal and Mo isotope systematics in petroleum fluids

COREY ARCHER[1], TIM ELLIOTT[1], SANDER VAN DEN BOORN[2], RICCARDO AVANZINELLI[3], AND PIM VAN BERGEN[4]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, BS8 1RJ, UK (c.archer@bristol.ac.uk)

[4]Shell Upstream International Europe, Aberdeen, UK

The presence of trace metals in oils has long been of interest for both their detrimental and beneficial effects during hydrocarbon exploration. For example, elevated levels of trace metals can cause problems during downstream refining processes due to catalyst poisoning. In contrast, the diagnostic potential of trace metals incorporated in fluids and host rocks has been successfully applied in various fingerprinting studies. The majority of work to date has focussed on the two most abundant metals found in oils, vanadium (V) and nickel (Ni), which have been used as tools in correlation and fingerprinting, and provide information on redox conditions during source rock deposition.

Here we focus on the molybdenum (Mo) isotope system, well known to display bi-polar redox chemistry [1], and thus providing a potentially valuable new tool to exploit in petroleum systems' studies. We have developed techniques for the determination of Mo isotopes in hydrocarbon (HC) fluids. Mo is extracted from its complex organic fluid matrix, through high pressure ashing, which renders the complete decomposition of the HC fluid, allowing the Mo to be purified via conventional ion-exchange methods [2]. Preliminary data from replicate samples suggest a precision of better than 0.1‰ in $\delta^{98/95}$Mo. We combine the Mo isotope data with more conventional elemental fingerprinting, as determined through isotope dilution HR-ICPMS analysis with a new multi-element spike. This method allows greater accuracy and precision than has been previously possible, both being better than 10%.

Samples display variably positive $\delta^{98/95}$Mo ratios, ranging from +0.4‰ to +1.7‰, within the range of sediments deposited under variably reducing conditions [3]. We will further explore the relationship between oil Mo isotope composition and its source rock, as well as biodegradation and maturation processes.

Ion association in hydrothermal systems: Strontium chloride, hydroxide and acetate to 350 ºC and 20 MPa

H. ARCIS,[1] G. ZIMMERMAN[2] AND P. TREMAINE[1]

[1]University of Guelph, Guelph, Ontario, Canada
[2] University of Bloomsburg, Bloomsburg, Pennsylvania, USA

The ion association constants of Sr^{2+} with common ligands under hydrothermal conditions are needed to model the geochemistry of naturally occurring radioactive materials ("NORM") [1] and the chemistry of Generation IV super-critical water nuclear reactor designs [2]. Moreover, because of its favourable solubility, Sr^{2+} is an attractive model system for predicting the thermodynamic properties of M^{2+} transition metals. This paper reports the first conductivity study of aqueous $SrCl_2$ and $Sr(OH)_2$ from 25 to 350 °C, using a novel high-precision flow-through AC electrical conductance instrument [3,4] at concentrations from $5{\cdot}10^{-5}$ to 0.2 mol·L^{-1}.

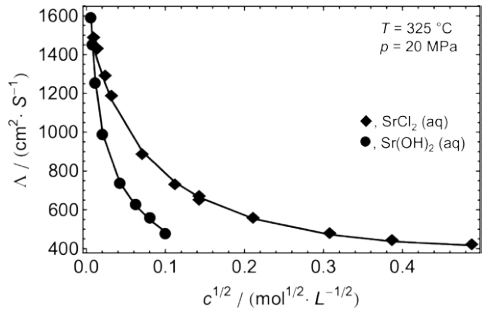

Figure 1: Molar conductivity Λ of aqueous $SrCl_2$ and $Sr(OH)_2$ *vs*. concentration *c* at 325 °C and 20 MPa.

Formation constants were determined from Λ vs *c* using the TBBK model [3,4]. The values for $Sr(OH)^+$ and $Sr(OH)_2^0$ are greater than those for $SrCl^+$ and $SrCl_2^0$ ion pairs, and both neutral species are significant above 10^{-3} mol·L^{-1} at 350 °C. Similar data have been obtained for the complexes of Sr^{2+} with acetate, $Sr(Ac)^+$ and $Sr(Ac)_2^0$ up to 275 °C at 20 MPa. The limiting molar conductivities can be used to estimate ionic mobilities and diffusion under hydrothermal conditions.

Modes of mantle flow and He travel in the northern Lau Basin

R.J. ARCULUS*, O. NEBEL, F.E. JENNER, J.A. MAVROGENES AND N. DYRIW

Research School of Earth Sciences, ANU,Australia
(*correspondence: richard.arculus@anu.edu.au)

High $^3He/^4He$ has been documented in dredged volcanic glasses from the Rochambeau Rifts (RR) and North West Lau Spreading Centre (NWLSC) in the northwestern Lau Basin, plausibly related to southerly ingress of the Samoan Plume into the mantle wedge underlying this rapidly opening backarc basin[1]. The Central Lau Spreading Centre (CLSC), offset south of the NWLSC by the right-lateral Peggy Ridge Transform Fault, has MORB-like $^3He/^4He$, suggesting the Ridge exerts control on asthenospheric mantle as well as fracturing the lithosphere. The relative fertility of the mantle supplying the actively extending rifts and spreading centres increases from south to north (CLSC through NWLSC to RR). In terms of elevated Fe8, the RR define a new, hot, fertile, global backarc basin end-member, with strongly elevated Hf*/Hf and Dy/Yb, consistent with a garnet-bearing residue during melt generation. Both RR and NWLSC show a positive correlation between Fe8 and $^3He/^4He$. Hf-Nd isotopic covariations provide additional constraints on the nature of mantle sources involved (SOPITA, Samoan plume, Pacific) and ingress of high $^3He/^4He$ material; RR samples with high $^3He/^4He$ have low ε_{Hf} and ε_{Nd} plausibly resulting from a Samoan-SOPITA mantle mix. However, high $^3He/^4He$ samples of the NWLSC show no mixing with Samoan-type Nd and Hf. It appears plume invasion is restricted to sub-RR. The Pacific mantle signature is prominent beneath the NWLSC but disappears south of the PR towards the CLSC being replaced by SOPITA-type mantle. Decoupling of $^3He/^4He$ with Nd and Hf may indicate flow of He in a plume-derived volatile phase.

Methane solubility under reduced conditions in a haplobasaltic liquid, applicable to degassing of magma ocean

P. ARDIA [1]*, A.C. WITHERS[1], M.M. HIRSCHMANN[1] AND R.L. HERVIG[2]

[1]University of Minnesota, Dept. of Earth Sciences, 108 Pillsbury Hall, Minneapolis, MN 55455 (*correspondance: pardia@umn.edu);
[2]Arizona State University, School of Earth and Space Exploration, Tempe, AZ 85287, USA

Oxygen fugacity (fO_2) may have a critical influence on the solubility of volatiles in silicate liquids, which in turn influences fluxes of volatiles from planetary interiors to their atmospheres. Carbon dissolves in oxidized basic melts as carbonate but under reduced conditions is limited by precipitation as graphite or diamond. At conditions where melt is in equilibrium with Fe alloy, the carbonate solubility will not exceed few ppm [1], limiting volcanogenic transport of C to the atmosphere. Therefore, dissolved C-H species may dominate C solubility and transport at low fO_2 [2][3].

We investigated the solubility of C-O-H fluid in a haplobasaltic melt ($Di_{40}An_{42}Ab_{18}$), adding C as $Si_5C_{12}H_{36}$+ H_2O to produce SiO_2+CH_4+H_2 and H_2O. Experiments were performed at 0.7, 1.5, 2.0 and 3.0 GPa at 1400°C and the fO_2 was buffered using a double Pt-capsule technique, where the external buffer (e.b.) fixed the fH_2 by transport across a H-permeable Pt barrier, and the internal buffer (i.b.) set the fO_2 of the silicate charge. We used three buffer combinations: 1) e.b. with Fe-FeO-Fe_3C-H_2O and i.b. with graphite; 2) e.b. with Fe-FeO-H_2O and i.b. Si^0, 3) e.b. with Ni-NiO-H_2O and i.b. Si^0. We examined resulting glasses by optical and SEM microscopy to establish equilibrium coexistence of the melt with a fluid phase and verified glass compositions with EMPA. Dissolved volatile species were identified by microRaman spectroscopy and OH and C concentrations were quantified by FTIR and SIMS, respectively. Results show that C dissolves as methane together with OH and H_2 in equilibrium with a volatile phase composed chiefly of CH_4 and H_2. At IW to IW-2 (buffer 1) the dissolved C increases linearly with pressure from 70 ppm at 0.7 GPa to 360 ppm at 3.0 GPa. Methane may therefore be the dominant C species outgassed from reduced planetary mantles.

Mobilization of Pb from weathered shots at a firing range in Athens, Greece

A. ARGYRAKI[1]*, A. GODELITSAS[1], N. PETRAKAKI[1], J.M. ASTILLEROS[2] AND A. KARAGEORGIS[3]

[1]University of Athens, 15784 Zographou, Athens, Greece (*correspondance argyraki@geol.uoa.gr)
[2]Univ. Complutense Madrid, E-2804 Madrid, Spain
[3]HCMR, PO Box 712 Anavyssos, Greece

The dispersion and accumulation of Pb and other heavy metals in soil depends on their source as well as interactions between the soil solution and mineral components, resulting in dissolution and precipitation of new solid phases which incorporate the metals. This research focused on mobilization of Pb from shots exposed to weathering within a recreational area in Athens, Greece. Parts of the study area were used in the past as firing ranges. Lead in surface soil was measured by AAS after dissolution with aqua regia and concentration values reached a maximum of 2400 mg g^{-1} with a median of 114 mg g^{-1}. Samples were subsequently collected from two vertical soil profiles located close to the areas with the highest measured Pb concentrations and analyzed by XRF in order to produce Pb profiles up to a depth of 0.5 m and investigate the downwards migration of Pb. The analytical results were interpreted in conjuction with XRD data and SEM observations on soil samples. An abrupt, ten-fold decrease of Pb soil content was observed within the upper 10 cm at both profiles. The fate of metallic Pb in soil was further studied through two experiments. The first, involved burial of unused Pb shots in uncontaminated soil at the wider area of the studied site which lithologically consists of carbonate and ophiolite rock. After a period of 4 months the shots were removed from soil. Study by SEM confirmed the formation of hydrocerussite crystals on their surface. The second experiment involved in-situ AFM in contact mode to directly monitor changes in surface microtopography of metallic Pb reacting with an aqueous solution of CO_2 at pH = 4. Data from this experiment indicated a rapid growth of Pb hydroxycarbonate phase from about 7 min to about 11 min from exposure.

In conclusion, the combination of chemical analyses and microscopic techniques contributed to the understanding of Pb mobilization process during weathering of Pb shots. This includes rapid formation of Pb carbonate phases on the surface of shots and their subsequent dissolution under surface soil conditions. Lead starts migrating downwards and is effectively immobilized through formation of secondary Pb hydroxycarbonate phases within the upper 10 cm of soil.

Processes and timescales of magma evolution prior to the Campanian Ignimbrite eruption (Campi Flegrei, Italy)

ILENIA ARIENZO*[1], ARND HEUMANN[2], GERHARD WÖRNER[2], LUCIA CIVETTA[1,3], ROBERTO MORETTI[1,4] AND GIOVANNI ORSI[1]

[1]Istituto Nazionale di Geofisica e Vulcanologia, sezione di Napoli Osservatorio Vesuviano, Via Diocleziano 328, Napoli, Italy (*correspondence:ilenia.arienzo@ov.ingv.it)
[2]GZG, Abteilung Geochemie, Goldschmidtstr. 1, 37077 Göttingen, Germany
[3]Dipartimento di Scienze Fisiche, Università di Napoli "Federico II", Monte S. Angelo, Napoli, Italy
[4]Dipartimento di Ingegneria Civile, Seconda Università di Napoli, Aversa, Caserta, Italy

The Campi Flegrei caldera collapsed 39 ka in the Neapolitan area (southern Italy) after the Campanian Ignimbrite eruption. This eruption, recognized as the largest and the most cataclysmic volcanic event in the Mediterranean area over the past 200 ka, extruded not less than 300 km^3 of trachytic magma. Controversy exists over the timescales required to assemble a such large volume of silicic melt and thus whether large magmatic reservoirs can actually persist below active volcanic systems over prolonged periods of time. Uranium-series analyses have been performed on Campanian Ignimbrite whole-rocks, glass matrixes and separated minerals. The compositionally most evolved sample which is most radiogenic with respect to Sr isotopes records a reference age of 71 ka. By contrast, U-Th internal isochrones of the three compositionally least evolved samples give identical initial Th isotope ratios and yield consistent ages predating the eruption by up to 6.4 ka. Therefore the time preceding this large caldera-forming eruption during which the large volume of Campanian Ignimbrite magma assembled and mixed is 6.4 ± 2.1 ka.

The highest Pb and Nd isotopic ratios and $^{230}Th/^{232}Th$ activity ratios together with the oldest reference age of the most evolved samples suggest the existence of a resident magma body possibly related to a magmatic system that is known to have fed earlier magmatic activity in the Campi Flegrei area. Conversely, the younger age of the least evolved and least radiogenic magma dates the crystallization/differentiation event of a chemically and isotopically new magma batch entering the reservoir of the resident magma some few thousand years before the cataclysmic eruption. The progress of crystallization yielded high-water contents (up to 6-7 wt%), thus producing an overpressurized gas cap. The onset of the eruption tapped this cap, with consequent depressurization and fast volume decrease that facilitated or even drove the caldera collapse, and allowed the water-rich magma to be discharged during the pyroclastic current phase.

Bahamian speleothems reveal increased aridity associated with Heinrich events

M.M. ARIENZO[1]*, P.K. SWART[1], K. BROAD[1], A.C. CLEMENT[1], A. EISENHAUER[2] AND B. KAKUK[3]

[1]RSMAS, University of Miami, Miami FL 33149, USA (*correspondence: marienzo@rsmas.miami.edu) (pswart@rsmas.miami.edu, kbroad@rsmas.miami.edu, aclement@rsmas.miami.edu)
[2]IFM-GEOMAR, Kiel, Germany (aeisenhauer@ifm-geomar.de)
[3]Bahamas Underground, Marsh Harbor, Abaco, Bahamas

During the last glacial period there is substantial evidence for global millennial scale variability in climate, dominated by Heinrich events and Dansgaard-Oeschger events. Heinrich events have been well documented in the ice core records, deep-sea sediment records and speleothems. These records document that Heinrich events are global and abrupt climate change events. Recent studies across Africa and Asia indicate that drying throughout the tropics of both hemispheres occurred during Heinrich event 1 [1]. Geochemical analysis of stalagmites from the Bahamas further support a more arid climate associated with Heinrich events in the subtropical Atlantic.

In this study, currently submerged speleothems have been collected at depths ranging from 10-40 meters below sea level. These stalagmites formed when sea level was lower than at present and the cave was subaerially exposed. The stalagmites were dated using U/Th methodologies and analyzed for stable carbon and oxygen isotopes at a resolution of 20 um (approximately one sample every 2 years). In the subtropics, it has been demonstrated that higher volume rainfall events generally leads to a depleted $\delta^{18}O$ and $\delta^{13}C$ signal, whereas heavier $\delta^{18}O$ and $\delta^{13}C$ values are attributed to lower amounts of rainfall. The geochemical results reveal a significant isotopic excursion associated with Heinrich events. The change across Heinrich events 1-4 averages about 4 ‰ for C and 2 ‰ for O. These changes were all from positive to more negative values. These results support a rapid shift from an arid to a much wetter climate in the Bahamas associated with Heinrich events. Based on our preliminary age analysis, these changes occurred over a period of approximately 50 years. These records provide a unique opportunity to study climate variations at a fine resolution and may better define the role of the sub-tropics in forcing climate change.

Geochemical features of the Aladag Fe-Cu-Zn-Pb skarn deposit (Ezine/Canakkale-North West Turkey)

F. ARIK[1]* AND Ü. AYDIN[2]

[1]Selcuk University, Geological Engineering Department, Konya, Turkey (*correspondence: fetullah42@hotmail.com)
[2]General Directorate of Mineral Research & Exploration, Ankara, Turkey (umitaydin77@gmail.com)

Aladag skarn zone located 8 km southwest of Ezine County (Çanakkale-Turkey). The basement of the study area is formed by recrystallized limestones of the Middle-Late Permian Bozalan Formation. Cretaceous Denizgoren Ophiolites thrusted over the Bozalan Formation. Upper Oligocene-Lower Miocene Hallaclar Volcanics consist of andesite, basalt, rhyolite and pyroclastic rocks cover the other units. Also Upper Oligocene-Lower Miocene Kestanbol Pluton cuts the older units and represented by mainly quartz-monzonite, monzonite, monzodiorite porphyry, syenite porphyry and quartz-syenite porphyry. Lower-Middle Miocene Ezine Volcanics composed of pyroxene-andesite and trachyte [1,2].

Skarn type mineralization was developed between the Bozalan Formation and Kestanbol pluton depending on the intrusion of the pluton at the north of Aladag. Endoskarn and exoskarn zones developed in the skarn zone. Some Ca-Mg silicate together with Fe, Cu, Pb, Zn oxide and sulphide minerals were developed in the skarn zone [1, 2]. (Fig. 1).

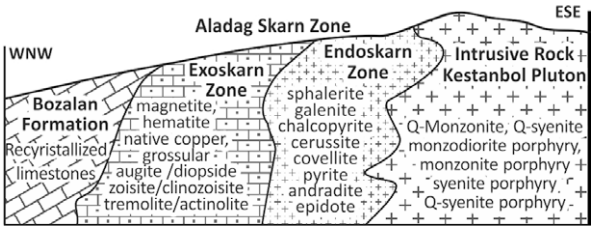

Figure 1. Schematic cross-section of Aladag skarn zone

Endoskarn zone is rich in Pb-Zn-Cu and the amounts of SiO_2, Al_2O_3, Fe_2O_3, Cu, Pb, Zn and Ag are 41.77%, 4.28%, 15.93%, 3.53%, 4.5%, 4.83% and 34 ppm respectively.

Exoskarn zone is rich in Fe and Fe_2O_3, SiO_2, Al_2O_3, MgO, CaO, Cu, Pb, Zn and Ag amounts are 66.75%, 14.85%, 1.37%, 4.34% and 8.63%, 112 ppm, 162 ppm, 213 ppm and 0.4 ppm respectively. There are significant increase in the amounts of Ca and Mg from intrusion rocks to wall-rocks in the skarn zone.

In situ secondary hydrocarbon cracking in a carbonate reservoir

S. ARKADAKSKIY[1]* B. ROSTRON[2] R. WIERZBICKI[3] AND V. ZRAL[3]

[1]Isobrine Solutions 4-341, 10230 Jasper Ave., Edmonton, T5J4P6, Canada (*correspondence: serguey@isobrine.com)
[2]University of Alberta, EAS, Edmonton, T6G2E3, Canada
[3]EnCana 1800, 855-2nd St. SW Calgary, T2P2S5, Canada

The Jean Marie member of the Redknife Formation in NE British Columbia, Canada is an Upper Devonian gas-rich (approx. 10 TCF) limestone zone, 15 to 100 m thick, lying unconformably on top of the Fort Simpson Formation and covered by the Redknife Fm. shale. The Jean Marie member is a low-permeability reservoir with dissolution related porosity and permeability locally enhanced by secondary dolomitization and fracturing. The reservoir is severely underpressured and of low water saturation. Carbon stable isotope analysis of natural gases has been used to assist hydrocarbon production from the reservoir. Here we present results from a $\delta^{13}C$ study of Jean Marie gases.

Natural gases in the Jean Marie exhibit significant compositional and $\delta^{13}C$ heterogeneity. Dry gases of reversed $\delta^{13}C_{C1}$ and $\delta^{13}C_{C2}$ compositions, lower $\delta^{13}C_{C2}$, and high C_2/C_3+ ratios are located in lower pressured NW domains of the study area, whereas C_2+ -richer gases of "normal" $\delta^{13}C$ compositions are produced to the SE. That trend is accompanied by increasing production pressures and gas condensate production. Geochemical data reveal limited gas mixing and significant reservoir compartmentalization. The $\delta^{13}C$ compositions and the low H_2S and CO_2 contents of the isotopically "reversed" gases indicate that these are not related to secondary processes such as sulphate reduction or microbial oxidation. Instead, the compositions of these gases are consistent with secondary cracking of hydrocarbons (SCH). The presence of pyrobitumen in the Jean Marie reservoir and the lack of liquid hydrocarbons in domains occupied with "reversed" gases both suggest that SHC occurred *in situ*. That challenges current models, which infer that the Jean Marie reservoir was charged first with oil and then with dry gas, both generated in the deeper, organic-rich Muskwa Formation. Instead, we propose that most natural gas in Jean Marie today was generated by secondary cracking of Muskwa oil and/or wet gas, and that late migration of dry Muskwa gas to Jean Marie was insignificant. SCH was more intense in the deeper western parts of Jean Marie where it produced dryer isotopically "reversed" gases. This study has important implications for the timing of migration and generation/destruction of hydrocarbons in the Jean Marie and similar carbonate reservoirs worldwide.

TAPP: Retrograde Mg-perovskite from subducted lithosphere?

L.S. ARMSTRONG* AND M.J. WALTER[1]

Department of Earth Sciences, University of Bristol, Queens Road, Bristol, BS8 1RJ, United Kingdom.
(*correspondence: L.Armstrong@bristol.ac.uk)

A phase with a tetragonal structure and compositional similarities to garnet was discovered as inclusions in diamonds over a decade ago, and given the acronym TAPP (Tetragonal-Almandine-Pyrope-Phase) [1]. TAPP has no known stability field, having never been synthesized in high P-T experiments, but a narrow stability region near the base of the transition zone has been postulated on the basis of associated inclusions [2]. Crystallographic arguments support the possibility that TAPP may be a retrograde phase formed when a higher pressure mineral was trapped in diamond then subjected to lower P-T conditions during ascent through the transition zone or upper mantle [3]. Here we propose that single-phase TAPP inclusions originated as Mg-perovskite (Mg-Pv) formed in deeply subducted mafic lithosphere.

Rare $MgSiO_3$ inclusions found in ultradeep diamonds are considered to represent former Mg-Pv, and their compositions generally match well with Mg-Pv formed in high P-T experiments on ultramafic bulk compositions (Fig.1). Likewise, the bulk compositions of TAPP inclusions match well with the trivalent-cation enriched Mg-Pv that forms in experiments on mafic compositions; Ti-rich TAPP inclusions are nearly exact matches to Mg-Pv expected to form in subducted MORB. REE abundances measured in a TAPP inclusion [4] also closely match those found in Mg-Pv inclusions [5]. Preliminary diamond anvil cell experiments on an average TAPP composition indicate formation of nearly phase-pure Mg-Pv at lower mantle conditions.

Metal-silicate partitioning of iodine at high pressures and temperatures: Implications for the Earth's core

ROSALIND M.G. ARMYTAGE[1], ANDREW P. JEPHCOAT [1,2], M. ALI BOUHIFD[3,1] AND DONALD PORCELLI[1]

[1]Department of Earth Sciences, University of Oxford, South Parks Rd, Oxford OX1 3AN, UK.
(*correspondence: rosa@earth.ox.ac.uk)
[2]DIAMOND Light Source, Diamond House, Chilton, Didcot, OX11 0DE, UK
[3]Laboratoire Magmas et Volcans, Université Blaise Pascal, 5 rue Kessler, Clermont-Ferrand 63038, France

The two major causes for the difference in elemental concentrations between the silicate Earth and primitive undifferentiated chondritic silicate material are volatility and/or partitioning in the Earth's core. Compositional models of the Earth [1,2,3] suggest that the depletion of some of the halogens in the Bulk Silicate Earth (BSE) are greater than can be explained by their volatility. The calculations indicate that up to 85% of the Earth's iodine could reside in the core but to date there is no published high-pressure liquid-metal, liquid-silicate partitioining experimental data for iodine to test this idea.

We present the first results for metal silicate partitioning behaviour of iodine. Candidate CI-like glass mixtures of silicate and iron (+iron alloy) were heated in a Laser Heated Diamond Anvil Cell (LHDAC) at pressures between 2-20GPa and at ~3000 K. No pressure dependence of the partition coefficient, $D_{\text{liquid-metal liquid-silicate}}$ was observed within this range, but the composition of the metal phase was shown to have an effect. When the dominantly iron liquid was alloyed with Ni, S, O and Si there was an increase in iodine solubility in the metal. Iodine exhibited siderophile behaviour over all the PT conditions with D_I = 1.22 ±0.73 (2 s.d.) (Fe metal) and D_I = 4.40±1.36 (2 s.d.) (Fe-alloy). In conjunction with a "best estimate" concentration for iodine in the bulk silicate Earth (BSE), it is calculated that the core could be a significant reservoir for iodine, depending on the model for separation.

The implications of iodine's siderophile behaviour are considered with regards to the decay system ^{129}I –^{129}Xe ($T_{1/2}$ = 15.7Myr). As it is thought the core would have formed while ^{129}I was still extant, preliminary modelling has been carried out to assess the core's radiogenic ^{129}Xe budget and the effect this may have on mantle xenon reservoirs and closure ages.

Ore metals from the subcontinental lithospheric mantle?

NICHOLAS ARNDT

ISTerre, UMR5275 CNRS, Université Joseph Forier, 38400 Grenoble, France (arndt@ujf-grenoble.fr)

The hypothesis that the metals in some ore deposits come from the base of the lithosphere arises because we know very little about the composition of this part of the mantle. It could conceivably be enriched in certain metals, and if so, these metals could conceivably be transported to the surface in magmas or other fluids and there become concentrated in ore bodies. There is very little substance to the model, and many arguments against it. The lithosphere is by definition the coldest part of the mantle and it only melts under special conditions. The normal product is a low-degree melt - an alkaline, Si-undersaturated magma of the type that, with rare exceptions, contains few metallic ore deposits. Some gold deposits may be associated with lamprophyres that could have come from the lithosphere, but a direct genetic association has not been demonstrated. In regions of continent rifting, the lower parts of the lithosphere may well up and melt, but metallic ore deposits are rare in continental rift zones. Major magmatic ore deposits form from high-volume, high-flux magmas that result from high-degree melting in large volumes of mantle. The normal source of such magmas is in deeper, hotter parts of the mantle – the asthenosphere or a mantle plume. If melting is to occur in the lithosphere, rather than in the hotter parts of the mantle, the melting point of the lithosphere must be drastically reduced by the presence of volatiles. There is little evidence, however, that the host magmas of ore deposits were unusually rich in water or CO_2. Magmas from a sub-lithospheric source will interact with wall rocks as they pass through the lithospheric mantle and they may pick up some metals through this interaction. However, there is ample geological and geochemical evidence that the origin of most magmatic deposits involves crustal contamination of asthenosphere- or plume-derived magmas at shallow levels of the continental crust of magmas and that the major source of the ore metals is the asthenosphere or the plume.

Unexpected changes in aggregation and mineralogy of goethite during the reduction of nitroaromatics

WILLIAM A. ARNOLD[1]*, R. LEE PENN[2] KIRSTEN MOORE[1], TRAM AHN DO[2] AND AMANDA M. STEMIG[2]

[1]Department of Civil Engineering, University of Minnesota, 500 Pillsbury Dr. SE, Minneapolis, MN 55455, USA (*correspondence: arnol032@umn.edu, moor0561@umn.edu)

[2]Department of Chemistry, University of Minnesota, 207 Pleasant St. SE, Minneapolis, MN 55455, USA (rleepenn@umn.edu; doxxx042@umn.edu; stemi002@umn.edu)

When studying the reduction of nitroaromatic compounds by ferrous iron in the presence of goethite, it is routine to use batch reactors. The ferrous iron and goethite are equilibrated in a pH-buffered solution, and the reaction is initiated by introducing a target contaminant in a cosolvent. These experiments have taught us much about the reactivity of nitroaromatic compounds in systems containing reduced iron, but there are two assumptions made in these systems. First, it is assumed that the particle size/surface area/aggregation state is constant. Second, it is assumed that the mineral phase composition does not change during the course of the reaction. We have previously shown that the particle size is not constant during such reactions [1]. Our results here reveal further limitations in the above assumptions.

Stable particle sizes are observed via dynamic light scattering (DLS) when goethite nanorods are suspended in a solution buffered with 3-(N-morpholino)propanesulfonic acid. Upon injection of a methanolic stock of 4-chloro-nitrobenzene, DLS measurements show rapid aggregation of the particles. Results to date suggest that the combination of cosolvent and contaminant lead to the agglomeration. This finding suggests that the method used to introduce the contaminant, including the presence of a cosolvent, may influence the measured reaction rate of the contaminant. These effects are beyond those caused by the buffer itself [2].

Results tracking the kinetics of trifluralin (a nitroaromatic herbicide) reduction in the presence of ferrous iron and goethite nanorods show suprising changes in particle agglomeration as well as phase composition of the solids. These results reveal a reaction system that is more dynamic that previously envisioned.

Optical properties, size distribution and composition of aerosol particles in the urban area of Sao Paulo

PAULO ARTAXO[1], JOHN BACKMAN[2], LUCIANA RIZZO[3], FABIO JORGE[1] AND MARKKU KULMALA[2]

[1]Institute of Physics, University of São Paulo, Brazil (artaxo@if.usp.br)
[2] Division of Atmospheric Sciences, Department of Physics, University of Helsinki, Finland.
[3] Department of Exact and Earth Sciences, Federal University of Sao Paulo, Diadema, Brazil.

The megacity of São Paulo with its 19 million people and 7 millions cars is a challenge from the point of view of air pollution. High levels of PM10, black carbon and ozone and the peculiar situation of the large scale use of ethanol fuel makes it a special case. Little is known about the impact of ethanol on air quality and human health and the increase of ethanol as vehicle fuel is rising worldwide An experiment was designed to physico-chemical properties of aerosols in São Paulo, as well as their optical properties. Aerosol size distribution is being measured with a Helsinki University SMPS and a GRIMM OPC. Optical properties are being meeasured with a TSI Nephelometer and a MAPPF absorption photometer. An CIMEL sunphotometer from the AERONET network measure the aerosol optical depth.

The measured total particle concentration typically varies between 10,000 and 30,000 cm-3 being the lowest late in the night and highest around noon and frequently exceeding 50,000 cm-3. Clear diurnal patterns in aerosol optical properties were observed ranging between 21 and 64 Mm-1 for light scattering coefficients (σSP) and between 12 and 33 Mm-1 for light absorption coefficients (σAP). The diurnal patterns measured at the site show peaks in light absorption and scattering coefficients during morning rush hours where the single-scattering albedo (ω0) is at its lowest. Surface mean diameters can be seen growing from the minimum at noon to late into the night which can also be seen from the size dependent Angstrom exponents calculated from the light scattering coefficients. During the first month a total of seven new particle formation events were observed with growth rates ranging from 9 to 25 nm h-1. During these events the condensation sink, vapour abundance explaining the growth, and vapour production rates were calculated. Interestingly enough there were also events were condensed vapours were evaporating from the condensed phase thus shrinking the size of the particles in all sizes. Aerosol optical thickness were relativelly small at 0.1-0.3 at 500 nm, indicating low boundary layer height.

Evolution of the cratonic lithosphere inferred from lithospheric mantle heterogeneity: A geophysical perspective

IRINA M. ARTEMIEVA

IGG, University of Copenhagen, Denamrk, (irina@geo.ku.dk)

Large-scale geohysical models indicate a significant lateral heterogeneity of the cratonic lithosphere. In contrast to xenolith data, which suggest little variation in lithospheric thickness in the cratons, significant lateral variations in lithospheric thickness are seen in global thermal [1] and seismic tomography models [e.g. 2, 3]. These variations reflect the cumulative effect of the processes of lithosphere formation and its later reworking by tectonic and mantle processes, and thus provide information on the preservation style of the lithospheric mantle. Thermal [1] and seismic tomography models [2, 3] of lithospheric thickness, complemented by a global 1 deg x 1 deg database for tectono-thermal ages for the continental crust [4], are used to calculate (i) the volume of the preserved continental lithosphere of different ages within the individual cratons, (ii) a global model of lithosphere preservation since the Archean. In accord with independent estimates of the growth rate of juvenile crust [5], three major peaks in lithosphere preservation rate can be recognized globally. However, the amplitude at 2.1-1.7 Ga is at least double of that at the peaks at ca. 2.7-2.6 Ga and 1.3-1.1 Ga, and significant differences both in the time and in the amplitude of the peaks exist between different cratons [6].

Extracting non-thermal signal from seismic tomography models allows for distinguishing compositional variations in the cratonic lithosphere, which also reflect the cumulative effect of varios processes related to lithosphere formation and its later reworking [7]. Compositional seismic velocity variations in the lithospheric mantle show strong qualitative correlation with its tectono-thermal ages and with regional variations in the lithospheric thickness. Their amplitude, however, varies both laterally and vertically, reflecting either a peripheral growth of the cratons in Proterozoic or their peripheral metasomatic reworking in the post-Archean time.

Modeling the dissolution and growth of whole mineral grains

ROLF S. ARVIDSON* AND ANDREAS LUTTGE

[1]Department of Earth Science MS-126, Rice University, Houston TX 77005, USA
(*correspondence: rsa4046@rice.edu, aluttge@rice.edu)

The reactivity of crystal surfaces reflects the distribution and interaction of kinks, steps, and defect-related sites. During the dissolution of whole mineral grains (e.g., Fig. 1), substantial changes are commonly observed along discontinuities such as grain edges, twin boundaries, and other complex macro-features [1]. We wish to understand the evolution of these changes during the dissolution and growth of the entire crystal, and how they relate to the integrated flux of material from the particle. We examine this general kinetic problem through a series of Monte Carlo models, beginning with simulations of dissolution and growth using a simple cubic Kossel crystal, and culminating in virtual experiments involving complex crystal structures. We can use these simulations to explore a variety of problems, including (1) the contribution of these features to the integrated rate as a function of crystal diameter, (2) how processes such as uptake and release at kink sites are coordinated with diffusive transport, (3) whether the changes observed during dissolution are reversible under growth conditions, (4) how the mean and variance of the reaction rate at these edge sites compare to those on interior terraces as a function of defect density, and (5) the implications for the behavior and properties of poly-crystalline grains and nano-particles.

Paleozoic tholeiite magmatism in the Kola Province, Russia: Relations with alkaline magmatism

A.A. ARZAMASTSEV AND L.V. ARZAMASTSEVA

Geological Institute KSC RAS, Apatity, Russia
(arzamas@geoksc.apatity.ru)

The Kola alkaline province, formed in the northeastern part of the Fennoscandian Shield include Khibina and Lovozero plutons, carbonatite intrusions, and numerous alkaline dikes, as well as remnants of subalkaline and alkaline extrusives. The discovered manifestations of tholeiite magmatism in the region are represented by dolerite dikes forming three swarms: Pechenga, the Barents Sea coast, and the East Kola. $^{40}Ar/^{39}Ar$ geochronology obtained for 5 dolerite dikes, together with Sm–Nd mineral isochron data yield a 405-385 Ma time span of tholeiitic magmatism in Kola part of the Fennoscandian Shield. In the Sm–Nd system, the εNd(T) values (+0.9...+5.4) are close to those for alkaline rocks of the province. They testify that the tholeiite melts originated from sources with a significant share of a depleted mantle component. Trace elements characteristics suggest that the Paleozoic dolerites belong to a group of continental plateau basalts.

The finding of the Devonian tholeiites leads to the need to define their position in the general evolution model of Paleozoic magmatism, and, first of all, to define their relationships with alkaline melts. Analysis of the spatial distribution of the Paleozoic dolerite dykes shows that they are located on the periphery of the area of predominant development of alkaline intrusions and alkaline dike swarms. The set of geochronological data shows that the main manifestations of alkaline magmatism occurred in the period of 380-360 Ma. The initial melts of the Paleozoic alkaline intrusions corresponded to olivine melanephelinite, which was generated under the conditions of garnet lherzolite facies. According to the above mentioned materials, we suggest that the tholeiites correspond to the initial phase of the Paleozoic plume-lithosphere interaction, during which the occurrence of tholeiite melts in the peripheral zone of the plume was the result of partial melting of the mantle substrate under the conditions of spinel lherzolite facies. During the subsequent development of the process of plume–lithosphere interaction, the deep mantle areas corresponding to the conditions of garnet lherzolite facies were in the zone of melting. The partial melting of these lherzolites under the conditions of mantle metasomatism led to the formation of melanephelinite melts, the basis of formation of the Paleozoic Kola alkaline province.

Crystallization kinetics of alkali feldspar in trachytic melts of Phlegraean Fields (Napoli, Italy)

F. ARZILLI[1]*, M.R. CARROLL[1] AND M. PIOCHI[2]

[1]University of Camerino, via Gentile III da Varano, Camerino, (MC) Italy (*correspondence: fabio.arzilli@unicam.it; michael.carroll@unicam.it)

[2]INGV-OV, via Diocleziano 328, Napoli (NA), Italy

The aim of this study is to quantify crystallization kinetics of trachytic melts and eruption dynamics of phlegraean volcanoes. In particular, studying the growth rate (G_L), through cooling experiments, of alkali feldspar and their crystal size distribution (CSD), is possible to constrain residence time of magma in magma-chamber and into the conduit during the eruption.

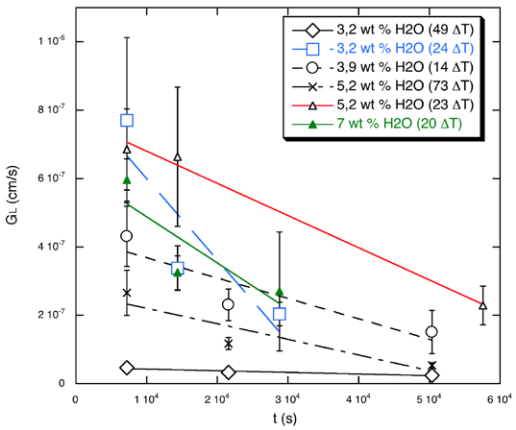

Figure 1: Relation between the growth rate (G_L) and the experimental time (t).

Discussion of Results

The order of magnitude of alkali feldspar growth rate obtained from cooling experiments varies between 10^{-7} and 10^{-8} cm/s (Fig. 1). This difference in order of magnitude depends on percentage of H_2O dissolved in the melt and degree of undercooling ($\Delta T = T_{liquidus} - T_{experimental}$) [1] (Swanson, 1977). Moreover, this difference implies significant variations of the ascent time. CSD studies on Monte Nuovo products carried out by Piochi *et al*. [2] to investigate magma dynamics in syn- eruptive conditions combined with G_L values obtained in this experimental work suggest ascent times between 2 days and several hours.

Molybdenum isotopes as oceanic paleoredox proxy of the Paleoproterozoic Shunga event

D. ASAEL[1]*, O. ROUXEL[2], C. REINHARD[3], T. LYONS[3] AND L. KUMP[4]

[1]Université de Brest, IUEM, UMR 6538, 29280 Plouzané, France (*correspondence: dan.asael@univ-brest.fr)

[2]IFREMER, Département Géosciences Marines, 29280 Plouzané, France (orouxel@univ-brest.fr)

[3]Department of Earth Sciences, University of California, Riverside, CA 92521-0423 USA

[4]Department of Geosciences, Penn State University, University Park, PA 16802 USA

Molybdenum (Mo) isotopes in ancient organic-rich black shales may directly reflect the contemporaneous seawater Mo isotope compositions and can thus be used as an oceanic paleoredox proxy. We measured Mo isotope composition and Fe speciation of black shales from the 2.0 Ga Zaonega Formation from the Eastern Fennoscandian Shield (ICDP FarDeep project, [1]). The studied section contains thick units of Paleoproterozoic C_{org}-rich sediments (up to 99% C) that represent a giant, petrified oil field, including petroleum source rocks and black shales. Samples were measured by MC-ICP-MS (Neptune), and data were corrected using double-spike iterations (using ^{97}Mo and ^{100}Mo). Mo isotope ratios are reported relative to our internal lab standard SPEX, where $\delta^{98/95}Mo_{SPEX} = \delta^{98/95}Mo_{NIST3137} - 0.37‰$.

Overall, the studied section shows relatively small Mo isotope variations, averaging $\delta^{98/95}Mo = 0.79 \pm 0.29$ ‰. Using Fe speciation ($Fe_{Py}/Fe_{HR} > 0.8$ and $Fe_{HR}/Fe_T > 0.38$), euxinic conditions were identified for several samples in the upper part of the section which also shows higher Mo concentrations. These samples show slightly higher $\delta^{98/95}Mo$ values of 0.88 ± 0.28 ‰, and are considered to represent contemporaneous seawater due to quantitative Mo removal to the sediment. Simple oceanic mass balance of the Mo isotope system shows that euxinic sinks dominated the Mo removal from the oceans and controlled the isotopic composition of seawater.

At this time, after the GOE, increasing oxygen levels in the atmosphere amplified the delivery of dissolved Mo to the oceans. However, the oceans were apparently dominated by anoxic, ferruginous/euxinic conditions with an oxic sink smaller than that suggested by [2] at 2.5 Ga.

[5]Tohoku university, Sendai 980-8578, Japan

Introduction

Stishovite is considered to be an important constituent of subducted oceanic basalts and sediments in the Earth's deep interior. It has the tetragonal rutile structure and transforms to an orthorhombic $CaCl_2$ structure at around 60 GPa in the pure SiO_2 system. Acccording to theoretical models, the phase transition is trigged by the lattice instability of a soft transverse acoustic mode associated with the shear elastic constant and it has been suggested that this elastic softning could relate to several distinctive seismic strucures in the Earth's lower mantle (e.g., [1], [2]). This possibility was denyed by the phase study of pure SiO_2 at high pressure and high temperature [3], however, natural stishovite in subducted basalts and sediments may contain several impuritities, such as Al, Mg, and Na. Therefore, the effect of impurities on the phase transition and elastic properties of stishovite should be clarified. In this study, we investigated elastic properties of sodium contained stishovite by simultaneous measurements of acoustic velocity and X-ray diffraction across the post-stishovite phase transition at room temperature.

Results

Simultaneous measurements of Brillouin scattering and X-ray diffraction on polysrystalline stishovite with 3 wt.% sodium as impurity were conducted at room temperature and the pressure range of 0-70 GPa using a combined system of Brillouin scattering and synchrotron X-ray diffraction at SPring-8/BL10XU, Japan [4]. The phase transition from rutile-structure to $CaCl_2$-structure was observed at around 35GPa with X-ray diffracton and a dipping of transversal velocity was also observed at the transion pressure.

Effects of fluorine on the solubility of Nb, Ta, Zr and Hf in highly fluxed water saturated haplogranitic melts

A. ASERI[1] AND R.L. LINNEN[2]

[1]Department of Earth and Environmental Sciences, University of Waterloo, (aaseri@uwaterloo.ca)
[2]Department of Earth Sciences, University of Western Ontario, (rlinnen@uwo.ca)

The effect of fluorine on the solubility of $MnNb_2O_6$, $MnTa_2O_6$, $ZrSiO_4$ and $HfSiO_4$ was determined for highly fluxed, water-saturated haplogranitic melts at 800 °C and 2000 bars. The melts correspond to the projection of the granite minimum to the intersection of the Ab-Or tieline in the Q-Ab-Or system ($Ab_{72}Or_{28}$) and also contain 1.1, 1.7 and 2.02 wt % of Li_2O, P_2O_5 and B_2O_3, respectively, Up to 6 wt% fluorine was added as AgF in order to keep the ASI of the melt constant. The nominal ASI of the melt is close to 1, so that if Li is considered to be an alkali element, the melts are alkaline. The experiments were conducted using cold seal pressure vessels with water as a pressure medium.

The solubility products $[MnO]*[Nb_2O_5]$ and $[MnO]*[Ta_2O_5]$ are nearly independent of F content, approximately $17x10^{-4}$ and $70x10^{-4}$ mol^2/kg^2, respectively, although there may be a weak negative dependence on F. These data are in agreement with [1] conducted on Li-B-free and P-poor melts. By contrast, there is a positive dependence of zircon and hafnon solubility, which increase from 0.25 wt% ZrO_2 and 0.85 wt% HfO_2 for melts with 0 wt % F to 0.38 wt% ZrO_2 and 1.16 wt% HfO_2 for melts with 6 wt % F, in agreement with [2]. However, the overall conclusion is that fluorine is less important than previously thought for the control on the behaviour of high field strength elements in highly evolved granitic melts.

[3]University of Vienna, Austria, (ntaflot9@univie.ac.at)
[4]University of London, G.Britain, (h.downes@ucl.ac.uk)

Reconstruction of PTXF conditions of SCLM for Ykutian [1,2] and ~70 worldwide kimbelites show high heating of Proterozoic mantle, lower heating stage to the mantle of the northern continentswith sicker SCLM in comparison with post Gondwana ones. The layering -7-12 horizons correlates with superplume events. The thransects for Siberia, Baltica, marginal N America and S Africa show motley inclined SCLM, in central parts prevail horizontal. Three traps for the melts: oxidized in- the 75-65, carbonatite- 45-40, and water-bearing basaltic- 20-30 kbar [3] are marked by pyroxenites [4]. Melt and diapiric upvelling from these levels in off-craton and rifting settings were basificated, reduced and rifted in superplume periods. Models of SCLM formation: the nucleation of restite from mantle diapirs; joining of exhousted or island-arc type blocks; the low angle subduction of submelted plates under superplumes; broken, folded high angle plates joined to the continental margins. Fluid/melt flows in the continent margins metasomitized SCLM [5]. Protokimbelites refertillized low part of mantle section in two steps–carbonatite/kimberlite and with H_2O bearing melts as evidenced by geochemical features of pyroxenes and garnets RBRF 11-05-00060a;11-05-91060-PICSa.

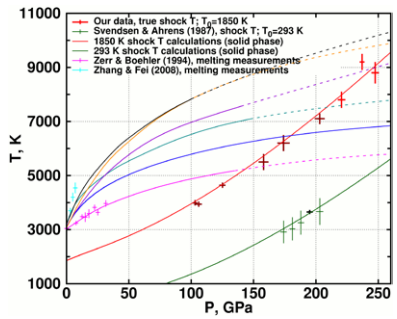
The melting curve of MgO from shock temperature experiments

P. D. ASIMOW* AND O. V. FAT'YANOV

Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena CA 91125, USA (*correspondence: asimow@gps.caltech.edu)

MgO is a major constituent of the lower mantle and its melting curve is an essential anchor point for understanding crystallization of magma oceans or melting at the core-mantle boundary. Despite the apparent simplicity of this material, its melting curve remains highly uncertain. The laser-heated DAC-based melting curve of [1], extrapolated to 135 GPa, is 1000 K below any of the published theoretical curves [2-6], which themselves range over nearly 2500 K. A recent study of the MgO-FeO binary loop supports a very steep liquidus [7]. To resolve this issue we determined shock temperature on single-crystal MgO pre-heated to 1850 K before impact. Our data are calibrated against a standard irradiance lamp and the known shock temperatures of NaCl and MgO shocked from 300 K and are corrected for shock-front reflectivity. Melting should manifest as a drop in shock T with increasing pressure and shock T lower than expected for solid periclase in the shock state. Our experiments reach 9000 K at 250 GPa and remain solid in the shock state. This rules out the melting curve of [1] and probably [2], but we have only a lower bound on the melting curve at this time. Experiments with initial temperature up to 2350 K are in progress.



A very high melting temperature of MgO implies minimum melts of the lower mantle that are silicate- and FeO-rich and a significant ferropericlase liquidus field.

^{39}Ar-^{40}Ar dating on plagioclases of metabasic and metagranitic rocks in the Yoncayolu metamorphics, NE Turkey

Z. ASLAN[1]* M.A. GUCER[2] AND M. ARSLAN[3]

[1]Dept. of Geol. Eng., Balıkesir Univ., 10145, Balıkesir, Turkey (*correspondence: zaslan@balikesir.edu.tr)
[2]Dept. of Geol. Eng., Gümüşhane Univ., 29100, Gümüşhane, Turkey (maligucer@gmail.com)
[3]Dept. of Geol. Eng., Karadeniz Tech. Univ., 61080, Trabzon, Turkey (marslan@ktu.edu.tr)

Low grade Yoncayolu (Erzincan, NE Turkey) metamorphics are overlined tectonically by ophiolitic units. The metamorphics are composed of widespread schists and metabasics, rare metagranitic rocks and calc-schists. All of these are represented by greenschist facies P-T conditions, with mineral assemblages of sericite, chlorite, illite, quartz, calcite, albite, epidote and rare muscovite in schists, and quartz, chlorite, albite, hornblende, epidote, clinozoisite and tremolite in metabasics.

Detailed mineralogical and petrographical studies are carried out on five metabasic and metagranitic samples to find out protolithic mineralogy and texture. Of these, metagranitic sample is a coarse-grained and contain anhedral quartz, plagioclase, aggregates of epidote, clinozoisite, and minor chlorite. The texture of the rock shows some evidence of minor cementation and annealing. Metabasic sample is fine-grained, sparsely phyric, consisting predominantly of altered (mainly sericitized, sometimes completely destroyed) plagioclase and hornblende. Hornblende occurs as part of the matrix, and the anhedral grains are intergrown with the plagioclase.

Metagranitic and metabasic samples were suitable for relict plagioclase separation and ^{39}Ar-^{40}Ar dating. Plagioclase of metagranitic sample (M16) yielded an age spectrum with two steps plateau characterized by 71% of ^{39}Ar and age value of 60.7±4.9 Ma, and plagioclase of metabasic sample (M32) yielded age spectrum with two steps plateau characterized by 56% of ^{39}Ar and age value of 94.1±3.3 Ma. Plagioclase plateau ages obtained from metabasic and metagranitic samples correspond Lower Cretaceous and Lower Palaeocene time, respectively. Hence the ^{39}Ar-^{40}Ar dating can be assumed as the crystallization ages of plagioclases, the metamorphism time and exhumation history of the low grade Yoncayolu metamorphics should have been later than Cretaceous-Palaeocene (?) time.

Fast iron sulfide oxidation in a region of land uplift and artificial drainage

M.E. ÅSTRÖM[1]*, A. BOMAN[2] AND S. FRÖJDÖ[3]

[1]Kalmar University, School of natural sciences, SE-39182 Kalmar, Sweden (*correspondence: mats.astrom@lnu.se)

[3] Abo Akademi University, Department of Geology, FI-20500 Åbo, Finland (soren.frojdo@abo.fi)

Postglacial isostatic uplift (currently up to 1 meter per 100 years) has brought large areas of land above the sea level in low-lying coastal areas of northern Europe. These exposed land masses are to a significant part covered by thick marine sediments, characterised by unusually high concentrations of fine-grained metastable iron sulfides (up to 1%) in an aluminosilicate clay-silt matrix [1, 2].

When drained for agricultural purposes, these sediments rapidly develop into acidic (acid sulfate) soils and release an abundance of metals (Mn, Al, Ni, Zn, Co, Be, Ln) into drains, despite the cold climate with frozen ground and a thick snow cover for about half of the year [3, 4]. We suggest that microbially mediated oxidation of the metastable iron sulfides initiate the soil ripening process, leading to a fast decrease in pH which favours further pyrite oxidation and silicate weathering.

The farmers are worried and the environment – including surface waters and down-stream sediments – is acidified and contaminated. There is thus an urgent need to increase the understanding of this on-going landscape-wide acidification process, in which the preservation and oxidation and toxic-metal content of the metastable iron sulfides is a key parameter.

The *Exxon Valdez*, BP MC 252, and other oil spills: What we learned about petroleum biodegradation and bioremediation

RONALD M. ATLAS

Dept. of Biology, University of Louisville, Louisville KY, 40292 USA (Correspondence: r.atlas@louisville.edu)

The oil spills from the *Exxon Valdez* oil spill in Prince William Sound, Alaska, the Gulf of Mexico (GOM) oil spill from the Deepwater Horizon MC 252 well accident and several other major spills highlight the role of microorganisms in oil weathering and the mitigation of environmental impact. Bioremediation employing fertilizer addition was used to accelerate rates of *Exxon Valdez* oil biodegradation. Rates of oil degradation were a function of the ratio of nitrogen/biodegradable oil and time. Bioremediation increased the rate of polycyclic-aromatic-hydrocarbon degradation by a factor of 2, and of aliphatic hydrocarbons by a factor of 5. Most of the oil has been eliminated from Alaskan shorelines, but some small patches of sequestered subsurface oil residue still remain 20 years after the spill where there is limited water flow. There is ongoing debate as to whether to leave the buried oil residues in place or whether to attempt to supply oxygen and nutrients in an effort to stimulate biodegradation today. The BP MC252 spill was in deep water. Physical and chemical dispersion of the MC252 oil released into the Gulf of Mexico between April 20 and July 15, 2010 resulted in a cloud of fine droplets at approximately 1100-1200 meters that generally moved in a southwesterly direction while larger droplets moved to the surface and formed slicks. During the release (April-July), concentrations of TPAH attenuated rapidly with distance from the release point (the wellhead). Reductions in concentrations as the oil moved away from the wellhead were accompanied by a decreasing ratio of C17/pristane and C18/phytane and degradation of PAHs based on ratios to the conserved hopane. The half lives for hydrocarbons in the deep sea cloud of oil was estimated to be only a few days, while oil in the surface was biodegraded more slowly.

Organic matter mineralization and trace element post-depositional redistribution in Western Siberia thermokarst lakes

S. AUDRY[1]*, O.S. POKROVSKY[1], L.S. SHIROKOVA[1], AND S.N. KIRPOTIN[2]

[1]Université de Toulouse, GET, 14 Av, Edouard Belin, F-31400 Toulouse, France (*correspondence: stephane.audry@get.obs-mip.fr)

[2]Tomsk State University, 36, Lenina Prospekt, Tomsk, 634050, Russia

This study was based on high-resolution sampling of sediments and their porewaters from three thermokarst lakes representing different stages of ecosystem maturity development located within the Nadym-Pur interfluve of the Western Siberia plain. Up to present time, the lake sediments of this region remain unexplored regarding their biogeochemical behavior. The aim was to document the early diagenesic processes to assess their impact on the organic carbon previously sequestrated in the underlying permafrost, and the post-depositional redistribution of trace elements (TE) and their impact on the water column.

Mineralization of organic matter (OM) in the sediments proceeded under anoxic conditions in all the three lakes. In the course of the ecosystem maturity development, a shift in OM mineralization pathways was evidenced with Fe- and Mn-oxyhydroxides (FMO) representing the main terminal electron acceptors in the early diagenetic reactions for the most mature stage. This shift was promoted by the diagenetic consumption of nitrate and sulfate and their gradual depletion in the water column due to progressively decreasing peat lixiviation occurring at the lake's borders. Early diagenesis was responsible for TE post-depositional redistribution. TE were mobilized from host phases (OM and FMO) and partly sequestered in the sediment in the form of authigenic Fe-sulfides. Arsenic and Sb cycling was also closely linked to that of OM and FMO. Shallow diagenetic enrichment of particulate Sb was observed in the less mature stages. As a result of authigenic sulfide precipitation, the sediments of the early stage of lake maturation were a sink for water column Cu, Zn, Cd, Pb and Sb. In contrast, all sediments were a source of dissolved Co, Ni and As to the water column. However, the concentrations of these TE remained low in the bottom waters, indicating that sorption processes on Fe-bounding particles and/or large-size colloids could mitigate the impact of post-depositional redistribution of toxic elements on the water column.

C- and S-transfer in subduction zones: Insights from diamonds

S. AULBACH[1,2], T. STACHEL[1], L.M. HEAMAN[1], R.A. CREASER[1], E. THOMASSOT[3] AND S.B. SHIREY[4]

[1]University of Alberta, Edmonton AB Canada
[2]Goethe-Universität, Frankfurt Germany, (s.aulbach@em.uni-frankfurt.de)
[3]Carnegie Institution-DTM, Washington, DC USA
[4]CRPG-CNRS, Nancy France

The formation of eclogitic and pyroxenitic diamonds may occur during subduction-related redox reactions. Sulphide-bearing diamonds and diamondiferous xenoliths from the central Slave craton (Diavik and Ekati pipes) are used to trace the mobility of C and S up the slab and mantle wedge.

There, eclogitic diamond formed along fluid conduits ca 1.85 Ga ago, penecontemporaneously with subduction beneath the western craton margin and with eclogitisation of basaltic protoliths. The radiogenic initial $^{187}Os/^{188}Os$ of the eclogitic sulfide inclusions is consistent with diamond formation in matured, high Re/Os oceanic basaltic crust. This may indicate that S in the inclusions was derived in situ, which is supported by fractionated S isotopes of eclogitic sulphide inclusions. Mantle-like $\delta^{13}C$ of associated diamonds suggests derivation of the carbon from reducing serpentinised oceanic mantle, which dehydrates at a depth consistent with diamond formation.

Subducting oceanic crust may release silicic melts that react with mantle wedge peridotite to form pyroxenite. A low-temperature pyroxenite xenolith has an age and initial $^{187}Os/^{188}Os$ that is identical to eclogitic inclusions in diamond, indicating that it inherited its radiogenic initial Os and S from oxidising slab-derived melt. Formation at shallow depth near the graphite-diamond transition and presence of an oxidised mantle wedge prohibits enough reduction to allow diamond formation from the slab melt and may explain why this lithology is rarely represented amongst diamonds from the central Slave craton.

A distinct group of sulphide inclusions in diamond, with Ni content similar to peridotitic inclusions, but 20 x lower Os contents have very unradiogenic Os but yield a Re-Os isochron age of 1.70±0.26 Ga, within error of the age of accretion at the craton margin. We suggest the diamonds formed through interaction of reducing Os-poor fluids with oxidising wedge mantle that was dragged down to the depth of serpentinite dehydration. The fluids may have remained reducing by extraction along conduits armoured by a reaction assemblage. They facilitated isotopic rehomogenisation of part of the mantle wedge, but did not add Os to the source. $\delta^{13}C$ will be measured soon to determine the carbon source.

Efficient analysis of seawater thorium and protactinium

M.E. AURO[1]*, L.F. ROBINSON[1,2], R. ANDERSON[3], M. FLEISHER[3] AND M.A. SAITO[1]

[1]Woods Hole Oceanographic Institution, Woods Hole, MA 02543 USA (*correspondence: mauro@whoi.edu); (msaito@whoi.edu)
[2]University of Bristol, BS8 1RJ, Bristol UK (lrobinson@whoi.edu)
[3]Lamont-Doherty Earth Observatory, Palisades, NY 10964 USA (boba@ldeo.columbia.edu; martyq@ldeo.columbia.edu)

With the advent of GEOTRACES, the requirement to analyse large numbers of seawater samples for ^{232}Th, ^{230}Th and ^{231}Pa has become more widespread. During the international intercalibration exercise we encountered unexpected difficulties with recovery and contamination of these isotopes, especially ^{232}Th. Multiple experiments were executed to identify the source of these issues. Two particular problems were (a) frits in columns supplied by Biorad contain isotope-binding surfactants and (b) new batches of Biorad AG1x-8 resin release more than 100pg of ^{232}Th after standard column cleaning. To improve yield (to 90%) and blanks (to 5pg ^{232}Th) we implemented a range of improvements including switching to Eichrom anion exchange resin and Environmental Express columns. In addition, we used Eichrom pre-filter resin to remove organics and prevent clogging during sample analysis. All Th samples were analysed on a Neptune multi-collector using peak hopping of ^{230}Th and ^{229}Th on the central SEM, with either ^{232}Th, ^{236}U (or both) used to monitor for beam intensity. We used two in-house laboratory standards to check for machine reproducibility, and the GEOTRACES intercalibration standard to check for accuracy. Over a one year period the 2 stdev reproducibility on the standard ^{232}Th concentration was 2.8% including all analyses, and 2% once contamination and yield issues had been resolved.

We apply the improved method to seawater samples in depth profiles collected from stations close to Bermuda and from 12.5S in the S. Atlantic (CoFeMUG cruise) and compare those data to published water column data. Apart from the very bottom waters and surface waters, both of which have elevated values, BATS samples average 79 pg/kg ^{232}Th. The ^{232}Th concentration in the S. Atlantic is higher throughout the water column with an average value of 195 pg/kg. In both cases ^{230}Th increases with depth, with the rate of increase greater in the S. Atlantic as expected from published water column profiles.

Geochemistry and mineralogical composition of the airborne particles of sand dunes and dust storms settled in Iraq and their environmental impact

SALIH MUHAMMAD AWADH

Earth Sciences Department, College of Science, University of Baghdad, Baghdad, Iraq. (Salihauad2000@yahoo.com)

Introduction

Five dust storms that are blown in 2008 and sand dunes disseminated in the Western Desert of Iraq are sampled. This work is going to discuss the origin of dust that blow on Iraq, and their environmental impacts.

Results

The enrichment of SiO_2/Al_2O_3 by mechanical and chemical processes produces quartz arenites (Orthoquartzites) [1]. Heavy minerals in dust storm and sand dunes formed 2.3% and 6.6% respectively. Clay appears to be domennanted (Figure 1).

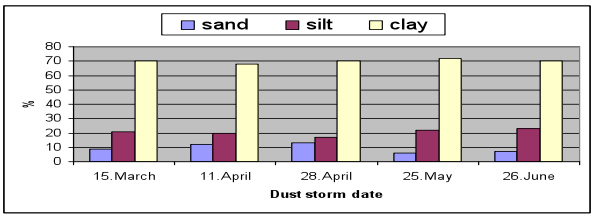

Figure 1: Average distribution of grain sizes in dust storm samples.

Conclusions

The Sahara of North Africa, lands in Saudi Arabia going to desertification. They provided 7 million tons of clayey dust during 8 dipping temperature 6ºC.

Reduction of carbon tetrachloride by organo-green rust

K.B. AYALA-LUIS, NICOLA G.A. COOPER*, C.B. KOCH AND H.C.B. HANSEN

Dept. Basic Sciences and Environment, University of Copenhagen, Thorvaldsensvej 40, DK-1871 Frederiksberg C., Denmark (*correspondence: ngac@life.ku.dk)

Layered Fe^{II}–Fe^{III} hydroxide salts (green rusts, GR) are redox reactive materials that are formed in anoxic soils and sediments and when iron corrodes. GRs are powerful reductants of environmental pollutants [1, 2]. GR intercalated with surfactants (organo-GR) is a new type of reactive hydrophobic material that has been recently synthesized in laboratory scale [3]. Due to the presence of structural Fe^{II} and a hydrophobic interlayer, organo-GRs are expected to react preferentially with non polar contaminants. Hence, the reductive properties of the novel organo-GRs were examinated against carbon tetrachloride (CT).

In the present work, we demonstrate that organo-GR can directly reduce carbon tetrachloride into less harmful non-chlorinated compounds (*in casu* carbon monoxide and formate). Chloroform (CF) was also formed as a minor end product (< 5%). Reduction of CT with other iron (hydr)oxides than GR formed mainly chloroform and other less chlorinated compounds [4]. The formation of less chlorinated compounds proceeds via hydrogen abstraction of trichloromethyl radicals ($\bullet CCl_3$) and/or protonation of the trichloromethyl carbanion ($:CCl_3^-$) following the hydrogenolysis pathway. The hydrophobic interlayer of organo-GRs may stabilize both the radical and the carbanion, sheltering them from proton donors and directing the reactions towards the formation of carbon monoxide and formate. Analyses of chloride in the reactions confirm the complete dechlorination of CT. These findings suggest that organo-GRs are promising reactants for remediation of groundwater and soil contaminated by chlorinated solvents.

Geochemical and Sr-Nd isotopic characteristics of the calc-alkaline volcanic rocks from Borçka (Artvin): Implications for genesis of Tertiary magmatism in the Eastern Pontides (NE Turkey)

E. AYDINÇAKIR[1]* AND C. ŞEN[2]

[1]Dept Geol Engn., Gümüşhane Univ.,TR-29100 Gümüşhane, Turkey (*correspondence:aydincakir61@gmail.com)
[2]Dept Geol Engn, Karadeniz Tech Univ., TR-61080 Trabzon, Turkey (csen@ktu.edu.tr)

Whole-rock geochemistry and Sr-Nd isotopic data are reported for the Tertiary Borçka (Artvin) volcanics in the eastern Pontide orogenic belt (NE Turkey). Borçka (Artvin) volcanics were made of two groups that comprise of basalt-basaltic andesite-basaltic trachyandesite (Group A) and andesite-trachyandesite (Group B). The Group A contains plagioclase (An_{31-93}), clinopyroxene ($Wo_{38-48}En_{38-44}Fs_{8-17}$), hornblende ($Mg^{\#}$=0.57-0.72) phenocrysts and titanomagnetite microphenocrysts, whereas the Group B rocks include plagioclase (An_{52-93}), clinopyroxene, hornblende ($Mg^{\#}$=0.64-0.71) phenocrysts and titanomagnetite and apatite microphenocrysts with porphyritic, microlitic porphyritic, hyalo-microlitic porphyritic, fluidal and cumulophiritic textures.

Petrochemically, the volcanic rocks show calc-alkaline character with their medium K contents. They are enriched in LREE and LILE, with pronounced depletion of HFSE. The chondrite-normalized REE patterns (La_N/Lu_N=1-7) show low to medium enrichment, indicating similar sources for the rock suite. Textural features and calculated pressures based on the Cpx-barometer in each series indicate that the calc-alkaline magma equilibrated at shallow crustal depths under a pressure of about 2-7 kbar and approximating a crystallization depth of 5-18 km.

The Borçka (Artvin) volcanics are slightly depleted in isotopic composition. $^{87}Sr/^{86}Sr$ values vary between 0.70423 and 0.70511 while $^{143}Nd/^{144}Nd$ values change between 0.51266 and 0.51288. Sr-Nd isotopic ratios imply that the rocks derived from depleted mantle source in their origin. The increasing values of SiO_2 (wt.%), Sr (ppm) and $(1/Sr)x10^3$ ppm^{-1} versus $(^{87}Sr/^{86}Sr)_I$ values reveal fractional crystallisation (FC) rather than assimilation (AFC) in their evolution.

Low molybdenum isotope compositions in euxinic Sapropel S1

I. AZRIELI[1]*, A. MATTHEWS[1], M. BAR-MATTHEWS[2], A. ALMOGI -LABIN[2], D. VANCE[3], C. ARCHER[3] AND N. TEUTSCH[2]

[1]Institute of Earth Sciences, Hebrew University of Jerusalem, Israel (*correspondence: irit.azrieli@mail.huji.ac.il)

[3]Bristol Isotope Group, School of Earth Sciences, University of Bristol, UK

Molybdenum isotopes are a powerful proxy for paleoredox conditions in organic-rich sediments. Here, we apply this isotopic system to a Holocene S1 sapropel layer sampled at 2550m depth in the Eastern Mediterranean Sea (ODP core 967D). Our study utilizes the isotopic systems of Mo and Fe, together with geochemical tracers (Ba/Al, Fe_T/Al, Mn/Al, S) to explore the relationship between the sapropel formation conditions and the Mo paleoredox proxy.

Euxinic (sulphidic) bottom water conditions during the sapropel formation are supported by Fe isotopic composition, which shows negative correlations between $\delta^{57}Fe$ and Fe_T/Al and S wt%. This is consistent with the benthic Fe shuttle model whereby Fe is exported from the oxic shelf to the deep euxinic basin[1]. The Mo paleoredox model for highly sulphidic restricted marine systems envisages organic-rich sediments acquiring Mo isotope signatures of sea water ($\delta^{98}Mo$ = 2.3‰) due to the quantitative removal of Mo from the sulphidic water column. This scenario is not realized in the 967D profile, which shows a decrease in $\delta^{98}Mo$ values from *ca* 0‰ in the pre-sapropel sediment to negative values of -0.8‰ within the sapropel, before gradually rising to values of 0 to 0.4‰ in the overlying post-sapropel sediment. Negative linear correlations between $\delta^{98}Mo$ values and Fe_T/Al, Ba/Al, Mo/Al and S indicate that maximum euxinic conditions are associated with the lowest Mo isotopic compositions.

The low $\delta^{98}Mo$ values are potentially compatible with sulphidization of Mo in mildly sulphidic euxinic conditions [2,3]. Nevertheless, increasing euxinia should lead to positive correlations between $\delta^{98}Mo$ and the geochemical proxies. Thus, additional factors such as open system conditions for Mo uptake may be required to explain the full workings of the Mo paleoredox proxy.

High-resolution, ultra-trace and major element chemical stratigraphy of a new Paleoproterozoic weathering profile

M.G. BABECHUK* AND B.S. KAMBER

Laurentian University, Sudbury, ON, Canada
(*correspondance: mbabechuk@gmail.com)

Paleosols contain information about ancient atmospheric and climate conditions, as well as the secular change in supply of nutrients to the ocean. A newly exposed, ~5 meters deep 1.85 Ga weathering profile is described. It developed on pillowed metabasalt (Flin Flon, Manitoba, Canada) and was sampled (~120 samples) and analyzed at much higher spatial resolution (>50 samples) than previous such profiles for ultra-trace, major element, and ferrous iron.

Consistent with previous studies on nearby paleosol exposures [1,2], the examined weathering profile is characterized by a spectacularly preserved, coherent upward Fe enrichment, accompanied by loss of Fe^{2+} and the development of a positive Ce anomaly, implying weathering in an oxic atmsophere. The new, high-precision trace element data collected reveal enrichment of several alkali (Cs, Rb, in addition to K, Na) and alkaline earth (Be, Sr, Ba) elements upward towards the paleosol contact with overlying sandstone. By contrast, the HFSE remained largely immobile in the profile which is evident through the highly consistent Zr/Hf, Th/Nb, and Nb/Ta ratios.

This presentation will discuss the distinction of original chemical features preserved in the profile, for example those inherited from the separate pillow basalt flows, versus those superimposed by weathering, water table fluctuation and possible extraneous sediment input.

The volcanic-plutonic connection

O. BACHMANN[1], C. DEERING[1], J. DUFEK[2] AND C. HUBER[2]

[1]Departement of Earth and Space Sciences, University of Washington, Seattle, USA
[2]School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta, USA

The broad similarities in age and compositonal range found in plutonic and volcanic exposures from a given magmatic province clearly indicate that these rocks types are closely related genetically. However, to which extent plutons (particularly the ones with intermediate to silicic compositions) are former magma reservoirs that have lost melt remains controversial. Recent work using both geochemical and physical modeling provides new avenues to explore these issues that are fundamental to our understanding of crustal evolution. First, mechanical constraints on rates of crystal-liquid separation indicate that most chemical differentiation is likely to occur within an melt extraction window located between 50 and 80 vol% crystals across the whole range of magma composition (from mafic to silicic). This extraction window will lead to compositional gaps in extracted liquids, as observed in numerous volcanic series around the world. In contrast, plutonic exposures will span a range of compositions that will vary continously as a function of how much melt was lost at a given location. Trace element modelling suggest that variable degrees of crystal accumulations are common in all plutonic sequences, including in intermediate to silicic compositions (tonalites - granodiorites). We also report erupted crystal cumulates, excavated from shallow magma chambers during large explosive eruptions. Such findings, alongside with thermal models of magma-crust interaction, suggest that crystal fractionation occurring by melt extraction in mush zones, and accompanied by a limited amount of crustal assimilation, is the dominant differentiation process in the Earth's crust. In this framework, volcanic rocks mostly represent liquids extracted from different reservoirs while plutons typically correspond to the left-overs crystal mushes that have been periodically stripped from a fraction of their interstitial melts.

Enhancing the accuracy of the environmental monitoring systems in mining areas

CALIN BACIU, DAN COSTIN*, CRISTIAN POP AND LAURA LAZAR

Babes-Bolyai University, Faculty of Environmental Science and Engineering, Fantanele 30, 400294 Cluj-Napoca, Romania (correspondence: dan_fl_costin@yahoo.com)

Mining operations generally have a significant impact on the environment. Traditional monitoring by periodically performing field measurements, sampling, and lab analyses is laborious, costly, and not always reproducible and reliable. Abundant series of monitoring data may be obtained by installing continuous measuring devices in selected points. In most of the mining areas, the number of such monitoring points is rather limited. The data series provided by such systems are usually interpreted as averages of the measured parameters for a certain area. Very often, this is not the case, either due to the limited representativity of the selected points, or because of the high dynamic of the environmental parameters. The environmental issues related to mining have become an ever increasing concern all over the world, with a direct impact on the prices of commodities, as opening a new mine is getting more and more difficult. A cost-effective and precise monitoring system is essential in the management of the environmental problems. Providing accurate monitoring data may also increase the confidence and acceptance of the communities and other stakeholders towards the mining activity. New methods and tools are needed for accomplishing this goal.

The EU-funded project ImpactMin (www.impactmin.eu) develops a combination of satellite remote sensing and aerial lightweight measurements for obtaining new methods of environmental monitoring in mining areas. Four test-sites were selected for calibrating and demonstrating the new toolset. Rosia Montana test-site (Romania) has a particular position in this context, as the cumulated impact of almost 2,000 years of gold mining can be observed. Currently the mine is inactive, the operations ceased in 2006 due to economic reasons. A new mining project is proposed on the same location, intending to implement a large scale open pit operation. The newly developed monitoring methods may represent an important contribution to the proper definition of the environmental baseline conditions, should the mining operations re-start.

Distribution of rare elements in mineral-forming environments of rare-metal granites

E.V. BADANINA[1], A.Y. BORISOVA[2], R. THOMAS[3] AND L.F. SYRITSO[1]

[1]St.Petersburg State University, St.Petersburg, Russia (elena_badanina@mail.ru)

[2]University of Toulouse III – CNRS – IRD – OMP, France (borisova@lmtg.obs-mip.fr)

[3]German Research Centre for Geosciences GFZ Potsdam, Germany

The composition of melt and its evolution in space and time is traced at formation of ore-bearing Li-F granites and them sub-effusive analogs (ongonites, rhyolites, felsit-porphyries) from Orlovka, Etyka and Sherlovaja Gora in Transbaikalia (Russia) on the basis of melt inclusions study in quartz [1]. It is established that process of fractional crystallization is not the unique mechanism of concentration of LILE (Li, Rb, Cs) and HFSE (Nb, Ta, Zr, REE, W, Sn). A role of various mechanisms of concentration (fractionation, liquid immiscibility, metasomatism) estimate by calculation of distribution coefficients and saturation degree of melt for ore minerals. Contrast behavior of various rare elements is established at different stages of melt evolution [1]. High concentration of Li, B, Ta, Zn are found out in hydrosaline and fluid inclusions of Orlovka [2]. High concentration of some rare elements are found out in fluid inclusions (FI) in quartz from Sn-bearing rhyolites of Sherlovaya Gora by LA-ICP-MS. So, the Sn concentration varies from 1864 to 5879 ppm that explains formation of large tin deposit with finely dispersed cassiterite at a hydrothermal stage. High concentration of Zr in a fluid (to 1,5 wt %) from ultrapotassic felsite-porphyriy explains the formation here saturation zones of fine crystalline zircon in a topaz from famous a topaz-aquamarine greisen of Sherlovaya Gora and confirms probability of its crystallization at a hydrothermal stage. High uranium concentration in melt of rhyolites (up to 42 ppm U) exceed those in rhyolites of a Streltsovsky deposit. Sharp increase of U in FI up to 116 ppm unequivocally testifies to a potential role of rhyolites in genesis of uranium deposits of Transbaikalia that closes discussion about a source of uranium for them.

Orbital scale alkenone based CO_2 records across the Pliocene intensification of Northern hemisphere glaciation

M.P.S. BADGER[1]*, G.C. BOWLER[1], C. DAVIS[2], A.C. HULL[1], M.D.A. POTTS[2], D.N. SCHMIDT[2] AND R.D. PANCOST[1]

[1]Organic Geochemistry Unit, School of Chemistry, University of Bristol, Cantock's Close, BS8 1TS, U.K. (*correspondance: marcus.badger@bristol.ac.uk, gb6139@bristol.ac.uk, ah7523@bristol.ac.uk, R.D.Pancost@bristol.ac.uk)

[2]Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queen's Road, BS8 1RJ, U.K. (cd9861@bristol.ac.uk, mp0702@bristol.ac.uk, D.Schmidt@bristol.ac.uk)

The most informative analogues for future anthropgenic climate change are likely to be those with boundary conditions similar to today. The late Pliocene is the most recent time in earth history with elevated global temperatures and CO_2 estimated to be similar to that anticipated by the end of this century [1, 2, 3]. Furthermore, Pliocene continental positions and vegetation distributions are thought to be broadly similar to today. Consequently the IPCC fourth assessment report highlighted the Pliocene as an important time period for further study. Recently our understanding of Pliocene CO_2 and temperature has improved, with publication of multiple records from alkenone and boron isotope reconstructions for CO_2 [2, 3], and Mg/Ca, $U^{K'}_{37}$ and TEX_{86} reconstructions for sea surface temperature. However, none of the published CO_2 records have sufficient temporal resolution to resolve orbital scale variations in CO_2, or to determine the relationship between the apparent reduction in atmospheric CO_2 and the intensification of northern hemisphere glaciation. Here we present new high resolution records of CO_2 and temperature from ODP Site 999 over the critical interval from 3.3 to 2.6 Ma using alkenone palaeobarometry and the $U^{K'}_{37}$ and TEX_{86} palaeothermometers. By combining these with a full analysis of the biotic response to changing conditions and reconstructing haptophyte cell sizes [4], critical for the alkenone palaeobarometer, we present well constrained, coupled records of the response of the climate system to changing CO_2.

A multidisciplinary study of core composition

JAMES BADRO

Institut de Physique du Globe de Paris, France. (badro@ipgp.fr)

Planetary cores form as a results of the major chemical differentiation even on a terrestrial planet; the melting of accretionary building blocks (dust, meteorites, planetesimals, protoplanets) leads to a separation of the metal from the silicate, ensued by a gravitationally-driven segregation of a dense metal-rich core at the centre of the planet, with the lighter buoyant silicates remaining on top. The process of core formation determines the composition of this deep reservoir, and leaves an imprint on the residual bulk silicate Earth.

Matching geophysical observables (seismically determined radial density and velocity profiles) and geochemical observables (siderophile trace-element concentration in the upper mantle, and through modelling in the bulk silicate Earth) with experimental and theoretical data provides a robust way to estimate both the present day composition of the core as well as the conditions under which it formed. Adding observational constraints, both from geophysics (gradients, anisotropy) and geochemistry (isotopic and trace-element fractionation) will help to continually improve the models and beyond that, define and refine the paradigm of core formation.

We will present the results obtained through (i) the study of phase equilibrium under extreme conditions in the laser-heated diamond anvil cell, (ii) the study of outer-core density and seismic velocity from first principles calculations, and (iii) the study of inner-core elasticity from experimental mineral physics. We will interpret these results in order to devise compositional models consistent with the observations, and to formulate scenarios for core formation.

Boundary depth of aragonite saturation during 10 years around Okinawa and East China Sea

D-Y. BAEK[1], H. FUJIMURA[1]*, T. OOMORI[1], T. HIGUCHI[2], B.E. CASARETO[2] AND Y. SUZUKI[2]

[1]Univ. of the Ryukyus, 1 Senbaru, Nishihara, Okinawa 903-0213, Japan (*correspondance: fujimura@sci.u-ryukyu.ac.jp)

[2]Shizuoka Univ., 836 Ohya, Suruga-ku, Shizuoka-shi, Shizuoka 422-8529, Japan

Introduction

Since industrial evolution, anthropogenic activities have been releasing CO_2 by fossil fuels combustion. Ocean absorbs about 2.0 Gt of CO_2 every year and act as a sink for atmospheric CO_2 [1]. However CO_2 dissolved into seawater lower the ocean pH and CO_3^{2-} concentration. About 0.1 pH unit has already been decreased since industrial evolution. Lower pH have influences on marine organisms especially on growth of calcareous foraminifera and corals as one of the problem in "ocean acidification". Because lower CO_3^{2-} caused lower aragonite saturation of $CaCO_3$, saturated boundary in the ocean is predicted to be shallower in the future. In this study, we investigated carbonate system by taking vertical profiles around Okinawa and East China Sea to find the shift of the boundary depth over the past 10 years.

Materials and Methods

Seawater samples were taken from East China Sea and adjacent sea around Okinawa Island, Japan at scientific survey of T/S *Nagasaki-maru* in 2000 to 2010. Parameters related to carbonate system were measured on total alkalinity (ATT05, Kimoto), total inorganic carbon (CM5012, UIC), pH and salinity (PortaSal8410A, Guildline). Aragonite saturation of $CaCO_3$ (Ω) was estimated from a calculation of carbonate chemical equilibrium in seawater samples taken at each depth of vertical profile.

Results and Discussion

The boundary depth at which aragonite saturation shows below a saturation level (i.e. Ω=1) were 537±36 m from a surface (averaged value during 2000-2002). This boundary depth was shifted to 513 m during 10 years. Although this value was within the range of uncertainties, the shift indicated that the intrusion of the anthropogenic CO_2 caused lower CO_3^{2-} and hence shallower depth of the saturation boundary.

Study of geochemical reaction of rocks the under the supercritical CO_2-rock-groundwater system

KYOUNGBAE BAEK*, HYUNMIN KANG, JINYOUNG PARK AND MINHEE LEE

Department of Environmental Geosciences, Pukyong National University, Namgu, Busan, 608-737, Korea (*darkbkb@naver.com)

Laboratory scale experiments to quantify the geochemical reaction in the supercritical CO_2-rock-groundwater system for CO_2 sequestration sites were performed in the high-pressurized cell. Seven types of rocks were cut into 1 cm x 1 cm x 0.3 cm size sections. Polished rock sections (granite, basalt, andesite, gneiss, limestone, sandstone and mudstone) and groundwater of 100 ml were reacted with supercritical CO_2 in the cell, maintaining the sequestration condition (100 bar and 50 °C). The gaseous CO_2 (99.99 % of purity) was injected into the cell and the high pressure condition was applied inside of the cell by using the periodic high pressure pump and the back pressure regulator. The temperature of the cell was maintained at 50 °C by using an oven. Each rock section was reacted with the supercritical CO_2 and groundwater for 10, 30 and 60days.

Before the experiment, the rock dried at 100 ℃ for a day and accurately weighed. After the reaction, the rock dried and reweighed to investigate the loss of minerals by dissolution. The alteration of pH was measured to compare before/after reaction. Rock surface was observed by using a reflecting microscope. Selected three minerals for each rock and three locations of each mineral on the rock surface were randomly selected for the image analysis of Scanning Probe Microscope (SPM). The average roughness value of those locations was measured to investigate the transmutation of rock surface compared to that before reaction. ICP-OES analysis was conducted to measure the major element concentrations dissolved in solution of the high pressure cell. SEM/EDS analysis was also performed to identify the precipitates in high pressure cell after the reaction.

Results of the experiment in the supercritical CO_2-rock-groundwater reaction showed that the concentration of cations in solution increased and the pH of solution decreased after the reaction. The average roughness value of the mineral surface in the rocks increased after 30 days. From the analysis of SEM/EDS, the interstitial spaces of rock surface could be infilled by secondary minerals, resulting in the change of void spaces (porosity) in the rock.

Controls on isotope and trace element systematics of slope facies Ediacaran carbonates, Yangtze Platform (South China)

W. BAERO*, H. BECKER AND U. WIECHERT

Institut für Geologische Wissenschaften, Freie Universität Berlin, Malteserstr. 74-100, 12249 Berlin, (*correspondence: wbaero@zedat.fu-berlin.de)

Trace element, Sr, C and O isotopic compositions of Ediacaran carbonates are used to assess the likely role of diagenetic processes and alteration by lokal fluid flow, relative to primary seawater derived signatures. The samples are from the slope facies Panmen section (Songtao, Guizhou) of the Yangtze Platform, South China. The section comprises the Ediacaran Doushantuo (DS) and Liuchapo Formations. At this section, carbonate bearing lithologies are restricted to the DS members I (cap carbonates in contact with Marinoan diamictites), III (dolostones and limestones) and IV (organic rich carbonate layers and carbonate concretions in black shales). Most of DS II appears to be missing from this section. Carbonates show variable negative $\delta^{18}O$ (-6 to -14) and $\delta^{13}C_{carb}$ (-2 to -10) values similar to DS I and III sediments at sections representing shallow water conditions. Acetic acid leachets of carbonates display decreasing $^{87}Sr/^{86}Sr$ upsection from high and variable values in DS I (0.722-0.717) to lower values in DS III (0.716-0.713). Ce/Ce* are near 1, with a few values significantly higher. The uppermost samples of DS IV show Ce/Ce* = 0.5 at $\delta^{13}C_{carb}$ of -1. Some of the extreme values in $\delta^{18}O$ are coupled with positive Ce (Ce/Ce* = 1.22) and Eu (Eu/Eu* = 1.33) anomalies, and particularly high $^{87}Sr/^{86}Sr$. Carbonate concretions in black shales of DS IV have extremely negative $\delta^{18}O$ but display normal $\delta^{13}C$, slightly neg. to no Ce/Ce* and strongly pos. Eu/Eu*. $^{87}Sr/^{86}Sr$ in the concretions are the lowest measured in the section (0.709), similar to values obtained for DS IV from shallow platform settings [1]. Most $^{87}Sr/^{86}Sr$ values of the section are substantially higher than seawater values during this time (0.708-0,709, [1]). High values of $^{87}Sr/^{86}Sr$, Ce/Ce* or negative $\delta^{18}O$ do not correlate with the amount of detrital material in the carbonates. Hence, we interprete high $^{87}Sr/^{86}Sr$ and Sr/Mn and the occasional presence of positive Ce anomalies to reflect recrystallization and interaction with reducing fluids that have interacted with silicate and organic material (and occasionally Fe-Mn oxides?) during the postdepositional evolution of the basin. The influence of these processes on $\delta^{13}C_{carb}$ is sometimes visible, but appears to be at the 1 ‰ level or less.

Fluid-rock interaction during eclogitisation: Evidence from HP metamorphic rocks from Sulawesi, Indonesia

R. BAESE* AND V. SCHENK

SFB 574: Volatiles and Fluids in Subduction Zones, Christian-Albrechts-University, 24118 Kiel, Germany (*correspondence: rb@min.uni-kiel.de)

Fluid-rock interactions within subduction zones are important for understanding recycling processes and magma generation at convergent margins that is triggered by fluid infiltration from the subducting slab. The aim of this study is to determine the composition of fluids liberated during eclogitisation reactions. The samples are high-pressure (HP) rocks from the Bantimala Complex in Sulawesi (Indonesia) that is part of the Cretaceous accretionary complex distributed all over Indonesia [1]. The eclogites are forming veins and vein networks within blueschists. The peak P-T-conditions are about 2.0-2.5 GPa and 450-550 °C. Trace element analyses of a relatively Cr-rich eclogite-blueschist pair reveal a pronounced depletion of fluid-mobile elements in the eclogite. Mass balance calculations show that the rock lost more than 80% of the REE during the fluid induced eclogitisation along the vein. The LILE (Cs, Ba, Rb, Sr), except K, are also depleted with up to 80%. In case of the HFSE (Pb, Zr, Hf, Ti, Nb) there is no depletion, and Zr, Hf and Ti are even enriched in the vein. Major element concentrations were not strongly affected by the dehydration process during eclogite formation. From these observations we deduce that the fluid produced during the blueschist-to-eclogite transformation in the veins should be enriched in the LILE and REE. The concentrations of the HFSE, Fe and Ni should be relativly low in the fluid, because these elements were incorporated in the vein minerals. These results are in agreement with those of a previous study by John *et al*. [2], who concluded that the mobilised elements during eclogitisation are those believed to be contained in slab fluids that trigger partial melting in the mantle wedge.

Many-body effects in XPS and chemical bonding

P.S. BAGUS[1]*, C.J. NELIN[2], H.-J. FREUND[3] AND E.S. ILTON[4]

[1]Chemistry, University of North Texas, Denton, TX 76203-5017, USA (*correspondence: bagus@unt.edu)
[2]C. J. Nelin Consulting, Austin, Texas 78730, USA
[3]Fritz-Haber-Institut der Max-Planck-Gesellschaft, Faradayweg 4-6, D-14195 Berlin, Germany
[4]Pacific Northwest National Laboratory, 902 Battelle Blvd., P.O. Box 999, Richland, Washington 99352, USA

A major goal with x-ray photoelectron spectroscopy (XPS) is to derive both the character of chemical bonding and valence states from the spectra. Ionic compounds, especially oxides, often have complex and intense satellite features that arise from a combination of inter-atomic and intra-atomic many-body effects that can reflect both bonding and oxidation state. [1] While multiplet splittings arise dominantly from the open-shell structure within the ionized atom, [2] inter-atomic many-body effects may also make important contributions to the satellite structure. [1] Although these inter-atomic effects have been studied extensively, a quantitative and definitive connection between the relative energies and intensities of the satellites on the one hand and both the extent of covalent bonding and oxidation state on the other, has not been established. In the present work, we consider two oxides, UO_3 and CeO_2, where the metal cations are closed shell, which increases the importance of inter-atomic relative to intra-atomic many body effects. The CeO_2 satellites are intense while the UO_3 satellites are weak. We have established relations between the satellite energies and intensities with the extent of the covalent bonding. This theoretical information has been obtained using relativistic many-body molecular orbital wavefunctions. With these wavefunctions, the covalent character of the orbitals arises naturally. This work is an important step toward inferring material properties of interest to both geochemistry and more generally chemistry from the XPS satellite structure. This research was supported, in part, by the Geosciences Research Program, Office of Basic Energy Sciences, U. S. Department of Energy (DOE) and Geosciences Research Program, Office and, in part, by the German Science Foundation (DFG).

Whole rock and mineral composition constraints on the genesis of the giant Hongge Fe-Ti-V oxide deposit in the ELIP, SW China

Z.-J. BAI[1], H. ZHONG[1,*], C. LI[2], W.-G. ZHU[1] AND G.-W. XU[1]

[1]SKLODG, Institute of Geochemistry, CAS, Guiyang 550002, China (* correspondence: zhonghong@vip.gyig.ac.cn)
[2]Department of Geological Sciences, Indiana Univ., Indiana 47405, USA

The Hongge giant Fe-Ti-V oxide ore deposit, related to a plume activity (~260 Ma), is hosted in a layered intrusion located in the central part of the Emeishan Large Igneous Province (ELIP), SW China. Most of the economic Fe-Ti-V oxide ore layers occur within the middle clinopyroxenite zone of the intrusion. Opinions on the origin of the oxides vary from oxide-silicate liquid immiscibility to accumulation of titanomagnetite crystallizing from a basaltic magma.

Our new results favor the crystallization model. The occurrence of multiple Fe-Ti oxide layers within a single cyclic unit and the repetitive appearance of sulfide, olivine and Cr-rich magnetite in the base of each cyclic unit suggest that multiple pulses of magma was involved in the formation of the Hongge Fe-Ti-V oxide deposit. Magnetite and coexisting olivine in the Hongge deposit have much higher MgO contents than those in other oxide deposits associated with large layered intrusions in the world, underscoring the importance of relatively primitive parental magma and relatively early saturation of titanomagnetite in the magma in the formation of the giant Fe-Ti-V oxide deposits in the ELIP.

Phase equilibrium constraints suggest that the Hongge parental magma is similar to that of some most primitive Emeishan high-Ti basalts. Depletion of incompatible trace elements in the oxide ores and associated rocks in the intrusion as compared to the coeval high-Ti basalts suggest that not all the magma involved in development of the Hongge intrusion has been retained. We propose that this intrusion was a magma conduit and that some of the liquid was lost to the peripheral sills, shallower intrusions or lavas.

[3]Dept. of Earth, Atmospheric, and Planetary Sciences, MIT, Cambridge, MA, USA

Isotopes behave differently in different processes involved in a subduction zone such as slab dehydration, mantle wedge hydration and partial melting. Therefore, they are indicative of when and where different processes are active. The aim of this study is to extend the 2D coupled petrological–thermomechanical numerical model (I2ELVIS) of intra–oceanic subduction processes to include a treatment of isotopic signatures. With this extension we hope to gain more insights into the recycling system within the mantle wedge and are able to visualize the interaction between slab components and the depleted mantle. This will allow us to draw conclusions form isotopic signatures in arc lavas about the involved chemical processes.

A chemical contamination of slab components with wedge peridotite leads to specified signatures in arc magmas. Two slab components play a key role in this contamination: first, the altered oceanic basalt crust, and second its thin layer of sediment (e.g. Poli & Schmidt, 2002). Based on these results and the well known enrichment of LILE, Pb, U, and Th as well as the decrease of HFSE, Nd and Hf in island arcs in respect to the N-MORB, we focus on a limited number of elements (Pb, Hf, Sr and Nd) for our numerical model.

Our first results show that combination of finite differences and marker in cell techniques allows successful coupling of thermomechanical evolution of subduction with mobilisation, transport and radioactive decay of isotopes. Preliminary modelling results reconcile well with observations. Particularly, our models predict a significant increase of Strontium and Lead and a slight increase of Hafnium and Neodymium in the newly formed magmatic arc crust relative to the depleted mantle (DMM), which is comparable with data from the literature. In addition, our model confirmed the evidence for slab derived fluid /melt in the newly formed crust.

Pyromorphite formation from natural and surfactant-modified montmorillonite adsorbed lead

T. BAJDA[1]*, A. FIGUŁA[1], M. MANECKI[1] AND T. MARCHLEWSKI[2]

[1]Dept. of Geology, Geophysics and Environmental Protection, AGH University of Science and Technology, Krakow, Poland (*bajda@geol.agh.edu.pl)
[2]Dept. of Geological Sciences, Miami University, Oxford, Ohio, USA

The objective of this study was to evaluate potential application of natural and surfactant-modified montmorillonite for sorption of Pb^{2+} and subsequent pyromorphite formation by the reaction of Pb-adsorbed smectite with aqueous PO_4 of various concentrations. Amine hexadecyltrimethylammonium bromide (HDTMA-Br) in the amounts of 2.0 Cation Exchange Capacity (CEC) of the clay was used to obtain surfactant-modified organo-smectite.

The reaction of Pb-adsorbed natural montmorillonite with aqueous solutions containing PO_4 and Cl ions results in the decrease in phosphate concentration associated with the formation of a new phase – pyromorphite $Pb_5(PO_4)_3Cl$. Precipitation of brom-pyromorphite $Pb_5(PO_4)_3Br$ is observed when surfactant is used for modification of montmorillonite.

Pyromorphite precipitates homogenously in the solution but crystals generally cover the surface of smectite (Fig. 1a). High concentration of K and Ca cations leads to a high desorption of Pb and formation of very fine crystals. On the other hand, low concentrations of cations results in the formation of larger crystals.

When PO_4 was sorbed on Pb–surfactant-modified smectite, formation of brom-pyromorphite $Pb_5(PO_4)_3Br$ was noted in the reaction products. Pyromorphite forms crystals on the surface of a surfactant-modified smectite (Fig. 1b). We gratefully acknowledge support of the MNiSW through grant N N525 461236.

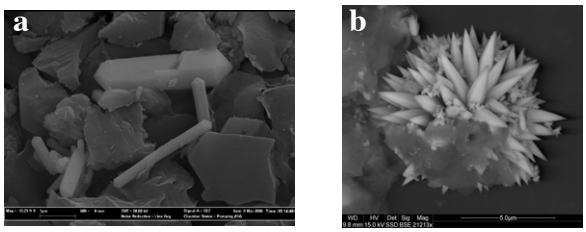

Figure 1: SEM microphotographs of (a) chlor-pyromorphite formed in the reaction of aqueous PO_4 and Pb-adsorbed montmorillonite, and (b) brom-pyromorphite formed in the reaction of aqueous PO_4 and Pb–surfactant-modified montmorillonite.

The influence of contaminant load on microbial ecology in a sandstone aquifer

K. BAKER[1,2], R. EDYVEAN[2], S. THORNTON[3], S. BANWART[2,3], J. SCHOLES[2] AND S. ROLFE[2]*

[1]School of Earth and Environment, University of Leeds, UK
[2]Cell-Mineral Research Centre, Kroto Research Institute, University of Sheffield, UK (*correspondence: s.rolfe@shef.ac.uk)
[3]Groundwater Protection and Restoration Group, University of Sheffield, UK

Due to widespread organic contamination derived from past industrial processes, microorganisms are becoming ever more important for the maintenance of potable groundwater supplies, as they have the ability to degrade organic contaminants *in situ*. Furthermore, the syntrophic relationships in mixed microbial communities found attached to geological surfaces results in an enhanced capability to degrade elevated levels of organic contaminants, making them integral to the natural bioremediation of contaminants [1]. Microbial biodegradation is also a sustainable alternative to costly and invasive engineering-based remediation techniques. However, contaminant toxicity can have a marked influence on microbial community structure and diversity [2], ultimately affecting the *in situ* biodegradation potential.

In this work, studies were conducted to investigate the effects of contaminant load on the indigenous microbial communities in a phenol-contaminated aquifer in the UK. Using denaturing gradient gel electrophoresis and pyrosequencing, groundwater (planktonic) microbial communities were profiled across the contaminant gradient, and compared to the attached communities formed on surrogate geological substrata incubated in the aquifer under the same hydrochemical conditions. Microbial community structure and function was found to be strongly influenced by contaminant load and groundwater hydrochemistry. Also, *in situ* microbial attachment studies reveal that the attached and planktonic communities differ markedly. These results are important for understanding the distribution and formation of microbial communities in contaminated environments and subsurface ecosystems, and lead to a better understanding of the function and limitations on *in situ* biodegradation processes in the Earth's Critical Zone.

[3]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China (xuderu@gig.ac.cn)

The famous Shilu iron-polymetallic ore deposit located in western Hainan Island, South China, occurs within Meso-Neoproterozoic, low-grade metamorphosed volcanoclastic sediments and carbonates. The Shilu deposit is considered to be a structurally reworked as well as hydrothermally altered and enriched ore deposit of Banded Iron Formation type. The deposit is very important iron producer from magnetite and hematite ores [1]. In our work we focused on the polymetallic sulfide mineralization, that is younger than iron oxide ores [2] and, in places, overprinted them. For the research we have chosen from the Shilu deposit several samples of sulfide ores from the Beiyi mine and its close vicinity. We have performed detailed ore microscopic studies as well as electrone microprobe analyses using CAMECA SX 100 equipped with EDS and WDS systems. In the studied samples pyrrhotite, chalcopyrite and Co-bearing pyrite (up to 11 wt% Co) dominated among ore sulfides. These ore minerals occur in quartz or calc-silicate rocks, either as disseminated grains, sometimes in veinlets, or in aggregates, that may form massive ores. Pyrrhotite and chalcopyrite may contain numerous solid inclusions, overgrowths and intergrowths of subordinate sulfides (sphalerite, galena), sulfosalts (glaucodot, costibite, cobaltite, arsenopyrite, ullmannite), sulfospinels (siegenite) and cassiterite, that belong to the minerals crystallizing at medium to low temperatures. Among these minerals siegenite and Co-bravoite dominate. Tiny crystals (10-20 μm in size) of Bi-minerals (matildite, cosalite) are also present. Moreover, in association with barite, calcite and chlorite, Ag-Hg amalgamate and cinnabar can occur. The results of our study point to the multistage medium- to low- temperature hydrothermal precipitation of ore sulfides that overprinted the Fe-oxide ores. We believe, our results will serve for better understanding of metallogenic processes in the Shilu iron-polymetallic deposit.

Biogeochemistry and stable isotope investigation of acid mine drainage associated with abandoned Pb-Zn mine in Balya, Turkey

NURGUL BALCI[1]*, NEVIN KARAGULER[2], M. SEREF SONMEZ[3] AND EROL SARI[4]

[1]Department of Geological Engineering, ITU, Turkey (*correspondence:ncelik@itu.edu.tr)
[2]Department of Molecular Biology and Genetics, ITU, Turkey (karaguler@itu.edu.tr)
[3]Department of Metallurgy and Materials Engineering, ITU, Turkey (ssonmez@itu.edu.tr)
[4]Institute of Marine Science and Management, Istanbul University, Turkey (erolsari@istanbul.edu.tr)

The abandoned Pb-Zn mine in Balya Region contains mainly galena, sphalerite, pyrite, chalcopyrite, and arsenopyrite. The mine tailings and smelting waste rocks produce significant amount of acidity and heavy metals. We used laboratory and field approaches to elucidate oxidation mechanisms of galena, sphalerite and pyrite in the region. The biological and abiotic oxidation experiments with galena, sphalerite and pyrite under various conditions (pH (2-4), (4-25 ºC) conditions were carried for the laboratory studies. Sediment and water samples were collected from the mine sites. Areas of the mine flooded by water have acidic pH (3) and high concentrations of metals (Pb, Zn, Cu, Fe, Co, Cd and As). In acidic, Fe-rich waters, oxidation of Fe^{2+} after exposure to air is microbially catalyzed and follows zero-order kinetics (range of 0.92 to 1.5 mmol L^{-1} h^{-1}). Biological oxidation experiments with galena and sphalerite at 25 ºC showed high oxidation rate compared to chemical –control and suboptimal temperature (4, 10ºC) experiments. *A. thioxidans* was still active even under 4ºC although the oxidation rate of galena and sphalerite were significantly lower compared to 25ºC. Oxidation of pyrite with or without bacteria did not show significant reaction rate. The S isotopic composition of dissolved sulfate collected from the mine areas closely reflect sphalerite and galena values rather than pyrite. The $\varepsilon^{18}O_{SO4\text{-}H2O}$ values of 8.0 ± 0.2 ‰ and 7.8 ± 0.1 ‰ obtained from the field measurements is consistent with the values calculated from biological oxidation of galena and sphalerite experiments relative to pyrite experiments ($\varepsilon^{18}O_{SO4\text{-}H2O}$ values of 0.0 to 4.0 ‰) [1] . A clear distinction exits among the $\varepsilon^{18}O_{SO4\text{-}H2O}$ values produced during pyrite and sphalerite experiments may help to determine the source of acidity.

Cosmogenic ^{21}Ne production systematics in quartz inferred from a 25-meter sandstone core

G. BALCO[1]*, D.L. SHUSTER[1], P-H. BLARD[2], L. ZIMMERMANN[2] AND J.O.H. STONE[3]

[1]Berkeley Geochronology Center, 2455 Ridge Rd., Berkeley CA 94550 USA (*correspondence: balcs@bgc.org)
[2]CRPG-CNRS-Université de Lorraine, 15 rue Notre Dame des Pauvres, 54501 Vandoeuvre-lès-Nancy, France
[3]Earth and Space Sciences, University of Washington, Seattle WA 98195-1310 USA

We measured ^{20}Ne, ^{21}Ne, and ^{22}Ne concentrations in quartz in a 25-meter sandstone core collected at Beacon Heights, Antarctic Dry Valleys, as part of the CRONUS-Earth project. ^{21}Ne concentrations computed as excess over atmospheric Ne are shown below. We intercalibrated measurements at BGC and CRPG by exchanging standards. A systematic difference between the two labs, most likely due to the effect of different sample preparation schemes on ^{21}Ne produced from alpha implantation at grain edges, is evident in deep samples. These data, with corresponding U and Th concentrations, permit resolution of the ^{21}Ne inventory into trapped, cosmogenic, and nucleogenic components, and thus estimates of ^{21}Ne production rates due to spallation and muon interactions.

A 3D snapshot from granitic system: Tourmaline nodules and their bearing on the granite evolution

D. BALEN* AND Z. PETRINEC

University of Zagreb, Faculty of Science, Croatia
(*correspondence: drbalen@geol.pmf.hr)

Peraluminous granites generated during the Late Cretaceous evolution of the LP-HT zone in the Adria-Europe plate boundary setting host tourmaline nodules. These tourmaline-bearing bodies from the Moslavačka Gora (MG), Croatia show great similarity with leucogranitic veins and can be described as compact spherical to ovoid aggregates (cm to dm in diameter) with a fine-grained (grain size 1-2 mm) core (slightly alkali-deficient dravite to schorl tourmaline (#Fe 0.40-0.66) + quartz + albite + K-feldspar ± muscovite) enveloped by a leucocratic halo (quartz + K-feldspar + oligoclase An_{11-21} ± muscovite). When observed in 2D sections solely, the isolated nature of tourmaline nodules can be easily mistaken with similar 2D cross-section of a leucogranitic vein. For that reason tourmaline nodules' spatial distribution inside the host, shape and internal structure of individual bodies have been reconstructed and visualized through destructive serial sectioning tomography with physical resolution of 3.5 mm (serial cutting) or 0.35 mm (serial lapping) between individual planes. Obtained 3D reconstructions of rock volumes containing tourmaline nodules showed that they are indeed isolated spherical bodies dispersed inside the granitic host and not vein formations. The two structural units of a nodule, core and halo, are clearly distinguishable in 3D and show sharp contacts to each other but also to the granitic host.

The morphology, peculiar texture, distribution and origin of tourmaline nodules inside granite can be most suitably explained through the emplacement mechanism and crystallization setting of the host granite at upper crustal level (at MG locality calculated approx. depth of 5-6 km, T=720 °C). During emplacement, decompression and arising immiscibility leads to melt unmixing and production of two different melt phases: "normal" granitic and B-rich one. Prominent depolymerization of B-rich melt, followed by density and viscosity decrease together with lowering of liquidus and solidus temperatures, leads to physical separation of a buoyant B- and fluid-rich phase in form of distinct B-rich bubbles or pockets, which coalesce in order to decrease surface tension. Such isolated volumes now contain necessary concentration of boron and other elements needed for tourmaline growth and become precursors for the future solidified tourmaline nodules.

Noble gases and halogens in the MORB-source mantle: Recycled?

C.J. BALLENTINE*[1], R. BURGESS[1], B. WESTON[1], D. CHAVRIT[1], H. SUMINO[2] AND D.A.H. TEAGLE[3],

[3]NOC, University of Southampton, Southampton, U.K.

Powerful information from the extinct ^{129}I and ^{244}Pu systems is derived from the distribution of the daughter ^{129}Xe and ^{136}Xe between terrestrial reservoirs. Because of its simplicity, the conclusion that the Earth was open to Xe loss until ~80Ma after the Earth accreted, for example, is unequivocal. The $^{129}Xe/^{130}Xe$ ratio in the atmosphere, mantle and any primordial volatile rich mantle reservoir will then be determined by the ^{129}I (and ^{244}Pu)/Xe ratio in that reservoir and any subsequent interactions between reservoirs. The Earth's atmosphere, for example, has a lower $^{129}Xe/^{130}Xe$ than the convecting mantle. While there has been an exceptional concentration of the halogens at the Earth's surface compared to other incompatible elements (>90% BSE) [1], this is balanced by the atmosphere's high relative Xe concentration.

In the simplest (reference) model we can make the key assumption that the closure of the respective mantle reservoirs is the same as the atmosphere closure time of 80Ma. In the case where 80% of the convecting mantle Xe is recycled air [2], we calculate the iodine concentration, required to provide the convecting mantle ^{129}Xe excess caused by ^{129}I decay to be $[I]_{model}$ ~0.14ppb I. We then predict one of three cases when comparing $[I]_{observed}$ with $[I]_{model}$: 1) They will be in close agreement, in which case we can consider the convecting mantle to be closed with respect to the I/Xe system; 2) $[I]_{observed}$ will be lower than $[I]_{model}$, which then requires either an earlier closure age of the reservoir or significant net loss of I from the system after ^{129}I has ceased to be active; or 3) $[I]_{observed}$ will be greater than $[I]_{model}$ due to a net excess of dead iodine being added to the system. Current convecting mantle I concentration estimates, based on MORB, range from <0.7 ppb to orders of magnitude higher [3] and point towards the latter, consistent with recent observation of noble gas and halogen subduction to at least 100km depth [4]. Iodine determination of the MORB (and OIB) source remains a critical objective for future work.

It is known for some time that relative to CI chondrite, Earth's mantle is depleted in elements more volatile than Mg and Si. Early workers attributed this to volatile loss from Earth's mantle during accretion. In recent years, however, consensus has been emerging that the opposite may be true: that the inventories of the Earth's mantle in moderately and highly volatile elements and compounds, including Earth's hydrosphere and atmosphere, may be late additions, to a silicate earth initially far more refractory than the present-day upper mantle.

We report metal-silicate experiments at 1 to 5 GPa over a temperature range from 1773 to 2573K to quantify how selected refractory and volatile elements may have partitioned between silicate and Fe metal melt. We study the partitioning of two refractory elements (i.e. W and Cr) and four elements (i.e. Pb, Cd, Sn, Se) from the volatile inventory of the Earth's mantle. Except for Se, all elements regardless of volatility become more siderophile with increasing temperature, reflecting the effect of thermal reduction. By correlating measured metal/silicate partition coefficients with the relative abundances of these elements in the mantle, the physical state of the mantle can reconstructed when the respective element abundances were established; W and Cr at magma ocean conditions around 2550K, and Pb, Cd, Sn, and Se to a mantle that must have been largely crystalline at the time of volatile addition, with core melt segregation inactive.

The experiments provide independent support for a latter-day volatile addition. Had Pb, Cd, Sn, and Se been present at magma ocean conditions, they would have been seriously depleted in abundance relative to the abundances in lithophile volatiles with similar condensation temperatures, far more than observed; Pb by up to two orders of magnitude relative to its present-day mantle concentration. Our Ds confirm that a large proportion of the volatile element inventory of Earth's mantle, including its water content, was part of a late volatile component, most likely material from the asteroid belt and added to a relatively cool mantle, at a time when core formation was completed. There is little basis to assume that the apparent Pb deficit in the silicate Earth is to be sought in the core. Rather, the $^{238}U/^{204}Pb$ ratio (μ) of Earth's mantle reflects late addition of Pb, to a highly refractory proto-mantle seriously depleted in volatiles. A late (post-core) addition of Pb via a CI-type impactor, to a refractory mantle highly depleted in lead, may also be key to solving the first lead paradox.

Surface characterization of biotite from a mesh bag field study

Z. BALOGH-BRUNSTAD[1,*,2], L. SACCONE[3], M.M. SMITS[4], C. BERNER[5], H. WALLANDER[5], T. J. MCMASTER[3] AND S.L.S. STIPP[2]

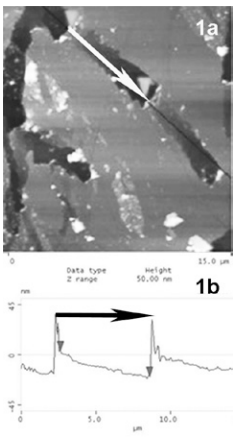
[5]Microbial Ecology, Lund University, Sweden

Direct fungal-mineral contact has been proposed to play an important role in soil mineral dissolution. Indeed, nanoscale observations in controlled laboratory settings have demonstrated both physical and chemical interactions with biotite at the scale of the individual fungal hyphae [1, 2]. We incubated biotite flakes in the soil, to test if similar fungal-mineral interactions could be observed in the field. The biotite was incubated in spruce forest soils for two years at three sites with serpentinite, leucogranite and amphibolite bedrocks and contrasting tree nutrient status. Mineral surfaces were examined with scanning electron microscopy and atomic force microscopy. Ectomycorrhizal biomass was determined by Ergosterol analyses.

Microscopy revealed patchy biofilms on the biotite surfaces (19 to 44%) with the highest values found at the low Mg site (leucogranite). Direct hyphal attachment was only 3 to 5% with the lowest values found at the low Mg site, which was supported by the the lowest Ergosterol concentrations at this site. We saw shallow channels, similar to hyphae in size and branching pattern on most of the flakes (Figure 1a). The channels widened with time, probably from dissolution, and at each "pulse," the channel deepened in the direction of growth (Figure 1b). We propose that this morphology reflects the pulsive growth of the hyphal tip, inducing shear stress to the top T-O-T biotite layers.



These observations support the laboratory results that fungal hyphae exercise both chemical dissolution and physical force at the hyphal-mineral interface.

Cloud condensation nuclei concentrations and actual supersaturations in real clouds

U. BALTENSPERGER, Z. JURÁNYI, E. HAMMER, M. GYSEL, N. BUKOWIECKI AND E. WEINGARTNER

Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland

The number of cloud condensation nuclei (CCN) at a given supersaturation has an important influence on cloud properties and is therefore crucial for a better quantification of the indirect aerosol effect on climate. Only in recent years, CCN data have become available from different sites in a systematic manner. We have measured the CCN number concentration continuously at the high alpine site Jungfraujoch (3580 m asl) continuoulsy for several years, in the framework of the Global Atmosphere Watch (GAW) programme of the World Meteorological Organization [1], and perfomed a closure with other aerosol variables measured simultaneously at the same site [2]. We show that the critical dry diameter, above which the aerosols activate as CCN, does not show a distinct seasonal cycle, nor substantial variability, indicating that aerosol hygroscopicity stays fairly stable throughout the year. Therefore, the CCN number concentration at this site can be reliably predicted from the time-resolved particle number size distributions with approximate knowledge of the time averaged chemical composition.

Since the Jungfraujoch is within clouds about 40% of the time this site provides the possibility to compare the measured CCN number concentrations with the activation that occurs in the real clouds. For this purpose, two different inlets were used: A total inlet, heated to 25°C was used to evaporate cloud droplets and ice crystals and to sample both their residual (previously activated and/or nucleated) particles and the interstitial (non-activated) particles. A second, interstitial inlet was equipped with a cyclone to remove cloud particles and sample only the non-activated aerosol particles (smaller than 2 μm). A comparison of the size distributions behind these two inlets allows to retrieve the activation diameter in the real cloud [3]. Together with the measured CCN spectra this provides the maximum supersaturation the cloud experienced in the vicinity of the Jungfraujoch.

Iron, copper and zinc are three essential metals for life. The concentration of these metals is regulated by the metabolism to reach body requirements, but almost nothing is known about the variations of the stable isotopes in the body. This could bring new insights on the metabolism of the metals, but the mapping of the isotopic variability in normal conditions is necessary prior to any applications for the study of metal metabolic disorders. Here, we report Fe and Cu isotope compositions (δ^{56}Fe and δ^{65}Cu) and concentrations in various organs of sheep raised experimentally with constant diet (δ^{56}Fe and δ^{65}Cu ≈ 0‰). Iron isotope compositions range from about -4‰ to -1‰ (muscle and liver/kidney, respectively), and copper isotope compositions range from -1.5‰ to +1.5‰ (liver and kidney, respectively), therefore covering almost the geological variability. The variability of the Fe and Cu isotope compositions is higher than for Zn (-0.6‰ to +0.6‰, [1]), suggesting that biologically-induced metals isotope fractionations depend more on redox conditions than on ligand coordination. Contrary to humans [2], the Fe and Cu isotope compositions are similar in serum and red blood cells. The isotopic cycling of the metals in the body is discussed using mixing equations and box modeling.

Particulate trace metals and dust particles in the subtropical Atlantic

W. BALZER*, W. BARKMANN AND H. DIERSSEN

University of Bremen, FB 2, 28334 Bremen, Germany
(*correspondence: balzer@mch.uni-bremen.de)

During the expedition Meteor M81/1 in the subtropical Atlantic Ocean (GEOTRACES Cruise A11; February/March 2010) particulate trace metals were sampled (by using *in situ*-pumps) to study (i) the fate of dust particles in the water column, (ii) its impact on the vertical distribution of particulate trace metals and (iii) to investigate the interaction between trace elements in solution and in the particulate phase.

The cruise track from the Canary Islands to the Brasil basin followed an approximate gradient from high to low dust input. While mineral dust and aerosol deposition is the most important source of trace elements in the open subtropical Atlantic, the surface distribution of particulate trace metals is also affected by the biotic productivity and the rate of organic matter sedimentation which tends to remove the mineral particles from the surface ocean and also decreases along the cruise track.

There is evidence to suggest that the small dust particles do not sink by themselves but that they are removed from the mixed layer by forming aggregates with sticky organic particles. These aggregates might be large enough to leave the surface ocean rapidly, sink, disaggregate, re-aggregate, etc., thus producing an observable vertical distribution of e.g. particulate Al (taken as a proxy for dust particles).

For this assemblage of processes acting on the distribution of suspended dust particles (including aggregation between organic and mineral particles, disaggregation and joint sinking) a model has been developed. The simulated concentration profiles of refractory trace metals (of suspended dust particles) are strongly related to the rate of atmospheric dust deposition and show a similar pattern as in the observed vertical concentration profiles.

Below the surface mixed layer, the different particulate trace metals exhibit extreme differences in the vertical distribution depending on the major form of their particulate transport: the concentration of the more refractory metals in inorganic entities (e.g. Al, Fe, Mn) tend to be constant or even increase with depth, while the nutrient-type elements (e.g. Cd, Ni) being associated with organic particles exhibit dramatic decreases of the concentration with depth in the deep sea. The results for the different elements are compared with those from a similar cruise in 1997 to evaluate interannual variability.

Petrogenesis of monotonous dacitic Taapaca Volcanic Complex, N. Chile

M. BANASZAK*AND G. WÖRNER

University of Göttingen, Geoscience Centre Göttingen, Goldschmidtstr. 1, 37077 Göttingen, Germany
(*correspondence: mbanasz@gwdg.de)

Taapaca Volcanic Complex (TVC) located in the Andean Central Volcanic Zone (18°S) generated monotonous high porphyric dacites (61-65.5 wt.% SiO_2) during its main eruptive history ~1 Ma [1]. Taapaca dacites show textural and mineralogical characteristics similar to the Fish Canyon Tuff [2], including sanidine megacrysts, lack of pyroxene and presence of mafic inclusions.

The occurrence of sanidine megacrysts up to 12 cm in length in intermediate volcanic rocks is a unique feature. All Taapaca sanidine show similar growth patterns, pronounced Ba-zoning, and invariable incompatible trace element contents as well as Sr- and O- isotopic compositions. Chemical characteristics of the sanidine, enclosed plagioclase, and magnesiohornblende compositions suggest crystallization in a closed-system at 700-770°C and 1.0-3.4 kbar. Microphyric basalt andesitic inclusions (52-54 wt.% SiO_2) in Taapaca dacite show a uniform mineral assemblage of plagioclase, magnesiohastingsite and Fe-Ti oxide with varying proportions of incorporated felsic components. The mafic inclusions represent compositionally two kinds of parental magma reported from neigbouring Parinacota Volcano [3], differing significantly in Sr and Ba contents, FeO^*/TiO_2 and REE patterns. Estimated P-T conditions from magnesiohastingsite composition reveal 900-1020°C and 2-8 kbar. Taapaca dacites reveal both P-T ranges obtained from two coexisting amphibole and plagioclase populations.

The composition of the dacites and compositionally diverse hybrid mafic inclusions form an array of distinct mixing lines, which converge to one rhyodacitic composition. The composition of the dacites indicates mixing between an evolved sanidine-bearing end-member composition of ~68 wt.% SiO_2 and a range of basaltic andesites in the constant ratio of 3:1. Neither basaltic andesite nor rhyodacite erupt as end-member compositions at Taapaca Volcano. Following reactivation, the uniform dacitic composition of TVC sugessts steady-state magma throughput, and a uniform volume-ratio between remobilized resident rhyodacite crystal mush and variable mafic input.

Spectroscopic study of influence of silica on the stability of actinide(IV) colloids at near-neutral pH

D. BANERJEE[1,2]*, S. WEISS[1], H. ZAENKER[1], A.C. SCHEINOST[1,2] AND C. HENNIG[1,2]

[1]Institute of Radiochemistry, Helmholtz-Zentrum Dresden-Rossendorf, 01314 Dresden, Germany
[2]The Rossendorf Beamline at ESRF, B.P. 220, 38043 Grenoble, France (*correspondence: banerjee@esrf.fr)

The migration of tetravalent actinides in natural waters occurs predominantly as sorption complexes at the surface of colloidal particles like clay, but also by the formation of actinide oxyhydroxide colloids ($MO_n(OH)_{4-2n}\cdot mH_2O$ where M = Th or U [1]). Colloid-facilitated migration of plutonium has also been documented in subsurface groundwater conditions [2]. In a recent study it was observed that the stability of U(IV) and Th(IV) oxyhydroxide colloids is dramatically enhanced by the presence of silica [3]. In this study we investigate the influence of silica on the formation and stability of U and Th colloids at near-neutral pH conditions, which might have important environmental implications due to the ubiquitous nature of silica in aquifers and surface waters.

U and Th colloids with varying U/Si and Th/Si ratios were synthesized and characterized using a range of spectroscopic and microscopic techniques. TEM and XRD measurements indicated that the structure of thorium/silica colloids is highly amorphous, which is clearly different from the ordered actinide(IV) oxyhydroxide colloids which are stable at pH < 3 but agglomerate and precipitate at near neutral pH within minutes. Comparison of O 1s X-ray photoelectron spectra (XPS) of actinide(IV)-silica and actinide(IV)-oxyhydroxide colloids revealed that two types of oxygen bonds (oxo and hydroxo) occur in presence of silica, which may explain the high degree of structural disorder. Moreover, the presence of O-Si bonds at near-neutral pH values suggest that silica is able to stabilize such colloids through modification of the structure by replacing the An-O(H)-An bonds of the oxyhydroxide structure with An-O(H)-Si bonds and consequently influencing the surface charge. These observations are consistent with X-ray absorption spectroscopy (XAS) data which demonstrate higher An-Si interaction and lower An-An interaction with increasing silica content in these colloids.

Sorption and redox behavior of neptunium on Opalinus clay and Callovo–Oxfordian argillite

N. L. BANIK*, C.M. MARQUARDT, D. SCHILD, J. ROTHE AND T. SCHÄFER

Karlsruhe Institute of Technology (KIT), Institute for Nuclear Waste Disposal (INE),D-76344 Eggenstein-Leopoldshafen, Karlsruhe, Germany (*correspondence: nidhu.banik@kit.edu, christian.marquardt@kit.edu, dieter.schild@kit.edu, joerg.rothe@kit.edu, thorsten.schaefer@kit.edu)

Clay stone is considered as a potential host rock for a high level deep nuclear waste repository. The Opalinus clay (OPA) and the Callovo-Oxfordian argillites (COx) are being investigated as candidate host rock formation at the underground research laboratory in Mont-Terri (Switzerland) and at Bure (France), respectively. The migration behavior of Np is strongly influenced by the oxidizing and reducing conditions of the geological environment. The understanding of Np sorption and diffusion mechanisms in argillaceous rocks is necessary for the safety assessments of a nuclear waste repository.

The objective of the present work is to use Kd values determined by batch experiments for transport modeling, and to gain understanding in underlying coupled redox and sorption phenomena. The batch sorption experiments of Np(V) on OPA (pH 7.6) and COx (pH 7.2) are performed at four different solid to liquid ratios, S/L (10, 20, 50, 200), in artificial pore water under argon atmosphere (<1 ppm O_2) with 1% CO_2 conditions, at Np concentrations between 3.0×10^{-4} and 1.0×10^{-8} M and with contact times up to 1 year. Np redox speciation in clay suspension is followed at low Np concentration by TTA extraction and capillary electrophoresis coupled to ICP-MS and at high Np concentration by UV-Vis, XAFS, and XPS spectroscopy.

Np(V) sorption increases with increasing sorbent amounts (S/L ratio) and with increasing contact time. More than 80 % of Np sorbed on the clay rocks within 4 months. The preliminary Kd values are calculated to 1.03 mL/g for OPA and 0.85 mL/g for COx (S/L ratio: 20) after 4 months contact time. In concentration series at 10^{-4} M, Np was identified on the clay in the form of Np(V) by XAFS and XPS spectroscopy after 1 week contact time, whereas in solution Np(V) is detected by TTA extraction and UV-Vis spectroscopy. At $<10^{7}$ M, Np(V) is found in solution by TTA extraction after 1 week contact time, while after 4 months Np(IV)/Np(V) mixtures are analyzed. The obtained results will be presented.

Sulfate mineral solubilities in Na-Ca-Cl brines

JONATHAN BANKS AND SIMONA REGENSPURG SIMONA

Helmholtz-Centre Potsdam, German Research Centre for Geosciences (GFZ) Potsdam, Germany (*jbanks@gfz-potsdam.de)

Geothermal brines produced from deep sedimentary basins show a strong tendency to produce mineral precipitants (scales) during operation of a power plant. Measured SO_4^{2-} concentrations (up to 3 mM) in the fluid at the Groß Schönebeck (GrSk) *in situ* geothermal laboratory, Germany suggest that sulfate-bearing minerals may be significant scale forming phases. Of particular concern are the behavior of (1) Ba^{2+} and Sr^{2+} in the high salinity (up to 5 M Cl^-) Na-Ca-Cl fluid, and (2) the overall equilibrium concentration of SO_4^{2-} that subsequently controls the mass of $CaSO_4 \cdot xH_2O$ precipitation. In order to predict the estimated amount and nature of these scales, we have both modeled and experimentally determined mineral solubilities in synthetic GrSk brines under proposed plant operating conditions (15 bar, 70°C – 150°C).

Modelling was performed using the PHREEQc Quintessa database, with anhydrite ($CaSO_4$), barite ($BaSO_4$), and celestite ($SrSO_4$) as the equilibrium phases. Experiments were performed using a "flooding method," in which a deliberately oversaturated concentration of SO_4^{2-} was injected into a Na-Ba-Ca-Sr- Cl brine filled pressure vessel. While there is general agreement between the PHREEQc and experimental results, some significant differences do exist. PHREEQc over-estimates the amount of barite precipitation by up to three orders of magnitude and underestimates the amount of celestine precipitation by up to one order of magnitude. In total, both PHREEQc and experimental results predict between 10^1 and 10^4 grams of total sulfate mineral precipitation per m^3 of produced fluid, depending on the conditions and total available SO_4^{2-} .

Microbial cycling of sulfur in the aphotic zone a meromictic lake

B. DYLAN BANNON[1], SHUHEI ONO[2], STEFANIE P. TEMPLER[3] AND TANJA BOSAK[4]

[1]EAPS MIT, Cambridge MA 02139, (bannon@mit.edu)
[2]EAPS MIT, Cambridge MA 02139, (sono@mit.edu)
[3]Emmy Group, Ostermundingen, Switzerland, (stefanie.templer@emmi.ch)
[4]EAPS MIT, Cambridge MA 02139, (tbosak@mit.edu)

Fayetteville Green Lake (FYG) is a meromictic euxinic lake characterized by large differences in the composition of sulfur isotopes of sulfides and sulfates ($\delta^{34}_{\text{sulfate-sulfide}}$ of 56-57.5‰) [1]. Similar $\delta^{34}_{\text{sulfate-sulfide}}$ values are commonly thought to involve microbial sulfate reduction (MSR) coupled with microbial disproportionation of sulfur (MSD). Because our recent study suggests that MSR limited by the availability and quality of organic compounds can produce similar $\delta^{34}_{\text{sulfate-sulfide}}$ in the absence of MSD, here we study molecular, metabolic and physiological diversity of microbes from the sulfidic water column and the bottom sediments of FYG.

Enrichment cultures confirm the presence of S-disproportionating microbes in the sediments and the water column. Preliminary most probable number counts (MPNs) suggest that these organisms may be as abundant in sediments as sulfate reducing microbes. The MPNs also indicate a marked increase with depth of organisms that are able to couple sulfate reduction to the oxidation of acetate. Isolated microbes from the lake bottom sediments include at least two phylogenetically distinct organisms that can disproportionate S.

Preliminary studies suggest that microbes in the bottom sediments of FGL can metabolize recalcitrant organic substrates, reduce sulfate and disproportionate S. Further physiological, metabolic and isotopic analyses of enrichment cultures and isolates, as well as molecular comparisons of the diversity of dissimilatory sulfate reductase genes (*dsrAB*) and 16s rDNA genes in the water column and the sediments are in progress.

The landscape change of salt and alkaline land in semi-arid district before and after flooding

CHUNHONG BAO[1,2] LINSHU XU[2] YUNJUN WU[3] AND SHUWEN ZHANG[4]

[1] Hunan Agricultural University, Changsha 410128, China (Email:baoch159@163.com)
[2]College of Urban and Environmental Sciences, Northeast Normal University, Changchun 130024, China
[3]The Land and Resources Deportment of Hunan Province, Changsha 410007, China
[4]China Graduate School of Chinese Academy of Sciences, Beijing 100049, China

This paper adopted relief map and TM, SAR image, impaling the image disposal technology of Remote Sensing and the space analysis technology of Geography Information System, and combining landscape ecology theory to analyze the effect of flooding before and after 1998 on soil salinization. The analysis includes several aspects such as quantiy, spatial distribution and landscape distribution of salt and alkaline land in Zhenlai county. The results show that the sun-acreage of saline-alkali land in Zhenlai Counly in creased by 13929.5hm2 after the flood. The connectivity and integrity of saline-alkali land increased as well. Furthermore, the center of Gravity of saline-alkali offset from west to east 1.57km. The offset of the flooded area is 1.53km, and that of the non-flooded area is 3.68km. The offset distance, flooding has the effect to slow up the offset of the saline-alkali land. By contrasting the change ratio of unit area of saline-alkali land between flooding zone and no-flooding zone , it is found that the change ratio of all kind of saline-alkali land in flooding zone is higher than that in no-flooding zone at large. For example, the ratio of heavy grade of saline-alkali land in flooding zone is 5 times of that in no-flooding zone. The ratio of moderate grade saline-alkali land in flooding zone is 4.5 times of that in no-flooding zone. The ratio of gentleness grade saline-alkali land in flooding zone is 1.1 times of that in no-flooding zone. It is conculuded that the flooding has the effect to promote the extension of saline-alkali land in half arid district after the flooding. Though studying the integrity and average area of the saline-alkali patch of the landscape distribution, the landscape distribution of the saline-alkali land in the flooded area is obviously different from the non-flooded area. At the same time, the degree of salinization is higher in the flooded area than that in the non-flooded area after the flooding. The flooding push forward the speed and speed of the saliniztion in the half arid district where the terrain is low-lying and level of groundwater is higher.

Paleoproterozoic crustal growth in West Africa: Archean or modern tectonics?

L. BARATOUX[1], J. GANNE[1], M.W. JESSELL[1], S. NABA[2], AND V. METELKA[134]

[1]IRD, GET, 14 Ave E. Belin, 31400 Toulouse, France (*correspondence: lenka.baratoux@get.obs-mip.fr)
[2]Dépt. de Géologie, Univ. de Ouagadougou, Burkina Faso

[4]Czech Geological Survey, Klárov 3, 11821, Praha 1, CR

The Paleoproterozoic granite-greenstone terrains of the West African Craton represent the key area to study the transition from the Archean so-called “vertical” tectonics towards the modern “plate” tectonics. Our study was focused on structural evolution, geochemistry and metamorphism of the eastern and western Burkina Faso and eastern Senegal.

Geochemical data suggest that the greenstone (GS) belts, composed of tholeiitic basalts/gabbros and voluminous calc-alkaline intermediate sequences, originated in the volcanic arc setting at ~2.2 Ga. Presence of subduction zones is furthemore supported by the cold metamorphic gradient in some of the metasediments found in the eastern Burkina Faso. Compared to the Archean terrains, the proportion of komatiites and ultramafic rocks is extremely low, which suggests only limited mantle plume activity.

The calc-alkaline tonalite-trondjemite-granodiorite magmas, associated with the subduction zones, as well as younger granitoids were syntectonically emplaced into the greenstone belts during a long period from 2.18 to 2.10 Ga. No structures indicative of “sagduction” of greenstones into granitoids were found in the study area. Structural analysis of three GS belts in western Burkina Faso shows that the regional scale geometry is controlled by the rheologically strong mafic and intermediate volcanic rocks, which form up to 400 km long synforms. The granitoids are syntectonically emplaced into the presumptive antiforms between the belts.

Some of the granitoid intrusions induced a thermal overprint of the pre-existing cold metamorphic gradient in the tectonically burried greenstone belts. This is recorded as isobaric heating of Barrovian-like assemblages of garnet, straurolite and kyanite bearing micaschists. Decompressional cooling documented by the growth of sillimanite and cordierite is consistent with tectonic exhumation from the depth of at least 18 km to the depths of 4-6 km.

To conclude, our data point to the existence of subduction and collisional zone settings, which operated in a modified way compared to the present-day analogues.

Past fire reconstructions in ice core through the determination of specific molecular markers

CARLO BARBANTE[1,2]

[1]University of Venice, Department of Environmental Science, Calle Larga S. Marta, 2137, I-30123 Venice, Italy
[2]IDPA-CNR, Calle Larga S. Marta, 2137, I-30123 Venice, Italy

The reconstruction of the chemical composition of aerosol during the past is important for understanding the organic component contribution of biomass burning emissions to the atmosphere and complements existing data on the signatures of direct organic emissions from biomass sources. Compounds from biomass burning include monosaccharide anhydrides (MAs), and the most important tracer compound among them is levoglucosan. This is a specific molecular tracer utilized for the assessment of particulate matter composition from biomass burning in the atmosphere because it cannot be generated by non-combustive processes or by non-wood combustion. Molecular markers such as levoglucosan are important tools in tracking the transport of particles produced by biomass burning.

In order to the current concentrations of levoglucosan in the atmosphere in prespective, it is important to quantify the fluxes of this compound during the past by examining environmental archives such as snow and ice cores. Polar ice core studies have extensively documented large changes in the content of aerosol constituents such as ionic species, dust, trace elements, and organic compounds during the late Quaternary period.

The study of past fire activity using ice core records opens regions of the world where no paleofire data previously exited. Polar and low-latitude, high-altitude ice cores provide data for regions which are not represented in the global charcoal database. The available temporal resolution matches that of the ice core, with the longest temporal resolution being that of the EPICA Dome C ice core that extends back approximately eight glacial cycles. The spatial resolution of chemical markers in ice cores depends on the location of the core itself. Low-latitude ice cores primarily reflect regional climate parameters, while polar ice cores reflect a global signal. Here, we present levoglucosan flux measured across the past 600,000 years in the EPICA Dome C ice core (75°06'S, 123°21'E, 3233 masl) ice core, during the past 4000 years in the Kilimanjaro (3°04.6'S; 37°21.2'E, 5893 masl) ice core, and the applicability for determining levoglucosan in the NEEM, Greenland (77°27' N; 51°3'W, 2454 masl) ice core.

Short term environmental reconstruction from rich CO_2-spring deposits (Massif Central, France)

F. BARBECOT[1]*, B. GHALEB[2], E. GIBERT[1] AND A. NORET[1]

[1]Université Paris-Sud, Laboratoire IDES, UMR8148, Orsay, F-91405, France (*correspondance: florent.barbecot@u-psud.fr)
[2]GEOTOP, Université du Québec À Montréal, BP 8888, suc. Centre ville, Montréal, QC, H2V 3W8, Canada

Our work focuses on the understanding of the hydrogeochemical processes related to carbo-gaseous springs relation with recent environmental changes (0-20 yr), including evolution of recharge areas and fluxes for surrounding aquifers. A 80-cm sequence has been cored from carbonated travertines in order to document recent environmental fluctuations (0-20 yr) and the related geochemical parameters that control isotopic signatures of modern carbonate deposits [1]. The core was drilled on a flat zone approximately located 200-m under the emerging spring in the Limagne Plain (French Massif Central). Sediments consist of indurated carbonate, ideal for the reconstruction of hydrological fluctuations at very high resolution as they are fine, laminated deposits. Samples were taken every 1 to 2 cm according to the induration degree of the core.

The chronology of these finely laminated deposits has been determined through $^{210}Pb/^{226}Ra$ radiometric method [2,3]. Deposits accumulation rate is of 5.5 cm/yr excepted for events at 30 cm and 60 cm depth that display gaps of carbonates accumulation. Those events correlate precisely with two historical main heat waves, 2003 and 1998 [4], that confirms the indirect records of both the recharge decrease and the drying-up of the springs.

While solid carbonates precipitating along the surface flowpath originate from water with a nearly constant ^{18}O composition, highlighting the inertia of the system that gives rise to the springs, the ^{13}C signatures of those carbonates have likely registered past meteorological conditions [4]. Moreover, this environmental record offers a significant correlation between ^{13}C signal and the East Atlantic Pattern of the North Atlantic Oscillation. Higher mean temperatures can be identified by an enriched ^{13}C content, because of prominent fractionating geochemical processes involved, such as degassing and carbonate precipitation.

REE behaviour in acid mine drainage conditions in the Ríos Tinto and Odiel (Iberian Pyrite Belt, SW Spain)

L. BARBERO[1], M. OLÍAS[2], A. HIERRO[3], M. CASAS-RUIZ[4] AND J.P. BOLÍVAR[3]

[1]Dpto. CC de la Tierra, Universidad de Cádiz, Spain. (luis.barbero@uca.es)
[2]Dpto Geodinámica y Paleontología, Universidad de Huelva, Spain
[3]Dpto Física Aplicada, Universidad de Huelva, Spain
[4]Dpto Física Aplicada, Universidad de Cádiz, Spain

The Ríos Tinto and Odiel constitues one of the most extreme cases of acid mine drainage in the word and they are considered as the origin of one of the most important heavy metal discharge to the world's oceans.

In the Odiel river, the uppermost waters are clean and show geochemical parameters (pH, C, TDS, ORP, etc) typical of non-contaminated waters. The Río Tinto river shows acidic conditions from the headwaters down to the discharge into the sea. Total disolved REE contents in both rivers increases suddenly at pH values below 2.5 reaching values as high as 16000 μg/L, being lower than 1000 mg/L at pH higher than 2.5. Most enriched NASC-normalized REE patterns in Río Tinto show a negative Eu anomaly, this being progressively reduced as waters are diluted downstream and element precipitation or coprecipitation occurs. In the Río Odiel this slight negative Eu anomaly is mantained downstream which suggest that this feature is a proxy of the succesive AMD inputs. This Eu negative anomaly indicate that REE pattern are inherited from the massive sulfide or the waste rock. Another characteristic of the REE patterns of the Rios Tinto and Odiel is a MREE enrichment typical of waters related to AMD. Hypothesis to explain this include: acid leaching/dissolution of MREE-bearing amorphous iron oxyhydroxides [1]; fractionation by surface/solution reactions between MREE-enriched minerals and acid waters [2]; stabilization and coagulation by colloidal material [3]; combined action of different mechanisms [4]. To these, the possibility of disolving minerals with contrasting REE fractionation patterns should be considered.

Geochemical profiles to study the last deglaciation and its impact on rivers

EDOUARD BARD

CEREGE, College de France, Aix-Marseille University, CNRS, IRD, Technopole de l'Arbois BP 80, 13545 Aix-en-Provence Cedex 04, France (*correspondence: bard@cerege.fr)

The last deglaciation is fascinating for climatologists as it allows to study first-order climate changes that accompanied the retreat of the large Laurentide and Fennoscandian ice-sheets [1, 3]. Between 21000 and 6000 years before present, the climate system experienced a complete reorganization of all its compartments, e.g. atmosphere, oceans, lakes and rivers together with their associated ecosystems and biogeochemical cycles.

Linking records of the last deglaciation on land and in oceans requires accurate dating and comparison of different geological archives. A complementary way is to measure geochemical tracers of terrestrial and marine origins in the very same sediments raised in coastal environments.

Paleoclimate records at a particular location witness the successive phases of the last deglaciation. These various events, pauses and accelerations, have been known for many years (famous events such as Heinrich #1, Bolling, MWP1A, Allerod, Younger Dryas…), but it is only recently that geochemistry has provided analytical techniques allowing to produce high-resolution time series of various proxies based on elemental ratios (e.g. [2, 8]), organic compounds (e.g. [4, 5]) or stable and radiogenic isotopes measured in different sediment fractions: detrital, biogenic, authigenic phases or even interstitial waters (e.g. [6]).

To illustrate this growing research field, I will review what we know about deglacial sea level based on tropical corals and then go on to consider the associated changes in a few selected records from coastal zones, past river mouths or marginal seas (e.g. [4-9]). The aim is to illustrate the complex linkage between sea level rise, paleoclimatic changes and the reactivation of rivers during the last deglaciation.

Redox reaction of pyrite with Se

FABRIZIO BARDELLI[1]*, MINGLIANG KANG[1,2], ANTOINE GEHIN[1] AND LAURENT CHARLET[1]

[1]ISTerre, Maison de Geosciences, 38041 Grenoble, France (*correspondence: fabrizio.bardelli@gmail.com)

[2]Chinese Academy of Sciences, Guangzhou, 510640, China

The radioactive isotope ^{79}Se with a half-life of 2.95×10^5 years, is presently considered as the key mobile fission product for the disposal of spent fuel and high-level radioactive waste [1]. Its solubility largely depends on redox conditions: Se(IV) and Se(VI) prevail as very mobile aqueous oxyanions, while the oxidation states 0, -I, and -II are solids with low solubility [2]. Due to the weak adsorption of Se(IV) and Se(VI) on natural minerals, and in particular on granite or claystone minerals, chemical reduction is considered to be the most effective way to immobilize ^{79}Se.

On the other hand, pyrite (FeS_2) is the most frequent sulfide mineral and is also present in geological barriers of nuclear waste repositories [3]. Its strong reducing capacity and its stability under anoxic condition make it a good candidate for the immobilization of redox-sensitive radionuclides, like ^{79}Se. Many works have focused on the identification of the reduced form of selenium when reacted with pyrite, but reported conflicting results [4,5,6]. Therefore we report a systematic where we investigate the effects of the reaction of Se(IV) and Se(VI) with pyrite in several different experimental conditions.

Experiments where conducted at ph 5.05, 5.65, 6.1, 7.0, and 8.5, reaction times of 7, 24, 36, and 48 days, and, at pH 7.0 and 8.5, with and without the addition of extra Fe^{2+} (10^{-4} mol/l). ICP-OES measurements where used to monitor the iron and Se concentrations and showed a decreasing trend of Se and increasing iron as a function of time. XAFS spectroscopy was used to unravel the selenium speciation. At pH 5.05 and 5.65 Se(0) was found to be the main reaction product, while at pH > 5.65, in addition to Se(0), XANES suggested the formation of iron selenides (Se -I or –II), in an amount which increased with the reaction time. The presence of iron selenides is further supported by Mössbauer spectroscopy clearly showing two different environments for Fe^{2+} in pyrite reacted with Se.

The results carried out in this study suggest that pyrite can significantly attenuate the mobility of ^{79}Se through chemical reduction.

Analysis of methanogen communities

LARRY BARESI

California State University, Northridge, CA 91330 USA (correspondence: larry.baresi@csun.edu)

Methanogens are an exciting group of microorganisms that live under conditions that are of interest to many engineers. They have been found to be active in coals, shales, and other carbon rich environments acting as both the final hydrogen and carbon sink producing methane as the final product. Physiological, molecular biology, biochemical, genetic, and ecological studies of these organisms can play a key role in optimizing their use. I will discuss the role of both past and present techniques such as DGGE/TGGE, 16s sequencing, bioinformatics, and metagenomics in expanding our understanding of this group and their associated organisms. I will also discuss how these new advances in our knowledge base can be used for the development of more effective biodegradation processes.

Speciation and dynamics of biologically reduced U(IV) in the Old Rifle, CO, aquifer

The chemical and physical forms of U(IV), as well as the biogeochemical processes by which they form and transform, profoundly influence the behavior of uranium in reduced sediments. Obtaining this information for sediments biostimulated *in situ*, *i.e.*, in the field, has been one of the most important and difficult scientific challenges in the field of uranium bioremediation. We have used in-well columns to obtain direct access to sediment U(IV) species, evolving microbial communities, and trace and major ion groundwater constituents in the Old Rifle, CO (USA) aquifer. Sediments were examined using x-ray and electron microscopy (XRM and SEM/TEM), x-ray absorption spectroscopy (XAS), and chemical digestions. EXAFS analysis showed that U(IV) occurred predominantly or exclusively as monomeric U(IV) complexes under both metal- and sulfate-reducing conditions, and was associated with biomass or Fe sulfides. Intriguingly, U(IV) was bonded to oxygen atoms, even when associated with iron sulfides. A fraction of these monomeric complexes transformed into uraninite in the aquifer over a subsequent 12 month period. This work establishes the importance of monomeric U(IV) complexes in subsurface sediments at the Old Rifle site and provides a conceptual framework in which previously observed U(IV) reduction products can be related. These experiments also establish that U(IV) species are dynamic in aquifers and can undergo non-oxidative transformation reactions. These new results have imortant implications for uranium reactive transport models and remediation technologies.

Influence of citric acid, EDTA and fulvic acid on U(VI) sorption onto kaolinite

M. BARGER* AND C.M. KORETSKY

Department of Geosciences, Western Michigan University, Kalamazoo, MI 49008, USA (*correspondence: michelle.l.barger@wmich.edu)

Batch sorption experiments were used to investigate U(VI) sorption on kaolinite (2 g/L KGa-1b) as a function of pH (3-10), ionic strength (0.001 - 0.1 M $NaNO_3$), pCO_2 (0-5%), U(VI) (10^{-6} - 10^{-4} M U) and organic acid (10^{-4} and10^{-2} M citric acid, 10^{-4} - 10^{-2} M EDTA, and 10 - 20 mg/L fulvic acid). Ligand sorption on kaolinite was also assessed in the absence of U(VI).

In the absence of ligands, U(VI) sorption on kaolinite increases from pH 3 to ~7, plateaus at nearly 100% between pH ~7 - 8.5, and decreases at pH > 8.5. Ionic strength has little effect on U(VI) sorption. Thus, at circumneutral pH, kaolinite could have a strong influence on U(VI) mobility in natural systems. Compared to atmospheric conditions, U(VI) sorption under 0 pCO_2 is slightly enhanced from pH 3 – 7, and unchanged from pH of 7-10, likely due to strong aqueous U(VI)-OH^- complexes. However, with increased pCO_2, up to 5%, U(VI) sorption diminishes significantly between pH 5-10, due to formation of U(VI)-carbonate aqueous complexes.

Addition of 10^{-4} or 10^{-2} M citric acid results in decreased U(VI) sorption at all pH values, with up to 50 or 90% reduction in U(VI) sorbed, respectively. Similarly, addition of 10^{-4} -10^{-2} M EDTA yields a decrease in sorption of up to ~70% compared to organic-free experiments. TOC analyses of citric acid and EDTA sorption on kaolinite in the presence or absence of U(VI) demonstrate that less than 10% of either ligand is sorbed to the solid surface. Thus, ternary complex formation at the kaolinite surface is unlikely to occur. Instead, U(VI) binds preferentially to organic acids as aqueous complexes. Addition of 10 or 20 mg/L fulvic acid causes an increase in sorption from pH 3 to ~5 respectively, and a decrease from pH ~5 to 10. Up to 40% of 10 mg/L fulvic acid or 20% of 20 mg/L fulvic acid sorbs on kaolinite at low pH, with the amount adsorbed linearly decreasing to ~10% at pH 10. Fulvic acid complexation at the kaolinite surface results in enhanced U(VI) sorption at low pH, likely due to the formation of ligand bridges. However, at high pH, U(VI) sorption is suppressed, presumably due to formation of strong aqueous U(VI)-fulvic acid complexes.

These data suggest that U(VI) sorption on kaolinite could be significant at circumneutral pH, but that organic acids may significantly retard or enhance U(VI) mobility. The data are currently being used to develop surface complexation model parameters describing U(VI) sorption to kaolinite.

Mantle lithologies from minor elements in olivine: Cape Verde

A.K. BARKER[1], P.M. HOLM[2] AND V.R. TROLL[1]

[1]CEMPEG, Dept. of Earth Sciences, Uppsala University, (Abigail.Barker@geo.uu.se)
[2]Dept. of Geography & Geology, University of Copenhagen.

The Cape Verde Archipelago is known to display source heterogeneity on a 100-200 km scale, with different isotopic domains sampled in the northern islands (mixed HIMU and DMM), compared with the southern islands (mixed EM1 and HIMU). Detailed temporal studies of lavas from Santo Antão and Santiago, representing the northern and southern islands respectively, have shown that the EM1 and DMM components have uniform composition with time, whereas the HIMU component shows a synchronous decrease in $^{208}Pb/^{204}Pb$ with time throughout the Cape Verde Archipelago.

We present minor element data for primitive olivines (Fo>75%), to unravel the mantle lithologies associated with the isotopic heterogeneity in the Cape Verde archipelago.

Lavas from Santiago with low $^{206}Pb/^{204}Pb$ (18.8) and positive Δ8/4, are associated with EM1. They have olivines with Ca = 990-2040 ppm, Mn/FeO = 90-150 and Ni*FeO/MgO = 480-750. Lavas from Santiago with high $^{206}Pb/^{204}Pb$ (19.4), associated with HIMU, have Ca = 2100-2600 ppm, Mn/FeO = 106-120 and Ni*FeO/MgO = 500-640 in olivines from the old volcanics. The Ca and Mn/FeO decrease and Ni*FeO/MgO increases with time from the old volcanics to the intermediate and young volcanics.

Lavas from Santo Antão with $^{206}Pb/^{204}Pb$ of 19.2 sample local DMM and have olivines with Ca = 1900-2750 ppm, Mn/FeO = 95-110 and Ni*FeO/MgO = 305-580. Lavas from Santo Antão with $^{206}Pb/^{204}Pb$ of 19.9, representing the HIMU component, have Ca = 2100-2650 ppm, Mn/FeO = 106-116 and Ni*FeO/MgO = 540-660 in the old volcanics and lower Ca, Mn/FeO and higher Ni*FeO/MgO in the young volcanics.

The DMM of Santo Antão is peridotitic in nature, whereas the EM1 and HIMU components are sourced from mixed peridotite-pyroxenite mantle lithologies. The uniformity of the DMM and EM1 components with time shown by the isotope heteorgeneity is also reflected in the mantle lithologies, i.e. dominantly peridotitic DMM and constant proportions of peridotite and pyroxenite in the EM1 source. However, the changes in $^{208}Pb/^{204}Pb$ of the HIMU component with time observed throughout the Cape Verde archipelago are also reflected by increasing proportions of pyroxenite in the source shown by minor elements in olivine. We will present modelling results of the proportions of peridotite and pyroxenite in the EM1 and HIMU sources with time.

Phosphate dissolution/precipitation controls on isotopic compositions of continental assimilants

J.E. BARKMAN[1]*, J.G. BRYCE[1], E.B. WATSON[2], J. BLICHERT-TOFT[3], E.F. BAXTER[4] AND S.A. BOWRING[5]

[1]UNH Earth Sciences, Durham NH, USA (*correspondence: julie.barkman@unh.edu)

[4]Boston University Earth Sciences, Boston, MA, USA
[5]EAPS, MIT, Cambridge, MA, USA

Partial melting and assimilation of lower and often ancient crustal rocks contribute to the chemical and petrologic evolution of continental magmas. In the past three decades, geochemical models have used isotopes and elemental abundances to improve the parameterization of thermal and mass transfer within the crust. Recent advances in microanalytical techniques have enabled the documentation of subtle isotopic and trace element variations at high spatial and temporal resolutions, allowing testing of assimilation models. Still, interpreting the geological implications of these chemical variations remains challenging, primarily due to the lack of experiments that can be used to parameterize the isotopic signatures of crustal anatexis products in existing assimilation models. Though experiments and theoretical treatments have improved the potential to assess Sr and Nd isotopic signatures of partial crustal melts, parameterization of Pb and Hf continue to be problematic. This has remained an issue because the isotopic signatures of Pb and Hf, two elements with many promising microanalytical applications, are strongly controlled by accessory phases.

To address these issues, we carried out isotopic measurements on partial melts generated experimentally at 900°C, 1 GPa by partially melting a 1.7 Ga two-mica granite. Resulting melts were rhyodacitic in composition (SiO_2 ~ 71 wt%), with elemental and isotopic measurements suggesting that with <10% melting, the Pb and Hf isotopic systems are in disequilibrium with their whole rock. Uranogenic ($^{206}Pb/^{204}Pb$ ~ 23) and thorogenic ($^{208}Pb/^{204}Pb$ ~ 47) Pb signatures and extraordinarily radiogenic Hf (ε_{Hf} ~ +250) suggest the melt isotopic systematics are strongly influenced by contributions from phosphates. This extremely radiogenic Hf, coupled with sluggish Hf diffusion and predictions from solubility models, provides support for the notion that ongoing dissolution and reprecipitation reactions of phosphates may play an important role in effectively redistributing radiogenic signatures of accessory phases through the melt.

The first multiple sulfur isotope evidence for a 2.9 Ga Mesoarchean sulfate reservoir

M.E. BARLEY[1]*, S.D. GOLDING[2], G.J. HEGGIE[1] AND M.L. FIORENTINI[1]

[1]School of Earth and Environment, The University of Western Australia, Crawley, Western Australia, 6009, Australia (correspondence: mark.barley@uwa.edu.au)
[2]School of Earth Sciences, The University of Queensland, Brisbane, Queensland. Australia

The relationship between the evolution of Earth's atmosphere and hydrosphere during the Archean are important and mass-independent fractionation (MIF) of multipe sulfur isotopes caused by ultrviolet photolysis of atmospheric SO_2 is a key contribution to this when the atmosphere was oxygen poor and ocean was sulfur poor. In particular understanding why there are significant variations in the degrees of mass independent fractionation during the Archean and why it was lowest in the Mesoarchean (from 3.3 to 2.8 Ga) is important. This had been suggested to be a result of an early rise of oxygen. However, more recent studies show there is no clear evidence that oxygen rose then and the strongest Mesoarchean $\Delta^{33}S$ MIF values ranged from -0.13 to 1.31 between 2.96 Ga and 2.9 Ga [1] that coincide with volcanic events during this period that erupted volcanic gasses to the atmosphere for development of MIF and the most abundant Mesoarchean sulfur. Because prior to 2.7 Ga there is a limited rock record and most samples analysed from the Mesoarchean are from continental margin sedimentary ocean basins, the lack of significant negative $\Delta^{33}S$ values has provided no evidence for oceanic sulfate during this period. However, the ~2.9 Ga Lake Johnston Greenstone belt in the Yigarn Craton is a marine rift with submarine volcanic rocks (basalts, felsic volcanics and komatiites) shales and banded iron formations (BIFs) with a significant amount of low temperature volcanogenic massive sulfides (VMS) and the Maggie Hays komatiite-hosted Ni sulfide deposit. The $\Delta^{33}S$ values we recently obtained from this belt range from -1.7 to 0.1 providing the first strong negative $\Delta^{33}S$ data from the Mesoarchean consistent with inorganic sulfate reduction similar to that observed in the Neoarchean VMS, komatiite-hosted Ni sulfides and BIFs. This provides evidence for a Mesoarchean sulfate reservoir linked to a subaerial volcanic plume and oceanic volcanic island eruptions.

An isotopic perspective on mass bias and matrix effects in MC-ICP-MS

JANE BARLING AND DOMINIQUE WEIS

PCIGR, EOS, University of British Columbia, Vancouver, BC V6T 1Z4, Canada (jbarling@eos.ubc.ca)

Precise and accurate correction for instrumental mass bias is required to achieve the level of precision and accuracy needed for isotope ratio measurements by multi-collector inductively coupled plasma mass spectrometry (MC-ICP-MS). However, instrumental mass bias and the causes of its variation are not well constrained. With the excellent internal precision of isotope ratio measurements by MC-ICP-MS, we can investigate mass bias variation at an isotopic as opposed to elemental level in order to shed light on the processes underlying mass bias variation in the plasma. For this study we measured the spatial variation of Pb and Tl isotope ratios in dry plasma and their response to the presence of matrix.

Mass dependent radial variation of Pb isotope ratios indicates that lighter isotopes show greater dispersion from the axis of the plasma than heavier isotopes, in agreement with elemental observations by ICP-MS [1]. Axial variations in Pb and Tl isotope ratios show that isotopic signal maxima (I_{max}) are distributed in a mass dependent manner (Pb I_{max} separation: 3.47±2.07μm/amu), with I_{max} for heavier isotopes closer to the load coil than I_{max} for lighter ones; the reverse of the elemental mass dependence observed in ICP-MS [2]. This difference in mass dependent behaviour may be due to processes in the interface related to, for example, the high acceration potentials (4-10kV) used in MC-ICP-MS.

Addition of a low first ionization potential (1.IP) element to the plasma promotes ionization of Pb and Tl closer to the load coil, whereas a high 1.IP element results in ionization further from the load coil. Elements with low second ionization potential and those forming refractory oxides may also promote ionization further from the load coil. In addition to shifting the position of Pb and Tl I_{max}, the presence of matrix also reduces run-to-run variations in the mass dependent separation of isotope I_{max} (Pb I_{max} separation: 3.50 ± 0.54μm/amu). This reduced variability in mass dependent isotope separation under matrix-loaded conditions may provide an explanation for improved accuracy and external reproducibilty of dry plasma Pb isotope ratio measurements in the presence of a common matrix [3].

1500 yr cyclicity during mid- Holocene in the Eastern Mediterranean

M. BAR-MATTHEWS* AND A. AYALON

Geological Survey of Israel, Jerusalem, Israel (*correspondence:matthews@gsi.gov.il, ayalon@gsi.gov.il)

High-resolution (~3 to 20 years) speleothems records from the Eastern Mediterranean (EM) during mid-Holocene (7.0 to 4.0 ka) reveals 4 important patterens: a) ~1500 years cyclicity; b) correlation between half a cycle and archeological time framework; c) "dogtooth" pattren representing fast ~50-100 years increase in rainfall followed by gradual drying over a longer period of ~100-500 years. The structure of these changes resembles the structure the D-O events d) rapid climate changes (RCC) lasting 20-50 years [Fig. 1]. It is not clear what controls the 1500 years cycle (Bond cycles) and the so called "D-O events" that are clearly recognized during mid-Holocene speleothems in mid latitudes, the EM.

Interestingly each half cycle is associated with cultural-technological tranzitions, suggesting that these tranzitions follow long term climate trends (~400-800 years) rather than a response to RCC. Two of the tranzitions occur at the peak of the wettest period: the tranzitions from Mid- to Late Chalcolithic and from the Early Bronze II to III at 6.55-6.45ka and 4.8-4.7ka respectively, when annual precipitation increased by up to ~30% relative to present. The end of the Chalcolithic period and the transition from Early Bronze IV to the end of the Mid Bronze age occurred after of a long drying trend at 5.7-5.6ka and at 4.2-4.05ka respectively when precipitation dropped by ~30% relative to present.

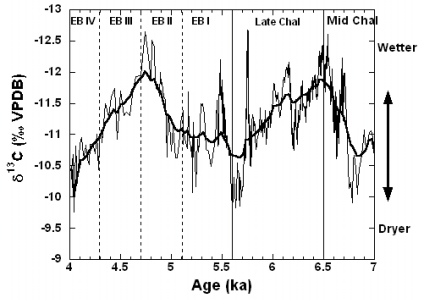

Figure 1: carbon isotopic composition showing the 1500 y cyclicity, D-O type events, RCC and the archeological time framework.

Li isotope compositions of Hawaiian post-shield lavas

ELSPETH M. BARNES, DOMINIQUE WEIS AND DIANE HANANO

Pacific Centre for Isotopic and Geochemical Research, University of British Columbia, Vancouver, BC V6T 1Z4 Canada (dweis@eos.ubc.ca)

Hawaiian post-shield lavas show more depleted geochemical signatures than their shield equivalents and the difference is attributed to material in the plume source, where the very enriched trace element concentrations in post-shield lavas clearly indicate that the source material is not MORB. We investigated Li isotope compositions in a series of well-characterized post-shield samples [1] to explain the origin of these geochemical characteristics and assess the potential contribution of recycled oceanic crust in post-shield lava.

Hualalai volcano δ^7Li values range between 1.91±1.00 (2SD) and 3.53±0.53‰, Mauna Kea samples show the smallest range, 3.39±0.89 to 4.93±1.92‰, contrasting with δ^7Li from the oldest sampled volcano, Kohala, which shows the broadest range, 1.97±0.35 to 4.04±0.44‰. For comparison, a 1993 tholeiitic sample from Kilauea volcano has δ^7Li of 3.72±1.29‰, while a Koolau Makapuu sample shows a relatively heavy δ^7Li value at about 4.5‰. In contrast to other isotopic ratios (e.g., ^{208}Pb/^{204}Pb), Kilauea and Koolau do not appear to represent compositional end-members of Hawaiian compositions in the Li isotope system.

Li isotope signatures of the studied post-shield lavas tend to be 'light' relative to shield lavas (δ^7Li 3.45 to 5.7‰; Mauna Loa and Mauna Kea)[2] and correlate positively with Nd, Hf and Pb isotope signatures, and negatively with Sr isotopes, possibly defining the history of the source material.

Our results indicate that the youngest post-shield lava sampled (Hualalai) has some of the 'lightest' δ^7Li values. Hualalai Volcano also has some of the lowest radiogenic Pb ratios that may derive from ancient recycled oceanic lithosphere and sediments that have geochemically evolved in the presence of low U/Pb during subduction dehydration processes in the upper mantle. We suggest that these dehydration processes may have driven ^{7}Li off in the fluid from the residual slab resulting in an isotopically 'light' Li signature in the plume source material [3].

Chlorine chemistry of altered oceanic crust

J.D. BARNES*

Department of Geological Sciences, Jackson School of Geosciences, University of Texas at Austin, Austin, TX, 78712, USA (jdbarnes@jsg.utexas.edu)

Chlorine strongly partitions into aqueous fluids, thereby making Cl and its stable isotopes (^{37}Cl and ^{35}Cl) powerful tracers of fluid-rock interaction, including interaction between oceanic lithosphere and hydrothermal fluids. Although altered oceanic crust (AOC) is considered to be a major Cl reservoir estimated to subduct ~2.5-3 x 10^{12} g of Cl worldwide each year [1, 2], work on the Cl chemistry of AOC is surprising limited. Here I present new Cl concentration and isotopic data for AOC from seven DSDP/ODP/IODP drill sites (801C, 735B, 894F/G, 504B, 1256D, 417A/D/418A, 332A/B), greatly expanding the previous data set.

Chlorine concentration and δ^{37}Cl values of AOC are heterogeneous among and within individual drill sites. Cl concentrations range from <0.01 to 0.09 wt% (n = 26) and δ^{37}Cl values range from -0.8 to +1.5‰ (error < ± 0.2‰) vs. SMOC (Standard Mean Ocean Chloride) (n = 20). These data greatly expand the range of previously reported AOC δ^{37}Cl values (-1.6 to -0.9‰; n = 3; Hole 504B; [3]). Neither Cl concentration nor isotopic composition is correlated with tectonic setting or crustal age. The Cl concentration decreases with depth in ODP Hole 735B from the SW Indian Ridge from 0.09 wt% at the top of the hole to <0.01 wt% at depth. A similar pattern is seen for δ^{37}Cl values ranging from -0.6 to +1.5‰ with the most positive values located near the top of the hole. The high Cl concentrations and δ^{37}Cl values are correlated with increased hydrothermal alteration (increased amphibole abundance) near the top of the hole. However, this trend is not consistent among all the holes implying that Cl chemistry is influenced by a variety of factors. Detailed future petrography and additional geochemical work will further test the correlation between Cl concentration and isotopic composition and mineralogy, as well as, examine the role of water-rock ratios, deformation, and temperature of hydrothermal alteration. These data can ultimately be used to reevaluate mass balance calculations improving our understanding of subduction recycling.

Is the platinum in the Bushveld complex derived from the lithospheric mantle ?

SARAH-JANE BARNES[1], WOLFGAND D. MAIER[2] AND EDWARD A. CURL[3]

[1]Universite du Quebec a Chicoutimi, G7H 2B1, Canada (sjbarnes@uqac.ca)
[2]University of Oulu, Finland, (wolfgang.maier@oulu.fi)
[3]Monash University, Australia, (edcurl@yahoo.com)

The Bushveld Complex of South Africa contains ~ 80 % of the world's Pt and almost half of its Pd resources in the form of three large ore deposits, the Merensky Reef, the UG-2 reef and the Platreef. Two questions arise a) were the magmas that formed the Bushveld Complex pariticularily Pt- and Pd-rich? and b) what is the origin of these magmas? In order to consider these questions we have estimated the compositon of the Bushveld magmas based on 40 new whole rock analyses of quench textured rocks from the margins of the intrusion.

Broadly speaking, there are two types of magmas present, a Mg-rich basaltic andesite and a tholeiitc basalt. Both of these magmas are enriched in large ion lithophile elemnts, light rare earth elements and in Pb. Both magmas have negative Ta, Nb, P and Ti anonmalies. The PGE contents of both magmas are similar to primary basalts and they do not appear to be enriched in PGE, except for Pt. The Pt/Pd ratio and Pt/Ti ratios are 1.5 to 2 times that of most basalts.

It is possible to model the lithophile element composition of the two magma types by up to ~ 50 % crustal contamination of komatiitic basalt or picrite. This conclusion is supported by Sr, Nd and oxgen isotopic work. However, the Pt contents of the model magmas and the Pt/Pd and Pt/Ti ratios are much lower than those observed. An alternative is to suggest that the Bushveld magmas formed by parital melting of the metasomatised lithosphere. But, modeling using Kaapvaal mantle xenoliths compositions and MELTS shows that this magma would be too Al_2O_3 rich and SiO_2 poor.

Two possible solutions to this are: a) the melts formed by zone refining melting of the lithosphere (to attain usually high Pt concentrations) followed by contamination with crustal melts; OR b) the current estimate of primitive upper mantle with a Pt/Pd of 1 is incorrect and it should be closer to 2, in which case mixing of a plume derived magma with continental crust melts approximates the composition of the Bushveld magmas

Microprospecting for platinum group minerals by X-ray fluorescence mapping using the Maia detector

STEPHEN J. BARNES[1], BELINDA GODEL[1] AND CHRISTOPHER G. RYAN[2]

[1]CSIRO Earth Science and Resource Engineerin Perth Western Australia (steve.barnes@csiro.au)
[2]CSIRO Earth Science and Resource Engineering Clayton Victoria

X-ray fluorescence microprobe mapping (XFM) has been used to locate micron-sized grains of platinum group element minerals in mantle nodules, komatiites and nickel sulfide ores using the Maia massively paralleled detector on the XFM beamline at the Australian Synchrotron [1]. The technique enables whole thin sections to be mapped at a pixel resolution of 2 microns, producing images up to 80 Mpixels in a few hours.

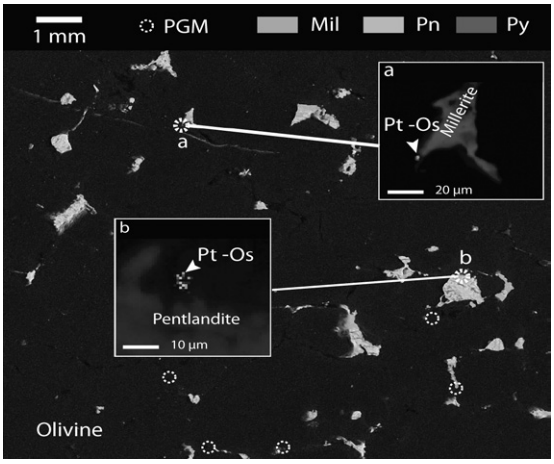

Figure 1. XFM image of sulfide-bearing dunite, Betheno, WA. Mil = millerite, Pn pentlandite, Py pyrite.

The example presented in Fig 1. shows one quarter of a standard thin section of a disseminated sulfide bearing fresh komatiitic dunite [2] containing 16 ppb Pt. XFM mapping revealed presence of 7 distinct PGM grains, only one of which had been located in a previous SEM search. This follows from the capability of the XFM method to detect buried grains within the 100 micron thickness of the section. PGMs are commonly found close to, but not in direct contact with, base metal sulfide globules.

Chalcophile elements in magmas and magmatic sulfide deposits: Can we see the mantle signals?

STEPHEN J. BARNES[1], MARCO L. FIORENTINI[2] AND WOLFGANG D. MAIER[3]

[1]CSIRO Perth Western Australia (steve.barnes@csiro.au)
[2]University of Western Australia Perth
[3]University of Oulu, Finland

Magmatic sulfide deposits are associated with a very wide variety of magma compositions from komatiites to andesites, spanning ranges of more than an order of magnitude in Ni content and three orders of magnitude in platinum group elements. Similar ranges are seen in sulfide ore tenors.

Late Archaean komatiites[1,2] show a strong consistency in PGE and Ni contents implying lack of S saturation except in the immediate environment of ore formation, and a broad homogeneity of deep mantle plume sources after 3 Ga.

Three trends are evident in post-Archaean basalts: source sulfide control, resulting in Pt and Pd depletion at high Mg#; cotectic sulfide fractionation, resulting in steady decrease in Pt and Pd with decreasing Mg#; and catastrophic depletion due to bulk crustal S assimilation [1]. Mantle signals are overprinted and difficult to discern in the latter two trends.

Basalts show very wide variability, and fall under a near-universal envelope of maximum Pt and Pd contents when normalised to moderately incompatible elements such as Ti. This maximum is lower than that for komatiites, implying either that all post-Archaean mantle sources are Pt-Pd depleted compared with Archaean plume sources, or that there is a universal global control owing to retention of sulfide in source mantle. However, source sulfide should produce a larger depletion, as seen in the Pt and Pd signal in primitive MORB and OIB. Within post-Archaean mafic magmas, only the Bushveld Complex sills stand out as being unusually PGE enriched, and even then the signal is only evident as a twofold enrichment in Pt [3]. Otherwise the Bushveld magmas appear to fall on extensions of the komatiite trends.

Iridium, Ru and Os are decoupled from Pt and Pd in basalts and komatiites, and show evidence for control by solubilities of Ir-rich phases [4]. This greatly limits the ability to read mantle abundances from magma compositions, and may have implications for Os iotope signals.

Volcanic, solar activity, and atmospheric circulation influences on cosmogenic 10Be fallout at Vostok and Concordia (Antarctica) over the last 60 years

M. BARONI[1], E. BARD[1], J.-R. PETIT[2], O. MAGAND[2] AND D. BOURLES[1]

[1]CEREGE, Aix-Marseille University, CNRS, IRD & College de France, Technopole de l'Arbois BP 80, 13545 Aix-en-Provence Cedex 04, France (baroni@cerege.fr)

[2]Laboratoire de Glaciologie et de Géophysique de l'Environnement (CNRS-UJF 5183), 38402 Saint-Martin-d'Hères, France

The cosmogenic nuclide beryllium 10 (10Be), recovered from ice cores, is often used to study solar activity on long timescales. However, the 10Be signal is also influenced by factors other than the Sun. In order to identify and quantify various contributions to the 10Be signal, two Antarctic snow records from the Vostok and Concordia sites spanning the last 60 years were studied at a sub-annual resolution. Three factors that contribute to the 10Be signal were identified. First, in both records, a significant period of approximately 11 years, that can be associated with the modulation of 10Be production by solar activity, was detected. Then, peaks in 10Be concentrations during the time of the stratospheric volcanic eruptions of the Agung (in 1963) and the Pinatubo (in 1991), respectively, were observed. The data indicate that stratospheric volcanic eruptions can impact 10Be transport and deposition. Also, an interannual variability of ~4yrs was determined in both 10Be records. As with species of marine origin, this 4yrs variability is interpreted as a tropospheric signal that could be associated with atmospheric circulation inherited from the coupled Southern Ocean ocean-atmosphere system. The results presented, here, from sites within the high Antarctic plateau open perspectives for ice cores dating over the last few centuries, as well as for the reconstruction of past solar activity in relation to climate.

Characterization of Anaerobic Methane Oxidation in Lake Kinneret (Israel)

ITAY BAR-OR[1], ORIT SIVAN[1], ADLER MICHAL[1], ARIEL KUSHMARO[2], ANN PEARSON[3], WERNER ECKERT[4]

[4]Israel Oceanographic and Limnological Research, The Yigal Allon Laboratory, Tiberias , Israel, (Werner@ocean.org.il)

In this study we show biogeochemical evidence for anaerobic oxidation of methane (AOM) in deep lake sediments and demonstrate that this AOM is likely driven by iron reduction. This is by producing porewater chemical and isotope profiles from Lake Kinneret (Sea of Galilee, Israel), together with incubation experiments, lipid analysis and molecular microbiology methods, including PCR, cloning and sequencing of archaea and bacteria.

Porewater profiles of methane and the stable carbon isotopes of the total lipid and methane indicate a sink for methane below the depths at which nitrate and sulfate are completely exhausted and the zone of methanogenesis. At that depths Fe(II) showed an increase, and iron isotopes decrease, suggesting that Fe(III) is the probable terminal electron acceptor. Based on these results incubation experiments of sediment cores and slurries were conducted to verify and quantify the rate of this process and its key parameters. This is by using amorphic ferric oxide and labelled methane. The results strengthened the iron dependent AOM hypothesis, and the obtained AOM rates were about 10% of the production rates. Analyses of the community structure and diversity of bacteria and archaea along the sediment gradients showed indeed the appearance of involved bacterial methanogens and methanotrophs in the deep sediment.

Gaseous mercury in soils over deeply buried sulfide deposits

F.C.D. BARROS[1,2], J. ENZWEILER[2]*, O.A.B. LICHT[3], Z. CASTILHOS[4] AND P.C. ARAUJO[4]

[1]University of Campinas/Votorantim Metais – Brazil, (fernanda.barros@vmetais.com.br)
[2]University of Campinas, P.O. Box 6152, CEP13083-970, Brazil, (*correspondence:jacinta@ige.unicamp.br)
[3] MINEROPAR - Serviço Geológico do Paraná - Brazil, (otavio@mineropar.pr.gov.br)
[4]Centro de Tecnologia Mineral (CETEM) - Brazil, (zcastilhos@cetem.gov.br; paraujo@cetem.gov.br)

The measurement of gaseous mercury in soils over a deep (~90 m) zinc sulfide mineralization was used to evaluate its potential as a mineral exploration technique. The Zn-Pb Santa Maria deposit (Camaquã Basin, RS, Brazil) contains sphalerite and galena as main ore minerals and up to 7 μg/g Hg. Holes at depths of 30 cm and 50 cm were made at preselected sample locations on three soil transects, two of them over the ore body. The Hg in soil pore gas was measured during 30 s, after inserting the hose of a portable Hg analyser in the hole and air purging. The concentrations of Hg in soil pore gas samples were typically low (< 5 ng/L) but significantly higher values were measured in the deeper holes, i.e., up to 18 ng/L. The higher Hg concentrations marked the position of the ore body. Total Hg in soil samples attained 40 ng/g, which also coincides with the mineralization, while median value was 21 ng/g.

Application of DSC and NMR to study the soil organic matter in the Atacama desert

N. BARROS, S. FEIJOO, J.A. RODRIGUEZ-AÑON, J. PROUPIN, M. VILLANUEVA AND J. SALGADO

Dept. Applied Physics. University of Santiago de Compostela. Spain. (nieves.barros@usc.es)

The study of the organic matter in desert soils makes necessary the development of sensitive methods to detect low percentages of SOM.Differential scanning calorimetry (DSC), together with ^{13}C CPMAS and 2D liquid H NMR was applied to study the SOM composition and structure of different mineral soils collected in the Atacama desert. DSC was very sensitive to study the SOM of those samples in base on their thermal properties. SOM combustion was detected in the DSC curves at C percentages up to 0.5 %. Most of them showed two well defined combustion peaks at temperatures atributed to carbohydrates and aromatic compounds.The heat of combustion obtained by the direct integral of those curves were directly correlated with the C and OM percentages of the soils as found in soils rich in organic matter content. The normalization of the heat of combustion to the OM content of the samples indicated different OM composition in the soils from Atacama. ^{13}C CPMAS NMR spectra indicated the existence of carbohydrates and aromatic compounds too.The aromatic compounds could be assigned to phenols derived from lignin. 2D liquid H NMR showed predominance of the aliphatic compounds when these soils are treated with chloroform.Most of the aliphatic C detected is attributed to Acetyl C and Methyl C in lipids or/and suberin. Nevertheless, the aliphatic fraction of the organic matter was not detected by the DSC and ^{13}C CPMAS NMR. Application of the three methods gives accurate information about the OM composition in these soils. It seems the carbohydrates and aromatic compounds are the main constituents in these mineral soils. Aliphatic C takes part of the general OM composition too but at lower percentages and it is necessary the specific extraction to be detected.

Stalagmite reconstruction of Moroccan climate from geographically spaced records

J.J. BARROTT[1]*, C.C. DAY[1], R.N.E. BARTON[2], A. BOUZOUGGAR[3] AND G.M. HENDERSON[1]

[1]Department of Earth Sciences, University of Oxford, UK, (*correspondence: julia.barrott@earth.ox.ac.uk)
[2]Institute of Archaeology, University of Oxford, UK (nick.barton@arch.ox.ac.uk)
[3]Institut National des Sciences de l'Archaéologie et du Patrimoine (abouzouggar@yahoo.fr)

Located at the boundary between Mediterranean and Saharan climates and within the southern limit of the North Atlantic storm tracks, Morocco is strategically placed for studying glacial to sub-millennial timescale shifting of climate boundaries. There is a specific lack, however, of high-resolution terrestrial records with high-precision, absolute chronology. Consequently, climate variation arising from interplay between climate systems is poorly understood and IPCC (2007) predictions of rainfall are presently uncertain. Precisely-dated, high-resolution, records of palaeoclimate linked with Morocco's extensive, rich archaeological records will also provide valuable insight into the potential effects of rapid climate change on pre-historic communities.

This study provides high-resolution and precisely dated U/Th records from speleothems discretely sampled from six caves in three sites (Ghar Cahal on the NW Mediterranean coast [5°3 W, 35°5 N]; 3 caves near Ouarzazate close to [7°3 W, 30°2 N]; and 2 caves in the SE close to Errachidia [4°2 W, 32°0 N]). Continuous growth and more negative $\delta^{18}O$ values in northern Morocco concurrent with abundant speleothem growth in the currently arid area south of the Atlas mountains suggests overall wetter conditions during the mid-Holocene and allow assessment of the pattern of rainfall and air-masses. We investigate the temporal and spatial relationships between these sites and compare them with existing records from the Holocene Climatic Optimum period, and with archaeological records in the region.

Comparison of oil sands process waters and natural water using Fourier transform ion cyclotron resonance mass spectrometry

MARK P. BARROW[1]*, JOHN V. HEADLEY[2], KERRY M. PERU[2], BRIAN FAHLMAN[2], RICHARD A. FRANK[3] AND L. MARK HEWITT[3]

[1]Department of Chemistry, University of Warwick, Coventry, CV4 7AL, United Kingdom (*correspondance: M.P.Barrow@warwick.ac.uk)
[2]Water Science and Technology Division, Environment Canada, Saskatoon, Canada
[3]Water Science and Technology Division, Environment Canada, Burlington, Canada

As the demand for petroleum has continued to rise, it has become necessary to increasingly turn to previously non-viable sources of oil, such as the oil sands in the Athabasca region of Canada. Using an alkaline hot water extraction process, the bitumen can be extracted from the oil sands prior to being upgraded to synthetic oil. Approximately three barrels of fresh water are required during the process to produce one barrel of synthetic oil. The exploitation of the Athabasca oil sands is therefore placing a burden upon the aquatic ecosystem in particular.

Fourier transform ion cyclotron resonance (FTICR) mass spectrometry has played a key role in the advent of the field of "petroleomics." The inherent ultra-high resolving power and mass accuracy is unrivalled within mass spectrometry, making the technique highly-suitable for the analysis of complex mixtures.

A 12 T Bruker solariX FTICR has been used to characterize a range of samples from the Athabasca region of Canada. The samples originate from natural water sources, such as rivers and lakes, and industrial sources, such as tailings ponds. High field FTICR mass spectrometry affords the ability to characterize the thousands of components present within the samples, which create characteristic signatures. Subsequent usage of principal component analysis (PCA) has demonstrated that these profiles can be used to determine the origins of samples, including distinguishing between industrial sources. There is potential for FTICR mass spectrometry to delineate between naturally-occurring profiles and anthropogenic sources.

Stable isotope (C-N) and noble gas (Ne-Ar) evidence for recycled plume components at the CIR

P.H. BARRY*[1], D.R. HILTON[1], E. FÜRI[1], B. J. MURTON[2], C. HEMOND[3] AND J. DYMENT[4]

[1]Geosciences Research Division, Scripps Institution of Oceanography, UCSD, La Jolla, California 92093, USA (*correspondence: pbarry@ucsd.edu)

[4] UMR-CNRS 7097, Institut de Physique du Globe de Paris, 4 Place Jussieu, 75005 Paris, France

We present new CO_2 ($\delta^{13}C$), N_2 ($\delta^{15}N$) and Ne-Ar isotope results on basaltic glasses of the Central Indian Ridge (CIR) (~17 – 21°S). Our aim is to assess whether the Réunion plume component evident along the CIR [1] also reveals a recycled contribution in the stable isotope and noble gas systematics. Positive $\delta^{15}N$ are attributed to post-Archean subduction whereas low $\delta^{15}N$ are associated with Archean recycling [2].

Nitrogen isotopes ($\delta^{15}N$) range from +3 to -3‰ (n=10) and overlap with positive $\delta^{15}N$ anomalies previously observed in Réunion xenoliths [3]. C-isotopes (n=17) range from -4 to -20‰ vs. PDB with the majority of samples falling in the MORB range. Equilibrium degassing models suggest that C-source characteristics may extend to -2.5‰. $^{20}Ne/^{22}Ne$ values range from 9.8 to 11.3 and when extrapolated to solar (Ne-B) values, $^{21}Ne/^{22}Ne$ ratios are ~0.049. $^{40}Ar/^{36}Ar$ ratios range from 298 up to 8413 with the highest $^{20}Ne/^{22}Ne$ value occurring in the highest $^{40}Ar/^{36}Ar$ sample. Notably, positive $\delta^{15}N$ samples display Ne and Ar only slightly higher than air-values, whereas negative $\delta^{15}N$ samples display distinct primordial Ne. $\delta^{15}N$ shows no correlation with $^{4}He/^{40}Ar^*$ [1] indicating $\delta^{15}N$ values are independent of degassing effects.

Taken together, the N-Ne-Ar results suggest multiple recycled components in CIR basalts, including Archean (low $\delta^{15}N$) and post-Archean (high $\delta^{15}N$) components, both of which are potentially integrated into the Réunion plume. Conversely, CO_2 results retain close to canonical MORB-like signatures, suggesting that either the source CO_2 is masked by external processes (e.g. - degassing and/or crustal contamination) or that CO_2 in the (upper and lower) mantle is homogenized to the extent that we cannot differentiate between the various reservoirs.

The influence of F, P and B content on pegmatitic melt viscosity

A. BARTELS[1], J. KNIPPING[1], H. BEHRENS[1], F. HOLTZ[1] AND B.C. SCHMIDT[2]

[1]Institute for Mineralogy, Leibniz University of Hannover, Germany, (a.bartels@mineralogie.uni-hannover.de)
[2]Experimentelle und Angewandte Mineralogie, GZG, Georg-August Universität Göttingen, Germany

The key property governing dynamics in strongly depolymerized partially melted systems is the melt viscosity. To test the individual influences of elements like F, P and B on melt viscosity of pegmatitic water-bearing systems a starting glass was prepared from a mixture of SiO_2, Al_2O_3, Na_2CO_3, and K_2CO_3. This starting composition (67.73wt% SiO_2, 20.20wt% Al_2O_3, 7.80wt% Na_2O and 4.27wt% K_2O) was then doped with different amounts of F (up to 4.8 wt%), P_2O_5 (up to 4 wt%) and B_2O_3 (up to 0.93wt%).

The viscosity of hydrous melts (1 to 6 wt% H_2O) was determined in internally heated gas pressure vessels using the falling sphere method (low viscosity range) in the temperature range 1173 - 1573 K at 200 MPa and 300 MPa. In the low temperature range the viscosity was determined between 580 and 880 K at ambient pressure using the micropenetration technique.

The results demonstrate that the viscosity decreases with the addition of F at all investigated temperatures. This viscosity decrease is more pronounced at low temperature and at low water content. The viscosity of pegmatitic melts containing ~ 6 wt% H_2O and 4.8 wt% F is 225 Pa·s at 1273 K. This value is about 1 log unit higher than that of complex pegmatitic melts containing F, B, P and Li [1]. Thus, although we confirm that F is clearly a fluxing agent, additional elements and their mutual interaction play a crucial role in the viscosity of natural pegmatite melts.

Our results indicate that phosphorus may not play a major role in viscous flow. In comparison to F the effect of P_2O_5 on melt viscosity is much lower (0.5 log units compared to 1.5 log units at 1373 K, 2.5 wt% H_2O), and in water-rich samples (~6 wt% H_2O) no significant effect of P_2O_5 has been detected. Additional experiments with variation of B_2O_3 content are in progress to determine wether this component will significantly influence melt viscosities in highly fluxed water rich systems.

The cause of high Nb/Ta in K-rich lavas from the Sunda arc system

A.R. BARTH[1,2], M. KIRCHENBAUR[1,2], S. KÖNIG[1,2], S. SCHUTH[3], A. LUGUET[2], A. IDRUS[4] AND C. MÜNKER[1]

[1]Institut für Geologie und Mineralogie, Universität zu Köln, Germany (anne.barth@uni-koeln.de)
[2]Steinmann-Institut, Rheinische-Friedrich-Wilhelms-Universität Bonn, Germany
[3]Institut für Mineralogie, Universität Hannover, Germany
[4]Department of Geological Engineering, Gadjah Mada University, Yogyakarta, Indonesia

The overall depletion of many terrestrial silicate reservoirs in Nb has been explained in some studies by the existence of superchondritic Nb/Ta reservoirs in either the core or mantle (e. g. [1–2]). As one example, K-rich lavas from the Sunda arc, Indonesia, have been invoked to tap such a high Nb/Ta reservoir, a hybridised mantle [3]. In order to elucidate the petrogenetic processes active beneath the Sunda arc and the causes for the apparently high Nb/Ta in some of these lavas, we determined major and trace element concentrations, Sr-Nd-Hf-Pb isotope compositions, and HFSE concentrations via isotope dilution by MC-ICP-MS on a representative set of 18 mafic samples, covering along and across arc sections from Krakatau to Lombok.

Similar Pb isotope compositions of all lavas, and mixing arrays of the Sunda arc lavas in εNd vs. $^{87}Sr/^{86}Sr$ space (εNd +1.3 to +5.6, $^{87}Sr/^{86}Sr$ 0.7040–0.7059) with local ocean floor sediments are in agreement with previous studies on the Sunda arc, suggesting a significant overprint of the mantle sources by fluids derived from subducted sediments. In contrast, the particularly K-rich back-arc lavas (e. g., Muriah volcano) do not lie on this mixing array (εNd -1.3 to +2.2, $Sr/^{86}Sr$ 0.7042–0.7046), and are the only ones exhibiting superchondritic Nb/Ta (18–25), attributed to slab melt overprint. However, other Sunda arc rocks yield sub-chondritic Nb/Ta (13–18).

In accord with previous studies [3–5], the incompatible trace element inventory of Indonesian high-K lavas can therefore be attributed to partial melts derived from rutile-bearing mafic oceanic crust with a thick cover of sediment. The more fluid-dominated trace element enrichment in the sources of the other Sunda arc lavas is also related to subducted sediments, resulting in distinct trace element and isotope compositions.

Karst versus sandstone and anthropogenic influences on small rivers of the Franconian Alb

J.A.C. BARTH*, M. MADER, R. VAN GELDERN, I. SCHREITER, P. ZIMMERMANN, T. TÜRK AND P. SCHULTE

GeoZentrum Nordbayern, Friedrich-Alexander Universität Erlangen-Nürnberg, 91094 Erlangen, Germany (*correspondence: barth@geol.uni-erlangen.de)

The small rivers Wiesent, Schwabach, Pegnitz and Regnitz drain the area of the Franconian Alb in Southern Germany, a typical karst terrain. Therefore the chemistry of the rivers should trace limestone weathering as the principal influence on river water composition. However, also urban influences by the city agglomeration of Nuremberg and signals of siliciclastic rock weathering may become more important in their lowland regions. Such changes of influence may best be studied in small rivers (< 52 $m^3 s^{-1}$ for the Regnitz and < 12 $m^3 s^{-1}$ for its tributaries) with major element and stable isotope analyses of dissolved organic and inorganic carbon. For instance, CO_2 partial pressures in the Wiesent River headwaters were up to 50 times higher than those in the atmosphere (> 21000 ppmV) and exceeded values found in African tropical rivers. For the Wiesent, such high pCO_2 values originate from soils and groundwater as they primarily occur in the groundwater-dominated source region. These waters are also characterized by carbon isotope signals of the dissolved inorganic carbon ($\delta^{13}C_{DIC}$) that are more negative than –14 per mil versus the VPDB standard. This deviates from typical values found in limestone weathering areas and indicates influences of CO_2 from recycled C3 plant material. These first data from the Wiesent indicate that weathering is not limited by CO_2. However, high pCO_2 values reduced rapidly towards values around 2500 ppmV over the course of the river due to degassing. In addition, lower reachers of the Wiesent showed dilutions in ion contents that may be related to increasing influences of sandstone weathering. First results of the other rivers studied showed mainly $\delta^{13}C_{DIC}$ signals of limestone weathering with values ranging around –12 permille and confirmed that carbonate weathering is the major control in these rivers. Influences of within-river turnover of dissolved organic carbon (DOC) may be revealed by simultaneous concentration and carbon isotope analyses.

Melting in the deep crust: Message from melt inclusions in peritectic garnet from migmatites

O. BARTOLI[1]*, B. CESARE[2], S. POLI[3], R.J. BODNAR[4], M.L. FREZZOTTI[5], A. ACOSTA-VIGIL[6] AND S. MELI[1]

[1]Dipartimento di Scienze della Terra, Univ. Parma, Italy (*correspondence: omar.bartoli@libero.it)
[2]Dipartimento di Geoscienze, Univ. Padova, Italy
[3]Laboratory of experimental petrology, Univ. Milano, Italy
[4]Fluids research laboratory, Virginia Tech, VA, USA
[5]Dipartimento di Scienze della Terra, Univ. Siena, Italy
[6]Instituto Andaluz de Ciencias de la Tierra, CSIC, Univ. Granada, Spain

S-type granites and leucosomes in migmatites provide information on the composition of crustal anatectic melts. However, their reliability as witnesses of primary anatectic melts has been questioned by several lines of evidence. Previously, the composition of the melt produced during crustal anatexis has been assumed from glass obtained in equilibrium melting experiments of crustal rocks. However, Cesare *et al*. [1, 2] have shown that peritectic minerals in migmatites can trap droplets of melt, that were formed by incongruent melting reactions during crustal anatexis.

We performed for the first time an experimental and analytical study of melt inclusions (MI) within peritectic garnets, using the metasedimentary migmatites from Ronda (S Spain). These garnets contain primary 2-10 μm MI that range from totally glassy to fully crystallized (*nanogranite*, [1]). Raman spectroscopy has documented the presence of liquid H_2O-filled micro-pores in nanogranites. Piston cylinder remelting experiments led to the rehomogenization of crystalline MI at conditions (700 °C, 500 MPa) close to those inferred for anatexis. Remelted MI have a peraluminous, granitic composition with high (up to 7.5 wt %) H_2O content; they overlap the composition of glassy MI, but differ from the composition of leucosomes in the host rock. Some CO_2 bubbles are present after remelting experiments, suggesting fluid present, $a_{H2O} < 1$ conditions, in agreement with graphite occurrence in the protolith. Our study identifies the natural anatectic melt composition and fluid regime at the onset of crustal melting, otherwise unknown. Hence, MI in migmatites represent a unique tool for the *in situ* characterization of anatexis in its early stages, and provide the only means of determining the volatile fluid content of anatectic melts.

Lime lumps in gothic joint mortars from Kruszwica (Central Poland): An insight into the lime production

W. BARTZ[1]* AND M. RUDY[2]

[1]University of Wroclaw, Cybulskiego 30, 50-205 Wroclaw, Poland (correspondence:wojciech.bartz@ing.uni.wroc.pl)
[2] Nicholaus Copernicus University, Sienkiewicza 30/32, 87-100 Torun, Poland

In this study we present the complete characterization of joint mortars from the 'Mouse Tower'. The tower is a remnant of a gothic castle, erected in mid-14th century by King Casimir the Great.

All mortars comprise a calcitic binder (micrite) and a fine- to medium-grained inert aggregate, dominated by a detrital quartz. Smaller or larger binder-related particles, so called 'lime lumps' could be found in the micritic matrix. The inner part of these lime lumps is typically composed mainly of calcite crystal and aggregates of minerals rich in CaO and/or SiO_2, identified by means of SEM-EDX as wollastonite, silica (identified as cristobalite by means of XRD), belite (C_2S), minerals with a composition close to the melilite group (gehlenite-åkermanite) and less common rankinite. The core of lime lump is rimmed by a thin zone composed of micrite and unidentified amorphous silicates.

As suggested by different authors, the presence of lime lumps is attributed to low water/quick lime ratios for slaking, rapid slaking, slaking with excess of water, or technologies based on the nonseasoning of lime. However, in our particular case the lime lumps should be considered as overburnt lumps, formed due to local increase of the temperature above mean in the kiln.

The chemical analysis revealed that the percentages of acid soluble SiO_2, which indicates the existence of hydraulicity, reach very low values. The cementation index (C.I. <0.13) classifies the joint mortars as non-hydraulic. The volume of hydraulic phases (i.e. belite) is very small, they are enclosed in the almost impermable structure, thus their presence had no impact on the hydraulic properties of whole mortar.

On the basis of our studies, we conclude the joint mortar was poorly homogenized, non-hydraulic lime, derived presumably from the calcination of impure limestone rich in clay and silt, possibly the lacustrine chalk. Deposits of this material, very common in post-glacial lakes of northern Poland, occur in the Gopło Lake, situated in the nearest vicinity of the tower.

U-Pb zircon ages of the Alto Paranaíba and Juína kimberlitic provinces, Brazil

M. BASEI[1]*, D. SVISERO[1], W. IWANUCH[2] AND K. SATO[1]

[1]Instituto de Geociencias, USP-Brasil
(*correspondence : baseimas@usp.br)
[2]Faculdade de Geologia, UERJ, RJ, Brasil

This work presents a set of zircon U/Pb ages of kimberlitic and akin rocks of the Alto Paranaíba (Minas Gerais – Goiás) and Juína (Mato Grosso – Rondonia) provinces. The Alto Paranaíba province is composed of hundreds of Cretaceous bodies intrusive in the southwestern border of the São Francisco Craton. The Juína Province is in the NW portion of the Mato Grosso State.

Ten zircon concentrates from APP corresponding to the Mata da Corda Group conglomerate and 74 zircon concentrates from intrusive bodies of kimberlitic affiliation of the Coromandel region were studied. Sixteen fractions corresponding to nine intrusive bodies yield $^{206}Pb/^{238}U$ ages around 87.36 ± 0.75 Ma Two younger bodies yielded ages around 80 Ma. Ten analyses corresponding to three kimberlitic bodies of the Juína Province present older $^{206}Pb/^{238}U$ ages of 93.69 ± 0.43 Ma. Whole-rock isotopic studies (Sr, Nd and Pb) suggest that the Alto Paranaíba Province kimberlitic-type rocks show signatures distinct from those that characterize the South-African bodies. The whole-rock Sm-Nd age of 850 Ma is similar to the zircon U-Pb ages of most of the juvenile granites that characterize the initial phases of the Goiás magmatic arc. It is possible that this value indicates the time of an important mantle melting associated with the Neoproterozoic subduction process that led to the generation of the arc. This frozen lithospheric mantle coupled to the base of the São Francisco Craton would be the source of the Cretaceous kimberlites of the Alto Paranaíba Province.

Seepage of subsurface brines into a major lake system using Ra and stable isotopes of oxygen and hydrogen: A case study from Lake Huron

M. BASKARAN[1]*, T. NOVELL[1], S. RUBERG[2], B.A. BIDDANDA[3], T. JOHENGEN[4], N. HAWLEY[2] AND V. KLUMP[5]

Exchanges of water between major reservoirs such as groundwater and lake water that are common can alter the biogeochemical cycling of chemical species and thereby affect relevant ecosystems. Recently discovered sinkhole vents in Lake Huron were found to discharge highly anoxic, reducing, high-sulfate and -chloride waters with strinkingly different chemical signatures.

We collected and analyzed a suite of water samples from three sinkhole vents and adjoining waters from Lake Huron for $\delta^{18}O$, δD, $^{223,224,226,228}Ra$ and a suite geochemical ancilliary parameters. Our results show: i) Ra concentrations in the vent waters are 1 to 2 orders of magntidue higher than that of the lake water; ii) A plot of δD vs $\delta^{18}O$ show considerable deviation from the Global Meteoric Water Line indicating mixing of different water masses that have undergone different evaporation cyles; and iii) The variations in the $^{223}Ra/^{226}Ra$ and $^{224}Ra/^{228}Ra$ activity ratios in the vent waters is related to the time-scales involved in the vertical movement of the vent waters. We also have modeled the variations in the Ra activity ratios in the vent waters to obtain time scales of transport from the source waters to the place where the vent water is discharged.

Comparing carbon isotopic signatures between meteorites and terrestrial mantle samples: Need for reassessment of carbon composition of Earth's mantle

S.BASU[1]*, S. MIKHAIL[1,2], A.P. JONES[1] AND A.B. VERCHOVSKY[2]

[1]Department of Earth Sciences, University College London (*correspondence: sudeshnabg@yahoo.com, s.mikhail@ucl.ac.uk, adrian.jones@ucl.ac.uk)

Carbon isotopic composition of Earth's mantle is supposed to be -5‰ based on mean values obtained from bulk measurements of oceanic basalts, carbonatites, diamonds and other terrestrial samples [1]. This value is the most significant assumption made in order to understand how carbon is cycled between the surface and interior of the Earth. But there are specific localities that exhibit different mean values, bimodality and outliers [2].

However, the value of -5‰ may not be representative of the entire mantle. Carbon compositions in the terrestrial mantle samples show considerable variations like E-chondrites, the fundamental building blocks of Earth [3]. The carbon composition of Earth does not coincide with the Martian mantle value of -20 ‰ although both the planets should have started with similar initial compositions [4]. Carbon can form various stable compounds in the mantle governed by different oxygen fugacity, and fractionation in isotopic composition is likely to occur under high pressure-temperature conditions [5]. It becomes important to reassess the mantle compositions of Earth, particularly since Si-rich carbide-bearing diamonds from great mantle depths (> 1100 km) is now available [6]. Following preliminary combustion investigations for carbon and nitrogen, measurements of carbon isotopic compositions of these Jagersfontein diamonds and inclusions at high resolution by NanoSIMS are underway.

[5]University of Virginia, Charlottesvile, VA, USA (wck@virginia.edu)

The oceans are a major source of aerosol number and mass to the atmosphere. Over the remote oceans, coarse-mode sea-salt particles dominate aerosol light scattering. Recent measurements suggest that direct emissions of ocean-derived particles also control the aerosol number concentration and thus the aerosol cloud condensation nuclei concentration. Measurements of atmospheric aerosols over the ocean include particles directly emitted from the ocean and particles produced by gas phase reactions in the atmosphere, making it difficult to distinguish between the two sources. Here we report recent measurements of particles directly emitted from the ocean using a newly developed *in situ* particle generator/sampler (SeaSweep). Bubbles were generated 1 m below the ocean surface alongside the research vessel *Atlantis* off the coast of California and swept into a hood/vacuum hose to feed a suite of instruments on board the ship measuring aerosol physical, chemical, optical, and cloud nucleating properties.

The number size distribution of the directly emitted (nascent) particles had a dominant mode at 55-60nm (dry diameter) and a secondary mode at 200-300nm. The aerosol was not volatile at 230°C. This temperature rules out ammonium sulfate and nitrate as significant components of the nascent aerosol but does not distinguish between particulate organic matter and sea salt. The organic component of the nascent aerosol volatilized at a temperature between 230 and 600°C. The nascent aerosol was not enriched in Ca, K, or Mg above that found in surface seawater. The submicrometer organic aerosol was primary composed of carbohydrates based on FTIR analysis. The nascent organic aerosol concentration did not increase in regions of higher surface seawater chlorophyll.

Geophysical and geochemical data used to infer origin and evolution of natural CO_2 in Italy

A. BATTANI, E. BROSSE AND C. LOISELET

IFPEN, Paris, France

CO_2-degassing is well documented throughout the whole Italian peninsula and previous studies based on geochemistry of gases have already shown the existence of different CO_2 sources, (Minissale *et al*., 1997) ranging from deep mantle-derived CO_2 related to volcanism, to more "crustal" sources", that are less documented. Italian Peninsula is characterized by a high R/Ra gradient increasing from the North to the South. Geochemical ratios (R/Ra and $CO_2/^3He$) fit quite closely to a mixing curve between a mantle-derived end member (in the south) and a crustal end member in the North.

The high R/Ra ratio recorded in Southern Italy is easily related to Calabria slab mantle wedge processes.
Concerning the central Italian volcanism, the R/Ra ratio reaches 4, indicating a strong influence of mantle-derived helium, with an important continental/ crustal contribution.

Geochemical (elemental and isotopic ratios) and seismological (P-wave tomography and SKS splitting) data support the existence of a large window in the Adrian plate underneath the southern Apennines. The influence of the slab mantle wedge is not observed here. However, window appears at the northern lateral Calabria slab edges allowing mantle inflow induced by the Calabria retrograde motion (Gasparini *et al*.,2002; Faccenna *et al*., 2005; 2007).

In the North-Central part of Apennines, the reported helium isotopic ratios point to a general prevalence of crustal influence (typical crustal values estimated around 0,02 and 0,05 Ra). A significant component of mantle-derived helium is only found in the geothermal areas of Larderello (Northern Italy) where a large thermal anomaly is present at depth. (Cloetingh *et al*., 2010). By combining geophysical and geological observations we propose to explain this local anomalous ratio by a local asthenospheric upwelling, probably associated with lithospheric delamination, or slab break off processes.

Using this approach, we provide a new insight on the origin of CO_2, and we propose a strong relationship between diagenesis and/or metamorphic processes associated with subduction dynamics, rather than thermal decomposition of carbonates.

Mussel shells as archives of geogenic and anthropogenic dissolved REE

M. BAU[1], G. MERSCHEL[1,2], S. KULAKSIZ[1], K. SCHMIDT[1], M. BRENNER[3], S. BALAN[1,4] AND A. KOSCHINSKY[1]

[1]Earth & Space Sciences, Jacobs University, Campus Ring 1, 28759 Bremen, Germany; (m.bau@jacobs-university.de)
[2]Environment and Resource Management, Free University, 1081 HV Amsterdam, Netherlands
[3]IMARE - Institute for Marine Resources GmbH, Klußmannstr. 1, 27570 Bremerhaven, Germany
[4]Environmental Science, Policy, and Management, UC Berkeley, 137 Mulford Hall, Berkeley, CA 94720, USA

Mussel shells may be used to evaluate trace element bioavailability, as the carbonate shell precipitates from the mussel's internal extrapallial fluid and not from external ambient water. We determined the REE distribution in shells of marine hydrothermal *Bathymodiolus* and littoral *Mytilus edulis* and of freshwater *Corbicula fluminea* mussels, and in the respective ambient river or seawater. Marine *Bathymodiolus* and *Mytilus edulis* shells reflect the presence and absence, resp, of positive Eu anomalies in their ambient waters, suggesting that positive Eu anomalies in mussel shells might be used to detect hidden or fossil high-temperature hydrothermal vent sites, thus helping exploration of VMS deposits [1]. Water from the Weser and Rhine rivers both display anthropogenic positive Gd anomalies that result from input of Gd used in MRI contrast agents, and the lower reaches of the Rhine River also show large an-thropogenic positive La anomalies [2]. While this La anomaly also occurs in *Corbicula* shells from the Rhine River, neither shells from the Rhine nor from the Weser River show a Gd anomaly. This demonstrates that in contrast to anthropogenic La, the Gd complexes used as MRI contrast agents are not bioavailable, which is further evidence of their conservative behaviour.

Analysis of δD and $\delta^{18}O$ in clay minerals for reconstructing paleoenvironmental parameters

K. BAUER[1,2]*, T.W. VENNEMANN[1] AND A. MULCH[2]

[1]Institut de Minéralogie et Géochimie, Université de Lausanne, Switzerland (*correspondence: kbauer@unil.ch)
[2]Institut für Geowissenschaften, Johann Wolfgang Goethe-Universität Frankfurt am Main, Germany

Clay minerals in Molasse sediments are potential proxies for the stable isotope composition of Neogene paleowaters in the circum-Alpine region. To use this proxy requires the formation of clay minerals in weathering zones in equilibrium with ambient surface waters and no post-formational diagenetic nor low-grade metamorphic exchange with the fluid phase. Knowledge of the water-mineral fractionation factors at temperatures of formation permits an estimation of the isotopic composition of the paleowaters and allows to reconstruct paleoaltitude, paleoclimate and paleotopography.

The isotope analysis of clay minerals, however, proves to be a challenging task. In particular members of the smectite family are highly hygroscopic, leading to potentially falsified results of the isotope measurements if the adsorbed water is not removed. A number of tests and experiments were conducted in order to validate the most accurate as well as economical procedure of sample preparation. While $\delta^{18}O$ values are readily analyzed using a CO_2 laser fluorination line, the adsorbed water fraction may pose problems for the hydrogen isotope analyses using the TC/EA method. Prior to H-isotope analyses, it proves advantageous to evacuate the samples at elevated temperatures before rapidly transferrring them to the TC/EA for measurements. Additional analytical methods including XRD, TGA, SEM, and studies of organic matter within the sample material have been applied for actual samples as well as for standard materials in order to evaluate the effects of sample treatment on final measured values. The results were also cross-checked through an inter-laboratory comparison of the results obtained.

Once established, this modified preparation technique will be applied to clay mineral separates from stratigraphically distinct Molasse sediment horizons, as well to samples from recent soil profiles in the Swiss Alps, and bentonites from volcanic ash layers in Switzerland. The present results from Molasse clay minerals are in agreement with proxies of changes in paleoclimate from marine sediments and also with related isotope studies on material from high-Alpine fault zones of similar age.

Which emission sector is winning the mitigation competition when direct, indirect and semi-direct effects are investigated seperately?

SUSANNE E. BAUER[1] AND SURABI MENON[2]

[1]Columbia University and NASA Goddard Institute for Space Studies, New York NY, (sb2273@columbia.edu)
[2]Lawrence Berkeley National Laboratory, Berkeley CA, (smenon@lnbl.gov)

Attention has been drawn to black carbon aerosols, as a target for short-term mitigation of climate warming. Regulating soot emissions could, as a short-term action, potentially buy time by slowing global warming until regulations for long-lived greenhouse gases are set in place. The scientific community debates the impacts of such mitigation measures, and mitigation modelling studies show incoherent answers. One of the main reasons for the disagreement are semi-direct aerosol effects, that are neglected in some studies and included and dominating the overall results in others. In this study we apply the GISS/MATRIX model, a global climate model including detailed aerosol microphysics, to understand the single contributions of aerosol forcings and feedbacks. The study goes beyond black carbon mitigation by investigating the whole suite of aerosol sources and sectors of the CMIP5 emission data sets.

Our study finds a regionally divers picture. For example aerosol-cloud effects over the United States lead to reduced cloudiness through semi-direct effects and increased cloudiness by the indirect effect and the reversed phenomena is simulated over Europe. This response will be explained by the chemical composition of the emission mix in the different regions and its impact on black carbon coatings. The most promising emission mitigation sectors differ greatly between geographically regions and even among industrialized countries.

D_2O as tracer to study diffusion processes through the quartz crystal

M. BAUMGARTNER, G. DOPPLER AND R.J. BAKKER

University of Leoben, 8700 Leoben, Austria
(*correspondence: miriam.baumgartner@unileoben.ac.at)

Laboratory synthesised fluid inclusions in natural quartz are used to study diffusion processes of H_2O and D_2O molecules through the quartz crystal. Feedstock of re-equilibration experiments are pure H_2O inclusions synthesised at 600°C and 337 MPa which correspond to a molar volume of 25 cm^3/mole of the liquid phase. Those inclusions are exposed to a D_2O fluid at equal experimental conditions. Due to the concentration gradient (chemical potential) diffusion is induced and fluid exchange between the "pore fluid" and the fluid inclusions is expected. D_2O is used for re-equilibration experiments because it is easily identified in the inclusions due the increase of the melting temperature of ice (pure D_2O at +3.8 °C) and its typical Raman spectrum between 2200 – 2800 cm^{-1}. After five days of re-equilibration the inclusions shapes are strongly modified and ice melting temperatures up to +1.8 °C are observed, which corresponds to about 47 mass% D_2O. In addition, Raman spectra taken from those inclusions reveal high amounts of D_2O (see Figure below). Nevertheless, the concentration of D_2O vary significantly and inclusions with low and high contents can be found. This variation is mainly caused by the position of the inclusion in the quartz sample (3-dimensional distance from the quartz surface) and the total volume of the inclusion itself. In addition structural effects, like nano cracks and crystal defects affect the fluid flow through the quartz crystal.

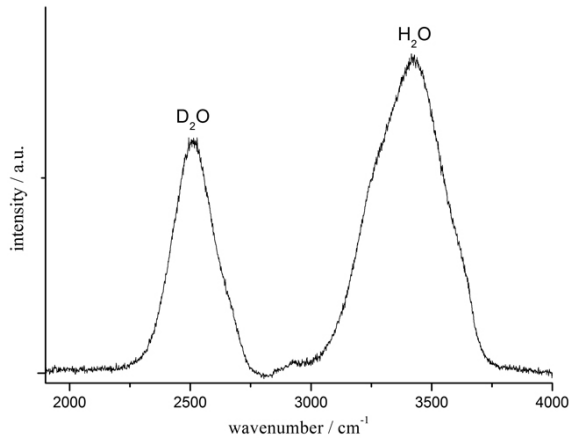

Figure 1: Raman spectrum of a fluid mixture of H_2O and D_2O measured in an inclusion after re-equilibration.

Microbially induced corrosion of depleted uranium metal in oxic soil

A.C. BAXTER[1,2] S. SHAW[3] M.N GARDNER[1] AND I.P. THOMPSON[4]

[1]Department of Earth Sciences, University of Oxford, UK
[2]AWE, Aldermaston, UK
[3]School of Earth and Environment, University of Leeds, UK
[4]Department of Engineering, University of Oxford, UK

To determine the enviomental impact of corroding depleted uranium (DU) munitions in oxic soils, fundamental information regarding the mechanisms and kinetics of DU breakdown are required. In particular, the key geochemical and microbiological factors which control the rate of corrosion. Previously, a study was conducted on DU metal pieces left *in situ* in two soil types (quartz rich dune sand and organic rich clay) for ≈8 years [1]. This concluded that a significant biological repsonse, e.g. oxalate production, was instigated from the indigenous microbes in response to the DU corroding in the soil, suggesting that microbes may have a significant influence on DU breakdown.

To detemine the microbial impact on the corrosion of DU metal, microcosm experiments were set up containing DU metal piece in a slurry containing either sterile soil or soil with the intact indigenous microbial communities.

After 5 months *in situ* corrosion had only occured in the microcosms containing the viable indigenous microbes (Figure 1).

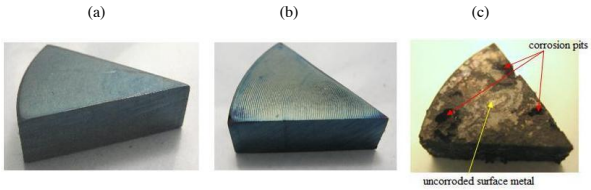

Figure 1: Digital photograph of the DU metal pieces (a) before addition to the microcosms, and after 5 months in situ in (b) sterile soil and (c) soil with viable indigenous microbial communities.

Imaging the DU metal pieces showed considerable pitting corrosion had occured on the surface. Within these pits bubble-like structures were observed which may have been caused by hydrogen generation at the metal surface. Fluorescent staining of the DU metal demonstrated diverse microbial communities had colonised within the corrosion pits.

Causes of pulsed mineral growth during metamorphism

ETHAN F. BAXTER*[1,2], MARK J. CADDICK[2], ALAN B. THOMPSON[2], BESIM DRAGOVIC[1], ANTHONY D. POLLINGTON[1,3] AND JAY J. AGUE[4]

[1]Boston University, Department of Earth Science, Boston MA, 02215, USA (*correspondence: efb@bu.edu)
[2]ETH Zurich, Institute for Geochemistry and Petrology, 8006 Zurich, Switzerland
[3]University of Wisconsin, Department of Geoscience, Madison, WI, 53706, USA
[4]Yale University, Department of Geology & Geophysics, New Haven, CT, 06520-8109, USA

A growing set of observations suggests that metamorphic processes and conditions frequently are pulsed or episodic in nature rather than steady and long-lived. We recognize a "pulse" as any process, condition, or manifestation thereof that persists or dramatically accelerates for a brief period of time (relative to the general timescale of background tectonic/geologic forcing). Such pulses may include some or all of the following, which may not always be genetically linked: increased temperature, fluid influx, magmatism, and deformation, any of which may also promote mineral growth (and thus potentially be recorded therein).

Mineral growth pulses can have different causes. We describe three end-member possibilities here. First, rapid changes in *P* or *T* can drive more rapid mineral growth by quickly moving rocks through sets of reaction isopleths requiring compositional or modal change. Thermal pulses require mechanisms for rapid heating followed by focused heat dissipation, not possible via conductive heat transfer alone. For example, advective heat flow, provided by migrating syn-orogenic magmas and/or related fluids can contribute to thermal pulses. Or, rapid changes in P (and T) may accompany deformation during vertical motion in shear zones or thrusts. Second, steadily changing *P* and *T* can also produce pulsed mineral growth if reaction isopleths become closely (and/or orthogonally) spaced along portions of the *P-T* path. Third, a kinetic trigger (such as the introduction of a catalyzing fluid, which itself may be related to a pulse of dehydration or deformation) can permit a thermodynamically overstepped reaction to suddenly activate. Using vividly documented examples of mineral growth pulses [1,2] and thermal pulses [3], we explore different pulses, their possible causes, and the likely extent of their interactions.

A global distribution map for Nd isotopes in European watersheds

G. BAYON*, S. TOUCANNE*, N. FRESLON AND E. PONZEVERA

Département Géosciences Marines, IFREMER, Plouzané, France (* correspondence : gbayon@ifremer.fr; stoucann@ifremer.fr)

The Nd isotopic composition of the detrital fraction of a sediment provides information on the geographical provenance of that material. Aplication of the ε_{Nd} proxy to sedimentary records can be used to deduce sediment input variations, and hence to constrain fluctuations in transport mechanism.

In this study, we have compiled literature data for Nd isotopes in river sediments from all over Europe. This compilation was completed by analysing an extensive series of fine-grained sediments collected from various european rivers, estuaries, upper continental shelves and endorheic basins. For each sediment, the obtained ε_{Nd} value was taken as representative of the corresponding drainage basin signature. The result of this work is a global distribution map for Nd isotopes in european watersheds, which covers about 70% of the continent.

Based upon this map, we will discuss on the potential of using Nd isotopes for adressing some of the key issues related to the Late Quaternary environmental history of Europe.

Zinc and cadmium behavior in low-density fluids

E.F. BAZARKINA[1]*, G.S. POKROVSKI[2], N.N. AKINFIEV[1] AND A.V. ZOTOV[1]

[1]IGEM RAS, 119017 Moscow Russia (*correspondence: elenabaz@igem.ru)
[2]GET, Géoscience, Environnement Toulouse , 31400 Toulouse, France

Low-density fluids and vapors (density ≤ 0.5-0.3 g/cm^3) are ubiquitous in the Earth crust from moderate depth (vapor-brine immiscibity) to the surface (volcanic degassing). Quantitative understanding the transport capacity of such fluids for metals is, however, weak owing to both experimental difficulties and imperfections of classical thermodynamic models (e.g., HKF) when applied to the low-density aqueous phase. Our study is aimed at quantifying the transport of Zn and Cd, typical base metals, in such phases. We combined solubility measurements of ZnO and CdO in H_2O and H_2O-NaCl-HCl fluids and vapors and Zn and Cd vapor-liquid partitioning experiments in water-salt systems across a wide range of temperature, pressure and density (T = 350-450°C, P = 150-600 bar, d = 0.01-0.5 g/cm^3) with physical-chemical modeling.

Results reveal significant differences in the behavior of Zn versus Cd in low-density fluids in the presence of chloride. For example, the Cd/Zn ratio in the H_2O-NaCl-HCl vapor in equilibrium with CdO and ZnO increases with increasing Cl content, which demonstrates a stronger stability of Cd-Cl complexes compared with their Zn analogs. Our thermodynamic model [1] allow accurate description of the obtained solubility data using the neutral chloride and hydroxide species of Zn and Cd. These findings in homogenous fluids are in agreement with our data in dense aqueous solution [2], and vapor-liquid distribution measurements, which demonstrate that although both Zn and Cd partition in favor of the dense Cl-rich brine, vapor-liquid partition coefficients ($K = m_{vapor}/m_{liquid}$) for Cd are much lower than for Zn (e.g., log K ~ -5.5 and -3.3 at 450°C/280 bar for Cd and Zn, respectively). The different stabilities of Cd- and Zn-Cl complexes may play a key role in Cd fractionation by low density fluids, and explain the elevated Cd/Zn ratios in volcanic gases compared to the mean Earth crust value.

Reactive transport modelling of natural carbon sequestration in ultramafic tailings

S.A. BEA[1,2], K.U. MAYER[1], S.A. WILSON[1,3] AND G.M. DIPPLE[1]

[1]Department of Earth and Ocean Sciences, University of British Columbia, 6339 Stores Road, V6T 1Z4, Vancouver, BC, Canada.
[2]now at: Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, USA (sabea@lbl.gov)
[3] now at: Department of Geological Sciences, Indiana University, Bloomington, IN, USA

Anthropogenic CO_2 is naturally sequestered in ultramafic mine tailings as a result of the weathering of serpentine minerals [$Mg_3Si_2O_5(OH)_4$] and brucite, and subsequent mineralization of CO_2 in hydrated magnesium carbonates such as hydromagnesite, $Mg_5(CO_3)_4(OH)_2{\cdot}4H_2O$ [1]. Understanding the CO_2 trapping mechanisms is key to evaluating the capacity of such tailings for carbon sequestration.

Natural CO_2 sequestration in ultramafic tailings at a mine site near Mount Keith, Australia is assessed with a modified version of the process-based reactive transport code MIN3P [2]. The model formulation includes energy and vapor transport fully coupled with fluid conservation in the aqueous phase and geochemical reactions. Atmospheric boundary conditions accounting for the effect of climate variations are also included. Kinetic dissolution of chrysotile, dissolution-precipitation of brucite [$Mg(OH)_2$] and primary carbonates [i.e. calcite, $CaCO_3$; dolomite, $MgCa(CO_3)_2$; magnesite, $MgCO_3$] as well as the formation of hydromagnesite, halite (NaCl), gypsum ($CaSO_4{\cdot}2H_2O$), blödite ($Na_2Mg(SO_4)_2{\cdot}4H_2O$) and epsomite ($MgSO_4{\cdot}7H_2O$) are considered.

Simulation results at ten years are consistent with field observations. Precipitation of hydromagnesite is predicted, and is mainly controlled by the dissolution of chrysotile (the source of Mg) and the equilibrium with the CO_2(g) ingressing from the atmosphere. The predicted rate for CO_2 entrapment in these tailings is 1.2 kg m^{-2} year^{-1}. Modeling results suggest that this rate is sensitive to CO_2 fluxes through the mineral waste and may be enhanced by several mechanisms, for instance by atmospheric pumping.

Distribution and activity of iron-oxidizing microorganisms in acidic geothermal environments

J.P. BEAM[1], H.C. BERNSTEIN[2], M.A. KOZUBAL[1], R. P. CARLSON[2] AND W.P. INSKEEP[1]*

[1]Department of Land Resources and Environmental Sciences and Thermal Biology Institute, Montana State University, Bozeman, MT 59717, USA (*correspondence: jacob.beam@msu.montana.edu, binskeep@montana.edu)

[2]Department of Chemical and Biological Engineering and Center for Biofilm Engineering, Montana State University, Bozeman, MT 59717, USA

Iron oxide mats of acidic geothermal springs in Norris Geyser Basin, Yellowstone National Park are inhabited by numerous deeply-rooted members of the domain *Archaea*. Microorganisms of the order Sulfolobales (e.g., *Metallosphaera yellowstonensis* and other novel phylotypes) have previously been shown to be important community members and are likely responsible for the oxidation of Fe(II) and subsequent formation of Fe(III)-oxide mats. Iron-oxidizing microorganisms are hypothesized to thrive in more oxic regions of Fe(III)-oxide mats and are likely most abundant at the water/mat interface where oxygen concentrations are high relative to deeper mat positions. The current study investigated the relationship among vertical distribution of specific microorganisms, mRNA transcript levels of genes involved in Fe(II)-oxidation, and corresponding oxygen gradients measured *in situ*.

Quantitative PCR primers designed around specific phylotypes were used to determine the vertical distrbution of organisms within the Fe(III)-oxide mats. Similarly, mRNA transcripts of genes, thought to be important in Fe(II)-oxidation (i.e., Fe-specific heme copper oxidases), were amplified with primers designed for various Fe(II)-oxidizing microbial populations.

Results suggest that the spatial distribution of aerobic Fe(II)-oxidizing microbial populations correspond with measured oxygen gradients. Specifically, Fe(II)-oxidizing microorganisms become less abundant at depths below ~600 µm corresponding to depths where dissolved oxygen concentrations approach detection. Transcripts of genes (mRNA) previously shown to be involved in Fe(II)-oxidation are well represented in the top 600 µm-layer. This study highlights the important linkage among hydrodynamics, oxygen in-gassing and diffusion, and the spatial location of active Fe(II)-oxidizing microorganisms (and associated transcription of specific genes) in the biomineralization of Fe(III)-oxide phases in acidic geothermal environments.

Residence time analysis of metal-desorption and mineral-dissolution kinetics using a Damkohler approach

Understanding processes that control coupled reaction and transport in contaminated and natural systems is important for predicting the behavior of metals. Mineral dissolution and metal desorption are two important processes that govern metal behavior. Reactive transport studies often assume that desorption occurs instantaneously and therefore apply thermodynamic equilibrium models, or that mineral dissolution is so slow that it is not relevant. This study investigates groundwater time scales where kinetic metal desorption and/or mineral dissolution are important mechanisms for accurate modeling of metal fate and transport. Compiled desorption reaction times for metal and metalloid rate constants show large variations, spanning over six orders of magnitude. Mineral dissolution rate constants span over thirteen orders of magnitude and overlap with the range of desorption rate constants.

The Damkohler number was used to calculate residence times where kinetic formulations for dissolution and desorption may be more accurate representations of metals behavior. According to this method, metal desorption kinetics are influential at residence times from a few days to ~ 2 years. For longer residence times, metal desorption should behave according to equilibrium desorption models. In constrast, kinetic mineral dissolution should be considered over nearly all residence times and length scales relevant to groundwater modeling. Groundwater models with residence times of minutes up to ~600 days should potentially consider both metal desorption and mineral dissolution rates, with greater residence times exhibiting equilibrium behavior and shorter residences resulting in negligible change in metal concentrations. Ultimately, this Damkohler analysis provides constraints on relevant metal release mechanisms for models of metal fate and transport, such as those used in the fields of carbon sequestration and acid mine drainage. Additionally, the results can be used in experimental design to determine the setup required to measure the desired variable, i.e. kinetic or equilibrium characteristics.

Fe kinetics of marine particle uptake and desorption determined from laboratory experiments

ANNA BECK* AND JESS ADKINS

Caltech, Geological and Planetary Sciences, Pasadena, CA 91125 (*correspondance: abeck@caltech.edu)

Particle residence times in the ocean are short enough for the adsorption and desorption of Fe(III) from marine particles to control the dissolved [Fe] profile. Previous laboratory experiments measured Fe(III) uptake rates using radiotracers under simulated natural conditions and in the presence of various particles. However, since at least 99.9% of dissolved Fe(III) in the ocean is bound to organic ligands, we carried out similar laboratory experiments with Fe(III) bound to desferryoxamine B, a naturally occurring siderophore, and used ^{54}Fe as a tracer.

We find the adsorption of ^{54}Fe onto a fresh, labile iron oxide (ferrihydrite) to be first order dependent on particle concentration and has a rate of -0.17 (±0.05) pmol Fe/(mg particle)/day. Experiments with ferrihydrite concentrations of less than 200 mg/L reach steady state after 100+ days, a time period two orders of magnitude larger than particle residence times in the water column, underscoring the significance of the adsorption kinetics on the profile of [Fe]. The uptake of ^{54}Fe onto clay (montmorillonite) has a very fast (<10 min) initial uptake followed by a slower, possibly first order, absorption that are both dependent on particle concentration. In stark contrast to clay and ferrihydrite, there is insignificant absorption of ^{54}Fe onto 3 other types of marine particles—stable iron oxide (goethite), opal (pulverized diatoms), and carbonate shells (forams). In desorption experiments, we find that 1) all particle types reach steady state in 1 week or less, and 2) the uptake mechanism onto ferrihydrite is irreversible. Fe cycling models currently lack these differences in particle preference and their respective rates.

Reconciling abundances of highly siderophile elements and major volatiles in the silicate and near-surface Earth

H. BECKER[1]* AND M. FISCHER-GÖDDE[2]

[1]Institut für Geologische Wissenschaften, Freie Universität Berlin, Malteserstrasse 74-100, D-12249 Berlin, Germany (*correspondence: hbecker@zedat.fu-berlin.de)

[2]Institut für Planetologie, Universität Münster, Wilhelm-Klemm-Strasse 10, D-48149 Münster, Germany

Ratios of highly siderophile element (HSE) abundances permit to distinguish between different classes of chondrites and may help in tracing the presence and evolution of differentiated metal and the differentiation of planetary crusts and mantles. The HSE can also play an important role in constraining the origin of the more abundant highly volatile elements in the terrestrial planets, in particular, if both groups of elements were added after core formation and the magma ocean stage. Recent constraints from peridotites and komatiites suggest that the relative abundances of Ru and Pd in the silicate Earth are suprachondritic. In contrast, other HSE show chondritic relative abundances, with Re/Os and Rh/Ir more similar to ratios in ordinary or enstatite rather than carbonaceous chondrites. HSE abundances and geochronological data for pre-3.8 Ga lunar impact rocks indicate that at least two ≥4.2 Ga old meteoritic components occur widely dispersed across the lunar nearside: a somewhat volatile element depleted (carbonaceous?) chondritic component in granulitic impactites and in some impact melt rocks, and a differentiated metal component, similar to some IVA iron meteorite compositions. The Earth may have accreted similar materials after 4.5 Ga, however, much larger quantities would be necessary to explain the HSE abundances in the Earth's mantle. Late accretion of 80-85 % of a slightly volatile depleted carbonaceous chondrite composition and 15-20 % of differentiated metal reproduces integrated abundances of the HSE, S, H, C and N in the silicate Earth + atmo- and hydrosphere, remarkably well, and would be consistent with the isotopic composition of S, H, C and N. Small discrepancies in abundances may reflect poorly known partition coefficients (Rh) and volatile loss (N). Reqired HSE abundances in the metal are equivalent to abundances in liquid metal that has fractionated 40-60% solid metal in the core of a ~2000 km diameter protoplanet. In order to prevent segregation of metal into the Earth's core, the bulk of this material should have accreted some time after the giant impact and solidification of the terrestrial magma ocean.

Atomistic approaches to determine redox reaction mechanisms of U, Np, and Pu on mineral surfaces

U. BECKER, L. SHULLER, D. RENOCK AND R. EWING

University of Michigan, Department of Geological Sciences, 2534 CC Little, Ann Arbor, MI 48109

The rich redox chemistries of U, Np, and Pu control the chemical and physical properties of nuclear materials at different stages in the nuclear fuel cycle from extraction to disposal. The redox chemistry of the actinides can be predicted based on the Eh-pH conditions; however, adsorption to mineral surfaces and redox reactions on the surface are impacted by the physicochemical properties of the mineral surface itself.

In recent studies, our research groups as well as others have been challenging the traditional way redox processes are being treated in the near-surface environment. One example that has been studied is the complicated interplay between uranyl complexes, sulfide/oxide surfaces, and organic and inorganic reductants. Our findings indicate that, despite many decades of research, the key controls of surface-mediated mechanisms and, hence, the rates of environmentally-important redox processes are still poorly understood. There are a number of reasons for this: 1) these processes almost always involve a complex series of elementary reactions, each involving the transfer of one electron at a time, 2) it can be unwieldy to resolve the influence of individual environmental parameters (pH, pe, pO2, concentration of other oxidants and reductants, other ions in solution, temperature, etc.) in rate experiments, 3) it can be challenging to differentiate rate constants for heterogeneous (surface) processes and homogeneous (solution) processes in order to assess the catalytic effects of the surface itself, and 4) rate-limiting processes such as spin transitions have been widely ignored so far. Our calculations address fundamental questions with regard to many different redox systems: Does the mineral surface directly participate in the redox event or indirectly participate by acting as a heterogeneous catalyst or an electron shuttling device for the transport of charge (and/or spin) between co-adsorbates.

Methane formation in abandoned coal mines: Role of acetogens and acetoclastic *Methanosarcinales*

S. BECKMANN[1]*, T. LÜDERS[2], M.KRÜGER[3], F. VON NETZER[2], B. ENGELEN[1] AND H. CYPIONKA[1]

[1]ICBM, Univ. of Oldenburg, Oldenburg D-26129, Germany (*correspondence: s.beckmann@icbm.de)

[3]BGR, Geomicrobiology, Hannover D-30655, Germany

Mine gas has come into the focus of the power industry and is being used increasingly for heat and power production. Worldwide, about 7% of the annual methane emissions originate from coal mining. In abandoned coal mines, stable carbon and hydrogen isotopic signatures of methane indicate a mixed thermogenic and biogenic origin. While thermogenic methane is a remainder of geological processes, biogenic formation is still going on [1]. Besides hard coal, possible sources for methane are large amounts of mine timber left behind after the end of mining.

In two abandoned coal mines in Germany, methanogenic archaea are responsible for the production of substantial amounts of methane [2]. The mines are characterised by low O_2 concentrations at high humidity and fungal mats mainly on the mine timber. We analysed active methanogens as well as the active bacteria involved in the trophic network by stable isotope probing (DNA-SIP). Therefore, the ^{13}C-labeled precursors of methane (acetate and H_2+CO_2) were fed to liquid cultures from hard coal and mine timber. Directed by the methane production kinetics, samples for DNA-SIP coupled to subsequent quantitative PCR and DGGE analyses were taken from long term incubations over 6 months. Surprisingly, the formation of ^{13}C-methane was linked to acetoclastic methanogenesis in both, the ^{13}C-acetate and H_2+$^{13}CO_2$-amended cultures of coal and timber. H_2+$^{13}CO_2$ was mainly used by acetogens related to *Pelobacter acetylenicus* and *Clostridium* species. Active methanogens, closely affiliated to *Methanosarcina barkeri*, utilized the readily available acetate rather than the thermodynamically more favourable hydrogen. Thus, the methanogenic microbial community appears highly adapted to the environment where acetate is a much more prominent intermediate than H_2.

PGE reference material heterogeneity – Estimating minimum analytical mass

L. PAUL BÉDARD[1], KIM H. ESBENSEN[2] AND SARAH-JANE BARNES[3]

[1]Sciences de la Terre, Université du Québec à Chicoutimi, Chicoutimi, Qc Canada; (pbedard@uqac.ca)
[2]Geological Survey of Denmark and Groenland, Copenhagen, Denmark; (ke@geus.dk)
[3]Sciences de la Terre, Université du Québec à Chicoutimi, Chicoutimi, Qc Canada; (sjbarnes@uqac.ca)

Very small analytical masses (mg to ng) are dictated by modern analytical instruments, either because of their high sensitivity, analytical protocols or because of the small sampling volume of micro-beam techniques. But small sample masses can create problems when trace elements are major constituent in some minerals (e.g. PGE as PGM) and are irregularly distributed in samples or reference materials. Accidental inclusion or exclusion could change the spatial concentration realised simply due to spatial heterogeneity issues [1,2]. Such effects influence mass balance calculation and element budgets. Recommended minimum mass for reference materials is generally determined by analysing smaller sample mass until variance become unacceptable. Is there a way to determine minimum sample mass directly related to RM heterogeneity? And is it identical for all analytes, or unique for each analyte, in each sample? In order to systematically investigate these questions, pressed-pellets of PGE-bearing reference materials (CHR-Bkg, CHR-Pt+, MASS-1, MASS-3, WMS-1, WMS-1a) were analysed with an EDAX EAGLE III micro-XRF. Approximately 10 000 contiguous measurements were made with a beam of 50 μm covering a total area of about 25 mm^2. Up to 25 analytes were measured including precious metals. Reproducibility was determined by analyzing the same location 1 000 times. In order to express the empirical heterogeneity, Angle Measure Technique (AMT) was employed [2]. The AMT transform describe the elemental map complexity as a function of geometrical scale from local to global. AMT provides a quantitative measure of the empirical heterogeneity for each element, RM, or analytical sample. From such results a minimum analytical mass for each analyte is proposed to ensure that analytical results are representative all the way down to the scale of RM fields-of-view. The proposed technique offers the advantage of defining the *effective* minimum mass for each analyte with better elemental sensitivity by allowing for a more meaningful estimation of the *global* minimum analytical mass.

Groundwater flow impacts on sediment biogeochemistry: A multivariate statistical approach

J. BEER[1]*, C. NEUMANN [1], J.H. FLECKENSTEIN[2], S. PEIFFER[1], AND C. BLODAU[3]

[1]Department of Hydrology, University of Bayreuth, Germany (*correspondence julia.beer@uni-bayreuth.de)
[2]Department of Hydrogeology, Helmholtzzentrum für Umweltforschung, Leipzig, Germany
[3]Department of Environmental Geology, University of Guelph, Kanada

Lakes in (former) mining areas are strongly affected by Pyrite oxidation leading to high loads of iron and sulfur and the acidification of local waterbodies. Whereas the groundwater surrounding such lakes is mostly only weakly acidic, the pH of acidic mine lakes (AML) often lies below about 3 due to iron oxidation and subsequent Schwertmannite precipitation. It has been described that advective and diffusive flow through AML sediments affect the distribution of solutes and the biogeochemical driver pH in such sediments (e.g. Beer *et al*., 2009).

To study the influence of groundwater – lake water – exchange on sediment biogeochemistry, we measured exchange rates along with sediment composition at 19 sites at an anthropogenic AML near Lauchhammer, Germany.

The pattern of the exchange rates was temporally and spatially heterogenous. Groundwater inflow dominated in the northern part of the lake and often exfiltration of acidic lake water was measured in the southern part.

To analyze the effects on the sediment, we cut sampled sediment cores according to color and textur into 3-5 layers and measured pH, sulfate reduction, contents of reduced sufur species and carbonate, etc., and analyzed the results by multivariate statistical analysis. E.g. using cluster analysis, samples were grouped into 7 clusters which showed two different spatial patterns: 1) vertically, samples representing “fresh” sediment were observed in upper layers whereas “older” sediment samples were present at depth 2) clusters combining samples with higher biogeochemical activity and higher amounts of e.g. reduced iron sulfur species, and thus trapped acidity, prevail in the northern part of the lake. This second cluster could be related to the predominance of groundwater inflow in this part of the lake.

Water content and OH speciation in natural Fe-bearing pyroxenes

K. BEGAUDEAU[1], Y. MORIZET[2] AND J-C.C. MERCIER[1]

[1]LIENSs, University of La Rochelle, La Rochelle, France
[2]LPGN, University of Nantes, Nantes, France
(*correspondence: yann.morizet@univ-nantes.fr)

H in NAMs plays a crucial role on the physical and chemical properties of the Earth's mantle [1]. FTIR and NMR analyses were used to measure H contents and constrain OH dissolution mechanisms for natural Fe-bearing pyroxenes of 40 mantle xenoliths brought up by alkaline basalts magmas. Crystal chemistry was analyzed by EMPA. Equilibrium P-T conditions were determined by a new geothermobarometer developped yielding T°C=644-1151 and P(GPa)=0.85-2.7. Polarized FTIR spectra display the main absorption bands in OH species region. H_2O estimates [2] range between 38-450 ppm H_2O for cpx and 19-184 ppm H_2O for opx. Cpx/Opx partionning coefficients range to 0.6-3.7. H_2O variations seem correlated to fO_2, P, T and crystals chemistry allowing us development of geohygrometers.

^{1}H, ^{27}Al, ^{29}Si MAS NMR were also carried out with different magnetic fields. ^{1}H spectra are not exploitable because of paramagnetic components [3]. Their influences on the change of NMR spectral features are tested with mixtures of kaolinite + magnetite. ^{29}Si and ^{27}Al spectra are slightly affected. Tests on pyroxenes show an Al species distinction. Additional data reveals H proximity around Al species confirming relationships described by FTIR [4]. Thus, the use of both spectroscopic methods opens new perspectives for mineralogy and geochemistry of mantle's peridotites.

Decarboxylation of fatty acids during petrogenesis: Qualitative and quantitative analyses of bitumen NSOs by FTICR-MS

F. BEHAR[1], E. SALMON[2], A.W. KAMGA[2] AND P.G. HATCHER[2]*

[1]IFP Energies Nouvelles, 1-4 avenue de Bois Préau, Rueil-Malmaison 92500, France. (Francoise.BEHAR@ifpenergiesnouvelles.fr)
[2]Department of Chemistry and Biochemistry, Old Dominion University, Norfolk, VA 23529. (esalmon@odu.edu, akamga@odu.edu, *correspondence: phatcher@odu.edu)

The NSO compounds generated during the artificial maturation of kerogen from Green River Formation were collected by successive *n*-pentane and dichloromethane (DCM) extractions and analyzed using electrospray ionization Fourier transform ion cyclotron resonance mass spectrometry (ESI-FTICR-MS). Compounds containing only CHO elements in their make-up are dominant in each spectrum and are comprised mostly of the series $C_nH_{2n}O_2$, $C_nH_{2n-2}O_2$, $C_nH_{2n-2}O_4$, and $C_nH_{2n-10}O_2$ which all correspond to carboxylic acid-containing compounds. By calibrating the FTICR-MS with internal standard, it was possible to assign a response factor for the carboxylic acids and consequently get better quantification of the total carboxylic acids content. This response factor is invariant in the carbon number range of C_{20} to C_{40}. Also, after calibration, the carboxylic acid yield remains dominant among the other peaks detected by FTICR-MS. The same quantitative strategy was used for determining the response factor of the alcohols and dicarboxylic acids in order to determine the quantitative proportions of these functional groups in the NSOs.

Results clearly demonstrate that hydrocarbon generation from kerogen is mainly attributed to decarboxylation of the NSOs compounds. Moreover, there is a strong qualitative and quantitative relationship between the hydrocarbon distributions and the fatty acid distributions. For example, the carbon preference index for hydrocarbons matches exactly that observed for the fatty acids.

Combined WAXS/XAFS measurements for studying the reaction of S(-II) with lepidocrocite

T. BEHRENDS[1], K. HELLIGE[2], M. SILVEIRA[3] AND S. PEIFFER[2]

[1]Utrecht University, Faculty of Geosciences, NL-3508 TA Utrecht, The Netherlands (behrends@geo.uu.nl)
[2]Department of Hydrology, University of Bayreuth, D-95440 Bayreuth, Germany
[3]Katholieke Universiteit Leuven, DUBBLE beamline, ESRF, 38043 Grenoble, France

The reaction of sulfide (S-II) with iron oxides is an important process linking the redox cycles of iron and sulfur in many subsurface environments. Here, we studied the reductive dissolution of lepidocrocite (γ-FeOOH) by S(-II) in batch reactors at constant pH. A combination of wide angle X-ray scattering (WAXS) and X-ray absorption spectroscopy (XAS) at the Fe K-edge (about 7.1 keV) was used to follow on line the progress of the reaction.

Addition of Na_2S solution to the lepidocrocite suspension led to a fast decrease in intensity of the characteristic lepidocrocite diffraction peaks. This change in the WAXS signal was larger than expected from the stoichiometric amount of consumed lepidocrocite and indicates that the long range order of the crystals was profoundly disturbed upon the attack of sulfide.

Principle component analysis of all collected XANES spectra revealed that the combination of two spectra is sufficient to reproduce the major features of all spectra. The two components can be attributed to the spectrum of Fe(III) in lepidocrocite and to that of Fe(II) tetrahedrally coordinated with S. The stoichiometry of the reaction regarding the consumption of H^+ and S(-II) per reacted Fe(III) was derived from relating the change in XANES spectra to the amount of acid, which was added during the experiment, and to the different amounts of initially added sulfide, respectively.

Analyses of EXAFS spectra demonstrated that mackinawite was not the product of the reaction, while mackinawite was shown to form when Na_2S solution was added to Fe^{2+} solution under the experimental conditions.

These observations suggest, that the reaction of lepidocrocite with S(-II) does not follow a surface controlled mechanism in which the release of Fe(II) from the surface is required for the reaction to proceed. An alternative mechanisms will be presented and the differences between observed and expected stoichiometric coefficients will be discussed.

Lithospheric control on geochemical composition of the Louisville Seamount Chain

CHRISTOPH BEIER[1], MARCEL REGELOUS[1], JOHN MAHONEY[2], LOŸC VANDERKLUYSEN[2] AND KARSTEN HAASE[1]

[1]GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Schloßgarten 5, D-91054 Erlangen, Germany. (Christoph.Beier@gzn.uni-erlangen.de)
[2]Department of Geology and Geophysics, University of Hawai'i Mānoa, 1680 East-West Road, Honolulu, HI 96822, USA

Chemical changes with time in lavas erupted on long-lived seamount chains can be used to test models for the origin of intraplate magmatism and examine the effect of sub-seamount lithosphere on volcanism. Major and trace element and Sr, Nd, and Pb isotope data for lavas from 12 seamounts along the westernmost 1500 km of the Louisville Seamount Chain (LSC) in the SW Pacific show that magmatism was compositionally remarkably uniform between 80 and 40 Ma. All 56 samples analysed are alkalic or transitional; most are basalts. The youngest lavas from a given seamount tend to have the least enriched incompatible element compositions. Unlike Hawaiian volcanoes, Louisville volcanoes appear not to pass through a tholeiitic shield-building stage. The oldest Louisville seamounts formed close to the Osbourn Trough fossil spreading centre, but there is no obvious effect on the composition of LSC lavas. Nor do Osbourn Trough MORB contain any contribution from Louisville mantle, which suggests that spreading at the Osbourn Trough ceased well before the construction of Osbourn Guyot at 79 Ma. Lavas from volcanoes in the central part of the LSC are more variable and extend to more enriched compositions. These volcanoes tend to be smaller and more widely spaced, and were underlain by the oldest, thickest oceanic lithosphere. Smaller degrees of melting of heterogeneous mantle may explain the more variable compositions of these volcanoes.

On carbonatization fronts in serpentinite: Implications for *in situ* CO_2 storage

A. BEINLICH[1,2,*], O. PLÜMPER[1], J. HÖVELMANN[1], H. AUSTRHEIM[1,2] AND B. JAMTVEIT[1]

[1]Physics of Geological Processes (PGP) University of Oslo, Norway (*correspondence: andreas.beinlich@fys.uio.no)
[2]Department of Earth Sciences, University of Oslo, Norway

In situ storage of CO_2 in ultramafic rocks is considered as a promising strategy to counteract global warming. In order to identify positive and negative feedback mechansims for the reaction, examination of natural analogues is essential. Here we present observations from a massively carbonatized serpentinite complex in northern Norway. The investigated area is comprised of several ultramafic fragments of a dismembered ophiolite complex. Individual fragments are hydrothermally altered to varying degrees resulting in coexisting serpentinite, ophicarbonate, soapstone, and listvenite. Generally, reaction fronts between the soapstone and the serpentinite presursor are extremely sharp and can be traced for hundreds of meters. Locally, soapstone forms m-wide reaction halos around talc veins that cross-cut the serpentinite. The reaction fronts are defined by the complete replacement of the former antigorite by talc and magnesite. Where present, listvenite is spatially related to soapstone and cross-cut by abundant subparallel quartz-magnesite veins. The vein minerals exhibit a homogeneous O-isotopic composition and indicate a formation temperature of ~ 300 ˚C. The corresponding isotopic signature of the fluid ($\delta^{13}C_{PDB}$ = 2.2(5)‰; $\delta^{18}O_{SMOW}$ = 7.8(1)‰) suggests an interaction with crustal rocks and devolatilization of associated carbonates as a possible source for the CO_2. Assuming that during alteration temperature differences between directly adjacent soapstone and listvenite units are insignificant, thermodynamic phase stability modeling suggests that the conversion of serpentinite to listvenite requires a higher PCO_2 than that of conversion to soapstone.

In situ carbon storage schemes should aim to convert peridotite to listvenite as the complete inventory of divalent metal cations would be incorporated into the carbonates. However, our observations show that listvenite is distinctly less frequent than soapstone, implying that a high PCO_2 was not maintained during the natural alteration. Furthermore, alteration with a lower PCO_2 developed sharp fronts between the reacted and unreacted rocks, indicating that the carbonatization reaction ceased abruptly before completion.

Oxygen overshoot and recovery during the Early Paleoproterozoic

A. BEKKER[1]* AND H. D. HOLLAND[2]

[1]Department of Geological Sciences, University of Manitoba, Winnipeg, MB R3T 2N2, Canada (*correspondence: bekker@cc.umanitoba.ca)
[2]Department of Earth and Environmental Science, University of Pennsylvania, Philadelphia, PA 19104 USA

During the Lomagundi Event, >2.22 to 2.06 Ga, marine carbonates recorded the largest and longest positive carbon isotope excursion, the earliest extensive marine sulfate evaporites were deposited, and the average Fe_2O_3/FeO ratio of shales increased dramatically. At the end of the Lomagundi Event, the first economic sedimentary phosphorites were deposited, and the carbon isotope values of marine carbonates returned to ~0‰ VPDB. Thereafter marine sulfate evaporites and phosphorites again became scarce, while the average Fe_2O_3/FeO ratio of shales decreased to intermediate values between those of the Archean and Lomagundi-age shales. We propose that the large isotopic and chemical excursions during the Lomagundi Event were caused by a positive feedback between the rise of atmospheric O_2 level, the weathering of sulfides in pre-2.3 Ga sedimentary rocks, and the flux of phosphate to the oceans. The rise in the terrestrial phosphate flux led to an increase in the burial rate of organic carbon and a major transfer of oxygen from the carbon to the sulfur cycle.

The end of the Lomagundi Event was probably caused by a decrease in the terrestrial phosphate flux related to the weathering of low-pyrite sediments that were deposited during the Lomagundi Event. The rate of deposition of organic matter and burial rate of sulfate evaporites decreased, the isotopic and chemical excesses of the Lomagundi Event were eliminated, and the ocean-atmosphere system entered the period frequently called the Boring Billion.

Chloride degassing and its effects on the evolution of magmatic redox state

AARON S. BELL[1], ADAM SIMON[2] AND JAMES D. WEBSTER[1]

[1]Department of Earth and Planetary Science, American Museum of Natural History. New York, NY. USA (abell@amnh.org)

[2] Department of Geoscience, UNLV, Las Vegas, NV. USA

Magmatic fO_2 is a parameter that plays an important role in ferromagnesian and sulfide phase equilibria, the speciation of redox sensitive volatiles, and the physical properties of silicate liquids. We have performed redox controlled experiments to investigate iron partitioning behavior between a coexisting chloride rich volatile phase and silicate liquid. The results of these experiments suggest that volatiles with relatively modest chloride contents may contain several wt % Fe as a chloride species. These experimentally generated data suggest that the degassing of chloride rich volatiles may reduce the concentration of the FeO component of the melt. Notably, the preferential scavenging of ferrous iron from the melt must increase the $Fe^{3+}/\sum Fe$, consequently causing the fO_2 residual degassed melt to also increase.

These data support a model wherein the degassing of a chloride-rich volatile phase may significantly increase the oxidation state of the residual melt. Model calculations indicate that the magnitude of the induced oxidation ranges from 0.5 to 1.0 log unit; where this value depends on the partition coefficient value and the volatile phase-melt ratio used in the calculation. The oxidation of magmas during degassing and ascent may have marked effects on the identity and composition of the hypersolidus phase assemblage. Most saliently, this oxidizing effect may be manifested in sulfide saturated arc magmas as the destabilization of coexisting immiscible sulfide liquids or crystalline magmatic suflides. Such an iron scavenging based oxidation process has important implications for the remobilization of sulfide bound chalcophile metals as well as the petrologic interpretation of compositional zoning patterns in crystallizing ferromagnesian phases.

Carbonatites and Pb isotopes – Insights into terrestrial evolution

K. BELL

Earth Sciences, Carleton University, Ottawa, Ont. K1S 2W8, Canada (kib@magma.ca)

Information concerning the depleted mantle has come from studies of oceanic basalts but these cover only a small amount of geological time, at best back to a few hundred million years. Carbonatites, however, ranging in age from 3.0 Ga through to the present, provide a means of monitoring the secular evolution of the sub-continental mantle. Initial Pb isotopic ratios in carbonatites and alkaline complex rocks from the Canadian and Fennoscandian Shields appear to trace the evolution of “depleted” subcontinental mantle over the past 2.7 Ga. $^{87}Sr/^{86}Sr$ and $^{206}Pb/^{204}Pb$ ratios from Archean carbonatites from Canada tend to cluster closely around model “bulk silicate Earth” values in isotope correlation diagrams suggesting a mantle not yet depleted. A marked depletion event >3.0 Ga indicated by the Sm-Nd and Lu-Hf systems indicates sampling of considerably older, depleted mantle sources. Mantle differentiation processes appear to have changed in some fundamental way around 3 Ga with extraction of sialic crust. The similarity in isotopic compositions of young carbonatites (<100 Ma) to some OIB components (FOZO, HIMU, EM1) with little or no involvement with DMM suggests similar sources, and sub-lithospheric, deep-seated magmatism. Analogues to present day mantle components are not recognized in Archean carbonatites. Binary mixing of mantle sources (e.g. HIMU and EM1 for many young carbonatites) can be traced back to at least 1900 Ma.

Dissolution rate of bunsenite (NiO) in acid solution to 130°C

A. BELLEFLEUR[1], M. BACHET[1], P. BENEZETH[2] AND J. SCHOTT[2]

[1]EDF R&D, Site des Renardières, Avenue des Renardières, Ecuelles 77818 Moret Sur Loing Cedex (alexandre.bellefleur@edf.fr ; martin.bachet@edf.fr)
[2]GET, 14 Avenue Edouard Belin, 31400 Toulouse (benezeth@get.obs-mip.fr ; jacques.schott@get.obs-mip.fr)

Rates of proton-promoted dissolution of bunsenite (NiO) were measured from 50 to 130°C in hydrochloric acid solutions (pH 3 and 4.5) in a titanium mixed flow reactor. Measurements were also realized at 25°C with the stationary pH method [1] to confirm data from literature [2]. Pure bunsenite powder (Alfa Aesar Puratronic, Lot n°23430) was used for dissolution rate measurements, after beeing calcinated for 2*20 h at 1000°C in air. To avoid plug up of the outlet filter by fine particles, the powder was not directly introduced in the titanium reactor but in a specifically designed cell with walls made of a porous membrane. Measured bunsenite dissolution rate at 25°C are $2.4\pm0.3.10^{-10}$ and $7.5\pm0.6.10^{-11}$ mol.m^{-2}.s^{-1} at pH 3 and 4.5, respectively. Apparent activation energies for dissolution rate (25-130°C) are equal to 59.7±5.3 kJ.mol^{-1} and 32.9±2.4 kJmol^{-1} at pH 3 and 4.5, respectively. Bunsenite proton-promoted dissolution rate can be expressed as $R_H=k_H\{>NiOH_2^+\}^n$ where, k_H, $\{>NiOH_2^+\}$ and n stand for the dissolution rate constant, the concentration of protonated surface sites and the order of reaction with respect to adsorbed protons, respectively [3]. A two pK, one site surface speciation model which assumes a constant capacitance of the electric double layer was used to calculate $\{>NiOH_2^+\}$ as a function of pH and temperature. The variation of the apparent activation energy with pH can be explained by the contribution of the enthalpy of protonation of surface sites to the dissolution reaction ([4], [5]). However, the variation in dissolution rate observed between pH 3 and 4.5 is not compatible with the surface protonation constant of $10^{8.17}$ from [2], suggesting a lower constant for the powder studied here. Therefore, more work on surface properties of NiO is foreseen.

Cesium is an important radionuclide in the waste from the nuclear power plant [1,2]. The diffusion and sorption of cesium into rock is important to the safety of the radiowaste disposal. The mechanisms of sorption onto the minerals are important mechanisms to predict migration rates in the host rocks [3, 4]. The low porosity of granites is considered to prevent the radionuclides migration from repository site to the biosphere. This work discusses ^{134}Cs diffusion in three brazilian granites of São Sepé Complex Granitic, Rio Grande do Sul, Brazil, in the laboratory conditions. One sample comes from an outcrop and the two others (fresh and altered) are borecores from Camaquã mine. The porosities and densities of the each sample were measured by a water saturation method (pycnometry and water immersion techniques [5]). The porosity was measured also by C-14-PMMA autoradiographic method [6, 7]. Batch experiments and in diffusion test were made on crushed rock samples with several size fractions and blocks having volumes of about 8cm^3, respectively, to obtain the distribution coefficients (K_d values) of cesium-134 and diffusion paths from ^{134}Cs autoradiographs.

Short residence time and fast transport of fine-grain detritus – From ^{7}Be in settled dust in the Judean desert

R. BELMAKER[1,2], B. LAZAR[1], M. STEIN[2] AND J. BEER[3]

[1]The Institute of Earth Sciences, Hebrew University of Jerusalem, Givat-Ram Campus, Jerusalem 91904, Israel; (reuven.belmaker@mail.huji.ac.il)

[2]Geological Survey of Israel, 30 Malkhe Israel St,. Jerusalem 95501, Israel; (motistein@gsi.gov.il)

[3]Swiss Federal Institute of Environmental Science and Technology (EAWAG), Uberlandstrasse 133, CH-8600, Dübendorf, Switzerland; (Juerg.Beer@eawag.ch)

The short-lived cosmogenic isotope ^{7}Be ($t_{1/2}$=53.3 d) was measured in dust collected from dust traps placed in the Judean Desert. This enabled us to: (a) Determine the ^{7}Be dry deposition flux in the Dead Sea region; (b) Estimate the residence time of dust in the Dead Sea drainage basin and (c) Estimate the recycled component of the long-lived cosmogenic isotope ^{10}Be ($t_{1/2}$=1.39·10^{6} y) of Judean desert dust. These estimations constrain the rate of transport of fine detritus material that is washed from the marginal terraces of the Dead Sea basin into the lakes that occupied the basin during the late Quaternary. The data show that: (a) the ^{7}Be flux in the Dead Sea regions is 2.0±0.6×10^{4} atoms·cm^{-2}·y^{-1} during summer and winter months and 5.3±0.7×10^{4} atoms·cm^{-2}·y^{-1} during fall months; (b) the residence time of dust in the drainage basin is less than one year and (c) the recycled ^{10}Be component in Judean desert dust is small. It appears that the inventory of ^{7}Be in dust settled in the Dead Sea drainage basin increases as a function of time and does not reach steady state. Thus, ^{10}Be may be used for reconstructing paleo-flood frequency and dust transport

Behaviour of dissolved silica (adsorption and coprecipitation) in the presence of calcite

D.A. BELOVA[1]*, O.N. KARASEVA[2], L.Z. LAKSHTANOV[2] AND S.L.S. STIPP[1]

[1]Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark. (*correspondence: db@nano.ku.dk)

[2]Institute of Experimental Mineralogy RAS, Chernogolovka, Russia (leonid@iem.ac.ru).

The replacement of carbonate minerals in sediments by silica is common during carbonate rock diagenesis. Silica, as well as organic material and clays, can be one of the inhibitors of chalk (>95% calcite) recrystallization process [1]. However, the mechanism of selective substitution of carbonate sediments by silica and the influence of different factors on silica uptake by adsorption and coprecipitation with calcite are still not clear. In this work, we studied the interaction between dissolved silica and calcite under a variety of experimental conditions to estimate the role of SiO_2 in chalk diagenesis.

The experiments were performed at 25 ºC, different CO_2 partial pressures (pCO_2=1 atm, pCO_2=$10^{-3.5}$ atm and no access to CO_2) and various SiO_2 concentrations ($\leq$ 2 mM). In monomeric silica solutions, no SiO_2 removal by adsorption was observed. The uptake of SiO_2 correlates with the amount of silica polymers and has its maximum value at basic pH, where some polysilicates are present.

Coprecipitation experiments were carried out by the constant addition method. The silica partition coefficient was calculated to be less than 1 and found to be dependent on calcite precipitation rate. The results of coprecipitation studies support that of adsorption experiments and also show that only insignificant amount of silica can be coprecipitated with calcite (maximum SiO_2 uptake is 4.8 μmol g^{-1}). This value increases with increasing dissolved silica concentration, increasing pH and the amount of silica polymers. Using the data from the adsorption study, namely, that polysilicic acid depolymerizes at the calcite surface, we can suggest two models for solid solution formation during coprecipitation.

We can conclude that interaction between dissolved SiO_2 at concentrations below the saturation with respect to amorphous silica and calcite is very weak and depends on adsorption of silica polymers.

The volatile content of subduction zone melts and fluids

A. BÉNARD[1]*, D.A. IONOV[1], N. SHIMIZU[2] AND P.Y. PLECHOV[3]

[1]Univ. J. Monnet, St Etienne & UMR6524-CNRS, France (*correspondence: antoine.benard@univ-st-etienne.fr)
[2]Woods Hole Oceanographic Institution, Woods Hole, USA
[3]Moscow State University, Moscow, Russia

Harzburgite xenoliths from the andesitic Avacha volcano (Kamchatka, Russia) contain two types of spinel-hosted melt inclusions: (a) high-T inclusions (homogenized at 1200°C) containing opx±cpx+glass and (b) low-T inclusions (homogenized at 900°C) containing amph±sulf+glass. Homogeneous glass in the high-T inclusions is similar in major element composition to basaltic andesite experimentally produced by high-degree, hydrous melting of peridotite [1]. Homogeneous glass in the low-T inclusions is silica oversaturated, Al- and Ca-rich, enriched in $LREE_N$ and $LILE_N$ relative to $MREE_N$-$HREE_N$; it displays a strong slab-related chemical overprint. The xenoliths also contain melt pockets originating from local, fluid-assisted melting, produced shortly before the entrapment of the xenoliths.

We analyzed the volatile content of melt inclusions and pockets by Secondary-Ion Mass Spectrometry (SIMS) with Cameca IMS 1280. Most inclusions contain much more CO_2 and H_2O than predicted by saturation curves for these species in silicate melt at 600 bar, implying that the melt entrapment occurred at mantle depth. High-T inclusions have 0.20±0.02 wt.% CO_2, 2.05±0.01 wt.% H_2O and 130±1 ppm S. Low-T inclusions display a wide range of CO_2 (0.01-0.57±0.01 wt.%) and H_2O (0.86-7.45±0.02 wt.%). The abundances of CO_2 and H_2O are positively correlated. The low-T inclusions define also an F-enrichment trend (from 50 to 672±5 ppm) with less variable Cl (540-759±14 ppm) and are strongly enriched in S (up to 0.59 wt.%). Glass in the melt pockets has the lowest CO_2 and H_2O contents (respectively ≤0.03±0.01 and ≤1.58±0.02 wt.%). The $\delta^{34}S$ range of +7.0 to +11.0‰ (±0.6‰, 2σ) in the melt inclusions indicates the presence of heavy oxidized sulfur, likely with surface provenance [2].

The results suggest and/or confirm that (1) the high-T inclusions trapped a mantle-derived primary melt, (2) the low-T inclusions are produced by polybaric entrapment of fluid-rich, hydrous melts in the lithospheric mantle; and provide the first "in situ" evidence for volatile recycling in the lithospheric mantle above a subducting slab.

Laser-induced photo-luminescence spectroscopies: Probes for sulfide crystal-chemistry

A. BÉNARD[1]*, T. OLIVIER[2], B.N. MOINE[1], D.A. IONOV[1], L.-S. DOUCET[1] AND M. BOYET[3]

[1]Univ. J. Monnet & UMR6524-CNRS, St Etienne, France (*correspondence: antoine.benard@univ-st-etienne.fr)
[2]Centre de Microscopie Confocale et Multiphotonique, Univ. J. Monnet, St Etienne, France
[3]Univ. B. Pascal & UMR6524-CNRS, Clermont-Ferrand, France

We combine Two-Photon Fluorescence (TPF), Confocal Laser Scanning Microscopy (CLSM) and Confocal Laser-Induced Luminescence (LIL) to acquire 2-D and 3-D-resolved luminescence emission spectra from transition metal- and (Ca, REE)-bearing mantle-derived and meteoritic (enstatite chondrite) sulfides. The latter include primary condensates and high-degree metamorphic crystals. A wide range of excitation λ (442-800 nm) is tested; Raman micro-spectrometry adds qualitative constraints on sulfide crystallinity. Despite the small amount of luminescence emitted by the sulfides, TPF and CLSM are sensitive enough to perform 3-D imaging with a resolution of ~0.5 μm laterally and ~5 μm axially, in particular using Near Infra-Red (NIR) femtosecond excitation (TPF). Versatile concofal microscopes allow to scan collected luminescence with a 20 nm spectral window to record spectra of roughly 10 x 10 μm regions of interest.

All sulfides emit a characteristic band at 710 nm under TPF NIR radiation that can be related to the sulfur 3sσ state [1]; its increased sharpness may be due to higher crystallinity degree. Pyrrhotite has a continuous emission along a broad λ range (400-710 nm) that allows to distinguish it both from lower temperature, NiAs-type monosulfide polymorphs with two individualized Gaussian-shaped bands (centered at 460 and 650 nm) and troïlite (one major band at 710 nm). We seek to identify *4d*- and *5d*-metal monosulfide heterogeneities (PtS and PdS clusters) with the super-resolution of the TPF.

Under a 633 nm LIL excitation, CaS emits the 710 nm band characteristic of sulfur while below 442 nm, the *4f* and *5d*-derived levels of $^{VI}Ce^{3+}$ are excited with the appearance of the $\Gamma_8(^2T_{2g}) \rightarrow {}^2F(\Gamma_7, \Gamma_8(^2F_{5/2}); \Gamma_6, \Gamma_7, \Gamma_8(^2F_{7/2}))$ transitions. With the use of point charge crystal-field modelling at constant Ce valency, we infer a direct correlation of the *5d* orbitals (t_{2g}-e_g set) splitting parameter Δ_0 to the CaS lattice spacing, controlling in turn Ce partitioning. We investigate REE fluorescence mapping with the TPF super-resolution.

On the radiogenic ^{40}Ca anomaly in seawater and limestone

MICHAEL L. BENDER* AND JOHN A. HIGGINS

Department of Geoscience, Princeton University, Princeton, NJ 08544, USA
(*correspondence: bender@princeton.edu)

Caro *et al*. [1] estimate that the silicate upper continental crust has a radiogenic ^{40}Ca anomaly of 2.5 epsilon units from ^{40}K decay. Surprisingly, Caro *et al*. show that epsilon ^{40}Ca of seawater and limestone is indistinguishable from the mantle value (epsilon ^{40}Ca~0, since the mantle has low K/Ca), with an uncertainty of about ± 0.3 units. To balance the modern oceanic ^{40}Ca budget, they suggest that the riverine flux of radiogenic crustal Ca is balanced by a small nonradiogenic flux from high-temperature hydrothermal processes at mid-ocean ridges, and a larger flux of nonradiogenic calcium from low-temperature hydrothermal systems on ridge flanks. If correct, waters in ridge flank hydrothermal systems must play a major role in the chemical mass balance of the oceans.

We discuss 3 factors that, without invoking ridge flank exchange, help explain the enigma that limestone and seawater Ca are much less radiogenic than the silicate crust. First, radiogenic ^{40}Ca is diluted into the large mass of limestone. Second, the time-averaged hydrothermal flux would be twice the present value if it scaled with past heat production. Third, nonradiogenic hydrothermal Ca would have been retained in the limestone and (via metamorphism) in the silicate crust; it would be recycled by subsequent weathering, thereby lowering epsilon ^{40}Ca in rivers. These three factors together can account for about two-thirds of the difference between the estimated ^{40}Ca anomaly of the silicate continental crust and the nonradiogenic Ca composition of seawater and limestone.

Limited early continents from the chemistry of Eoarchean rocks

VICKIE C. BENNETT[1] AND ALLEN P. NUTMAN[2]

[1]Research School of Earth Sciences, The Australian National University, Canberra, Australia (vickie.bennett@anu.au)
[2]School of Earth and Environmental Sciences, University of Wollongong, NSW, Australia (allen.nutman@gmail.com)

Continuing and fundamental questions in Earth history focus on the timing and mechanisms of early continent formation. These questions take on additional significance in consideration of potential early life habitats and early tectonic regimes. Key approaches used to argue for, and against, massive early continents, have centered on the signatures of long-lived isotopic systems, i.e. initial εNd and εHf, preserved in the oldest rocks. For example, positive deviations from bulk silicate Earth compositions have been equated with massive early crust formation. Such interpretations contain the assumption that continental crust has been the primary complement to the depleted mantle throughout Earth history. However, using an expanded ^{142}Nd,^{143}Nd,^{176}Hf database derived from Eoarchean rocks worldwide we demonstrate that Nd and Hf isotopic data do not record the distinctive correlations observed in younger granitic terranes; these correlations are generated in the mantle by long term crust extraction. Furthermore, positive ^{142}Nd anomalies (relative to modern terrestrial compositions) measured in some Eoarchean rocks require extremely early (4.53 Ga - 4.4 Ga) Sm/Nd fractionation. Overall, neither Sm-Nd or Lu-Hf fractionation in the >3.7 Ga mantle can be linked to continental crust extraction.

Other types of observations from ancient rocks further support the case for limited crustal volumes. Eoarchean rocks are now recognised in 8 gneiss complexes worldwide. In each area, the oldest felsic rocks (ca. 3.7-4.0 Ga) are typically tonalites, with no evidence of pre-existing crust in the form of inherited zircon grains with older U-Pb ages. Where data are available, the initial εNd and εHf values range from chondritic to positive and δ^{18}O isotopic compositions are mantle-like; thus there is no chemical evidence for reworking of older components. In contrast, younger (≤3.65 Ga) granites (*sensu stricto)* often contain inherited zircons whose U-Pb ages match the oldest crust in each region; initial εNd and εHf values become more negative with decreasing rock age, reflecting incorporation of older felsic components. We consider that, at present, there is no compelling evidence for the existence of extensive early continents, prior to ~3.65 Ga.

An experimentalist call to theoreticians about XANES spectra theoretical simulation at the C K-edge, Ca and Fe $L_{2,3}$ edges

KARIM BENZERARA[1], OLIVIER BEYSSAC[1], MATTHIEU GALVEZ[1], SYLVAIN BERNARD[2] AND JULIE COSMIDIS[1]

[1]Institut de Minéralogie et de Physique des Milieux Condensés, UMR7590, CNRS, UPMC & IPGP, 4 Place Jussieu, 75005 Paris, France

[2]LMCM, UMR 7202, MNHN & CNRS, 61 rue Buffon, 75005 Paris, France

Scanning transmission x-ray microscopy (STXM) is increasingly used in geobiology and more generally in Earth sciences [1-5]. It is a transmission microscopy providing images with 25-nm spatial resolution and a x-ray absorption near-edge structure (XANES) spectrum for each pixel of this image. The few beamlines that are available worldwide (e.g., 11.0.2 at the ALS or 10ID-1 at the CLS) give the opportunity to scan over a large energy range (e.g. 70-2200 eV) with high energy resolution enabling the study of elements such as C, N, O, Mg (using K-edges), or P, Ca, Fe or As (using L-edges). XANES spectra coupled with high spatial resolution can thus provide unique information on the speciation of diverse elements which is a 1st order interest for a variety of applications. However, very often, the use of the spectroscopic information is limited to a fingerprinting approach. We believe that theoretical developments would help retrieving significantly more information from these spectra. Here we will review some of the experimental work that we have done over the last few years in order to identify some key needs that we have and that might be adressed by theoreticians. In particular, we will discuss the use of XANES spectroscopy at the C K-edge to study the chemical composition and structure of organic carbon in (ancient) rocks and mention the implications for the study of metamorphism and/or search for ancient traces of life. Absorption variations due to linear dichroism in particular will be presented. The use of XANES spectroscopy at the Fe $L_{2,3}$ edges and difficulties to retrieve Fe redox state values will be adressed.

Arsenic contamination of groundwater in Vietnam: Delta-wide survey and 3D geospatial modelling

M. BERG[1]*, L.H.E. WINKEL[1], P.T.K. TRANG[2], V.M. LAN[2], C. STENGEL[1], M. AMINI[1], N.T. HA[3], AND P.H. VIET[2]

[2]Centre for Environmental Technology and Sustainable Development (CETASD), Hanoi, Vietnam.

[3]Centre for Water Resources Monitoring and Forecast (CWRMF), Hanoi, Vietnam.

Arsenic contamination of shallow groundwater is among the biggest health threats in the developing world. The Red River Delta was recognized to be affected in 1998, but the spatial extension remained unknown [1]. Here we present the results of a groundwater survey of the entire Red River Delta combined with a unique probability model based on 3-dimensional (3D) Quaternary geology. Our investigations reveal that ~7 million delta inhabitants use groundwater that contains unsafe levels of As, Mn, Se, and Ba.

Global and sub-continental arsenic risk maps based on surface geology were recently shown to be a successful tool to initiate mitigation measures [2,3]. For the Red River delta we now established a 3D model based on stratigraphy of Quaternary geology, which visualizes As hot-spots at depths and identifies safe regions for drinking water production.

This 3D model further reveiled anomalities of As enrichment in the aquifers. Particularly in the Hanoi area, depth-resolved probabilities and As concentrations indicate drawdown of As-enriched water from Holocene aquifers to naturally As-safe Pleistocene aquifers, most likely as a result of more than 100 years of groundwater abstraction. Vertical As migration induced by large-scale pumping from deep aquifers has been discussed to occur elsewhere, but has never been shown to occur at the scale seen here. The present situation in the Red River Delta is hence a warning for other As-affected regions where groundwater is extensively pumped from uncontaminated aquifers.

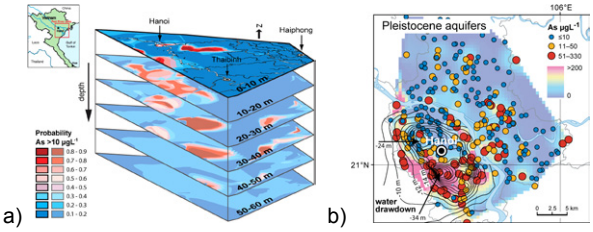

Figure 1: a) As risk map (3D), Red River Delta. b) As levels in the Pleistocene aquifers, and water drawdown in Hanoi [4].

[3]SYRMEP Group, Sincrotrone Trieste, Basovizza, Italy

Magma-crust interaction in magma reservoirs and conduits is a crucial process during magma evolution and ascent. This interaction is recorded by crustal xenoliths that frequently show partial melting, inflation and disintegration textures. Frothy xenoliths are widespread in volcanic deposits from all types of geological settings and indicate crustal gas liberation. To unravel the observed phenomena of frothy xenolith formation we experimentally simulated the behaviour of crustal lithologies in volcanic conduits. We subjected various sandstones to elevated temperature (from 810 to 916 °C) and pressure (from 100 MPa to 160 MPa) in closed-system autoclaves. Experimental conditions were held constant for 24h up to 5 days, then controlled decompression simulated xenolith ascent. Pressure release was a function of temperature decline in our setup. Temperature lapse rate proceeded exponentially; the first 20 minutes experienced an enhanced decline of 24-20°C/min, whereafter 6-8 hours of slow cooling followed towards room temperature. The experimental xenoliths have been analysed by synchrotron X-ray μ-CT at a resolution of 3.4 – 9 microns/pixel. This method permits visualisation and quantification of internal vesicle volumes, -networks and -connectivity in 3D.

Experimental products closely reproduced the textures of natural frothy xenoliths in 3D and define an evolutionary sequence from partial melting to gas exsolution and bubble nucleation that eventually leads to the development of three-dimensional bubble networks. The lithology proved decisive for degassing behaviour and ensuing bubble nucleation during decompression. Increased volatile content (chiefly water) and amount of relict crystals in the partial melt promote bubble nucleation and subsequent bubble coalescence to form interconnected bubble networks. This, in turn, enables efficient gas liberation. Our results attest to significant potential of even very common crustal rock types to liberate volatiles and develop interconnected bubble networks upon heating and decompression. Volatile input from xenoliths may therefore considerably affect explosive eruptive behaviour, and our experiments offer a detailed mechanism of how such crustal volatile liberation is accomplished.

Cr-isotopes and REE variations in a laterite profile: Implication for redox processes and element mobility during weathering

ALFONS BERGER AND ROBERT FREI

University Copenhagen, Denmark (*correspondence: ab@geo.ku.dk)

The isotope composition of redox sensitive elements are a powerful tool to reconstruct transport of elements depending on their oxidation state. One major application is the study of element transfer from weathering to redeposition. However, the understanding of the "output" during weathering requires insights to processes during erosion and soil development. In this context, the mineralogy and oxidate state of certain elements in weathering profile are key informations.

We will give some insights into a modern laterite profile of Madagascar. The profile is taken in an quarry near RN7 south of Antisrabe, including bed rock, saprolith and top soil. The fresh rock are a Panafrican tonalite. The sample site is characterized by minor topography and groundwater flow is controlled by small rivers. The fresh rock is dominated by two feldspars, quartz, biotite, hornblende, ilmenite, magnetite, apatite, allanite and chevkinite. Weathering starts along cracks and is accompined by change mineralogy and major elements abundances. Trace element concentrations and Pb isotopes indicate no or only minor solid mass transport. The profile reflects an *in situ* weathering profile with a water level horizon above the saprolith. The water flow horizon includes a change in Ce concentrations related to deposition of ceriate. This is most likely related to insolvable Ce(IV) in this part of the profile. In contrast, transformation during weathering from allanite/chevkinite to rhabdophane did not change the REE whole rock pattern. Cr is strongly depleted in the soil and in the saprolith and reflects mobilization of Cr by oxidation to the hexavalent state. This change of oxidation change is corroborated by fractionated Cr isotopes in the saprolith (δ^{53} Cr -0.4 – -0.5‰), relative to the δ^{53}Cr value of ~0.15‰ of the tonalite

The different behaviour of the redox sensitive elements Ce and Cr is either related to the redox potential of the elements and/or is kinetically controlled by the respective host minerals. The REE´s are predominantly hosted by accessory minerals (chevkinite, allanite, apatite), whereas Cr are incorporated rock forming silicates and oxides. Comparison of Ce anamolies and Cr isotopes provide important insights to the behaviour of these elements during weathering and consequently to the relative concentrations in the solvent.

Hydrothermal synthesis of cubanite under conditions relevant to the CI-chondrite parent body

E. L. BERGER*[1], D. S. LAURETTA[1] AND L. P. KELLER[2]

[1]Lunar & Planetary Laboratory, Tucson, AZ 85721 (*correspondence: elberger@lpl.arizona.edu)
[2]NASA Johnson Space Center, Houston, TX 77573

The low temperature form of $CuFe_2S_3$, cubanite, has been identified in the CI chondrites and in samples returned from Comet Wild 2 by the Stardust Mission [1]. We report the first synthesis of this mineral under aqueous conditions consistent with predictions for the CI-chondrite parent body.

An aqueous system can be described as the interplay between pH, temperature, oxygen and sulfur fugacities [2]. We form cubanite at 150 and 200ºC (fig. 1) by controlling oxygen fugacity (fO_2), pH and T. Oxygen isotope measurements and modeling of aqueous conditions on asteroidal bodies [3, and ref. therein] predict: T of 20-150ºC, pH of 7-10 and log $fO_2 > 10^{-55}$ -10^{-70}.

EMPA and FIB-TEM techniques are used to determine composition and crystal structure.

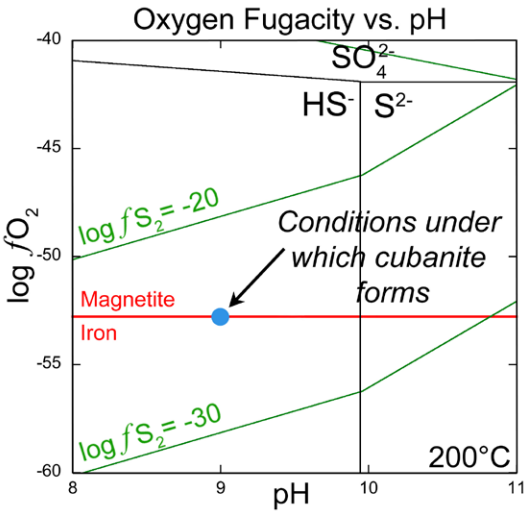

Figure 1: Oxygen fugacity vs. pH for an aqueous system containing 0.025M S. Major S species (aq), lines of constant sulfur fugacity and the iron-magnetite buffer are indicated.

Fluoride patterns in a boreal stream influenced by bedrock and hydrology

T. BERGER*, P. PELTOLA, H. DRAKE AND M. ÅSTRÖM

Department of Natural Sciences, Linnaeus Univ., Kalmar, Sweden (*correspondence: tobias.berger@lnu.se)

The spatial and temporal variation of fluoride in the Kärrsvik catchment (27 km^2) in SE Sweden has been monitored monthly for up to 6 years (2002 - 2009). The bedrock is characterized by 1.8 Ga old granite to quartz monzodiorite. However, in the lower reaches the F-rich, 1.45 Ga old, Götemar granite crops out.

Fluoride increased significantly at this intrusion and showed a strong negative relationship with flow, ranging between 0.6 and 4.2 mg L^{-1} (median 1.04 mg L^{-1}). In the upper reaches the concentrations were lower, <0.20 - 0.85 mg L^{-1} (median ~0.4 mg L^{-1}). The spatial concentration pattern of fluoride in well waters was concordant with that of the surface waters within the catchment.

On a continental scale, European streams (n=808, 25 countries) have median fluoride concentrations of 0.1 mg L^{-1} [1]. The Kärrsvik catchment is therefore an area with anomalous fluoride concentrations. Stream waters can be major sources of drinking water and the World Health Organization guideline value is set to 1.5 mg L^{-1}.

The fluoride pattern can be explained by three main sources associated with weathering processes in the lower reaches of the catchment: 1, glacial deposits partially enriched in weathering products from the Götemar granite, 2, larger input of baseflow water (longer interaction time with F-bearing minerals) and 3, intrusion-related fractures strongly enriched in fluorite.

Detailed studies of near-surface groundwaters in the region will further increase the understanding of the dynamics of this element in these kinds of environments.

Early Neoproterozoic arc magmatism along the northwestern margin of the Yangtze craton and its connection with the South China Block evolution during the Rodinia assembly

W. BERKANA[1,2] ,W-L. LING[1,2]*, X-F. QIU[1,2] AND S-S. LU [1,2]

[1]State Key Laboratory of Geological Process and Mineral Resources, China University of Geosciences, Wuhan 430074, P R China (lingwenli2008@126.com)

[2]Faculty of Earth Sciences, China University of Geosciences, Wuhan 430074, P R China (wafaberkana@yahoo.fr)

The South China Block (SCB) comprises the Yangtze craton and the Cathysian block, welded during ~1.0-0.95 Ga. Neoproterozoic igneous activities of ~830-750 Ma are widely recorded in the SCB. However, their origin and tectonic setting have long been debated, resulted in competing models for the correlation of the SCB with Rodinia supercontinent.

The Wangcang igneous complex occurs along the northwestern Yangtze craton, which has long been regarded as early Precambrian basement. Our present study reveals that both the intrusive and volcanic suites were formed at ~880 Ma. The mafic rocks show tholeiitic geochemistry with initial ε_{Nd} values of +2.1 to +7.7, whereas the felsic samples are calc-alkaline series with a ε_{Nd} range of -2.1 to +4.7. These suites are suggested to have an arc magmatic origin, and their intensive deformation and high metamorphism occurred during ~880-820 Ma.

Integrating with proofs such as Nd isotope stratigraphic studies of the Yangtze craton, we suggest that the Yangtze craton had experienced a continent growth during the Rodinia assembly by microcontinent merging before the SCB unification. This study was supported by National Nature Science Foundation of China (Grants 40873017, 40673025).

The advantage of the use of Focused Ion Beam technique to specify the mantle fluid inclusions

M. BERKESI[1]*, T. GUZMICS[1], C. SZABÓ[1] AND J. DUBESSY[2]

[1]Lithosphere Fluid Research Lab, Institute of Geography and Earth Sciences, Eötvös University Budapest, 1117 Pázmány Péter sétány 1/C, Budapest, Hungary (correspondence: martaberkesi@caesar.elte.hu)

[2]UMR G2R and CREGU, Nancy University, BP-70239, 54506-Vandœuvre-les Nancy Cedex, Nancy (France) (jean.dubessy@g2r.uhp-nancy.fr)

The Focused Ion Beam (FIB) coupled with scanning electron microscopy (SEM) technique has became one of the most promising tools for many geochemical studies in the last decade [1].

It is known that within the fluid inclusions solids (referred to as daughter phases) may crystallize as a result of cooling and/or reaction with their host mineral. If the volume proportions of the daughter phases are not known, the fluid composition determined can be misinterpreted. However, *in situ* measurement of the daughter phases can be complicated and ambiguous with conventional techniques because of their size and/or composition. In this study we report our results using FIB-SEM technique on investigation of daughter phases in orthopyroxene-hosted fluid inclusions in mantle xenoliths from the Pannonian Basin (Hungary).

Solid phases such as magnesite and quartz have been found within the fluid inclusions. They have a size between 200 – 2000 nm occurring as cluster on some parts of the inclusion walls. In addition, S-bearing solid phase (probably sulfide) has also been identified. One of the most interesting feature observed was a thin film covering the wall of the studied fluid inclusions. This film has a feature that is typical for the volcanic glasses, containing numerous spherical-shaped holes (vesicles) on the surface as a result of the exsolution of volatiles. It is to emphasize that previous works on fluid inclusions have already proposed the presence of the glass film on the wall [2] in mantle fluid inclusions, however, in this work the glass film has been found *in situ*.

The acquired results of this study contribute to 1) quantification of the bulk fluid composition and 2) better understanding the mechanisms of the post-entrapment processes in fluid inclusions entrapped at lithopheric mantle condition.

Can we use variations in volatile concentrations in volcanic glass to study degassing?

KIM BERLO[1], DAVID PYLE[1], JENNI BARCLAY[2], TAMSIN MATHER[1] AND HUGH TUFFEN[3]

[1]Department of Earth Sciences, University of Oxford, Oxford, UK. (kim_berlo@inbox.com, David.Pyle@earth.ox.ac.uk, Tamsin.Mather@earth.ox.ac.uk)
[2]School of Environmental Sciences, University of East Anglia, Norwich, UK. (J.Barclay@uea.ac.uk)
[3] Lancaster Environment Centre, Lancaster University, Lancaster, UK. (h.tuffen@lancaster.ac.uk)

Decompression of volatile rich magma results in the exsolution of a separate gas phase. Major volatile species, H_2O, CO_2, SO_2, as well as many minor volatile species, $PbCl_2$, $ZnCl_2$, Hg, AsS etc, will be partitioned between the gas and the melt phase. However, the rate of magma ascent and eruption does not always allow for the equilibrium distribution between gas and melt of such species to be reached. Instead elements are quenched in transition towards an equilibrium that constantly changes as the magma ascends. Volatile elements can thus display diffusive profiles towards gas escape features, such as bubbles, tubes or fractures. This exploratory study aims to map out the extent of heterogeneity in rhyolitic glasses. Samples with different gas pathways, bubbles, fractures, channels and tuffisite veins have been selected and will be mapped for H_2O and selected trace metals (Cu, Zn, Bi, Pb) using synchrotron FTIR and XRF. The results of this study will allow us assess the extent to which volcanic gases can be in equilibrium with a melt shortly before eruption.

Calcium isotopes in lunar crust

K. BERMINGHAM[1], T. MAGNA[1,2], N. GUSSONE[1] AND K. MEZGER[3]

[1]Universität Münster, Germany
[2]Czech Geological Survey, Prague, Czech Republic
[3]Universität Bern, Switzerland

Calcium isotope compositions were determined in lunar crustal rocks in order to quantify possible mass-dependent (MDF) and mass-independent (MIF) isotope fractionation. Anorthosites show ~0.4‰ variation in $\delta^{44/40}$Ca; pristine anorthosite 60025 has an identical value to previous reports [1] but appears to be slightly heavier than the other anorthosites ($\delta^{44/40}$Ca=0.65–0.91‰) which may reflect a larger proportion of isotopically heavy olivine. Norite 77215 has $\delta^{44/40}$Ca=1.06‰, which is identical to pristine terrestrial mantle rocks [2] and likely represents a mixture between isotopically light plagioclase and heavy orthopyroxene. In general, anorthosites and norite mimic the range of terrestrial and Martian basalts [2–4] as well as lunar low-Ti and high-Ti lithologies [4]. The $\delta^{44/40}$Ca uniformity of lunar crust and mantle-derived rocks is dissimilar to the Ca systematics of major terrestrial reservoirs with predominantly light Ca isotope signature in continental crust and may suggest cessation of magmatic activity early in the lunar history without further material exchange with deeper parts of the Moon. A tight negative correlation of $\delta^{44/40}$Ca with K contents could reflect either the chemical development of the magma ocean or a collateral effect of immiscibility between Ca and K feldspars. However, only a detailed experimental investigation could provide tight constraints on the role of plagioclase in lunar Ca budget. This may be particularly important for the Moon considering that, in contrast to the Earth where >99% Ca budget is dominated by mantle, lunar crust is a significant Ca repository and hosts ~11% of the total lunar Ca. New data for lunar mare basalts coupled with data for anorthosites could help constrain the lunar Ca evolution in the context of lunar magma ocean crystallization.

The MIF effects are indiscernible for individual Ca isotopes in all investigated lunar rocks in this study. This is in agreement with previous findings for some Solar System material [5–7]. In particular, lack of resolvable MIF variations in lunar samples may imply Ca isotope homogeneity on the planetary scale.

Nanoscale study of the mineralogical and geochemical evolution of black shales with increasing maturity

S. BERNARD[1,*], B. HORSFIELD[2], H-M. SCHULZ[2], A. SCHREIBER[2], R. WIRTH[2] AND N. SHERWOOD[3]

[1]LMCM, MNHN, CNRS, Paris, France (sbernard@mnhn.fr)
[2]Deutches GeoForschungsZentrum GFZ, Potsdam, Germany (horsf@gfz-potsdam.de, schulzhm@gfz-potsdam.de, schreiber@gfz-potsdam.de, wirth@gfz-potsdam.de)
[3]CSIRO, North Ryde, Australia (Neil.Sherwood@csiro.au)

Gaseous hydrocarbon generation processes occur within gas shales as a response to increases in thermal maturation. While efforts have been directed at unravelling the resource potential of these unconventional systems [1], their spatial variability in chemistry and structure is still poorly understood at the sub-micrometer scale. For instance, intra-particle nanoporosity has been documented within overmature gas shale samples but has not yet been attributed to any specific organic macromolecule [2]. Here, we have characterized samples of the Lower Toarcian Posidonia Shale from northern Germany at varying stages of thermal maturation using a combination of compositional organic geochemistry and spectromicroscopy techniques, including synchrotron-based scanning transmission X-ray microscopy (STXM). We document geochemical and mineralogical heterogeneities down to the nanometer scale within the investigated samples at all levels of thermal maturity [3,4].

In particular, authigenic albite crystals containing nanometric halite inclusions have been documented within the investigated mature and overmature samples. The presence of such tracers of palaeobrine-carbonate interactions supports a maturation scenario for the Lower Toarcian Posidonia Shale intimately related to ascending brine fluids. In addition, various types of asphaltene- and NSO-rich bitumen have been detected within the same samples, very likely genetically derived from thermally degraded organic precursors. Furthermore, the organic macromolecules displaying intra-particle nanoporosity have been identified as pyrobitumen residues, such nanoporosity likely resulting from the formation of gaseous hydrocarbons. By providing *in situ* insights into the fate of bitumen and pyrobitumen as a response to the thermal evolution of the macromolecular structure of kerogen, the results reported here constitute an important step towards better constraining hydrocarbon generation processes during natural gas shale maturation.

Does the electron transfer process determine the product of U(VI) reduction?

RIZLAN BERNIER-LATMANI[1], DANIEL S. ALESSI[1], HARISH VEERAMANI[1], JONATHAN O. SHARP[1], ELENA DALLA VECCHIA[1], ELENA I. SUVOROVA[1], JOANNE E. STUBBS[2], JUAN S. LEZAMA-PACHECO[3] AND JOHN R. BARGAR[3]

The bioremediation of uranium-contaminated sites is based on the amendment of an electron donor to stimulate microbial activity. Typically, Fe(III) and U(VI) serve as electron acceptors for microorganisms with the former supporting microbial growth. However, this biostimulation process may generate competing mechanisms of uranium bioreduction. While direct enzymatic reduction of U(VI) by microbes is a possible route of immobilization of U(IV), Fe(II) produced by the reduction of Fe(III) also is thermodynamically capable of abiotically reducing U(VI).

Here we investigate the question of whether different U(IV) products are expected from these various U(VI) reduction processes. Specifically, we consider the reduction of U(VI) via direct enzymatic reduction by both Gram-positive and Gram-negative bacteria, via abiotic reduction by Fe(II)-bearing minerals as well as through a potential combination of these direct and indirect processes in sediment columns.

The results indicate that geochemical conditions dictate the product of U(VI) reduction. For example, the same microorganism produced a monomeric sorbed U(IV) complex in the presence of particular solutes but nanoparticles of the mineral uraninite in their absence. A phosphate-reacted magnetite (Fe_3O_4) suspension produced a similar monomeric U(IV) product while unreacted magnetite produced uraninite. Finally, in studying U(VI) reduction in sediments, both laboratory and field-run columns yielded non-uraninite U(IV), suggesting that *in situ* geochemical conditions favor monomeric U(IV) formation.

This work shows that, while the kinetics of U(VI) reduction have been shown to depend on the reduction mechanism, the end-product of the reduction is largely determined by the geochemical conditions under which the reduction–biotic or abiotic- takes place.

Solubility of fluorine and chlorine in nominally anhydrous mantle minerals: Implications for mantle metasomatism and arc magmas

D. BERNINI[1], D. DOLEJŠ[1,2], N. DE KOKER[1], A. AUDÉTAT[1], H. KEPPLER[1] AND M. WIEDENBECK[3]

[1]Bayerisches Geoinstitut, University of Bayreuth, 95440 Bayreuth, Germany
[2]Institute of Petrology and Structural Geology, Charles University, 12843 Praha 2, Czech Republic
[3]Deutsches GeoForschungsZentrum, 14473 Potsdam, Germany

Subduction fluxes and recycling of halogens are important for interpreting the fate of halogen budget of altered subducting slab, availability of ligands for complexing in aqueous fluids, origin of high-pressure brines, and volatile signatures of arc magmas. We investigated solubilities of fluorine and chlorine in forsterite, enstatite and pyrope, and halogen partitioning between aqueous fluids and these minerals by piston-cylinder experiments at 1100 °C and 2.6 GPa. The chlorine solubility in forsterite, enstatite and pyrope is very low, 0.2-0.9 ppm, and it is independent of the fluid salinity (0.3-40 wt. % Cl). The fluorine solubility is 16-31 ppm in enstatite and 24-52 ppm in pyrope, also independent of fluid salinity. Forsterite dissolves 246-267 ppm up to a fluid salinity of 1.6 wt. % F. At higher fluorine contents in the system, forsterite is replaced by the minerals of the humite group. The fluid-mineral partition coefficients are 10^1-10^3 for fluorine and 10^3-10^6 for chlorine. The latter values are approximately three orders of magnitude higher than those for hydroxyl partitioning suggesting a gradual increase in the fluid salinity during fluid percolation through the mantle wedge. Energetics of fluorine incorporation in forsterite and the forsterite-humite chemical equilibria in the system Mg_2SiO_4-MgF_2 were further explored by first principles computations. The fluorine solubility in forsterite strongly increases with temperature, from 0.01 ppm F at 500 K up to 0.33 wt. % F at 1900 K and 0 GPa. By contrast, the effect of pressure on the fluorine solubility is very small, producing a decrease by a factor of two to three at 12 GPa. Consequently, partition coefficients of fluorine between forsterite and aqueous fluid (or silicate melt) are expected to increase with increasing temperature and decreasing pressure. When fluids or melts pass through the mantle wedge, fluorine will most efficiently be stored in the high-temperature portions of the wedge, promoting mantle metasomatism beneath the arc, and it will be released when the metasomatized mantle is advected to colder regions or to higher pressures.

Diffusion and microbial consumption of oxygen in an acidic geothermal iron-oxide mat

H C. BERNSTEIN[1], J. P. BEAM[2], R. P. CARLSON[1] AND W.P. INSKEEP[2]*

[1]Department of Chemical and Biological Engineering, Montana State University, Bozeman, MT 59717, USA (*correspondence:hans.bernstein@biofilm.montana.edu,binskeep@montana.edu)
[2]Department of Land Resources and Environmental Sciences, Montana State University, Bozeman, MT 59717, USA

The role of dissolved oxygen as a primary electron acceptor for microbially mediated iron oxidation was investigated within the primary flow path of an acidic geothermal spring in Norris Geyser Basin, Yellowstone National Park. Previous data has suggested that Fe(II)-oxidizing microbial populations (e.g., Metallosphaera yellowstonensis and potentially other novel members of the domain Archaea) represent the primary-producers within these microbial communities. Consequently, the availability of oxygen is hypothesized to limit microbial Fe(II)-oxidation and primary-productivity in this system. In situ measurements of oxygen profiles were obtained perpendicular to the direction of convective flow across the aqueous phase-Fe(III)-oxide interface using oxygen microsensors. Dissolved oxygen concentrations drop below detection by ~ 600 μm into the Fe(III)-oxide mat, indicating reactive oxygen consumption and defined spatial gradients. Evaluation of the oxygen flux across the liquid-mat boundary showed that convection was negligible compared to diffusive transport in the mat. Reaction-diffusion models were evaluated assuming both zero and first-order reaction kinetics. The in situ measurements and models suggest that the rate of oxygen consumption exceeds the rate of diffusion. Thus, microbially mediated Fe(II)-oxidation in this system is likely limited by oxygen diffusion, resulting in an active surface layer of Fe(III)-oxide biomineralization.

Quantitative mapping of the oxidation state of iron in mantle garnet

A.J. BERRY[1]*, G.M. YAXLEY[2], B.J. HANGER[2], A.B. WOODLAND[3], M.D. DE JONGE[4], D.L. HOWARD[4] AND D. PATERSON[4]

[1]Department of Earth Science and Engineering, Imperial College London, South Kensington, SW7 2AZ, UK (*correspondence: a.berry@imperial.ac.uk)
[2]Research School of Earth Sciences, Australian National University, Canberra, ACT 0200, Australia
[3]Institut für Geowissenschaften, Universität Frankfurt, Frankfurt am Main, D60438, Germany
[4]Australian Synchrotron, Clayton, VIC 3168, Australia

The garnet structure can accommodate both Fe^{2+} and Fe^{3+} and $Fe^{3+}/\Sigma Fe$ of garnets in garnet peridotite can be used to determine the oxygen fugacity (fO_2) of the cratonic lithosphere. This is important as an indicator of diamond (versus carbonate) stability. Post-formation metasomatic processes in the upper mantle, or during transport in kimberlites, may impose high fO_2s that result in diamond breakdown or resorption. Such events will usually be recorded by the coexisting garnet.

$Fe^{3+}/\Sigma Fe$ of garnets has traditionally been determined by Mössbauer spectroscopy of powdered samples. This lacks spatial resolution and the data for each measurement take several days to acquire. X-ray absorption near edge structure (XANES) spectroscopy is now commonly being used to determine $Fe^{3+}/\Sigma Fe$, is capable of micron spatial resolution and spectra can be recorded in ~15 minutes. We have recently reported a new method for quantifying $Fe^{3+}/\Sigma Fe$ from the XANES spectra of mantle garnets with an accuracy and precision comparable to Mössbauer spectroscopy [1].

XANES spectra were recorded in fluorescence mode from garnets prepared as either polished thin sections or electron probe mounts. A calibration curve relating the XANES spectra to $Fe^{3+}/\Sigma Fe$ of mantle garnets previously analysed by Mössbauer spectroscopy allowed garnet unknowns to be quantified. By recording the fluorescence intensity at a small number of energies as a function of position $Fe^{3+}/\Sigma Fe$ maps could be produced. It is possible to quantitatively map the oxidation state of Fe with a spatial resolution and acquisition time comparable to elemental mapping using the electron microprobe. This allows zonation of $Fe^{3+}/\Sigma Fe$ due to metasomatic processes to be identified.

Carbonation of Steel Slag I

ELEANOR J. BERRYMAN[1]*, ANTHONY E. WILLIAMS-JONES[1], ARTASCHES A. MIGDISOV[1] AND SIEGER VAN DER LAAN[2]

[1]Department of Earth and Planetary Sciences, McGill University, Montreal, Quebec, Canada *(berryman.eleanor@gmail.com)
[2]Tata Steel RD&T, Ceramics Research Centre, IJmuiden, The Netherlands

Mineral carbonation provides a durable and environmentally inert method of sequestering CO_2 emissions. Larnite (Ca_2SiO_4), a major constituent of steel slag, is highly reactive with aqueous CO_2 [1]. Consequently, carbonation of steel slag offers an opportunity to reduce CO_2 emissions while recycling an industrial by-product. This study investigates the reactions taking place during the dissolution and carbonation of steel slag, and is part of a larger study designed to determine the conditions under which conversion of larnite and other calcium silicates to calcite is optimized.

Experiments were conducted on 2 – 3 mm diameter steel slag grains supplied by Tata Steel RD&T. A H_2O-CO_2 fluid mixture (XCO_2 = 0.05) was pumped through a flow-through reactor containing these grains. Temperature ranged from 120°C to 200°C, the pressure was 250 bar and the flow rate was 3.00 mL/min. The duration of experiments varied from 3 to 7 days.

The slag grains reacted to form Ca-carbonate and –phosphate phases upon contact with the CO_2-saturated fluid. These phases subsequently dissolved, forming a porous aluminium and iron oxide framework around the edges of the grains. The compositions of the reacted fluid reflect the observed dissolution of Ca-bearing phases and the buffering of Si by the formation of quartz. These results are in good agreement with predictions from thermodynamic calculations, indicating that the system achieved local equilibrium.

Effect of CO_2-enriched fluid on three argillite type caprocks

G. BERTHE[1,2]*, S. SAVOYE[3], C.WITTEBROODT[1] AND J.-L. MICHELOT[2]

[1]IRSN, DEI/SARG/LR2S,92260 Fontenay-aux-Roses, France (*correspondence: guillaume.berthe@cea.fr)
[2]IDES,CNRS-Université Paris-Sud F-91405 Orsay, France
[3]CEA, DEN/DANS/L3MR, F-91191 Gif-sur-Yvette, France

The sequestration of CO_2 under impervious caprocks as argillite is proposed to reduce the greenhouse effect. CO_2 impact on the containment properties of argillite has to be assessed, as performed by [1] on Upper Toarcian rocks from Tounemire site (France). In the current study, we widened the approach to two other levels from Tournemire (Lower Toarcian and Domerian), displaying distinct carbonate contents (30% and 8%, resp.).

^{36}Cl, HTO, Br^- and D_2O were used as tracers in through-diffusion experiments carried out with and without CO_2-enriched fluids. The through-diffusion technique consists in imposing a concentration gradient of the tracer between the two faces of the sample. For the cells simulating an acidic fluid attack, dissolved CO_2 was injected inside the upstream reservoir. Chemistry evolution was also monitored in the up and downstream reservoirs.

Tracer data analyses indicated a degradation of the containment properties of the samples, increasing from the Paper Shale (unaffected) up to the Toarcian (Fig.1)

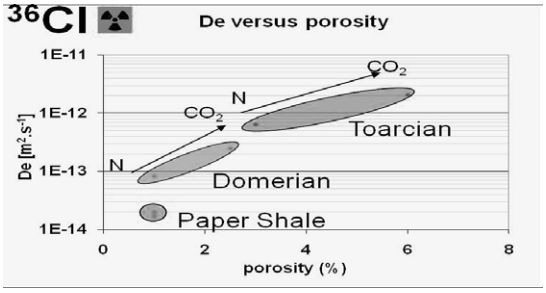

Figure 1: evolution of the diffusive parameters for the 3 levels

Such a difference can be accounted for by the distinct kinetics for achieving the chemical equilibrium regarding carbonates as shown by [Ca2+], [Mg2+] and alkalinity monitoring. This demonstrates the role played by the initial petrophysical properties of the rocks, in addition to their carbonate content.

On the use of nucleation barriers in numerical simulation of water-rock interactions

P. BERTIER*, C. WEBER AND H. STANJEK

Clay and Interface Mineralogy, RWTH-Aachen University, Bunsenstrasse 8, D-52072 Aachen Germany, (*correspondence: Pieter.Bertier@cim.rwth-aachen.de)

Numerical simulations of water-rock interactions in diagenetic or CO_2 sequestration systems generally predict mineral alteration processes that are considerably faster than those observed in experiments or diagenetic environments. This has been attributed to several reasons, among which the common disregard for nucleation of precipitating mineral phases in such models.

The effect of the implementation of nucleation barriers was evaluated on a kinetic reaction path model of sandstone diagenesis. Critical levels of supersaturation required for precipitation, based on literature data of formation water compositions, substantially slow down reaction kinetics due to their feedback on the dissolution rates of the minerals supplying the component species of the precipitating phase.

The implementation of nucleation barriers and rates based on classical nucleation theory have a similar effect, but often predict unrealistically high levels of supersaturation. One of the crucial parameters in classical nucleation theory is the mineral-water interface tension. Literature data on mineral-water interface tension is scarce and ambiguous. Different methods for measuring or calculating interface tensions produce very different results.

A methodology, based on capillary rise in powder beds as described by Washburn's equation, was developed for quantifying mineral water interface tensions under conditions typical of diagenetic systems. The interface tensions of several common rock forming minerals were determined. Application of these new data in the classical nucleation theory based kinetic reaction path model results in more realistic levels of supersaturation.

The climate of Chilean Patagonia is highly influenced by the Southern Westerlies, which control the intensity and latitudinal distribution of precipitation in the Southern Andes. In austral summer, the Westerly Wind Belt (WWB) is restricted to the high latitudes (> 47°S). It expands northward in winter, which results in a strong seasonal signal in precipitation between ~47 and ~30°S. In addition, the area is characterized by a steep latitudinal Sea Surface Temperature (SST) gradient, which reflects the regional influence of the Antarctic Circumpolar Current (ACC). Here, we present a new precipitation proxy record from the Chilean fjords at 45°S, and we compare our results with regional SST records to assess the ocean-continent interactions in Chilean Patagonia during the last 2 millennia. Our precipitation record is based on a high-resolution inorganic geochemical analysis of a 2m long sediment core from Quitralco fjord (45°S), using ICP-AES and XRF core scanning techniques. Since our coring site is located in front of a small river that drains the Patagonian Andes (Rio Pelu), it is particularly sensitive to changes in river discharge, and therefore precipitation. Our data demonstrates a significant increase in Fe/Al and Ti/Al between ~700 and ~50 cal. yr BP, which corresponds to a decrease in mean sediment grain-size from ~30 to ~20 μm. This shift is interpreted as a decrease in the energy of river sediment discharge, which most likely reflects a decrease in seasonal floods. The comparison of our precipitation record with published SST records from the region demonstrates that lower (higher) SSTs are systematically coeval with a decrease (increase) in seasonal floods in the Patagonian Andes. The decrease in seasonal floods at 700-50 cal. yr. BP corresponds to a SST decrease of ~1°C. We argue that the synchronicity of changes in precipitation and SST during the last two millennia likely reflects concomitant migration of the zonal systems, i.e., the WWB and the ACC.

Evolution of the macromolecular structure of biopolymers during pyrolysis: A C-XANES study

Identifying traces of life in ancient rocks can be challenging as they may have experienced significant structural and chemical transformations during diagenesis and metamorphism. Natural organic matter may indeed evolve during fossilization processes and hence lose all chemical and textural information relative to its original precursor. Recently, advanced spectromicroscopy techniques have allowed evidencing that morphological, textural and chemical bio-signatures might be preserved in some contexts despite intense metamorphism [1,2], notably depending on the chemical nature of the organic precursor [3]. Synchrotron-based techniques are thus increasingly used to *in situ* characterize natural kerogens and study fossilization processes although standard data sets are still only scarcely available [4,5]. Therefore, information obtained from these recently developed techniques remains barely exploited.

Here, we have investigated the evolution of reference organic biocompounds more or less resistant to biodegradation (e.g. sporopollenin, lignin and cellulose) heat-treated at different temperatures up to 1000°C at ambient pressure using X-ray absorption near edge structure (XANES) spectroscopy at the Carbon K-edge. In addition to evidencing the differential evolutions of these precursors during carbonification and early steps of graphitization, quantitative information extracted from our results provide a calibration for the spectroscopic evolution of reference biocompounds with increasing temperatures. By providing new insights into the thermal evolution of the macromolecular structure of reference biopolymers, the present results constitute a new step towards better constraining the fate of natural organic matter during burial.

Active microbial communities at the base of glaciers and ice sheets provide a mechanism for (a) subglacial organic carbon metabolism on various timescales, and (b) the present-day export of labile carbon to downstream ecosystems. Prior studies point towards the importance of both these processes in modulating carbon cycling. Here we describe for the first time the bulk-level carbon composition of meltwater draining the GrIS. We investigate the dissolved (DOC) and particulate organic carbon (POC) concentration, age, and lability in the subglacial discharge throughout the summer. The early season discharge contains higher organic carbon concentrations, and exports younger DOC (~ 2 kyr ^{14}C age) compared to the peak season discharge, where the concentrations are lower and the age is older (~ 4 kyr ^{14}C age). Conversely, the age of the exported POC (~ 2.5 kyr ^{14}C age) does not change throughout the meltseason. We hypothesize that overwinter subglacial microbial processes shift the type of DOC exported, and use the dissolved ion loads in the discharge to explore this idea. These results illustrate (1) that chemically-distinct organic carbon pools are accessed by seasonally-evolving hydrology and (2) that the GrIS may deliver labile, old carbon to the North Atlantic Ocean.

Sr-Nd isotopic studies of Narcondam Volcanics, India: Constraints on Andaman-Indonesian arc magmatism

RAJNEESH BHUTANI*[1], R.S. SMITHA[1], JYOTIRANJAN S. RAY[2], HETU C. SHETH[3], S. BALAKRISHNAN[1], ALOK KUMAR[2] AND NEERAJ AWASTHI[2]

[2]Geosciences Division, Physical Research Laboratory, Navrangpura, Ahmedabad-380009, India
[3]Department of Earth Sciences, Indian Institute of Technology Bombay, Powai, Mumbai-400076, India

Narcondam island, part of Andaman group of islands of India is a dormant volcano of Andaman-Indonesia island arc related to oblique subduction of Indian plate beneath the SE Asian plate.

Unlike the active Barren Island volcano of Andaman arc, which erupts basaltic to basaltic-andesite lavas, Narcondam samples, studied during the present study, range from basaltic-andesites to dacites with majority of them plotting in andesitic field of Total Alkali Silica (TAS) classification diagram.

Origin of andesitic lavas has been explained variably, ranging from models of hydrous melting of mantle-wedge to models of mixing of basaltic magma with rhyolitic magma at shallower depths [1].

Narcondam andesites show mineral textures, such as resorbed rims of plagioclase phenocrysts, Na rich layers sandwitched between Ca rich layers of plagioclase crystals and at least two generations of phenocrysts, indicating compositional changes in magma not related to fractional crystallization. Presence of rhyolitic glass inclusions, and olivine and quartz crystals together are reported from Narcondam samples in an earlier study [2]. It is therefore suggested that andesitic lavas are not primary melt but probably resulted from mixing of basaltic and rhyolitic magmas.

Sr and Nd isotope ratios are used to quantify the mixing and it appears that andesites of Narcondam and also other andesitic volcanoes of Sunda arc may have resulted from variable but small inputs of sediments (<5%) to the mixed magma which has 70 to 80% contribution from Barren Island type basaltic melt and 15-20% of rhyolitic melt similar to that erupted in Sunda arc elsewhere [3].

U-Pb cassiterite dating by LA-ICPMS and a precise mineralization age for the superlarge Furong tin deposit, Hunan Province, Southern China

XIANWU BI[1], HU RUIZHONG[1], LI HUIMIN[2], DONG SHAOHUA[1,3], CHEN YOUWEI[1] AND PENG JIANTANG[1]

[1]State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China (bixianwu@vip.gyig.ac.cn)

[2]Tianjin Institute of Geology and Mineral Resources, Tianjin, 300170, China

[3]Graduate School of Chinese Academy of Sciences, Beijing 100039, P.R. China

Cassiterite is an important tin mineral in the W-Sn deposit. Furthermore, it is also a common accessory in a variety of deposits, and the successful use of cassiterite as a geochronometer would resolve many genetic questions. The direct dating of cassiterite with U–Pb and Pb–Pb methods was initially attempted by Gulson and Jones. In recent years, the U–Pb isotope data on cassiterite from tin deposits using TIMS were reported and the potential of cassiterite as a geochronometer for directly dating hydrothermal mineralization was evaluated. This study aims to directly date the U-Pb age on cassiterites from the Furong tin deposit using LA-MC-ICPMS techniques, to validate the utilization of cassiterites for precise dating of ore formation.

The Furong deposit is a newly-discovered superlarge tin deposit in the central Nanling district, South China. In this study, cassiterite from the Furong tin deposit has been successfully dated by LA-MC-ICPMS and it is the first report of the U–Pb isotope dates on cassiterite using LA-MC-ICPMS. In situ analysis of two cassiterites (WCP2-1 and WCP2-2), yield U–Pb isochron age of 155.8±1.6Ma (MSWD=20). This U–Pb age from the cassiterites in skarn type ores which is the main type ore in Furong tin deposit, yielded indistinguishable mineralization ages with U–Pb isochron age of 160.0±5.5Ma (MSWD=1.74) by TIMS and published Ar–Ar dating on hydrothermal muscovite, hornblende and phlogopite from greisen type tin ore and skarn-type ores, reveal the main stage age of Furong tin mineralization was around 155Ma. The dates obtained in this study indicated that the cassiterites with high content U are the potential directly dating minerals.

[3]Atmospheric Chemistry and Dynamics Branch, NASA Goddard Space Flight Center, Greenbelt, Maryland, USA

The capability to simulate nitrate and ammonium aerosols has been developed in NASA GMI model by implementing a thermodynamic equilibrium model that treats gas and aerosol multiphase chemical equilibrium reactions in a SO_4-NO_3-NH_4-H_2O system. Nitrate and ammonium can influence air quality and ecosystems substantially, and their importance will be increasing in the future due to the predicted increase of nitrogen emissions. An immediate outcome from the work is the possibility to improve tropospheric O_3 simulation. Currently, the model treats HNO_3 solely as a gas phase tracer. This semi-volatile species now partitions between gas and aerosol phases, and the tracer in each phase is subject to different chemical and physical processes. A preliminary analysis has been conducted by comparing results simulated with and without new nitrate package and by comparing model results with the ground station observations from CASTNET and EMEP.

High resolution minor and trace element study on mussel shells from coastal region of Tatoosh Island, Washington, USA

NANXI BIAN[1]*, PAMELA MARTIN[1], CATHERINE PFISTER[2], AND ALBERT COLMAN[1]

[1]Department of Geophysical Sciences, University of Chicago, Chicago, IL, USA (*correspondence: nanxibian@uchicago.edu

[2]Department of Ecology and Evolution, University of Chicago, Chicago, IL, USA

The successively deposited calcium carbonate layers and annual growth bands in mollusk shells could offer high resolution archives of the environmental conditions the mollusk has experienced during its life. Previous studies have shown that the elemental composition of mollusk shells is related to environmental parameters[1, 2, 3].

Here, we present high resolution data of a suite of minor/trace element/Ca ratios collected from shells of mussel species, *Mytilus californianus*, using laser ablation sector field inductively coupled plasma mass spectrometry (LA-ICP-MS) as well as an ICP-MS solution based method. The mussel shells were ~10 years of age and were collected live in 2009 and 2010 from Tatoosh Island, Washington, USA, where instrumental data of various enviromental parameters over the last decade are available. We also analyzed several shells present in middens on Tatoosh Island. Radio-carbon dating data of these mussels show they lived ~1000 years ago; shell banding suggests individual ages of ~12 years. Age models were constructed using annual banding, a growth model and high resolution stable isotope composition ($\delta^{18}O$) of the shell.

Our preliminary results show that several of a suite of trace elements exhibit promising correlation with nutrient concentration and oxygen level in the sea water, and could serve as proxies for coastal geochemical cycling and a means to probe rapid changes documented in seawater chemistry at this site[4]. Data for a suite of element/Ca ratios from different transects on the same shell generally show good reproducibility. Element/Ca data from midden shells and modern shells show different ranges of variation suggesting that there have been significant differences in geochemical cycling in this coastal environment over the last 1000 years.

[3]Graduate University of the Chinese Academy of Sciences, Beijing 100049, China

Cold hydrocarbon seepage is a frequently observed phenomenon in marine settings worldwide. Authigenic carbonates from hydrocarbon seeps are unique archives of past seepage and associated environmental parameters. Carbonate rocks were collected from fluid and gas expulsion sites of Green Canyon lease block 140 (GC 140) at 260 m water depth on the Gulf of Mexico continental slope during Johnson-Sea-Link dive 2591 in 1989. The carbonate rocks occur as blocks, crusts, and nodular masses incorporated in carbonate breccias. Most carbonates are composed of aragonite and high-Mg calcite as determined from X-ray diffraction. However, one sample was found to have compositoon of nearly 100% dolomite. Petrographically, high Mg-calcite peloidal matrix and acicular to botryoidal aragonitic void-filling cements are the most frequent associations. The carbon isotopic compositions of the carbonates ($\delta^{13}C_{Car}$) range from –36.5‰ to +4.9‰ V-PDB, indicating complex carbon sources that include ^{13}C-depleted methane, seawater CO_2, and ^{13}C-enriched residual CO_2 from methanogenesis. A similarly large variability in $\delta^{18}O_{Car}$ values (+1.6‰ to +5.5‰ V-PDB) demonstrates the geochemical complexity of the studied area. The considerable range of mineralogical and isotopic variations of the studied cold seep carbonate suggests that local controls on the fluid and gas flux, types of the local hydrocarbon reservoir may play an important role in determining carbonate mineralogy and isotope geochemistry. In addtion, the ^{14}C ages of bivalve shells incorporated in the carbonate matrix will be used to determine the timing and duration of fluid seepage in order to provide preliminary insight into probable factors governing seepage processes at the studied site.

Pb-Hf-Nd isotopic decoupling in peridotite xenoliths from Mega (Ethiopia): Insights into the multistage evolution of the East African Lithosphere

G. BIANCHINI[1,2]*, J.G. BRYCE [3], J. BLICHERT-TOFT[4], L. BECCALUVA[1] AND C. NATALI[1],

[1]Università di Ferrara, Ferrara, Italy (bncglc@unife.it)

[4]Ecole Normale Supérieure de Lyon, Lyon, France

New Hf and Pb isotopic data from clinopyroxenes from East African Rift (EAR) mantle xenoliths (Mega, Sidamo region, southern Ethiopia), coupled with recently published Nd isotope and trace element compositions, provide compelling evidence for multiple episodes of mantle depletion and metasomatic enrichment. Radiogenic values (ε_{Nd} up to +22.5 and ε_{Hf} up to +1076) suggest mantle domains currently located beneath the Main Ethiopian Rift suffered extreme melting regimes, possibly in the presence of residual (majorite?) garnet, effectively fractionating Sm/Nd, Lu/Hf and Nd-Hf systematics. Positively correlating Lu/Hf and $^{176}Hf/^{177}Hf$ provide an apparent ingrowth of 1.96 Ga, close to the CHUR model age of the most radiogenic sample (1.95 Ga, consistent with other local records of Proterozoic melting events). Pb isotopes are clearly decoupled from the Nd-Hf systematics, displaying $^{206}Pb/^{204}Pb$ up to 20.1, $^{207}Pb/^{204}Pb$ up to 15.70, and $^{208}Pb/^{204}Pb$ up to 39.8. These data suggest vigorous convection cells, possibly triggered as a far field dynamic consequence of the Afar plume impingement, preferentially occurred beneath this site, where important lithospheric discontinuities exist between the Archean/Early Proterozoic Tanzanian craton and the Late Proterozoic Panafrican mobile belt. Such deep mantle dynamics may contribute to stabilizing distinct EM1 and HIMU metasomatic components in the EAR lithospheric mantle.

Early Archean crust of the Ukrainian Shield – Evidence from detrital zircons

E. BIBIKOVA, L. SHUMLYANSKYY, C.J. HAWKESWORTH, S. CLAESSON, C. STOREY, B. DHUIME AND A. FEDOTOVA

Data on continental sediments remain the basis for many models for the generation and evolution of the crust [1]. Detrital zircons from old metasedimentary rocks can provide valuable contributions to the knowledge of the Early Earth crust. We have studied geochronologically (U-Pb, zircons, Sm-Nd) and geochemically (Hf-isotopes and REE) detrital zircons from two greenstone structures in the Azov domain, Ukrainian Shield. U-Pb isotopes of zircons from five samples of mica schists from the Soroki and Fedorof greenstone belts were analysed on ion microprobe NORDSIM at the Swedish Museum of Natural History, focusing mainly on cores identified by CL. The data include a group of ages in the range 3.5-3.6 Ga, and some zircon cores older than 3.7 Ga.

The REE patterns of metasediments and zircons are similar to those of TTG Archaean rocks [1]. Lu-Hf isotopic system was studied by La ICP-MS at University of Bristol [2] at the same spots inside zircons where the most concordant ages were obtained. In our interpretation of Hf isotope data, we follow the model proposed by [3]. The majority of granites have isotope signatures that preclude direct mantle genesis, rather we constrain the $^{176}Lu/^{177}Hf$ ratio of the crustal material that was initially extracted from the mantle to be 0.22-0.25, typical for mafic magmas. In such interpretation, the age of this crust will be about 4.2 Ga. The model age of zircons in metasediments derived from the TTG rocks with low ≤ 0.01 $^{176}Lu/^{177}Hf$ ratio, is 3.8-3.6 Ga.

Sm-Nd model ages of 3.3-3.4 Ga and εNd (T) for the analysed samples are in a good agreement with the zircon data. Our new results indicate that Eo and Paleoarchean crust in the Azov domain was widely distributed.

Geological carbon storage: Geochemical processes

MIKE BICKLE

Dept. Earth Sciences, University of Cambridge, Downing St., Cambridge CB2 3EQ, UK (mb72@esc.cam.ac.uk)

Modelling the complex physical and chemical processes that govern retention of CO_2 in geological reservoirs over long time scales present some interesting challenges, although not perhaps as challenging as coping with the consequences of unabated CO_2 emissions.

CO_2 may be held in geological formations by structural, capillary, dissolution and mineralisation trapping. CO_2 or CO_2-charged brines may corrode reservoir minerals and caprocks. Remote imaging of CO_2 reservoirs, such as at Sleipner [1,2], captures the complex physical behaviour of CO_2 but is unable to completely explain this behaviour or resolve all potential trapping and escape mechanisms. Direct sampling of field small-scale injection experiments offers the best chance to do this [3]. Estimates of capillary trapping can be made by analysis of isotope spikes [4]. Dissolution trapping will be enhanced by the complexities of the flow processes and sampling of brines will be essential to monitor this. Prediction of the reaction rates between CO_2-charged brines and reservoir minerals or caprocks is even more difficult. Observations on geological analogue sites have recovered the rates of the sluggish reactions between silicate minerals and brines [5]. Curiously the much more rapid rates of dissolution of carbonate, evaporite and oxy-hydroxide minerals in field conditions seen in small scale injection experiments [6] are poorly known. These reactions may also release contaminants.

Modelling of fluid-mineral interactions currently uses averaged fluid properties in pseudo- 1 dimensional models [e.g. 7]. It is not clear if this is an appropriate way to approximate the complex flow paths. What is needed is a method for inverting geochemical data to constrain the key attributes of flow heterogeneities.

A bond-valence view of interfacial structure and reactivity

B. R. BICKMORE*

Geological Sciences, Brigham Young University, Provo, UT 84602, USA
(*correspondence: barry_bickmore@byu.edu)

Studies of interfacial structures will be most useful in cases where we can relate structure to reactivity. However, a quantitative structure-activity relationship (QSAR) requires that structural information be couched in terms that are easily translatable into energy. The bond-valence model (BVM) [1] has proven fairly effective for this purpose, and it has been used to formulate a number of QSARs, including the MUSIC model for predicting surface functional group acidity on oxide surfaces [2]. Such BVM-based QSARs have had varying success, but they are typically applicable under a fairly restricted set of conditions [3].

It is not readily apparent when QSARs like MUSIC should work or fail, however, because nobody has yet worked out a full BVM-based accounting of the relationship between molecular structure and energy. E.g., the most commonly used aspect of the BVM involves summing bond valences calculated from the lengths of bonds to counter-ions surrounding a central ion. The valence sum is then compared to an ideal value, and the difference is taken to be indicative of some aspect of structural energy. But this does not account for directionality in bonding or interactions between co-ions.

We are currently using some lesser-known aspects of the BVM, including vectorial bond valence (VBV) sums [4] and "effective valence" between co-ions [1], combined with some concepts borrowed from the Valence Shell Electron Pair Repulsion (VSEPR) model of molecular geometry, to create a more complete BVM-based model of structure-energy relationships. By analyzing oxide crystal structures and *ab initio* molecular dynamics simulations of aqueous solutions, we have shown that ideal VBV sums have a fairly straightforward relationship with bond character and coordination number. VBV sums also exhibit a strong relationship with deviations from ideal valence sums.

In addition, we will be applying such analyses to simulated interfacial structures to see how our indicators of "structural energy" vary with distance from the interface, salinity, etc. Such information could then be related to double layer theory.

Mineral and whole-rock chemical properties of pyroxenites in the peridotites of the Kop Ultramafics, NE Turkey

Ö. BILICI * AND H. KOLAYLI

Department of Geological Engineering, Karadeniz Technical University, 61080-Trabzon, Turkey
(*correspondence: ocubil@hotmail.com)

The Kop ultramafic unit in NE Turkey is one of the largest Alpine type peridotites. Petrographic and field studies in the ultramafic unit indicate that there are widespread two main rock types as harzburgites and dunites. In addition to these, pyroxenites are also locally observed and associated with peridotites.

Pyroxenites crop out as veins/dykes in varying size within peridotites [1]. Orthopyroxenites (>500 m^2) cover larger area than clinopyroxenites (between 10 to 100 m^2) and websterites (<1 m^2). Clinopyroxenites and orthopyroxenites exhibit dyke-like body in dunites and harzburgite, respectively. Websterites are only observed as veins in harzburgitic zone. Orthopyroxenites show coarse grained texture whereas clinopyroxenite and websterites have porphyritic texture. Clinopyroxenites and websterites contain variable amounts of olivine, spinel and magnetite.

Both whole-rock and pyroxene mineral chemistry data of the pyroxenites are characterized by low contents of Al, Na, K, Ta, Zr, Hf, Ti and REE, high Mg-numbers and LILE enrichment relative to less incompatible elements. The mineral and petrochemical data suggest that clinopyroxenites and websterites from the pyroxenites have not been directly crystallized from primary magma(s) derived by partial melting of depleted mantle. Whole-rock and pyroxene compositions of orthopyroxenites are similar to those of ultra-depleted mantle-derived pyroxenites, whereas cliopyroxenites and websterites have very close chemical features to those of pyroxenites in suprasubduction zone mantle.

[3]ESS, UCLA, Los Angeles, Ca;
[4]GPS, Caltech, Pasadena, Ca;
[5]IGEM-RAS, Moscow, Russia;
[6]Geol & Geophys., Yale Univ., New Haven, CT

Paleoproterozoic amphibolites and gneisses - that are remarkably depleted in ^{18}O are found in the Belomorian Belt in Karelia, Russia [1,2]. We mapped their extent to exceed 200x20km and affect metamorphosed mafic intrusions (est. ~2.4 Ga intrusion age) and host 2.6Ga gneisses found in this 1.9 Ga collisional belt. $\delta^{18}O$ values of –7 to –27.3‰ characterize minerals and rocks from several of these localities; some of these rocks are also remarkably depleted with respect to δD (-212 to –235‰ amphiboles). All have typical terrestrial $\Delta^{17}O$ values of 0‰. Based on previous paleogeographic reconstructions, we attribute the origin of these exotic O and H isotope compositions to the hydrothermal alteration associated with subglacial rifting during the Paleoproterozoic panglobal ice ages, but discuss additional possibilities: extremely low-$\delta^{18}O$ Paleo- proterozoic sea water, and excursion of Karelia to polar latitudes. Given that at high-T hydrothermal exchange equilibrium $\Delta^{18}O$(rock-water) is close to zero, but water-rock interaction is rarely 100% efficient, the lowest measured $\delta^{18}O$ value in silicates likely gives the upper $\delta^{18}O$ bound for the altering meteoric fluid; we thus continues our quest to find the lowest $\delta^{18}O$ material such as a mineral assemblage or a tiny zircon fragment that would provide record of $\delta^{18}O_{water}$.

Zircons in these rocks have survived metamorphism and record normal $\delta^{18}O$ cores and extremely low $\delta^{18}O$ rims (down to $\delta^{18}O_{SMOW}$ = 27.3 ‰). The rims are in oxygen isotope exchange equilibrium with host metamorphic assemblages at each locality. We present data from the ongoing investigation of these zircons using large radius ion microprobes for *in situ* U-Pb ages and $\delta^{18}O$ values, ion microprobe profiling using a ~1 μm gallium beam, and NanoSIMS isotope mapping of the zircon with 23 to 34‰ and sharp (~3-5 μm) isotope gradients.

High-precision Mg isotope measurements of inner solar system materials by HR-MC-ICPMS

M. BIZZARRO*, C. PATON, M. SCHILLER, K. LARSEN AND D. ULFBECK

Center for Star and Planet Formation, Natural History Museum, University of Copenhagen, Øster Voldgade 5–7, 1350, Copenhagen, Denmark (*correspondence: bizzarro@snm.ku.dk)

Magnesium has three naturally occurring isotopes - ^{24}Mg, ^{25}Mg and ^{26}Mg - with relative abundances of 79%, 10% and 11%, respectively. Variations in the isotopic composition of Mg can potentially occur in solar system materials through a number of processes including (*1*) stellar nucleosynthesis, (*2*) the former presence and decay of the ^{26}Al nuclide (half-life ~0.73 Myr) and (*3*) mass-dependent isotopic fractionation during high temperature processes such as partial evaporation and condensation as well as from low-temperature fluid/ rock interactions. Thus, studying the potential variability of ^{26}Mg/^{24}Mg and ^{25}Mg/^{24}Mg ratios in solar system solids can be used to infer genetic relationships between early solar system reservoirs and terrestrial planets.

We have developed novel methods for the chemical purification of Mg from silicate rocks, and high-precision analysis of Mg-isotopes by high-resolution multiple collector inductively coupled plasma source mass spectrometry (HR-MC-ICPMS) [1]. Based on the repeated analyses of international rock standards of variable matrices, we show that it is possible to routinely analyze the Mg-isotope composition of silicate materials with an external reproducibility of 2.5 and 20 ppm for the μ^{26}Mg* and μ^{25}Mg values, respectively (μ notation is the per 10^6 deviation from the DSM-3 reference material).

Using these techniques, we have analyzed to unprecedented precision the Mg-isotope composition of a strategically-selected suite of inner solar system materials, including calcium-aluminium-rich inclusions and amoeboid olivine aggregates from the reduced Efremovka CV chondrite as well as bulk chondrite meteorites and meteorite samples originating from differentiated asteroids. These new data provide important constraints regarding the relative and absolute Mg-isotope composition of bulk inner solar system planetary reservoirs, the distribution of ^{26}Al in the solar protoplanetary disk, and the mechanism and timescale of asteroidal differentiation in the young solar system.

Lithium is a mobile element, with a high diffusion coefficient, and a large difference in solution diffusivities for the two stable isotopes, ^{6}Li and ^{7}Li [1], making it an ideal element for studying isotopic fractionation during electro-deposition processes. Rates of mass-transport and deposition can be dialed-in using experimental electrochemical techniques to study the competing isotopic fractionation effects of reduction/precipitation and diffusion. Previous experiments measured the equilibrium fractionation between Li metal and Li^+ in a propylene carbonate (PC) solvent [2], and large fractionations (up to -30 per-mil in ^{7}Li/^{6}Li) were observed between electrodeposited Li and stock solutions [3]. The magnitude of fractionation was largest closest to the equilibrium reduction potential, and decreased as the thermodynamic driving force (and thus deposition rate) was increased (Fig. 1) [3]. Two hypotheses for this trend are 1) mass-transport-limited supply of Li to the reactive interface resulted in an attenuated isotopic signature, and 2) the observed changing isotopic signature is an intrinsic rate-dependent kinetic effect. These competing hypotheses will be directly tested in models and experiments of temperature-depenedent isotopic fractionation during Li electrodeposition.

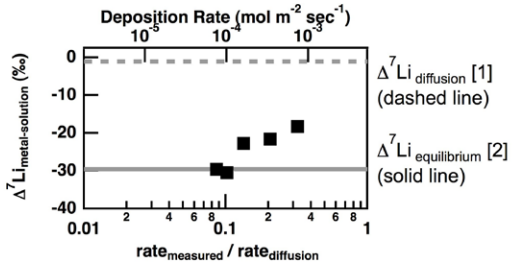

Figure 1. Lithium isotope composition of metal samples electroplated from 1M Li(PC) solutions, squares [3].

A long-term record of continental lithosphere exhumation via U-Pb thermochronology of the lower crust

TERRENCE BLACKBURN[1]*, SAMUEL BOWRING[1], TAYLOR PERRON[1], KEVIN MAHAN[2] AND FRANCIS DUDAS[1]

[1]EAPS, MIT, Cambridge, MA, USA (*correspondance: terrence@mit.edu)
[2]Dept of Geol. Sci., Univ. of CU Boulder, CO, USA

Exposures of cratonic lithosphere (shields) are generally characterized by low long-term erosion and sediment accumulation. Seismic tomography and mantle xenolith studies of cratons reveal keels of seismically fast and relatively buoyant and viscous mantle; physical properties intimately linked with their long-term stability and topographic expression. Missing from these observations is a long-term record (>1000 Ma) of continental exhumation/burial that can be used to quantity the forces operating within these ancient regions. The exhumation or burial of the continent surface has a direct effect on the rate of heat loss within the lithosphere. By reconstructing the thermal history for the lithosphere using thermochronologic techniques, the magnitude of burial and exhumation through time can be estimated. Here we demonstrate how a long-term record of lithosphere exhumation or burial can be reconstructed using U-Pb thermochronology on lower crustal xenoliths. The U-Pb system is sensitive to cooling at temperatures of ~400-650 °C, corresponding to lower crustal depths of 20-50 km. Integration of this thermochronologic record with thermal models for the stable lithosphere allows one to reconstruct the magnitude of surface exhumation/burial during long-term cooling of the continents. In Montana, USA, lower crustal samples record extreme slow cooling consistent with low exhumation rates (<0.01 km/Ma) over time scales billions of years. Constraining the magnitude and variation of lithosphere exhumation over a billion years or more provides the opportunity to understand the degree of thermal and mechanical coupling between continental lithosphere and the underlying convecting mantle in the deep geologic past.

Are noble gases in the sediment pore water of Lake Van promising proxies for paleoclimate conditions?

R. BLÄTTLER[1], Y. TOMONAGA[1]*, M.S. BRENNWALD[1], O. KWIECIEN[1], R. KIPFER[1,2], AND THE PALEOVAN SCIENTIFIC PARTY

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, CH-8600 Dübendorf, Switzerland (*correspondence: tomonaga@eawag.ch)
[2]Institute of Geochemistry and Petrology, Swiss Federal Institute of Technology (ETH), CH-8092 Zurich, Switzerland

As noble gases are chemically inert, they are ideal tracers to study physical processes in water bodies. The noble-gas partitioning between the atmosphere and the respective water body occurs according to Henry's Law, which is mainly controlled by the temperature and salinity of the exchanging water phase. Therefore, atmospheric noble gases (He, Ne, Ar, Kr, and Xe) have been successfully used in the past to reconstruct the physical conditions in aquatic systems such as groundwater, lakes, and oceans.

Several decades ago, noble gases in the pore water of unconsolidated sediments have been proposed as proxies for the reconstruction of environmental conditions in lakes and oceans. During sedimentation, a certain volume of the water overlying the sediment/water interface is trapped in the pore space of the growing sediment column. If the noble-gas diffusion within the pore water is sufficiently attenuated, the sediment column can conserve noble-gas concentrations over long time scales. However, only recently analytical methods allowing robust and reliable determination of noble-gas concentrations in the sediment pore water have been developed and improved. In Lake Issyk-Kul, a large closed-basin lake in central Asia, atmospheric noble gases in sediment pore water have been successfully applied for the first time as proxies for paleoclimate conditions.

In this study we present concentration profiles measured in the sediment column of Lake Van (Turkey). Lake Van is one of the largest terminal lakes and the largest soda lake on Earth. The lake is known to react very sensitively to changes in the local climate conditions.

We interpret the measured noble-gas concentrations in terms of possible changes in the physical conditions of the water body of the lake (i.e., changes in temperature and salinity). In particular we discuss the potential of noble gases as proxies for paleoclimate reconstruction considering the ongoing ICDP deep drilling project PALEOVAN (http://www.icdp-online.org).

First-principles simulation of arsenate adsorption on the (1 $\bar{1}$2) surface of hematite

M. BLANCHARD*, G. MORIN, M. LAZZERI, E. BALAN AND F. MAURI

MPMC, Univ. Paris VI, CNRS, IRD, Univ. Paris VII, IPGP, 4 Place Jussieu, 75252 Paris Cedex 05, France (*correspondence: marc.blanchard@impmc.upmc.fr, guillaume.morin@impmc.upmc.fr, michele.lazzeri@impmc.upmc.fr, etienne.balan@impmc.upmc.fr, francesco.mauri@impmc.upmc.fr)

Recent experimental studies [1, 2] revealed an unprecedented bimodal distribution of arsenate at the hematite (1 $\bar{1}$2) surface, with a simultaneous adsorption of inner-sphere and outer-sphere complexes. In the present study, first-principles calculations based on density functional theory were performed to make a detailed analysis of the structural and electronic properties of these inner-sphere and outer-sphere adsorption complexes on two hydroxylated terminations of the hematite (1 $\bar{1}$2) surface. For bidentate corner-sharing complexes, the most-stable adsorption configurations display interatomic distances in excellent agreement with EXAFS-derived data (i.e. As-Fe distances of ~3.3 Å). Our calculations also suggest that edge-sharing bidentate complexes can also form on clean (1 $\bar{1}$2) hematite surfaces and do not necessarily need step edges. These edge-sharing complexes would display two As-Fe distances at about 2.85 and 3.45 Å, instead of the unique short As-Fe contribution that is usually considered. For outer-sphere complexes, the most favorable adsorption configurations indicate the stabilization of the arsenate molecule by strong hydrogen bonds as well as the involvement of electrostatic forces. It is therefore essential to include these outer-sphere complexes in the thermodynamic models used to understand the arsenic fate in the environment.

Response of vegetation and erosion dynamics to changes in precipitation in the Nile River drainage basin during the African Humid Period

CECILE L. BLANCHET[12], JANNE LORENZEN[3], RIK TJALLINGII[2], STEFAN SCHOUTEN[2] AND MARTIN FRANK[1]

[1]IFM-GEOMAR at the University of Kiel, Whischhofstrasse 1-3, 24148 Kiel, Germany
[2]NIOZ Royal Netherlands Institute for Sea Research, Landsdiep 4, 1797 SZ 't Horntje, The Netherlands
[3]University of Kiel, Ludewig-Meyn-Strasse 14, 24118 Kiel

During the mid-Holocene, the gradual decrease in summer insolation induced a decrease in monsoon strength and subsequent aridification of northern Africa. However, the timing of environmental and climatic responses to this slow orbital forcing is still being debated, with studies reporting either a gradual or an abrupt termination of the African Humid Period (AHP).

Here we use 6 m-long sediment core P362/2-33 that was retrieved at 700 m water-depth on the Nile deep-sea fan. Detailed ^{14}C dating shows that the core covers the last 9,500 years, with laminated sediments being deposited at very high rates (up to 600 cm/ka) during the AHP. These sediments allow to investigate the linkages and feedbacks between climate, vegetation and erosion dynamics at millennial to seasonal resolution. The variations in sediment and fresh-water input, as well as sediment provenance and vegetation changes are monitored using a combination of inorganic and organic geochemical proxies (major and trace elements ratios, $\delta^{18}O$ and $\delta^{13}C$ of planktonic foraminifera, radiogenic isotope compositions of sediments, foraminifera and seawater-derived ferromanganese coatings, and abundance and isotope composition of specific biomarker lipids). Massive amounts of fresh water and sediments were delivered by the Nile River to the deep-sea fan between 9.5 and 8 ka, as indicated by high sedimentation rates, high titanium/calcium ratios and sea-water εNd values similar to the Nile River. This time interval was also characterised by the dominance of C4 grasses and soil development, as indicated by heavier $\delta^{13}C$ values for higher plants n-alkanes and elevated concentrations in soil biomarker. A first rapid decrease in fresh-water and sediment delivery was recorded around 8.5 ka in sea-water εNd and sedimentation rate followed by a gradual decrease between 8 and 4 ka identified in all proxies. The transition from C4- to C3-dominated environment occurred between 8 and 6 ka, and might reflect the aridification of the Sahara, with n-alkanes mainly originating from southern sources after 6 ka. Sediment source tracing by mean of their radiogenic isotope composition is being processed.

A new calibration site for cosmogenic ^{3}He production rate in the Central Altiplano

PIERRE-HENRI BLARD AND JÉRÔME LAVÉ

CRPG-CNRS, Université de Lorraine, Vandoeuvre-lès-Nancy, France. (blard@crpg.cnrs-nancy.fr)

It is critical to refine the accuracy and precision of the *in situ* cosmogenic dating tool, especially for establishing reliable glacial chronologies that can be compared to other paleoclimatic records. Indeed, the fiability of this chronometer is highly dependent on the accuracy of the spatial and time dependent correcting factors. Potential bias are particulary important for the high altitude tropical area. There is thus a crucial need of well-dated calibration sites allowing to establish robust regional production rates.

We present here a new calibration site for cosmogenic ^{3}He that is located in the tropical Altiplano (20°S, 68°W), on the southern flank of the Tunupa volcano, in the vicinity of the Salar de Uyuni at ~3800 m. The calibration site consists in a fluvio-glacial outwash that has the remarkable characteristic to be stratigraphically bracketed by two successive lacustrine shorelines. These shorelines are well-dated by ^{14}C and U-series dating [1,2], allowing to define an absolute age of 15.1±0.3 ka for the outwash deposition. We sampled 10 andesitic boulders on this site and analyzed the cosmogenic ^{3}He contents in the pyroxenes phenocrysts. The measured ^{3}He concentrations are characterized by a very low scatter: 9 samples agree within analytical uncertainties, suggesting that pre-deposition or post-deposition processes dit not produce any detectable bias. If the nucleogenic contribution from ^{6}Li capture is lower than 2% (as measured in similar samples on the same volcano [3]), these clustered data will allow defining a new reference value for the local production rates of ^{3}He with a precision better than 5% (1σ).

Changes in global weathering indicated by the Ca-isotope record of Oceanic Anoxic Events 1a and 2

C.L. BLÄTTLER[1]*, H.C. JENKYNS[1], L.M. REYNARD[2] AND G.M. HENDERSON[1]

[1]Department of Earth Sciences, University of Oxford, South Parks Road, Oxford OX1 3AN, U.K. (*correspondence: Clara.Blattler@earth.ox.ac.uk)

[2]Research Laboratory for Archaeology and the History of Art, University of Oxford, South Parks Road, Oxford OX1 3QY, U.K.

Oceanic Anoxic Events (OAEs) are huge perturbations to climate that offer an opportunity to observe the response of the Earth system to large and abrupt changes in the carbon cycle. Calcium-isotope ratios ($\delta^{44/42}$Ca) were measured by MC-ICPMS in carbonate-rich sedimentary sections deposited during OAE1a (Early Aptian) and OAE2 (Cenomanian–Turonian). A negative excursion in $\delta^{44/42}$Ca of ~0.20‰ is observed in two sections spanning OAE1a from Resolution Guyot (Mid-Pacific Mountains) and Coppitella (Gargano, Italy); a negative excursion of ~0.10‰ is observed in two sections spanning OAE2 from the English Chalk (at Eastbourne and South Ferriby, UK).

These Ca-isotope excursions occur at the same stratigraphic level as the C-isotope excursions that define the anoxic events, but they do not correlate with lithological changes or evidence for carbonate dissolution in the sections. Diagenetic and temperature effects on the Ca-isotope trends are discounted, leaving changes in global seawater composition as the most probable explanation for the change in $\delta^{44/42}$Ca in the carbonate records.

An oceanic box model with coupled Sr- and Ca-isotope systems indicates that a global weathering increase is likely the dominant driver of transient excursions in Ca-isotope ratios. Contributions from hydrothermal activity and carbonate dissolution are likely to be too small and short-lived to generate the observed changes in the oceanic Ca-isotope composition. A modelled increase in weathering flux, on the order of three times the modern flux, combined with increased hydrothermal activity due to formation of the Ontong-Java Plateau (OAE1a) and Caribbean Plateau (OAE2), can produce trends in both Ca- and Sr-isotope ratios that match the signals recorded in the carbonate sections. These data are the first major-element records of a weathering response to Oceanic Anoxic Events.

Aerobic methanotrophs drive the formation of a seasonal anoxic benthic nepheloid layer in a monomictic lake

H.J.R. BLEES[1]*, H. NIEMANN[1], C.B. WENK[1], J. ZOPFI[2], C.J. SCHUBERT[3], M.L. VERONESI[4] AND M.F. LEHMANN[1]

[1]Institute of Environmental Geosciences, University of Basel, Switzerland (*correspondence: jan.blees@unibas.ch)
[2]Laboratory of Microbiology, Institute of Biology, University of Neuchâtel, Switzerland
[3]Swiss Federal Institute of Aquatic Science and Technology (EAWAG), Kastanienbaum, Switzerland
[4]Institute of Earth Sciences, University of Applied Sciences of Southern Switzerland, Canobbio-Lugano, Switzerland

Monomictic lakes experience thermal stratification throughout most of the warmer seasons. Often this leads to seasonal bottom water anoxia, particularly if monomixis is paired with eutrophic conditions. The southern extension of Lake Lugano is a warm, monomictic basin with bottom water anoxia, and formation of a dense benthic nepheloid layer (BNL) during summer and fall. A sharp redox gradient marks the upper boundary of the BNL, which extends to up to 15m from the sediment into the water column. Previous work has revealed that the bulk organic matter in the BNL is strongly depleted in ^{13}C ($\delta^{13}C < -60‰$), indicating that the BNL in the Lake Lugano South Basin is largely composed of methanotrophic bacteria. In this study we present radio-label rate measurement and compound specific C isotope data that confirm i) high rates of aerobic methane oxidation (MOx) at the redoxcline (i.e. just above the BNL) and ii) the dominance of bacterial methanotrophic biomass in the BNL of Lake Lugano's southern basin. MOx is restricted to a narrow zone at the top of the BNL reaching maximum rates of up to 1.8 μM/day. MOx activity leads to the formation of a sharp CH_4 concentration gradient (80 μM at 92 m; 100 nM at 82 m). The C kinetic isotope effect of methane consumption is strongly suppressed at the community level (ε = -2.4‰), highlighting the near perfect methane sink at the oxycline, where > 99.9% of the CH_4 diffusing from the sediment is oxidised. Fatty acids (FAs) indicative of type I aerobic methanotrophs are depleted in ^{13}C ($\delta^{13}C$ = -65 to -80‰) and are the dominant lipids in the FA fraction. In addition, preliminary molecular analysis of the microbial community provides further evidence that the formation of the BNL is driven by aerobic methanotrophs rather than by resuspension of sediments or accumulation of organic matter from the epilimnion, as is often observed in other lakes. Prior to water column mixing, these methanotrophs greatly limit the emission of accumulated methane to the atmosphere.

Hf isotope evidence for depleted and enriched reservoirs in the Hadean

J. BLICHERT-TOFT* AND F. ALBARÈDE

Ecole Normale Supérieure, 69007 Lyon, France (*correspondence: jblicher@ens-lyon.fr)

Chase and Patchett [1] and Galer and Goldstein [2] argued for the existence of a hidden enriched reservoir in the early mantle, a perspective that has since received strong support from Hf isotope [3] and ^{142}Nd [4] evidence. The geochemistry of the earliest magmatic minerals is critical in this context. The Jack Hills zircons (JHZ) have been analyzed for Pb and Hf isotopes by several groups using either *in situ* [5-7] or solution chemistry [5,8,9] techniques. The data support the presence of normal continental crust at 4.1±0.1 Ga, with Hf model ages and inferred Lu/Hf characteristics further suggesting a 4.35 Ga protocrust formed from KREEPy upper mantle [7,9]. Whereas all studies find the same predominantly enriched signature indicating apparently massive crustal recycling and reworking during the Hadean and the Archean, only the solution chemistry studies [5,9] see evidence for a depleted reservoir in the Hadean mantle. Statistical analysis of the *in situ* data sets strongly suggests that zircons with the most radiogenic Hf were mistaken for analytical artifacts such that the high-ε_{Hf} end of the distribution became unduly trimmed. We therefore conclude that, although the JHZ protolith seems to have been largely enriched, it also contained undifferentiated and depleted components. Hf and Nd isotopes in komatiites [10] likewise suggest that the Archean and Hadean mantle comprised long-term depleted sources, identical in terms of time-integrated lithophile trace element characteristics to the Early Depleted Reservoir [11] deduced from $^{146,147}Sm$-$^{142,143}Nd$ and Lu-Hf isotope studies of modern mantle material and chondrites. The uppermost KREEPy mantle likely held enough radioactive elements and water to have outlasted the crystallization of the magma ocean for 100s of Ma. If embedded within and between magma ocean cumulates and a thin hydrous lithosphere, such material may have jump-started early plate tectonics.

Towards a resolution of the timing of Martian magmatism: Diffusion study of Hf in clinopyroxene and geochronological implications

E. BLOCH AND J. GANGULY*

Dept. of Geoscience, Univ. of Arizona, Tucson, AZ, 85721, USA (*correspondence: ganguly@email.arizona.edu)

The igneous crystallization age of the Shergottite suite of Martian meteorites has been a subject of considerable debate. While ^{147}Sm-^{143}Nd and ^{176}Lu-^{176}Hf mineral isochrons yield relatively young ages of ~150-225 Ma, ^{206}Pb-^{207}Pb ages from the same samples exceed 4.0 Ga. It has been proposed that the ^{206}Pb-^{207}Pb dates reflect the true crystallization age of the Shergottites and that the ^{147}Sm-^{143}Nd and ^{176}Lu-^{176}Hf "isochrons" represent either a mixing line with phosphate-hosted material or reflect the effect of thermal resetting at ~200 Ma [1,2]. Alternatively, it has been argued that the ^{206}Pb-^{207}Pb array is simply a mixing line arising from contamination by modern terrestrial Pb [3].

Lapen *et al*. [4] argued against the "mixing hypothesis" for younger Lu-Hf age on the basis of lack of correlation between ε(Hf) and 1/[Hf] of the samples defining Lu-Hf "isochron". In order to test the alternative hypothesis of thermal resetting via diffusion of Hf, we have determined the diffusion kinetic properties of Hf^{4+} in clinopyroxene, which is the primary host mineral of Hf. To evaluate thermal resetting due to a shock event, we assume a maximum estimate of post-shock temperature of ~1000°C. Using the average clinopyroxene radius (r) in the Shergottite RBT-04262 (0.5 mm), our diffusion data yield ~210 kyr as the time required for diffusive re-equilibration of Hf isotopes, which precludes resetting within a shock-heated and -ejected material. We have also addressed the problem of extended heating during a non-ejection impact event (or other thermal perturbation) by measuring and modeling Cr diffusion profiles in olivine in RBT-04262. Using Cr diffusion from [6], we obtain a time scale of ~1 year at the peak temperature of 1150 °C [7]. This leads to a vlue of Dt/r^2 of ~$3x10^{-5}$ for Hf in clinopryoxene, which precludes any significant diffusive resetting of Lu-Hf chronometer for the sample [8].

What defines a saline aquifer for CO_2 injection?

MADALYN S. BLONDES* AND MARGO D. CORUM

U.S. Geological Survey, 12201 Sunrise Valley Dr., Reston, VA 20192, USA (*correspondence: mblondes@usgs.gov, mcorum@usgs.gov)

The U.S. Geological Survey is currently assessing potential CO_2 subsurface storage formations in the United States. The U.S. Environmental Protection Agency requires that any U.S. CO_2 sequestration assessment or project avoid subsurface formations containing potential drinking water. The Underground Injection Control Program (UIC) for Class VI (CO_2 storage) wells protects fresh water, defined as water with a total dissolved solids (TDS) concentration < 10,000 mg/L. However, the UIC does not define how the limit must be interpreted statisically or spatially to determine potential storage formations. For example, if one analysis has a TDS concentration > 10,000 mg/L, is the entire formation considered a saline aquifer? Could a saline water analysis from a previous injection well in the same reservoir then be cited as evidence of a saline formation available for CO_2 injection? Other possibilities include using a median or mean within uncertainty for a water chemistry dataset. Though site-specific hydrogeological studies would be required before injection to predict CO_2 migration to aquifers, the concern is whether fresh water aquifers could be defined as saline based on existing subsurace water quality data.

For example, the Mesaverde Formation in the Southwestern Wyoming Province is a known aquifer with fresh water near the surface and saline water at depth. Using multiple water quality databases that cover the Rocky Mountain region, we find n = 789 independent analyses with non-null reported TDS concentrations between 72 and 249,838 mg/L at depths > 1 km. Whereas the mean TDS concentration is "saline" (13,240 ± 17,191 (1σ) mg/L), the median concentration is "fresh" (9,482 mg/L).

Since the scale of a sequestration project is not across an entire basin, we can also provide a spatial definition of salinity. If we see a region with suitably saline data, how far from those wells can we assume the formation is saline? Though this is a complex hydrogeologic problem, our interest is simply to define whether a potential storage region is "saline" or "fresh." Using 1-D Darcy flow (neglecting convection and dispersion) for a range of applicable reservoir properties and time-scales, we model length scales of saline water flux. These results then define the radial distance from a saline data region that could be considered saline at the time-scales relevant to long-term CO_2 storage.

Effects of sodium borohydride reduction and dioxygen concentration on the photochemical properties of humic substances

NEIL V. BLOUGH*[,1], KELLI GOLANOSKI[1], YI ZHANG[1], AND ROSSANA DEL VECCHIO[1,2]

[1]Department of Chemistry and Biochemistry University of Maryland College Park MD United States (*correspondence: neilb@umd.edu)

[2]Earth System Science Interdisciplinary Center University of Maryland College Park MD United States

Previous results have demonstrated that the reduction with sodium borohydride of Suwannee River humic and fulvic acids, a commercial lignin, and a series of solid phase C18 extracts from fresh, estuarine, coastal and offshore waters of the middle Atlantic bight produces a preferential loss of long wavelength (visible) absorption and enhanced, blue-shifted emission [1], consistent with a previously proposed electronic interaction model [2,3]. Here the effects of this reduction on the photosensitized oxidation of 2,4,6-trimethylphenol (TMP) and on the photoproduction of hydrogen peroxide is examined. For unreduced samples, the initial rate of TMP loss (R_{TMP}) increased with decreasing [O_2] concentration over the range from 1.2 mM to ~ 50 μM; below [O_2]~50 μM , R_{TMP} decreased precipitously, with no observable loss under N_2. Borohydride reduction substantial reduced R_{TMP} at all [O_2]. These results are consistent with the (aromatic ketone) triplet sensititization model of Canonica and co-workers [4,5]. In contrast, borohydride reduction only slightly decreased the intial rates of hydrogen peroxide production and similar dependencies of the initial rates on [O_2] were observed with both reduced and unreduced samples. Preliminary work, however, indicates interesting differences in peroxide yields between these samples under conditions in which they are first irradiated under N_2 followed by the introduction of O_2 at increasing delay times.

Amendment of mill tailings for *in situ* treatment of mine drainage

D.W. BLOWES[1], M.B.J. LINDSAY[1], A.H.M. HULSHOF[1], C.J. PTACEK[1], P.D. CONDON[1] AND W.D. GOULD[2]

[1]Dept. Earth and Environ. Sci. Univ. Waterloo., ON, Canada, N2L 3G1 (blowes@uwaterloo.ca; matt.lindsay@uwaterloo.ca; ptacek@uwaterloo.ca)

[2] CANMET - Mining and Mineral Sciences Laboratories Ottawa, ON,K1A 0G1 (dgould@nrcan.gc.ca)

Field studies conducted at two mill-tailings impoundments suggest that amendment of sulfide-rich tailings with small masses of organic carbon has the potential to provide passive treatment of pore water through microbially-mediated sulfate reduction, metal-sulfide precipitation and alkalinity production. At the Kidd Creek Metallurgical Site, Timmins, Ontario, fine-grained mill tailings containing 15 – 20 wt. % sulfide minerals and 8 wt.% carbonates, were amended with 20 vol. % organic carbon in the form of pulp and paper sludge or wood chips. At the Greens Creek Mine, Alaska, mill tailings containing 34 wt. % pyrite were amended with 5 or 10 vol. % organic carbon as varied mixtures of peat, spent brewing grain and municipal biosolids. Increased populations of sulfate-reducing bacteria (up to 10^6 cells g^{-1}), and increased alkalinity concentrations were observed at both sites. These changes were accompanied by decreases in pore-water concentrations of SO_4, Zn and other metals as a function of time and relative to control cells. Mineralogical investigations indicate the precipitation of secondary Fe-S and Zn-S phases. However, increases in dissolved Fe and As concentrations were observed near the onset of the Greens Creek field experiments. Combined, these experiments demonstrate the potential for tailings drainage management using organic carbon amendments, but also indicate that care must be taken to limit the inadvertent release of dissolved constituents due to the reductive dissolution of Fe(III) and SO_4–bearing phases.

Cell permeability/senescence controls the reduction rate of iodate to iodide in marine phytoplankton

K. BLUHM[1], P. CROOT[2], K. WUTTIG[3] AND K. LOCHTE[4]

[1] IFM-GEOMAR, Kiel, Germany (kbluhm@ifm-geomar.de)
[2] Plymouth Marine Laboratory, Plymouth, United Kingdom (pecr@pml.ac.uk)
[3] IFM-GEOMAR, Kiel, Germany (kwuttig@ifm-geomar.de)
[4] AWI-Bremerhaven, Germany (Karin.Lochte@awi.de)

The role of marine organisms in the redox cycling of iodine in the ocean is not well understood presently. Previous studies have suggested that phytoplankton play an important role in the biogeochemical cycling of iodine, and were responsible for the appearance of the non thermodynamically favoured species iodide in the euphotic zone. A key question that arises however is how this reduction occurs; Is it driven by primary production, via direct biologically mediated uptake, or alternatively is it driven chemically by redox reactions related to the passive release of reduced substances from the decay of biological materials?

To directly address this question we have recently performed laboratory experiments and field measurements (Tropical Atlantic and Pacific, Southern Ocean) for this purpose. In culture experiments, including a variety of phytoplankton taxa (diatoms, dinoflagellates and prymnesiophytes), we observed changes in the speciation of iodine over the course of an experiment indicating the apparent ability to reduce iodate to iodide. Production rates were found to be species specific and not related to biomass. In all but one species tested the iodide production commenced in the stationary growth phase and peaked in the senescent phase of the algae. This indicates that iodide production is connected to cell senescence and suggests that iodate reduction results from increased cell permeability. We hypothesize that this is due to subsequent reactions of iodate with reduced sulphur species exuded from the cell. Combined with our field observations we suggest that cell senescence and other related processes that cause cell breakage (e.g. grazing, viral lysis) are responsible for the production of iodide.

Our data additionally suggest that the iodine redox cycle is completed via biological processes also. We observed that an experimentally induced shift from senescence back to the exponential growth phase resulted in a decline in the iodide concentrations, suggesting reoxidation back to iodate. Our new data help to provide a more complete picture of iodine cycling in the ocean.

Fault zone stability in cap rocks affected by CO_2

J. BLUME[1], J. D. ECKHARDT[4], H. G. STOSCH[1], TH. NEUMANN[2], K. BALTHASAR[3], TH. MUTSCHLER[3] AND TH. TRIANTAFYLLIDIS[3]

[1]Institute of Applied Geosciences,
[2]Institute of Mineralogy and Geochemistry,
[3]Institute of Soil Mechanics and Rock Mechanics,
[4]Laboratories for Materials Testing and Research, KIT, 76131 Karlsruhe, Germany (jennifer.blume@kit.edu)

A safe geological storage of CO_2 requires a better understanding of alteration processes in cap rock formations as a function of temperature, pressure, fluid and cap rock mineralogical composition. Alterations in the cap rock can influence the tightness and the stability of a storage site. With regard to fault zones it may lead to increases or decreases of permeability due to solution with widening of flow paths or precipitation with self-healing effects. Increased permeability and consequently leakage might also change the stress field and the rock mechanical properties.

To investigate these relationships, an experimental setup was designed within the BMBF-funded GEOTECHNOLOGIEN joint project CO_2SEALS, to study experiment-related shear planes in natural rock samples, the changes in the mineralogical and rock mechanical properties and their interactions.

Annular shear planes were produced within samples of several pelictic reference rocks by a punching process. The punched samples were installed in newly developed reaction vessels, in which they were continuously percolated with a CO_2-saturated NaCl-brine at a constant pressure (5 bar) and different constant temperatures (45 to 100°C). By varing temperature and reaction time (up to 24 months) it was expected to extract reaction rates from the experiments and also study the extent of alteration.

Results of the experiments with duration up to 6 months show that interactions between CO_2-saturated brine and cap rock are most visible at temperatures >75°C. Changes in the chemical composition of the effluent and in the solid phase show, that beside carbonate dissolution and precipitation, which is the dominant short term process, silicate alteration must have occured also. Thin-layer shear tests at high pressures up to 40 MPa normal stress on powder samples (before and after reaction with CO_2) will be carried out to characterise the change of the geomechanical properties due to alterations.

Geothermobarometric results at the northern tip of Antarctic Batholith: Tectonic implications

H. BOBADILLA[1]*, M. CALDERÓN[2] AND F. HERVÉ[1]

[1]Departamento de Geología, Universidad de Chile. Plaza Ercilla 803. Santiago, Chile. (*correspondence: hbobadil@ing.uchile.cl)
[2]SERNAGEOMIN. Av. Santa María 104. Santiago, Chile. (mccaldera@gmail.com)

The geological relationships between the Antarctic Peninsula (AP) and South America (SA) have been the subject of sustained study in recent decades. However, there are many problems unsolved yet [1]. This work provides new information that could be used to compare and relate the magmatic and tectonic processes occurring at the northern end of AP and southern tip of SA.

Using EPMA analysis in diorites from the northern Antarctic Batholith, we have determined the composition of a selected group of minerals. Knowing the compositions of amphiboles, we have estimated the temperature (T) and pressure (P) at which they crystallized, according to several geothermobarometers [2, 3].

The results indicate that minerals are not homogeneous, but most are zoned. Particularly for amphiboles, the difference of crystallization T for the many zones could reach 200ºC. These results are interpreted as crystallization in, at least, three stages.

The crystallization T and P of amphiboles in their many zones are revealed and, by extension, an approximation for the T-P crystallization conditions of the plutons. Using a preliminary approximation of lithostatic pressure we propose a specific range of depths of intrusion; they all have been emplaced at upper crust (less than 10-15 kms). Using SHRIMP zircon U-Pb crystallization ages, exhumation rates have been inferred. They seem to rise up since Eocene to Miocene in almost ten times.

Boron, lithium and nitrogen isotope geochemistry of K- and NH_4-rich illite/smectite clays in fossil hydrothermal systems

I. BOBOS[1] AND L. B. WILLIAMS[2]

[1]Centre of Geology, University of Porto, 4169-007 Porto, Portugal (ibobos@fc.up.pt)
[2]SESE, Arizona State University, Tempe, Arizona 84287-1404, USA (Lynda.Williams@asu.edu)

Boron (B), lithium (Li) and nitrogen (N) transported by hydrothermal fluids may be incorporated into illite – smectite (I/S), as progressive illitization of smectite occurs [1]. Two illitic size fractions (<0.2μm; 0.2 – 2.0μm), distinct in age and composition, were selected corresponding to K-I/NH_4-I mixtures and to a continuous conversion series of smectite to NH_4-I via interstratified structures.

The $\delta^{11}B$ (‰) values range from -5.1 to -5.5‰ in the K-I/NH_4-I mixed phase samples and from -12.6 to -22.4‰ in the mixed-layered NH_4-I-S. The δ^7Li values measured in K-I/NH_4-I mixed phase ranges from +5 to +12.8‰ and in NH_4-I-S samples ranges from -0.5 to -12.3‰. Lower Li concentrations around few ppm were measured, whereas the B concentrations range from 400 to 1457 ppm. The $\delta^{15}N$ measurements in K-I/NH_4-I clays show a mean value of +5.4‰ and in NH_4-I-S series range from +4.8 to +14.6‰. Nitrogen contents range from 0.15 to 1.2 wt.%.

The results obtained have important implications for understanding sources of fluids cycling through subduction zones. The $\delta^{11}B$, δ^7Li and $\delta^{15}N$ values obtained on NH_4-I-S indicate two different fluids, one very high in B and N, confirming a contribution from sedimentary organic matter. The $\delta^{11}B$ and δ^7Li composition of fluids that produced older K-I/NH_4-I clays fits best with a magmatic source. The isotopically light composition of these trace elements provides an important contribution to subducted sediments in volcanic arcs.

Na-bearing majoritic garnets in the system $Mg_3Al_2Si_5O_{12}$–$Na_2MgSi_5O_{12}$ at 11–20 GPa: Solid solutions and structural peculiarities

A.V. BOBROV[1]*, A.M. DYMSHITS[1], L. BINDI[2], K.D. LITASOV[3], A.F. SHATSKIY[3], E. OHTANI[3] AND YU.A. LITVIN[4]

[1]Geological Faculty, Moscow State University, Moscow, Russia (*correspondence: archi3@yandex.ru)
[2]Museo di Storia Naturale, Sezione di Mineralogia, Università di Firenze, Firenze, Italy
[3]Department of Earth and Planetary Materials Science, Tohoku University, Sendai, Japan
[4]Institute of Experimental Mineralogy, Chernogolovka, Russia

The phase with composition $Na_2MgSi_5O_{12}$ (Na-majorite), end-member of sodium-rich majoritic garnet [1], was synthesized and garnet/pyroxene *PT* phase boundary was determined in multi-anvil experiments at 11–20 GPa and 1500–2100 °C. Na-majorite was obtained at 16 GPa and 1500°C; its stability spreads to the high-temperature region with pressure (1900 °C at 17 GPa and 2100 °C at 19.5 GPa) [2]. Single-crystal study of Na-majorite provided evidence for its tetragonal symmetry, space group $I4_1/acd$, and cell parameters a = 11.3966(6), c = 11.3369(5) Å and V = 1472.5(1) Å^3 [3]. Experiments at 18 GPa and 1600 °C on the pyrope ($Mg_3Al_2Si_3O_{12}$)–Na-majorite join allowed us to study mixing peculiarities for sodium-rich majoritic garnet. The study demonstrated that the transition from cubic to tetragonal symmetry is observed for the starting composition with ~80 mol % $Na_2MgSi_5O_{12}$, which is consistent with the similar change of the structure in the pyrope–majorite ($Mg_4Si_4O_{12}$) system [4]. Significant Na-majorite solubility in pyrope, as well as findings of natural garnets with high Na concentrations (>1 wt % Na_2O) allow us to consider Na-bearing majoritic garnet as a phase accumulating sodium in the deep upper mantle and transition zone. Successful synthesis of the Na-majorite end-member and study of its structure are of key importance for obtaining of thermodynamic constants for this phase, which together with the computer modeling will allow us to suggest the new version of thermobarometer for mineral assemblages containing Na-bearing majoritic garnet.

Application of the Linkam TS1400 X-Y heating stage to melt inclusion studies

R.J. BODNAR[1]*, R. ESPOSITO[1], R. KLEBESZ[1,2], Y.I. KLYUKIN[1,3], D. MONCADA[1] AND A. DOHERTY[1,2,4]

[1]Virginia Polytechnic Institute & State University, Department of Geosciences, Blacksburg, VA, USA (*correspondence: rjb@vt.edu)
[2]Università di Napoli Federico II, Dipartimento di Scienze della Terra, Naples, Italy
[3]Institute of Geology and Geochemistry of UB, RAS, Yekaterinburg, Russia
[4]Università degli Studi di Messina, Dipartimento Elementi e Ambiente, Messina, Italy

One of the major limitations in studying melt inclusions in natural samples has been the lack of availability of easy-to-use microscope-mounted heating stages that allow the user to heat the inclusion while it is being observed and to quench the sample rapidly to maintain a homogeneous glass and to avoid reequilibration during cooling.

The recently introduced Linkam TS 1400 X-Y stage has been tested and found to produce satisfactory results for many types of melt inclusions. Several experiments have been performed on recrystallized melt inclusions (MI) contained in olivine and sanidine phenocrysts from eruptions at Campi Flegrei, Italy, and in clinopyeoxene from the Sarno eruption at Monte Somma-Vesuvius Italy. During the heating experiment, a constant flow of argon gas was introduced into the sample chamber at a flow rate of 0.5 ±5% liter/min. During heating the temperature is easily controlled and the heating rate can be adjusted during the heating experiment. In all cases, it was possible to homogenize the MI and, importantly, to quench the melt to a glass after homogenization. In one experiment, the sample was heated to 1340°C. At that temperature, the field of view became a darkish-red and it was difficult to observe the behavior of the MI. At lower temperatures the optics were excellent. The quality of the optics during heating appears to be dependent on the sample characteristics, with samples containing matrix glass being most problematic.

In most of the experiments, the MI were homogenized completely (crystals + bubbles) and remained homogeneous during quenching to room temperature to produce a glass. In one case, the MI was heated to 1340°C and the solids all melted but the bubble did not dissolve back into the melt. When the MI was quenched, the single bubble remained in the MI and grew larger during cooling. The bubble in this MI may represent a trapped vapor bubble (i.e., the MI trapped a volatile-saturated melt plus a vapor bubble) and thus the bubble should not be expected to dissolve back into melt.

Tracing the late Paleozoic to early Mesozoic crustal evolution of coastal Southern Peru

F. BOEKHOUT [1]*, R. SPIKINGS [1], M. CHIARADIA [1], T. SEMPERE[2], A. ULIANOV [3] AND A. GERDES U. SCHALTEGGER[1]

[1]Earth and Environmental Sciences, University of Geneva, Switzerland (*correspondence : Flora.Boekhout@unige.ch)
[2]IRD et GET, Toulouse, France
[3]University of Lausanne, Switzerland
[4]Goethe University, Frankfurt am Main, Germany

Subduction related magmatism along the Andean margin started as early as 550 Ma ago. Previous studies reveal a complex magmatic history from the late Paleozoic to the early Mesozoic that involved contributions from both mantle and crust.

This study aims to trace crustal growth and recycling through time along the South Peruvian margin with U-Pb laser ablation ICPMS dating on (Jurassic) plutonic and (Carboniferous – Jurassic) detrital zircons combined with a LA-MC-ICPMS Hf isotope study. This margin is especially suited for this type of study as no evidence is know of terrane accretion along this part of the margin since the Ordovician.

Our ages on detrital and plutonic zircons confirm periods of subduction related magmatism in the Ordovician, Permo-Carboniferous, and late Triassic-Jurassic, but also show periods of magmatic quiescence in the early Triassic and late Devonian.

A combination of Hf, Sr, Nd and Pb isotopes on the Jurassic plutonic rocks will be employed to quantify the relative contributions of mantle and crust to the melts formed along this part of the Andean margin. Additionally, Hf isotopes on detrital zircons will reveal periods of recycling and juvenile input. Preliminary results point towards crustal recycling as the dominant process of crustal evolution along the south Peruvian Andean margin between Carboniferous and Jurassic.

Aerosols, chemistry and the onset and evolution of fog layers

R. BOERS*

Royal Netherlands Meteorological Institute (KNMI) De Bilt, Netherlands (*correspondence: reinout.boers@knmi.nl)

In Western Europe, the occurrence of fog is on the decline since the 1980's. A reduction in the emission of anthropogenic aerosols due to increasingly strict regulatory measures and technological improvements on car and industrial exhaust seems a plausible reason for this decline. However, the onset and evolution of fog is the result of an interplay between a number of complex meteorological and aerosol – chemical factors. Here we model the evolution of fog and its sensitivity to atmospheric cooling rate, variation in aerosol size parameters and the aerosol chemical hygroscopicity parameter. First conclusions from these simulations can be summarized as follows:

1) Below RH=100% the three most important parameters controlling the visibility are the hygroscopicity parameter ($\varkappa$), the total number of aerosols and the relative humidity (RH) itself. For moderate to high values of $\varkappa$ (>0.4) and aerosol concentration typical for continental conditions (2000 - 4000 cm^{-3}), visibility can easily be reduced to below 1 km so that the meteorological condition for the occurrence of fog is satisfied, even though RH < 100%.

2) When RH > 100% and particle activation occurs, the parameter $\varkappa$ rapidly loses it significance in determining visibility. Rather it is the radiative cooling rate that exerts control over the value of visibility. The physical interpretation is that only a few particles (typically less than 150 cm^{-3}) are activated no matter what the value of $\varkappa$ is. Since these few particles grow rapidly upon activation they become increasingly more important in contributing to the reduction in visibility in the fog as the cooling progresses, so that the original sensitivity of visibility to $\varkappa$ when RH was still below 100% is quickly lost.

In atmospheres with RH<100% improved visibility may have been caused by reduced numbers of aerosols. However, for RH = 99% a reduction of $\varkappa$ from 0.9 to 0.5 yields an improvement of visibility from 1 to 2 km. Further work will be necessary to investigate whether changes in emission sources and land usage combined with possible changes in the relative humidity are contributing factors in explaining improved visibilities in the last three decades.

Structural distortion of $MgSiO_3$ perovskite and the influence of Fe and Al at pressures of the Earth's lower mantle

T. BOFFA BALLARAN[1], A. KURNOSOV[1], K. GLAZYRIN[1], M. MERLINI[2,3], M. HANFLAND[3] AND D.J. FROST[1]

[3]ESRF - European Synchrotron Radiation Facility, 6 rue Jules Horowitz, BP 220, 38043 Grenoble, France.

The $MgSiO_3$ perovskite-type structure is considered the dominant phase in the Earth's lower mantle. As such a detailed understanding of its elastic properties and density as well as how such properties are affected by chemical substitutions are of great importance to mineral physics, seismology and geodynamics. Many studies have reported the compressibility of $MgSiO_3$ perovskite with or without additional element (mainly Fe and Al) substitution [1, 2, 3]. It has also been proposed that changes in the spin state of Fe at high-pressures may influence the compressibility of perovskite [4, 5]. Little is known, however, about the structural state of perovskite at very high pressures. Such knowledge is essential not only for constraining its physical-properties at lower mantle conditions, but also for understanding the structural instability leading to the perovskite to post-perovskite phase transition, which may cause complex seismic signatures within the D'' layer.

We have studied three single-crystals of $MgSiO_3$ with the end-member composition and containing either Fe^{2+} or Fe^{3+} and Al by means of X-ray diffraction at the ID09 beam line of the European Synchrotron Radiation Facility. Intensity data have been collected up to 90 GPa at room temperature with diamond anvil cells loaded with He as pressure transmitting medium and ruby chips as pressure calibrants. All perovskites display with increasing pressure only a small increase of the octahedral tilting, but undergo major octahedral distortions, which are more pronounced in the Fe^{3+}, Al-bearing perovskite. No evident structural changes associated with the Fe spin transition have been observed.

Modelling the aqueous Al^{3+} System using Density Functional Theory

S. BOGATKO[1]*, E. CAUËT[2] AND P. GEERLINGS[1]

[1] Eenheid Algemene Chemie, Vrije Universiteit Brussel (VUB), Faculteit Wetenschappen, Pleinlaan 2, 1050 Brussels, Belgium (* sbogatko@vub.ac.be, pgeerlin@vub.ac.be)

[2] Service de Chimie Quantique et Photophysique CP 160/09, Université Libre de Bruxelles, 50 Av. F.D. Roosevelt, B-1050 Bruxelles, Belgium (ecauet@ulb.ac.be)

We have shown (1) that the speciation of aqueous Al^{3+} is well described over a wide range of solution pH by Density Functional Theory calculations on gas phase $Al(OH)_x(H_2O)_y^{(3-x)+}$ clusters embedded in a continuum solvent. Cluster geometry, electronic structure and Gibbs Free Energies all display similar trends suggesting increased acidity as the coordination number decreases. These results are in complete agreement with the observed cooperativity of Al^{3+} hydrolysis products (2).

Extending our model (3) to include coordination by an F^- counterion shows that this ligand coordinates the Al^{3+} cation in a similar way to the OH^- ligands thus inducing important changes in $AlF(OH)_x(H_2O)_Y^{(2-x)+}$ complexes in the direction of increased acidity, in agreement with the observed elevated acidity of natural waters in which AlF^{2+} species occur (4). Furthermore, in light of recent NMR observations (5) of a fast proton-coupled water exchange mechanism on Al^{3+} aqueous complexes, we suggest this mechanism is also present in the aqueous AlF^{2+} system.

Finally, a large array of $Al_2(OH)_x(H_2O)_y^{(6-x)+}$ aqua/hydroxo Al^{3+} dimer species have been investigated. Our results suggest that many species are possible and their stability may be understood in terms of the number of coordinating water and hydroxide ligands and the hydroxide bridging geometry. This novel approach thus provides a revealing picture of the extremely complex aqueous Al^{3+} environment and may thus be of great use to the geochemical and environmental chemistry communities.

Element behavior in technogenic systems and methods of mine waste treatment

A.A. BOGUSH [1]*, E.V. LAZAREVA[1], V.G. VORONIN [2], O.G. GALKOVA [1] AND N.V. ISHUK [1]

[1]Institute of geology and mineralogy SB RAS, Koptyug Pr. 3, Novosibirsk 630090, Russia (*coresspondence: annakhol@gmail.com)

[2]Planeta-Ra Ltd., Lazurnay str. 4/3, Novosibirsk 630133, Russia

A huge amount of waste has accumulated in the world during the last century as a result of industrial activity. Research of element migration in technogenic systems and their accumulation on geochemical barriers is the important fundamental problem of the environmental geochemistry. The purpose was to describe migration, distribution, and redistribution of heavy metals by the example of the old tailings of the Lead Zinc Concentration Plant and Ursk tailings of the Gold Concentration Plant (Kemerovo region, Russia). The waste products of the ore mining and processing industry can be oxidized by atmospheric oxygen and microbial activity, forming acid mine drainage (AMD), with high concentrations of SO_4^{2-}, Fe, Zn, Cu, Cd, Pb, and other elements. The result obtained about element species in the sulfide tailings and the bottom sediments, using modified sequential extraction procedure, explain the main features of element migration and redeposition. In the mine waste and technogenic bottom deposits, there is vertical and horizontal substance transformation with formation of following geochemical barriers: 1) the evaporative barrier where secondary species of element, especially water-soluble, are redeposited; 2) the lithological barrier (Hardpan) which reduce migration of elements, pore water and pore gases such as O_2 and CO_2; 3) complex organic-mineral barrier on which heavy metals coprecipitate/sorb with/on iron oxy-hydroxides, organic matter and clay minerals. On the basis of the sulfide waste investigation, environmentally safe and cost-effective ways of liquid and solid waste treatment have been developing using natural (peat, clay, limestone, etc) and modified materials (peat-humic agent, organic-mineral complex, etc.), for example: 1) complex organic-mineral geochemical barriers for binding and long-term retention of pollutants; 2) methods of acid rock drainage treatment; 3) methods of solid waste conservation; 4) prevention of eolian transportation of tailings particles; 5) new method of metal extraction from acid mine drainage. This research was supported by the RFBR (grant 03-05-64529 and 06-05-65007).

Reconstruction of the Atlantic circulation back to the last interglacial by a combined proxy approach

E. BÖHM[1]*, J. LIPPOLD[1], S. WEYER[2], M. GUTJAHR[3] AND A. MANGINI[1]

[1]Heidelberger Akademie der Wissenschaften, Im Neuenheimer Feld 229, 69120 Heidelberg, Germany (*correspondence: eboehm@iup.uni-heidelberg.de)

[2]Inst. für Mineralogie, Universität Hannover, Callinstr. 3, 30167 Hannover, Germany

[3]Dept. of Earth Sciences, University of Bristol, Wills Memorial Building, Queen's Rd., Bristol BS8 1RJ, UK

The Atlantic Meridional Overturning Circulation (AMOC) plays an important role in the global climate system, due to the transport of heat and carbon. Theoretical studies and measured data suggest that the AMOC underwent different circulation modes and the transitions between these modes can be triggered by variations of freshwater runoff into the North Atlantic [1, 2, 3].

The purpose of this project is to trace these transitions by creating a high resolution data set of ε_{Nd} and $^{231}Pa/^{230}Th$ for the last interglacial (Eemian) and the following glacial. ε_{Nd} gives information about the water mass provenance, signal $^{231}Pa/^{230}Th$ serves for reconstruction of AMOC export. Thus, the combination of $^{231}Pa/^{230}Th$ and ε_{Nd} from deep sea sediments is a promising tool to derive the past paleoceanography.

First measurements of ε_{Nd} have been accomplished for the time range from 60 to 154 ka with a temporal resolution of in average 3 ka. The data display the presence of Southern Source Water during MIS 6 to MIS 6.4 and indicates an active deep water formation in the North Atlantic at the beginning of the Eemian Interglacial (MIS 5.5). The transition between these two different modes in AMOC is marked by a distinct drop in the ε_{Nd} values (-11.5 to -14). This is consistent with ε_{Nd} results obtained from the same core [4] and from a neighbouring core [5] at the transition from MIS 2 to MIS 1.1. The similar temporal behaviour of ε_{Nd} during Termination I and II implies recurring millennial-scaled identical processes converting the AMOC from a Glacial mode into an Interglacial mode.

Calcium isotope fractionation during dolomite formation

FLORIAN BÖHM[1]*, ANTON EISENHAUER[1], JAN FIETZKE[1], SVENJA RAUSCH[2], ANDREAS KLÜGEL[2] AND WOLFGANG BACH[2]

[1]IFM-GEOMAR, Kiel, Germany (*fboehm@ifm.geomar.de)
[2]Geoscience Department, University of Bremen, Germany

Dolomite is an important component of the global calcium cycle, being a source of Ca to the oceans [1]. Calcium released to the oceans by dolomitization of chalk and limestones can potentially be quantified using marine Ca isotope records [2]. However, little is known about Ca isotope fractionation and the Ca isotopic composition of dolomitic rocks. Theoretical calculations point to a -2 ‰ depletion in $\delta^{44/40}$Ca of dolomite relative to calcite at 25°C [3]. Ordovician dolostones interbedded with limestones were reported to be depleted in $\delta^{44/40}$Ca by -0.6 ‰ relative to the limestones [4].

We have investigated dolomites from an ODP core (Site 183-1140) drilled at the Northern Kerguelen Plateau (46.3°S 68.5°E, 2394 mbsl). The core penetrated 235 m of nannofossil ooze and chalk of early Oligocene to middle Miocene age, and 88 m of pillow basalts forming the basement for the sediments. The basalts erupted at about 34 Ma (latest Eocene) [5]. An interbedded chalk layer was found in the basalt, about 40 m below the top of the basement. The chalk was partly dolomitized at the contact with the basalt.

We measured oxygen, carbon, calcium and radiogenic strontium isotopes of bulk chalk and dolomite samples. The $^{87}Sr/^{86}Sr$ ratios indicate an age of dolomitization of about 10 Ma (late Miocene). Dolomitization obviously occurred about 20 Ma after eruption of the basalts, in a deep burial setting. Oxygen isotope values of chalk and dolomite demonstrate that dolomitization occurred at slightly elevated temperatures (10-20°C). The calcium isotopes of the dolomite are enriched in $\delta^{44/40}$Ca by about +0.5 ‰ compared to the chalk. This is in contrast to the depletion of $\delta^{44/40}$Ca in dolomite reported in the literature. On the other hand, dolomite veins in ocean crust basalts (DSDP/ODP Sites 37-332 and 129-801) are depleted in $\delta^{44/40}$Ca compared to calcite veins of similar age. Fluid composition, diagenetic history and kinetic isotope fractionation have to be considered when interpreting Ca isotope values of dolomite.

Hydroxyl group reactivity at FeOOH/gas and FeOOH/water interfaces

JEAN-FRANÇOIS BOILY

Department of Chemistry, Umeå University, Sweden
(correspondence: jean-francois.boily@chem.umu.se)

Reactions involving mineral surfaces and their surrounding environments play important roles in atmospheric and geochemical processes. Knowledge of the types, distributions and orientations of reaction centers on minerals with different surface structures is notably essential for molecular-scale resolution of mineral/gas and mineral/water interactions.

This work is focused on properties of hydroxyl functional groups of important crystal planes of FeOOH minerals exposed to vacuum, gaseous as well as liquid water. Molecular dynamics simulations were carried out to identify hydrogen bonding patterns and calculate their properties in these different systems. These efforts formed the basis of an interpretative framework to our Fourier transform infrared measurements of α-, β-, and γ-FeOOH particles (Fig. 1). These measurements, which were limited to gaseous systems, were used to extract spectroscopic signatures for distinct isolate and hydrogen-bonded hydroxyl groups.

Our combined computational and experimental efforts are helping categorize different crystallographic terminations of FeOOH minerals on the basis of their site distributions, hydrogen bonding patterns and reactivity towards water.

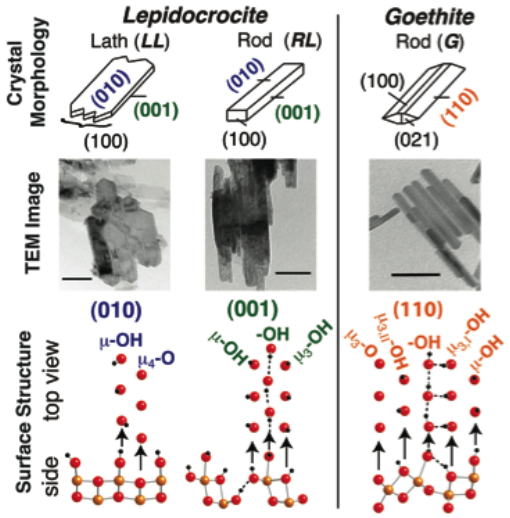

Figure 1: Morphology, TEM imaging (scale bar = 50 nm) and surface structures in three types of particle used for this work.

Trace elements in sediments of lakes in the Warta river basin

IZABELA BOJAKOWSKA*, TOMASZ GLIWICZ AND JAROSŁAW KUCHARZYK

Polish Geological Institute-National Research Institute, Warsaw, Poland (izabela.bojakowska@pgi.gov.pl)

The Warta River catchment (length 808.2 km), occupies an area of 54 529 km^2. The northern part of the catchment area covered by the Vistulian glaciation deposits, characterized by high abundance of lakes, while the southern part of the basin is practically without lakes.

The lake sediment samples taken from 5cm surface layer from profundal zone of 207 lakes, were analyzed for the content of As, Ba, Cd, Co, Cr, Cu, Mn, Mo, Ni, Pb, Sn, Sr, Ti, V, Zn, Al, Ca, Fe, K, Mg, Na, P and S using ICP-OES method after digestion in aqua regia. From solid samples the Hg content was measured by AAS method and C_{org}. was determined using coulometric method.

Geometric mean contents in the sediment were for: Ag - <0.5 mg/kg, Ba - 96 mg/kg, Cd - 0.5 mg/kg, Co - 2 mg/kg, Cr - 7 mg/kg, Hg - 0.10 mg/kg, Cu - 13mg/kg, Ni - 7 mg/kg, Sr - 148 mg/kg, V - 11 mg/kg and Zn - 72 mg/kg. Sediments of most of the studied lakes are characterized by low contents of trace elements, similar to the geochemical background values. Markedly increased levels of Cd, Cu, Hg, Pb, Sr and Zn were recorded in the sediments of several lakes located within the cities or their boundaries, e.g. Lakes Człuchów, Trzesiecko, Wierzysko and lakes which are used as places of recreation (e.g. Lake Jasień) and their maximum contents were for: Cd - 7.0 mg/kg, Cr - 135 mg/kg, Pb – 153 mg/kg, Zn – 1413 mg/kg, Hg - 1.163 mg/kg. High levels of Cu (579 mg/kg), Ba and Sr were detected in lake sediments, whose waters are included in the cooling system power plants Pątnów and Konin (among them Lake Goławskie and Licheńskie). Warta basin lake sediments compared to sediments of lakes, created on postglacial sediments associated with other glaciations show significantly higher contents Ba, Sr and Ca, and lower contents of Cr, Pb, Zn and Fe. Sediments from lakes of the Warta catchment are also characterized by lower contents of Ni and V as compared to the sediments of lakes of the Pomeranian phase of the Vistulian glaciation.

The presence of high amounts of Cd, Cu, Hg, Pb and Zn in sediments of some lakes in the basin of the Warta is linked to anthropogenic factors (the functioning of cities, recreation, industry). The differentiation has been observed in the contents of trace elements in sediments of lakes situated on postglacial deposits associated with various glaciations.

Submarine groundwater discharge, the subterranean estuary and climate change: *Quo vadis*?

H. BOKUNIEWICZ

School of Marine and Atmospheric Sciences, Stony Brook University, Stony Brook, New York 11794-5000 U.S.A.

The elusive role of submarine groundwater discharge (SGD), and groundwater in general, to global geochemical budgets has special importance in models of climate change. Conversely, geochemical fluxes *via* SGD can be expected to be altered significantly by a change in global climate. Our understanding is distilled from multifaceted case studies. Over the past several decades, the study of SGD has matured from being a fairly interesting novelty studied at a handful of sites before 1985; to a previously unrecognized nutrient source to coastal waters recognized in 45 studies at 39 sites worldwide by 2000 [1]; to a recognizably ubiquitous phenomenon of global importance investigated in over 300 studies and 160 sites, and counting, worldwide today. SGD is often, but not necessarily, confined to the shoreline and it is typically many times greater than the flow of terrestrial, fresh groundwater under the shoreline (i.e. the underflow). In special cases, other drivers might be considered, geothermal gradients, osmotic pressures and consolidation. Deciding its role in global geochemical budgets is, of course, compounded by variations in scale and geology. Nevertheless, issues, such as the flux of carbon, need to be addressed on the largest possible scale. Better distribution of sampling sites is warranted not only to better define current geochemical budgets, but also to anticipate future alterations. Research at sites in high latitudes, in arid environments and around oceanic islands are to be encouraged.

Kinetics of coupled Fe(II)-catalysed ferrihydrite transformation and U(VI) reduction

D.D. BOLAND[1], R.N. COLLINS[1,2], C.J. GLOVER[3], T.E. PAYNE[1,2] AND T.D. WAITE[1,*]

[1]School of Civil and Environmental Engineering, The University of New South Wales, Sydney, NSW 2052, Australia. (*correspondance: d.waite@unsw.edu.au)

[3]X-ray Absorption Spectroscopy Beamline, Australian Synchrotron Company Ltd, 800 Blackburn Rd, Clayton, VIC 3168, Australia.

The Fe(II) accelerated transformation of ferrihydrite to more crystalline Fe(III) oxides such as goethite has implications for the environmental mobility of uranium and other toxic elements. In this study we used X-ray absorption spectroscopy (XAS) on samples obtained from both batch and real time experiments to measure the kinetics of ferrihydrite transformation to goethite and U(VI) reduction across a range of Fe(II) concentrations.

Linear combination fitting of Fe K-edge Extended X-ray Absorption Fine Structure (EXAFS) and U L(III)-edge X-ray Absorption Near Edge Structure data revealed similar time scales of ferrihydrite transformation and U(VI) reduction to U(V) for each treatment, inversely proportional to Fe(II) concentration. The higher rate of U(VI) reduction by Fe(II) on pure goethite than the ferrihydrite/goethite system suggested that it is the associated enhanced rate of goethite formation, rather than the higher Fe(II) itself that causes faster U reduction. The use of quick-scanning XAS, which allowed the collection of Fe K-edge EXAFS spectral data to k = 15 $Å^{-1}$ in < 1 minute for the real time experiments, provided improvements in experimental efficiency.

As predicted by calculations using the Nersnt equation and solubility products of the relevant Fe(III) oxides, the oxidation-reduction potential of the systems also declined on time scales similar to the transformation of ferrihydrite to goethite, further providing evidence for the strong reducing power of Fe(II) associated with goethite and that the presence of goethite is necessary for U(VI) to be reduced.

The effect of Sb(V) on the transformation of ferrihydrite to goethite, hematite, and feroxyhyte

R.M. BOLANZ[1], J. MAJZLAN[1] AND S. ACKERMANN[2]

[1]Inst. of Geosciences, Friedrich-Schiller-University Jena, Germany (ralph.bolanz@uni-jena.de)
[2]SGS INSTITUT FRESENIUS GmbH, Kölliken, Switzerland

Antimony is released into the environment in some natural and man-induced processes. [1]. Yet, its impact on the transformation processes of heavy metal-adsorbing minerals remains poorly understood. In acid-mine drainage systems and shooting ranges, the adsorption of antimony by iron oxides such as ferrihydrite can play a major role. The poorly crystalline 2-line ferrihydrite represents one of the most common Fe oxides in these settings and can transform to goethite (α-FeOOH) or hematite (α-Fe_2O_3) with time [2]. The rate of transformation depends on the pH, temperature, and on the ions and molecules present during the transformation process [3]. This study focuses on the transformation of synthetic ferrihydrite to crystalline iron oxides in the presence of Sb(V). Transformations were carried out for 1-16 days at 70 ºC and at pH 4, 7 and 12, with different concentrations of Sb(V) (0.00, 0.23, 0.75, 2.25 and 6.00 mM Sb). Samples taken from aqueous suspensions were washed, dried, and characterized by X-ray diffraction (XRD) and atomic absorption spectroscopy (AAS). At pH 12, goethite (Sb concentrations up to 3.7 mg Sb/g) is favored and the transformation is completed after one day. Only a concentration of 6 mM Sb retarded the transformation, where even after 8 days only 50 % of the ferrihydrite was transformed into goethite. Transformations at pH 7 led to a mixture of 75 % hematite and 25 % goethite (4.3 mg Sb/g). However, at concentrations of 6 mM Sb, feroxyhyte (δ-FeOOH) (9.1 mg Sb/g) was favored instead. At pH 4, hematite (32.3 mg Sb/g) was favored except for concentrations of 6 mM Sb, were again feroxyhyte (141.1 mg Sb/g) occurred. We assume that increased Sb concentrations favor feroxyhyte and indicate the incorporation of Sb into the structure of feroxyhyte.

Mineralogy and petrogenesis of the precambrian basement rocks, around Ede, Southwestern Nigeria

A.T. BOLARINWA[1], M.T. JIMOH[2] AND O.O. ODUSI[3]

[1]Department of Geology, University of Ibadan.
[2]Department of Earth Sciences, Ladoke Akintola University of Technology, Ogbomosho.
(*correspondence:jimohmustapha@yahoo.com)
[3]United Geophysical Nigeria Limited, Lagos.

Basement rocks around Ede southwestern Nigeria consist of Banded migmatite-gneiss, pegmatites, Amphibolites and lenses of charnockites. Petrographic studies revealed that the gneisses are composed of 50% quartz, 20% plagioclase. The pegmatite is made up of 50% quartz, 25% microcline, 20% muscovite and 5% microperthite.

The study is aimed at showing the compositional features, petrogenesis and tectonic setting of the rocks mentioned above by analysing the whole rock and trace element chemistry of the various rock types present.

Ten representative samples of the pegmatites and banded gneisses in the study area were collected and analysed for major, trace and rare earth elements. Geochemical analyses reflected the highest average SiO_2 value (72.43%) for the pegmatites while the lowest average SiO_2 content (62.48%) was obtained for the banded migmatite-gneiss. Mean Al_2O_3, Fe_2O_3, MnO, CaO and MgO are higher in the banded migmatite-gneiss than in the pegmatites. However mean Na_2O and K_2O values are higher in the pegmatites than in the banded gneisses.

Average bivariate plots indicates that the precursors of the gneisses are sedimentary while that of the pegmatites are igneous. Mode of occurrences involving partial melting seems to be compatible with the high Zr contents from the result of the trace element analytical data.

Geochemical discriminant diagrams show the rocks to have originated in a continental environment whose tectonic setting is similar to an active continental margin and a continental island arc. Geochemical studies and plots also indicate trends comparable to those typical of the calc-alkaline plutonic suites. Abundances and variations of major and trace elements suggest that part of the protoliths of the rocks are of sedimentary origin with an evolution involving partial melting and subsequent contamination by the plutonic episodes of the Pan African orogeny.

Ferric iron and water incorporation in wadsleyite under hydrous and oxidizing conditions

NATHALIE BOLFAN-CASANOVA[1], MANUEL MUÑOZ[2], CATHERINE MCCAMMON[3], E. DELOULE[4], ANAIS FÉROT[1], SYLVIE DEMOUCHY[5], LYDÉRIC FRANCE[5], DENIS ANDRAULT[1] AND SAKURA PASCARELLI[6]

[4]CRPG, Nancy, France
[5]Géosciences Montpellier, France
[6]ESRF, Grenoble, France

Wadsleyite is the most hydrous nominally anhydrous mineral of the mantle transition zone (410-510 km depth). It also has a high affinity for trivalent cations such as Fe^{3+}. However the relationships between ferric iron and hydrogen incorporations in this mineral are unknown.

We conducted experiments at ~13 GPa and 1400°C, under oxidizing and hydrous conditions. The recovered samples were studied using micro-XANES (X-ray Absorption Near Edge Structure) to determine the ferric iron contents in polyphasic samples and SIMS (Secondary Ion Mass Spectrometry) to determine the water concentrations. XANES analyses show that ferric iron content increases with increasing total iron content, and reaches a maximum of 45 mol% of the total iron. The use of infrared spectroscopy highlights a new protonation scheme in wadsleyite, with most of the protons associated with the high frequency band near 3600 cm^{-1}. SIMS analyses show that water contents in wadsleyite vary from 0.5 to 0.7 wt% H_2O. Hydrogen content in wadsleyite is negatively correlated with ferric iron content. The divalent cations (i.e., $Mg^{2+} + Fe^{2+}$) and the Si content in wadsleyite decrease with increasing Fe^{3+} content, evidencing an incorporation mechanism via substitution into the metal sites with charge compensation by metal and Si vacancies.

These results bring new constraints on the contents of Fe^{3+} and H^+ defects in relation with the chemical environment. Such information is important in order to interprete electrical conductivity of wadsleyite in terms of hydrogen content.

Preliminary estimates on magma storage conditions of the Heise volcanic field, Snake River Plain

T. BOLTE[1]*, M. ERDMANN[1], B.P. NASH[2], H.E. CATHEY[2], R. ALMEEV[1] AND F. HOLTZ[1],

[1]Institute of Mineralogy, Leibniz University of Hannover, Germany (*t.bolte@mineralogie.uni-hannover.de)
[2]Department of Geology and Geophysics, University of Utah, Salt Lake City, UT, USA,

Tuffs and ignimbrites of the Heise and the Yellowstone Plateau eruptive centers, representing the silicic magmatism of the Snake River Plain – Yellowstone volcanic province, were studied to evaluate pre-eruptive storage conditions prevailing in rhyolitic magma chambers. We performed petrographic study of Blacktail Creek Tuff (6.62Ma), Tuff of Wolverine Creek (5.59Ma) and Kilgore Tuff (4.45Ma) of the Heise and the Huckleberry Ridge Tuff (2.05Ma) of the Yellowstone eruptive centers. Mineral and glass shard compositions obtained by electron microprobe were used to estimate temperatures, redox conditions and relative melt water contents.

In general, the set of mineral phases observed in studied rhyolites is similar to that of observed in BJR eruptive center [1] and are: Pl, ± Fsp, ± Cpx, ± Pig, Mt, ± Ilm, ± Qtz,± Fa, apatite and zircon. QUILF thermometry calculations performed on low- and high-Ca pyroxene pairs yield the ranges of temperatures between 818 and 830°C for Heise and 905 and 930°C for Huckleberry Ridge rhyolites. The ilmenite-magnetite oxybarometer yields oxygen fugacity values to be about QFM, which is in a good agreement with previous data [2]. The water contents of the natural rhyolitic melts, which are below 2 wt%, were only roughly estimated by projecting glass shard compositions on the ternary Qz – Ab – Or diagram with eutectic and cotectic compositions experimentally determined at hydrous conditions in the range of 50MPa to 1000MPa.

Our temperature estimates obtained for younger centers together with previously determined relatively high temperatures for Bruneau Jarbidge eruptive center (~11Ma, 905 – 980°C, [1]) suggest the change of pre-eruptive temperatures in rhyolitic magma bodies along the track of Yellowstone hotspot.

The study of melt inclusions hosted in plagioclase and fayalite is still in progress and will be presented in addition to mineral thermometry data.

Numerical modelling for peridotite phase melting trends in the SiO_2-Al_2O_3-FeO-MgO-CaO system at 2 GPa

C. BONADIMAN AND M. COLTORTI

Department of Eath Sciences, University of Ferrara, Italy. (bdc@unife.it)

The partial melting is the mechanism that better explain the variability of the major refractory lithophile elements (RLE) of the upper mantle rocks through time and space. Several numerical and experimental models (e.g.: Hirshmann *et al*., 1998; Herzberg, 2004 Niu, 2004) are available to simulate major element depletion trends using whole rock but no particular attention has been devoted to the compositional evolution of the single minerals. On the basis of various primitive chemical composition of the mantle (PM) and using the experimental results of Herzberg (2004) at 2.0 GPa, various melting trends which constrain the composition of the four mineral phases in the peridotite system, are calculated. This accounts for the 98.59 wt% of the upper mantle composition (SiO_2-Al_2O_3-FeO-MgO-CaO) with spinel as the aluminium phase admitted for these bulk compositions. A mass balance calculation has been applied to find the theoretical compositions of ol, cpx, cpx and sp at various degrees of partial melting. The modelling was constrained by i) mineral compositions adjusted in order to account for the properly formula units and ii) the experimental and theoretical intermineral Fe/Mg and Al partition coefficients. An iterative calculation varying the modal contents of the peridotite phases where applied to minimize the differences between calculated and whole rock compositions experimentally determined at various melting degrees. The starting point for each phase depends on the chosen whole rock PM composition and on the modal percentage that minimize the residuum. The several melting trajectories may account for a multiplicity of mantle occurrences where bulk rock analyses are not available. This model provides a new tool for unravelling the melting processes occurring within the Earth's mantle.

Sorption of Hg(II) by nanocrystalline mackinawite (tetragonal FeS)

SHARON BONE[1]*, KIDEOK KWON[2], JOHN BARGAR[3] AND GARRISON SPOSITO[1]

[1]Environmental Science, Policy and Management, UC Berkeley (*correspondance: shbone@berkeley.edu) (gsposito@berkeley.edu)
[2]Earth Sciences Division, Lawrence Berkeley National Laboratory (kkwon@lbl.gov)
[3]Molecular Environmental & Interface Science, Stanford Synchrotron Radiation Light Source (bargar@slac.stanford.edu)

Mercury is transformed to the biomagnifying species monomethyl mercury by sulphate reducing bacteria in anoxic sediments. The iron sulphide mineral, mackinawite ($FeS_{(s)}$), can limit Hg(II) bioavailability by sequestering Hg in the solid phase or by reducing it to volatile Hg (0). We use a combination of extended X-ray absorption fine structure (EXAFS) spectroscopy, density functional theory (DFT) geometry optimization and X-ray diffraction (XRD) to examine the speciation of Hg sorbed by $FeS_{(s)}$ as a function of Hg concentration, pH, and reaction time. Analysis of the Hg L_{III}-edge EXAFS spectra indicates that Hg exists in multiple coordination environments upon sorption by $FeS_{(s)}$, including a metacinnabar ($HgS_{(s)}$)-like phase and a component that we have tentatively identified as surface bound Hg. We use DFT geometry optimization to clarify the coordination environment of the putative surface complex and our preliminary results indicate that Fe-bound Hg is energetically favoured relative to S- bound Hg, as we had previously hypothesized. Lastly, Hg L_{III}-edge EXAFS spectra indicate Hg (0) forms in the presence of $FeS_{(s)}$, while spectroscopic and diffraction analysis of $FeS_{(s)}$ leads us to hypothesize that Hg(II) reduction results in the formation of surface-bound Fe^{III}. This research demonstrates that Hg(II) interacts with $FeS_{(s)}$ through multiple mechanisms, leading to the production of both sorbed and volatile Hg species, which vary in their reactivity and bioavailability in Hg-polluted sulphidic waters.

Inhibited water diffusion and inhomogeneities in glassy atmospheric aerosol proxies

D.L. BONES[1], D.M. LIENHARD[1,2], U.K. KRIEGER[2] AND J.P. REID[1]

[1]School of Chemistry, University of Bristol, Bristol, BS8 1TS, United Kingdom
[2]Institute for Atmospheric and Climate Science, ETH Zürich, Zürich, Switzerland

Atmospheric aerosol particles are typically complex mixtures of organic and inorganic species with correspondingly complex behaviours in changing humidity regimes. We investigate the formation of glassy or highly viscous phases in aqueous sugar aerosols such as sucrose and levoglucosan and aerosols of mixtures of sugars and inorganic compounds. It has recently been recognised that many aerosols exist as highly viscous solutions or as amorphous glasses, rather than a crystalline state, over a wide range of relative humidities (Virtanen, *et al*. 2010).

We use optical tweezers to trap single aerosol particles, exploiting subtle changes in the Raman spectra to deduce the size changes due to water uptake and evaporation from aqueous particles exposed to varying RH. We compare the experimental data with a kinetic model of diffusional limited size change.

Changes in size are dramatically hindered at low RH, with time scales approaching 10000s, for both increasing and decreasing RH regimes. The shift in resonance modes suggests initial formation of a layer of water on the surface of the glassy particle and subsequent establishment of a steep concentration gradient within.

To distinguish the country of origin of beefs that are currently sold in Korean market, a comparative analysis was conducted to examine carbon and oxygen isotopic compositions of beefs imported (from the USA, Mexico, Australia and New Zealand) and domestically produced beef. The result of the carbon isotope analysis showed good distinction between Korean beef and beef imported from the USA, Mexico and New Zealand. Based on carbon isotope values, it was difficult to distinguish between beef produced in Korea and beef imported from Australia, but these origins were easily distinguishable from oxygen isotope values. The oxygen isotope values reflect differences in consumed waters of the animal [1,2], according to the latitude of the country in which the beef was produced [3]. Such a result can be utilized to identify the origin of beef samples.

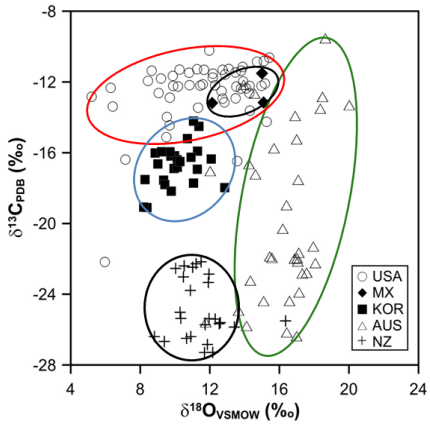

Figure 1: Cross plot of $\delta^{13}C$ and $\delta^{18}O$ values obtained from dry material from beefs produced in several countries.

Rare earth elements fractionation as proxies of unconformity uranium deposit mineralized fluids

J. BONHOURE AND O. POURRET

HydrISE, LaSalle Beauvais, 60026 Beauvais cedex, France (jessica.bonhoure@lasalle-beauvais.fr)

To better understand the formation of uranium deposits, rare earth elements (REE) and particularly REE compositon of oxides is a powerful tool. Indeed, REE fractionation occurs in uranium oxide [1] by substitution with U and REEs are poorly affected by post-crystallization events [2]. In such a case, REE should provide information on the temperature and redox conditions during deposition, pH and complexing ion concentrations of mineralizing fluids.

We herein document the case of the Athabasca Basin unconformity type, for which REE patterns show a MREE enrichment during incorporation as free species in U oxide for a pH between 3 and 5 [3]. In order to understand the speciation of the mineralized fluid, REE speciation in three multi-ligand solutions (reduced seawater, groundwater and F-rich groundwater) was calculated using PHREEQ-C and Nagra/PSI data base [4], which was modified to include well-accepted infinite-dilution (from 25 to 200°C) of inorganic species. Results from 25 to 200 °C show that at 3<pH<5 (i) in the reduced seawater lanthanides exists; (ii) in the groundwater, lanthanides occur as sulfate and fluoride complexes and free ionic species displaying a MREE enrichment; (iii) in the F-enriched groundwater, lanthanides occurs as free ionic species (HREE enriched) and complexed with fluoride (LREE enriched). Eventually, U oxides patterns are comparable with results of REE speciation in groundwater and LREE ratio indicates a deposition temperature between 125 and 150°C.

Calibration and applications of the dolomite clumped isotope thermometer to high temperatures

MAGALI BONIFACIE[1]*, JOHN M. FERRY[2], JUSKE HORITA[3], CRISOGONO VASCONCELOS[4], BEN H. PASSEY[2] AND JOHN M. EILER[5]

[5]California Institute of Technology, Pasadena, CA, USA

Carbonate clumped isotope paleothermometry is based on the temperature-dependent formation of $^{13}C^{18}O^{16}O_2^{2-}$ ion groups within solid carbonate minerals. This thermometer has now been calibrated for various synthetic and natural biogenic and abiogenic minerals (calcite, aragonite and carbonate-apatites [e.g., 1, 2]) at temperatures below ~ 50°C. Here we extend the use of the carbonate clumped isotope thermometer to shallow crustal environments by determining the Δ_{47} values of CO_2 extracted from natural and synthetic dolomites grown at know temperatures from 25 to 350ºC. The experimental temperature dependance is not linear in the Δ_{47} vs T^{-2} plot and resembles the predicted theoretical temperature dependence, both in shape and absolute value [3]. These data for synthetic dolomites overlap the previous calibrations for inorganic calcite and some forms of biogenic carbonates between 25 and 50°C, and are consistent with a single trend that also intersects data for synthetic calcite equilibrated at 1200°C. These observations suggest that a single temperature dependant relationship reasonably approximates the calibration for both phases. Data from a variety of slowly-cooled (i.e., over geological timescales) natural marbles and rapid (i.e., laboratory timescales) heating experiments provide insights into the kinetics of solid-state ^{13}C-^{18}O bond reordering in carbonates and its closure temperature. More generally, our new calibration and constraints on high-temperature kinetics have implications for the application of this technique to burial and metamorphic processes. These issues will be illustrated through estimates of the thermal history and oxygen isotopic compositions and abundances of pore fluids for several suites of late Neoproterozoic carbonates [e.g., 4].

Seasonal and tidal variations of dissolved thallium in coastal waters

P. BÖNING*, M. BECK, B. SCHNETGER AND H.-J. BRUMSACK

Institute for Chemistry and Biology of the Marine Environment, University of Oldenburg, Germany (*correspondence: p.boening@icbm.de)

Little is known on the distribution and behaviour of Thallium (Tl) in oceanic and coastal waters, perhaps due to its very low concentration level (8-20 ng L^{-1} or 40-90 pmol L^{-1}). Thallium is as highly toxic as Hg and Cd and is involved in redox reactions, which makes it an interesting candidate for the study of environmental processes.

Here we present a method for the rapid and reliable determination of dissolved Tl in sea water using sector field inductively coupled mass spectrometry (SF-ICPMS) without any preparation except 10 times dilution. Our method is suitable for the measurement of large time series of sea water samples [1]. Precision is 7 % RSD except for samples below the quantification limit (0.3 ng L^{-1}). Validation was done using the standards CASS-4 and NASS-5. For both CASS-4 and NASS-5 (salinity of 30.5) we calculated a concentration of about 11 ng L^{-1} assuming a Tl concentration of 14±2 ng L^{-1} at a salinity of 35±1. For CASS-4 we measured 10.6±0.7 ng L^{-1}, for NASS-5 10.3±0.8 ng L^{-1}[1], the latter of which is close to the value of 9.37±0.02 ng L^{-1} determined by isotope dilution-ICPMS by Nielsen *et al*. [2].

We applied our method to surface waters from the Jade Bay (an embayment of the Wadden Sea in NW Germany) [1]. Sampling was done hourly for 48 h during January, April, July and November 2010 at a fixed station located close to tidal flats, with a subsequent offshore transect. Pore waters were taken from sediments close to the fixed station.

In general, the results of all transect measurements (9-12 ng Tl L^{-1}) indicated conservative mixing since Tl varied with salinity. The time-series at the fixed station, however, yielded Tl concentrations of 6-11 ng L^{-1}, which only in part correspond to determined salinities. Hence, the distinct tidal variations in the concentration of dissolved Tl are rather explained by changes in the contribution of pore waters low in Tl (below the quantification limit).

Vegetation and climate: The potential role of terpene emissions and aerosol particle formation on local climate conditions

BORIS BONN

WG Aerosol and Environmental Sciences, Institute for Atmospheric and Environmental Sciences, J.W. Goethe University, D-60438 Frankfurt/Main, Germany, (bonn@iau.uni-frankfurt.de)

Any ecosystem and its individual biogenic species survive at specific climate conditions such as temperature, water supply, nutrients and chemical stress factors. In order to take measures to buffer extremes several possible pathways have been suggested. One of these include the emission of terpenes, their influence at ambient oxidant levels as well as in new aerosol particle formation. In this talk the role of individual mono- and sesquiterpenes will be discussed in a broader context emphasizing the ability of coniferous forests to compete with deciduous invaders in the context of changing climate conditions. The presentation is started with unraveling of new particle formation induced by organic volatile compounds conducted at three different scales, i.e. from gas-phase smog chamber studies via plant chamber to ecosystem smog chamber investigations. I will present a detailed understanding of the particle formation process taking into account the mixture of different mono- and sesquiterpenes emitted and their reactivity with ozone and OH. Both are essential for understanding since they limit the formation process at different steps via production of different large radicals. Since isoprene produces too small radicals any addition of isoprene attributed to changing environmental conditions leads to serious consequences on feedback processes and climate cooling. In this context I discuss the effect of a) deciduous emissions such as isoprene and b) of anthropogenic emissions such as of NO on the intensity of new particle formation. My presentation is then finalized by drawing conclusions on potential radiation and climate effects.

Chromium isotopes as an indicator of redox conditions in the Cryogenian shallow oceans

P. BONNAND[1]*, I.J. PARKINSON[1], R.H. JAMES[2] AND I.J. FAIRCHILD[3]

[1]Dept. of Earth and Environmental Sciences, The Open University, Walton Hall, Milton Keynes, MK7 6AA, UK (*correspondence: p.bonnand@open.ac.uk)

[3]University of Birmingham, Edgbaston, Birmingham B15 2TT, UK

Variations in atmospheric oxygen concentrations and the oxygenation level of the oceans during the geological past have been widely studied over the last 30 years [1]. A large increase in atmospheric O_2 during the Neoproterozoic has been postulated and is probably associated with a change in the redox condition of the oceans which enabled the explosion of life on Earth. Several models have been proposed, which have attempted to determine oceanic redox conditions during this Era [2]. The deeper oceans during the Neoproterozoic are generally believed to be anoxic until the end of the Ediacaran Period. However, little is known about redox conditions in the shallow oceans during the Neoproterozoic.

This study aims to determine the variation in redox conditions in the Cryogenian shallow oceans using REE chemistry and Cr isotopes in carbonate rocks. Chromium is a redox-sensitive element and its isotopes are fractionated during redox reactions [3]. Cryogenian carbonates from the Scottish Dalradian and the Greenland Eleanore Bay Supergroups are characterised by the lack of a Ce anomaly and positive $\delta^{53}Cr$ values. The lack of a Ce anomaly in ancient carbonates has been interpreted to reflect anoxic conditions [4]. However, these samples do record positive $\delta^{53}Cr$ values which are similar to modern and Phanerozoic carbonates [5]. These heavy $\delta^{53}Cr$ are interpreted to reflect oxidative weathering and the presence of sufficient O_2 to produce Cr(VI). These Cr isotopes data indicate that the shallow oceans during the Cryogenian was not anoxic and modelling suggests either dysoxic or suboxic conditions.

Terrigenous input and microcharcoal changes in the Gulf of Papua during the last 60 kyrs

N. BONNET*, T. DE GARIDEL-THORON, G. MENOT, L. BEAUFORT, N. BUCHET AND E. BARD

CEREGE, Univ. Aix-Marseille, CNRS, IRD & College de France, Technopole de l'Arbois BP 80, 13545 Aix-en-Provence Cedex 04 (*correspondence: bonnet@cerege.fr)

The last glacial cycle is characterized by abrupt climate changes at high latitudes. Less documented at low latitudes, they seem to strongly impact the hydrological cycle, and therefore the amount of burnable vegetation. In Melanesia, though records of the aborigine's first migrations are scarce, it is established that human settlement occurred during the last glacial. To unravel the human impact on the fire regimes from the natural hydrological variability, we reconstruct microcharcoals and records of terrigenous inputs in a sediment core (MD97-2134) in the Gulf of Papua. We use MicroCharcoals Morphotypes (MCM) and BIT index, as respective indices of the types of burnt vegetation (woodland or grassland) and of terrigenous inputs. We assume that past terrigenous inputs in the Gulf of Papua respond to precipitations changes over the mainland which also control the frequency and intensity of fires.

The most striking feature of these records is the abrupt change in the MCM record at about 47 ka BP. Prior this change, from 60 ka BP to 47 ka BP, the BIT and MCM indexes are correlated, which suggests a direct forcing of droughts on the burnt vegetation. After 47 ka BP, each proxy shows a different dynamics: the elongation of microcharcoals decreases abruptly, whereas the BIT index still records high frequency oscillation until 31 ka BP. We interpret this abrupt decoupling of terrigenous and microcharcoal records as likely influenced by anthropogenic fires related to aboriginal practices consecutively of the first migration wave.

The MCM record further shows an increase during the early Holocene, indicating an increase in the proportion of bush/forest fires ratio. This increase might be due to the development of agriculture over Papua New Guinea, though the reduced frequency of El Niño Southern Oscillation events might have also contributed to this event.

Fungi accelerate mineral weathering via a synergy of mechanical and chemical attacks

S. BONNEVILLE[1,2]*, D.J. MORGAN[2], A.W. BRAY[2], A. BROWN[3], A. SCHMALENBERGER[4], S. BANWART[5] AND L.G. BENNING[2]

[5]Kroto Research Institute, University of Sheffield, UK

Rock weathering, through net transfer of atmospheric carbon into the Earth's crust, is the main climatic feedback over geological timescales. So far, the role of plant roots and, in particular, the ability of their symbiotic fungi (mycorrhiza) to accelerate mineral weathering remains debated. Mycorrhiza grow preferentially around, and on the surface of nutrient-rich minerals, making such mineral-fungi contact zones potential hot-spot of alteration in soils. However, because of their microscopic nature (only ~ 5 μm wide but up 1 mm long) and their tendency to strongly adhere to mineral substrates, an *in situ* quantification of the interfacial alteration rates by hypha on minerals has never been achieved.

Here, an ectomycorrhiza (*Paxillus involutus*) grown symbiotically with a pine tree (*Pinus sylvestris*) in the presence of freshly-cleaved biotite under humid, yet undersaturated, conditions typical of soils. A sequence of interfacial alteration cross-sections was sampled via FIB (Focussed Ion Beam) ion-milling along a single, surface-bound hypha. Elemental depth-profiles of Si, O, Fe, Al, Mg and K measured by high-resolution electron micro-spectroscopy (STEM-EDS) across these interfaces showed significant elemental transfer (for Fe, Mg, Al and K) from the mineral substrate into the hypha. A quantitative model based on solid-state diffusion was developed and hyphal interfacial alteration rates were derived from these profiles. When compared *consistently* with abiotic dissolution rates measured in batch and flow-through reactors (i.e., same substrate - biotite (001) basal plane-, pH and temperature), the results reveal that the surface bound-fungi were between 3.5 to 30 times faster to alter the basal plane of biotite. The remarkable capacity of surface-bound fungi to degrade biotite is not ascribed to hyphal acidification or organic acid exudation, but rather to the mechanical strain that these micro-organisms exert, simultaneously to chemical alteration, on the mineral substrate over which they grow [1].

Palaeomag-dating of Kupferschiefer ore at Sangerhausen, Germany – An epigenetic, Late Jurassic age for stratabound Cu-mineralization

G. BORG[1]*, S. WALTHER[1], K. KAWASAKI[2] AND D. SYMONS[2]

[1]Petrology and Economic Geology Research Unit, Institute for Geosciences, Martin Luther University, Halle-Wittenberg (*correspondence gregor.borg@geo.uni-halle.de)

[2]Department of Earth and Environmental Sciences, University of Windsor, Windsor, Ontario, Canada, N9B3P4 (dsymons@uwindsor.ca)

Palaeomagnetic Dating of Mineralization

We have carried out paleomagnetic and rock magnetic measurements on 205 specimens from 15 underground sites from the abandoned Sangerhausen Mining District, Germany. Cu-mineralization is richest in Upper Permian (258±2 Ma) Kupferschiefer black marly shale (9 sites), extending into footwall sandstones (3 sites) and hanging wall carbonates (2 sites). ChRM directions were isolated for all sites using detailed alternating field and thermal step demag-netization. The site mean ChRM directions from the mine stratigraphic section yield a negative fold test that indicates that the ChRM post-dates Triassic to Jurassic fault block tilting of the strata.

Discussion of Results

The mean of all site mean directions gives a Late Jurassic paleopole at 149±3 Ma on the APWP for Europe [1]. This is significantly different (>>99% confidence) from a previous, hematite-alteration- derived paleopole [2] that initially gave an age of 254±6 Ma but cannot be maintained any longer. Our Late Jurassic, i.e. epigenetic, age for the ChRM in the black shale-hosted Kupferschiefer Cu-Pb-Zn ores at Sangerhausen correlates with crustal extension that formed the nearby North German Basin north of the Harz Mountains. This event reactivated major NW-SE striking faults and - arguably - major (ore)fluid pulses, associated with such fault movement. Spatial coincidence of major ore zones with intersections of NW-SE faults and fertile basement rocks additionally support our late, epigenetic metallogenetic model.

$\delta^{13}C_{carbonate}$ chemostratigraphy of the Carrapateira Outlier (Lower Kimmeridgian), Southern Portugal

M. BORGES[1]*[,2], R. GOOGHUE[3], P. FERNANDES[1], Z. PEREIRA[2], V. MATOS[1] AND B. RODRIGUES[1]

[1]CIMA, University of Algarve, 8005-139 Faro, Portugal, (*correspondence: marisa.borges@lneg.pt)

[2]LNEG, 4466-901 S. Mamede de Infesta, Portugal, (zelia.pereira@lneg.pt)

[3]Department of Geology, Trinity College Dublin, Ireland (goodhuer@tcd.ie)

The Carrapateira Outlier (CO) located 20 km north of Sagres is formed by Upper Triassic to Kimmeridgian sediments. The studied section is located at Três Angras bay and consists of approximately 50 m of limestones interbedded with marls, assigned to the Early Kimmeridgian based on corals, foraminifera and dinoflagellate cysts. The uppermost limestone beds are rich in macrofossils with well-preserved corals in life position. To compile $\delta^{13}C$ chemostratigraphy for this section, sixty five bulk carbonate samples were studied.

The $\delta^{13}C$ values vary gradually throughout the succession showing a baseline with a general decreasing trend up section, ranging from 1,59‰ to -0.68‰. However, the $\delta^{13}C$ curve indicates two main negative $\delta^{13}C$ excursions, the first related to a coarse grained interval with a minimum value of -1.38‰ and a second excursion with a minimum value of -3,10‰, immediately below the bioclastic rich beds of the top of the section. In general, the decreasing baseline trend agrees with the global $\delta^{13}C$ curve for the Kimmeridgian in the Tethyan Realm, where the CO was located. The two negative excursions are tentatively related to regional perturbations in the carbon cycle. Hence, both are interpreted as a result of large input of ^{12}C to the basin as a result from regressive pulses as suggested by the sedimentological and palynofacies analysis studied.

Acknowledgments: This study was sponsored by FCT (PhD grant SFRH/BD/48534/2008).

Pyroxenites in peridotites from External Liguride ophiolites (Italy): Insights on small scale heterogeneities in MORB mantle

G. BORGHINI[1,2], E. RAMPONE[1], A. ZANETTI[3], C. CLASS[2], A. CIPRIANI[2], A.W. HOFMANN[2,4] AND S.L. GOLDSTEIN[2]

[1]DIPTERIS, Università di Genova, Corso Europa 26, 16132 Genova, Italy
[2]Lamont-Doherty Earth Observatory, Palisades NY 10964, USA
[3]CNR-Istituto di Geoscienze e Georisorse, Sezione di Pavia, via Ferrata 1, I-27100 Pavia, Italy
[4]Max Planck Institute for Chemistry, P.O. Box 3060, 55020 Mainz, Germany

The occurrence of mafic layers in peridotites constitutes an important compositional heterogeneity in the mantle, and their role in mantle melting and basalt generation is currently debated. We present field, chemical and isotopic data on pyroxenites and host peridotites from the western peridotite massifs of the External Liguride ophiolitic Units (Northern Apennines, Italy). Pyroxenites (mostly spinel-websterites) occur as cm-thick bands (up to 12 cm) parallel to the tectonite mantle foliation, and ,together with the peridotites, they are partially recrystallized at plagioclase-facies conditions. Whole-rock and mineral compositions are extremely heterogeneous, covering almost the entire compositional range of worldwide lithospheric pyroxenites (Mg# = 74-88, Al_2O_3 = 10-17 wt%, CaO = 7-20 wt%). The pyroxenite chemistry reflects high-pressure magma segregation of tholeiitic melts dominated by clinopyroxene crystallization. A multi-step, sequential leaching procedure on clinopyroxene separates enables us to remove partial contamination and provides reliable Sr isotope data. The Sr and Nd compositions of clinopyroxenes from pyroxenites and peridotites fall in the typical range of normal MORB ($^{87}Sr/^{86}Sr$ =0.7023-0.7029; $^{143}Nd/^{144}Nd$ =0.5134-0.5128). Internal Sm-Nd isochrons on plagioclase-clinopyroxene pairs from two pyroxenites yield ages of 183±14 Ma and 177±12 Ma for the low-P mantle exhumation. On a slightly larger spatial scale, chemical and isotopic profiles through the pyroxenite-peridotite boundaries indicate cm-scale modification of the wall-rock peridotite, presumably related to emplacement of the pyroxenites. This suggests that deep melt intrusion can locally modify the host peridotites and introduce small scale compositional heterogeneity in a MORB mantle.

Heating organoclays: Does it affect their potential to interact with organic compounds in aqueous environment?

M. BORISOVER[1]*, S. YARIV[2], N. BUKHANOVSKY[1] AND I. LAPIDES[2]

[1]The Institute of Soil, Water and Environmental Sciences,The Volcani Center, ARO, Bet Dagan, Israel (*correspondence: vwmichel@volcani.agri.gov.il)
[2]Institute of Chemistry, The Hebrew University of Jerusalem, Edmund Y. Safra Campus, Jerusalem, Israel

By replacing inorganic exchangeable cations in clay minerals with organic cations, hydrophilic mineral/water interfaces may be converted to organoclay interfaces of variable and controlled lipophilicity. This paper summarizes the data on aqueous sorption of a series of organic compounds on organoclays preheated at different temperatures [1]. Sorptive properties of thermally treated organoclays are of interest since: (1) they can shed light on mechanisms of organic compound - organoclay interactions; (2) the thermal treatment is considered as a tool to regenerate organoclays after their use in different environmental applications; (3) thermally treated organoclays can provide a model for examining such important environmental issue, as fire-affected soils. Thus, organoclays were (*i*) prepared from the Na-montmorillonite rich bentonite with a series of quaternary ammonium salts and freeze-dried, (*ii*) heated during two hours in air at different temperatures, from 150 ^{0}C to 420 ^{0}C, and (*iii*) characterized by C/N, FTIR, XRD, TG-DTG and surface area analyses. Mild preheating of organoclays at 150 ^{0}C was not associated with chemical changes in the sorbent structure but was able to enhance interactions with organic compounds present in water. The extent of this enhancement reflected the different abilities of organic sorbates to compete with water molecules for sorption sites on organoclays. This observation supported the earlier idea that the partial, incomplete hydration of preheated organoclays can be a reason of increased organic sorbate – organoclay interactions [2,3]. Yet, there is no clear understanding why this rehydration of preheated organoclays is partial. When organoclays were heated at higher temperatures, the significant changes in the organoclay chemistry did not result in the remarkable loss of the organoclay sorptive potential towards organic compounds present in aqueous solution.

In recent years, interest in the biogeochemical roles of fungi in the environment has increased rapidly. Part of this research involves studying the ability of macrofungi to accumulate trace elements in fruit-bodies. Available data on some elements are rather scant or even equivocal. Specifically, ambiguous data have been reported for U, Th and REE. Since recent studies highlighted the possible role of fungi in the environmental biogeochemistry of U (Fomina *et al*. 2007, Env. Microbiol. 9: 1696-1710), there is an obvious need for more knowledge of macrofungal ability to accumulate U.

We have determined concentrations of U, Th and REE (HR-ICP-MS) in a representative set of macrofungi from unpolluted sites with differing bedrock geochemistry. Analytical results are supported by use of certified reference materials and the reliability of the determination of U was verified by epithermal neutron activation analysis (ENAA).

It appears that some data recently published on these elements are erroneous, in part because of use of an inappropriate analytical method; and in part because of apparent contamination by soil particles resulting in elevated levels of Th and REE. Macrofungi from unpolluted areas, in general, did not accumulate high levels of the investigated metals. Concentrations of U and Th were generally below 30 and 125 ng g^{-1} (dry weight), respectively. Concentrations of REE in macrofungi did not exceed 360 ng g^{-1} and their distribution more or less followed the trend observed in post-Archean shales and loess.

Concentrations of U in macrofungi from mine tailings and U-polluted forest plantations in the former Příbram mining district (Central Bohemia, Czech Republic) were significantly elevated but rather low; the highest values were in lower units of μg g^{-1}.

This research was supported by the Grant Agency of Charles University (project 3010) and the Czech Science Foundation (project P504/11/0484).

The roentgenoluminescence of feldspars from granitoids of the Kolyvan'-Tomsk folded belt as a typomorphic character

N.N. BOROZNOVSKAYA, T.S. NEBERA, S.I. KONOVALENKO, A. BAYOVA AND O. ZHEREBETSKAYA

Tomsk State University, Tomsk, Russia

Basic luminogens within the earth's crust, 92 % of which is formed of silicates, are defects in silicon-aluminum-oxygen tetrahedron (O^-) and isomorphic admixtures instead of K, Na, Ca, Mg, Al, Si (Tl^+, Pb^{2+}, Mn^{2+}, Fe^{3+}, Cr^{3+} and rare earths). L of O^- defects may be regarded as background. Its intensity is often determined by presence of decay structures and cooling rate. L of impurity defects in the earth's crust minerals depends on formation conditions (depth, crystallization temperature and cooling rate). The study has been carried out on the roentgenoluminescence spectra in the wavelength optical range (250-900 nm) in common potash feldspars (CPFS) and plagioclases from granitoids of the Kolyvan'-Tomsk folded belt (KTFB). Feldspars (FS) from all rock diversities of the Kolyvanskiy, Barlakskiy, Obskoy and Novosibirskiy massifs situated in the western part of KTFB nearby the Novosibirsk Trough have been the object of the investigation. The cause and effect relationship has been ascertained between the composition, structural ordering, crystallochemical characteristics and luminescence of the feldspars under consideration. The RL spectra of the Barlakskiy, Obskoy and Kolyvanskiy feldspar massifs are of similar character and result from the slow cooling in the conditions between the average and hypabyssal depths. The peculiarities of the RL spectra of the FS granitoids of the Novosibirskiy massif suggest the quick cooling of these rocks in the conditions of shallow depths or of the tectonically active zone (in the zone of crush). The dominating and extremely intensive RL of Fe^{3+} in the rocks of all massifs is frequently indicative of the existence of the hyperalkaline silicate melt for all objects under consideration. The presence of the Tl^+ RL with the maximum of 285 nm is the distinctive property of leucogranites from the Kolyvanskiy and Barlakskiy massifs, suggests the presence of the rare metal mineralization and is applicable as a typomorphic character. *These researches have been supported by the Ministry of Education and Science of Russia*.

Putative Cryogenian ciliates from Mongolia

TANJA BOSAK[1], FRANCIS MACDONALD[2], DANIEL G. LAHR[3] AND EMILY D. MATYS[4]

Major lineages of modern eukaryotes, represented primarily by microscopic taxa, are thought to have originated during the Neoproterozoic. However, microfossils older than 635 Ma rarely bear unambiguous relationships to modern microscopic eukaryotes.

Here we report exceptionally preserved 715-635 million year old eukaryotic tests in limestone strata of Mongolia. These structures are most abundantly preserved within rhythmite and ribbonite strata that record a large negative anomaly in $\delta^{13}C$ of both carbonate and organic matter.

The ~100 μm long organic-rich three-dimensional tests have flask-like shapes, constricted necks, distinct and often thickened collars. The test walls are flexible, composed of densely packed alveolar structures and stainable by dyes that react with polysaccharides. The combined morphological and ultrastructural properties of the Cryogenian tests are remarkably similar to the lorica of modern group of planktonic ciliates, tintinnids.

The presence of putative tintinnids in the pre-635 Ma strata places an upper bound on the divergence of ciliates, marks the increasing diversity of phagotrophic eukaryotes during this time and suggests a reorganization of Cryogenian foodwebs. The advent of planktonic organisms forming recalcitrant organic or mineral-rich tests may have increased export and burial fraction of organic carbon, driving an increase in atmospheric oxygen and the subsequent radiation of metazoans.

Origin and signficance of basic and ultrabasic outcrops from northeastern algeria (Edough massif)

D. BOSCH[1], D. HAMMOR[2], O. BRUGUIE[1], R. CABY[1], AND M. MECHATI[2]

[1]University Montpellier 2, Place Eugene Bataillon 34095, Cedex 05, France (bosch@gm.univ-montp2.fr)

The Maghrebian, Betics and Apenninic chains outcrop around the mediterranean basin and constitute dismembered fragments of the Alpine orogen. Conflicting geodynamic models have been proposed in order to explain the different paleogeographic settings from which these fragments derived. Crust-mantle interactions following subduction of Jurassic oceanic crust and collision-related tectonic events of Eocene age in relation to the northward motion of Africa have been demonstrated by numerous works. The incorporation of mafic/ultramafic rocks into the basement is evidenced in various peri-mediterranean areas, in particular at c. 22 Ma. This work is focused on the basic and ultrabasic rocks from the easternmost internal part of the Maghrebides. An extensive petrological and geochemical study has been performed on three distinct outcrops, i.e. Bou Maiza gabbros, amphibolites from La voile Noire and Sidi Mohamed peridotites. Peridotites display a primitive character (Mg number >85), but slightly enriched trace elements patterns (1 to 10 times CHUR) characterized by negative Nb anomalies and flat to slightly LREE-depleted patterns. Associated isotopic constraints suggest a possible continental contamination of the peridotites by the surrounding gneisses. These ultrabasic rocks are interpreted as parts of the lithospheric mantle incorporated into the continental crust during a late Burdigalian extensional event that opened the Algerian basin. The Bou Maiza gabbros and La Voile Noire amphibolites show complementary trace elements spectra suggesting derivation from a common MORB source reservoir, but without filiation with the Sidi Mohamed peridotites. Such affinities suggest they represent a fragment of the Neothetys lithosphere obducted onto the North African margin during Miocene times.

Natural analogue of CO_2 mineral sequestration: The Tuscan magnesite deposits

C. BOSCHI[1], L. DALLAI[1], A. DINI[1] AND G. RUGGIERI[2]

[1]Istituto di Geoscienze e Georisorse, CNR, Pisa, Italy
[2]Istituto di Geoscienze e Georisorse, CNR, Firenze, Italy

The magnesite deposit of Malentrata (Tuscany, Italy) was derived from silicification–carbonation of Ligurian serpentinites embedded in pelite-carbonate formations, and represents a natural analogue of *in situ* CO_2 mineral sequestration. Serpentinites were transformed to a brownish friable mineral assemblage of opal, chromian montmorillonite, Fe-rich magnesite and minor iron sulfides and oxides. The serpentinite alteration was accompanied by the formation of magnesite and dolomite veinlets, and large magnesite–dolomite veins along major tectonic structures. The major veins are characterized by the following crystallization sequence: i) early magnesite, ii) green and late pale-brown dolomite cementing the early brecciated magnesite vein infill, and iii) late quartz, chalcedony and opal. The observed mineral assemblage is indicative of low temperature hydrothermal alteration driven by Si- and CO_2-rich fluids under relatively low pH conditions. Geochemical data along transects from carbonated host rocks to carbonate-silica veins suggest a marked variation of fluid composition through the main stages of precipitation. Dolomites are more enriched in Cr, Sr, Y, U and REE with respect to magnesites. Magnesites are the most REE-depleted, whereas green dolomites show quite flat enriched patterns approaching the pattern of sedimentary formations. $\delta^{18}O$ of magnesites range from 23 to 32‰, and $\delta^{13}C$ from -2 to 0‰. Both dolomite types are depleted in $\delta^{18}O$ with respect to magnesite, especially late pale-brown dolomite. $\delta^{13}C$ of dolomites is similar to magnesite with slightly lower values in green dolomites. It seems to be conceivable that fluids first interacted with serpentinites precipitating magnesite. After the magnesite precipitation, fluids interacted with the sedimentary formations, becoming progressively enriched in calcium and REEs, and depleted in $\delta^{18}O$ due to the partial equilibration with the pelite portion. At this stage dolomite precipitation recorded geochemical variations of fluids. Malentrata deposit lies at the periphery of Larderello geothermal field and it highlights the near surface local interaction between low temperature fluids and serpentinite bodies in favourable tectonic conditions.

Deciphering arsenic sources in surface waters and the role of bacterial oxidation

A. BOSSY[1]*, C. GROSBOIS[2], C. JOULIAN[3], F. BATTAGLIA-BRUNET[3] AND A. COURTIN-NOMADE[1]

[1]EA GRESE, Limoges Univ., 87060 Limoges, France (*correspondence: angelique.bossy@etu-unilim.fr)
[2]UMR 6113 CNRS ISTO, Tours Univ., 37000 Tours, France
[3]Process and Environment Division, BRGM, 45060 Orléans, France

In a geochemical anomaly in As, different potential As contributions to stream waters, such as groundwaters, runoff and As-bearing phase weathering present within the soils were studied with a high sampling frequency. It allowed deciphering the contribution of each compartment to As contamination of surface waters. The role of indigenous bacteria in As oxidation state in ground- and surface waters was also studied in laboratory.

In the soil profile, total As concentrations indicated depletion (1500 to 385 $mg.kg^{-1}$) during pedogenesis relative to a mineralogical evolution of As-bearing phases upwards the soil profile: from arsenates (Ba-rich pharmacosiderite: 14-26 wt.% As) to Fe-oxyhydroxides (ferrihydrite-like: 4-16 wt.% As; ferrihydrite-type, hematite and goethite: <3 wt.% As). Conversely, an increase of dissolved As concentrations (15-52 $\mu g.L^{-1}$) was observed in soil solutions.

In stream waters, As concentrations (7.5 to 69.4 $\mu g.L^{-1}$) were attributed to several inputs: (i) runoff and soil solutions, (ii) waters from former adits (97-120 $\mu g.L^{-1}$ As), (iii) wetland and groundwaters (up to 169 and 215 $\mu g.L^{-1}$ As, respectively). The latter inputs were characterized by dissolved As(III) during low flow period which was rapidly oxidized, suggesting the contribution of bacterial oxidation.

Bacterial As oxidation tests showed a decrease of dissolved As(III) concentrations in stream and wetland waters (-17% and -41%, respectively). In groundwaters, a stronger decline for dissolved As(III) (-95% in 15 h) was observed, then followed by an As(III) release (+51%), suggesting the presence of As(V)-respiring bacteria. The study of the As(III)-oxidizing bacterial community (PCR-DGGE method on *aoxB* genes, a genetic marker of these bacteria), showed a divergence in the community structure between (i) surface and wetland waters, and (ii) groundwaters, probably due to variable As concentrations, redox conditions and bacteria number.

The effect of Cl on the solubilty of Au and Pd in andesitic melts

R.E. BOTCHARNIKOV[1]*, R.L. LINNEN[2], M. GUILLONG[3], F. HOLTZ[1] AND V.S. KAMENETSKY[3]

[1]Institut für Mineralogie, Leibniz Universität Hannover, Callinstr. 3, D-30167, Hannover, Germany (*r.botcharnikov@mineralogie.uni-hannover.de)
[2]Department of Earth Sciences, BGS 1000B University of Western Ontario, London, ON, N5A 5B7 Canada
[3]ARC Centre of Excellence in Ore Deposits, University of Tasmania, Hobart, Tasmania, 7001 Australia

Chlorine is considered as an important agent responsible for the mobilization and transport of metals in magmatic systems associated with porhyry ore mineralization and with late-stage metal-rich horizons of large igneous intrusions. In the former case, the considerable role of Cl is confirmed by the observation that fluid inclusions associated with porphyry ores are often composed of low-salinity aqueous vapor and high-salinity brines, whereas in the later case it is believed that the mobility of metals in different horizons of layered intrusions might have been controlled by the general process of chromatographic separation of metals during migration and evolution of Cl-enriched fluids. Since at given magmatic conditions the mobility and transport of metals by exsolving Cl-bearing fluid phase(s) is presumably dependent on chemical potential of metal components complexing with Cl in silicate melt, quantitative experimental data on metal solubility in melts and melt-fluid partitioning are required.

Here we report the results of experiments on the solubility of Au and Pd in andesitic melts equilibrated with $Au_{80}Pd_{20}$ capsule material at 1200°C, oxidizing conditions (FMQ+3) and pressures in the range from 50 to 500 MPa as a function of Cl content in the system. Due to non-ideality of mixing in Cl-bearing fluids, the investigated systems are characterized by coexistence of andesitic melts with vapor, vapor+brine, brine, or supercritical single-phase fluid, depending on the bulk Cl content and P. The obtained data show that an addition of Cl to the system increases significantly the solubility of both metals in the silicate melt at all investigated pressures, in particular in melts coexisting with brine or supercritical fluid. The concentration of Au increases from 1-2 upto 40-50 μg/g, whereas the concentration of Pd increases from 0.1 to 20 μg/g with increasing Cl content of the melt from 0 to 2.5 wt%. Since the calculated activity coefficients of Au and Pd in the $Au_{80}Pd_{20}$ capsule are both close to 0.7, the solubility values of pure metals should be slightly higher. The results clearly show that Cl can indeed control on the mobility of Au and Pd in natural magmas.

The transformation of ACC to vaterite; An *in situ* SAXS/WAXS study

P. BOTS[1]*, J.D. RODRIGUEZ-BLANCO[1], T. RONCAL-HERRERO[1,2], S. SHAW[1] AND L.G. BENNING[1]

[1]School of Earth and Environment, University of Leeds, LS2 9JT, United Kingdom (*eepbo@see.leeds.ac.uk)
[2]Department of Geosciences, University of Oslo, PB 1047, Blindern, Oslo, Norway.

Vaterite (μ-$CaCO_3$) is rarely observed in natural systems, as it is thermodynamically unstable with respect to calcite and aragonite [1]. However, some organisms produce and stabilize vaterite as biominerals [2]. At high supersaturation vaterite forms via a nanoparticulate, poorly-ordered and metastable precursor, amorphous calcium carbonate (ACC). In the pure system, ACC transforms to vaterite within minutes, and subsequently to calcite [3]. The detailed mechanisms of the ACC to vaterite transformation are however still lacking due to the fast kinetics of this first step of crystallization. In this study we demonstrate the use of *in situ* time-resolved synchrotron-based Small- and Wide-angle X-ray Scattering (SAXS/WAXS) combined with off-line characterization to quantify the kinetics and crystallization mechanisms of vaterite at fast time scales.

The SAXS/WAXS data collected at 1 second / frame for up to 32 minutes, revealed that the ACC to vaterite transformation occurs in 3 stages. The initial stage (0-2 min) was governed by ACC precipitation and growth (to Ø ~ 38 nm). During this stage ~70 % of the total vaterite (Ø ~ 10 nm) formed via spherulitic growth at the expence of the metastable ACC [4]. The end of the spherulitic growth (at 2 min) was concomitant with a drop in supersaturation below the limit for spherulitic growth of vaterite (SI≈1.4 [4]). During the 2nd stage (2-7 min), remnant ACC lead to a further increase of the amount of vaterite (~30 %) due to ACC dissolution and vaterite nanocrystal reprecipitation. During this stage the vaterite crystallite size increased from ~10 to ~35 nm. Finally during the 3rd stage (> 7 min), no *de nuovo* precipitation of vaterite occurred, however the vaterite crystallite size continued to increase reaching ~60 nm at the end of the experiment (32 min). This increase in crystallite size was solely governed by Ostwald Ripening.

Understanding late accretion on the Earth, Moon, and Mars

W.F. BOTTKE[1], R.J. WALKER[2], J.M.D. DAY[3], D. NESVORNY[1] AND L. ELKINS-TANTON[4]

[1]Southwest Research Institute & NASA Lunar Science Institute, Boulder, CO, USA (bottke@boulder.swri.edu)

[3]Geosciences Research Division, Scripps Inst. Oceanography, La Jolla, CA 92093 USA
[4]MIT, Cambridge MA 02139 USA.

Highly siderophile elements (HSE) have low-pressure metal-silicate partition coefficients that are high [$>10^4$]. It is assumed the silicate portions of rocky planetary bodies with metallic cores are effectively stripped of HSE immediately following primary accretion and final core segregation. Accordingly, the 'giant impact' on Earth that formed the Moon should have cleansed HSE from the mantles of both worlds.

Curiously, the Earth and Moon (and Mars) have disparate, yet elevated HSE abundances. We argue late accretion may provide a solution, provided that ≥ 0.5% Earth masses of broadly chondritic planetesimals reaches Earth's mantle, and that ~10 and ~1,200 times less mass go to Mars and the Moon, respectively [1]. Our models show that leftover planetesimal populations dominated by massive projectiles can explain these additions, with our inferred size distribution matching those derived from the inner asteroid belt, ancient martian impact basins and planetary accretion models. The largest late terrestrial impactors, at 2,500-3,000 km in diameter, potentially modified Earth's obliquity by ~10°, while those for the Moon, at ~250-300 km, may have delivered water to its mantle.

To keep the iron core from such a large projectile sequestered in Earth's mantle, HSE delivery there may involve a "hit and almost run" collision. Here most of the projectile's core (and HSE) plows through the target mantle and emerges on the other side in a highly-fragmented state. The debris then evolves into a long spiral-arm-like structure that rains down across the target. These events may allow massive impactors to deliver large quantities of HSE, but in a manner akin to small body accretion that optimizes emulsification into the upper mantle. This potentially explains why mantle peridotites have similar HSE abundances and how the iron in the projectile's core became oxidized.

Direct Injection Nebulization with MC-ICP-MS: Performances and prospects

J. BOUCHEZ*[1,2], P. LOUVAT[1], G. PARIS[2,3], J. GAILLARDET[2] AND J. MOUREAU[2]

[1]IPG Paris (UMR CNRS 7154), Université Paris Diderot, 1 rue Jussieu, 75252 Paris Cedex 05, France
[2]GFZ, Telegrafenberg, Potsdam, Germany (*correspondence: bouchez@gfz-potsdam.de)
[3]CalTech, Pasadena CA 91125, USA

The advent of MC-ICP-MS during the last decade has considerably improved isotope ratio measurements in terms of accuracy, precision, reproducibility and rate of sample throughput. Nevertheless, the search continues for more efficient, more stable, more sensitive and cleaner introduction systems. This is particularly true for (1) "sticky" elements displaying long washout times (2) volatile elements whose sensitivity cannot be improved by desolvation systems.

Boron belongs to both categories. Recent development of the d-DIHEN [1] (demountable Direct Injection High Efficiency Nebulizer) allows for faster and more precise determination of boron isotope ratio by MC-ICP-MS [2]. The principle of direct injection is to place a long quartz nebulizer in the plasma torch, spraying the sample directly into the plasma.

Using d-DIHEN along with Neptune MC-ICP-MS, sensitivity of 10 V/ppm (at an uptake rate of 30 μL/min) are obtained, with washout times of 2 to 3 minutes to reach background levels of less than 1 ‰ of the previous sample signal. Recent automation using a SC sampler and the FAST system (ESI) allows for systematic triplicate measurements of each sample, thereby improving the reproducibility to less than 0.2‰ (2 S.D.) in most cases. Performances obtained with the improved interface pumping capacity along with a Teflon spray chamber will also be presented for comparison.

Li isotope measurements with d-DIHEN yield reproducibilities similar to the ones obtained with the APEX desolvation system (ESI), despite a lower sensitivity and rounder peak shape, while allowing for faster measurements because of shorter washout times.

At this level of precision, drastic intensity matching between standards and samples appears to be highly critical, and has to be within 5%. Forthcoming improvements seem to lie in even more drastic chemical purification procedures.

Carbonates are the main C-bearing minerals that are transported deep in the Earth's mantle via subduction of the oceanic lithosphere [1]. The fate of carbonates at mantle conditions plays a key role in the deep carbon cycle. Decarbonation, melting or reduction of carbonates will affect the extent and the way carbon is recycled into the deep Earth.

High-pressure high-temperature experiments were carried out up to 105 GPa and 2850 K on oxide assemblages of (Mg,Fe)O + CO_2. The presence of $Fe^{(II)}$ in starting materials induces redox reactions from which $Fe^{(II)}$ is oxidized and a part of the carbon is reduced. This leads to an assemblage of magnetite, diamonds, and carbonates or, pressure depending, their newly discovered $Fe^{(III)}$-bearing high-pressure polymorphs based on a silicate-like chemistry with tetrahedrally coordinated carbon [2]. Our results show the possibility for carbon to be recycled in the lowermost mantle and provide evidence of a possible coexistence of reduced and oxidized carbon at lower mantle conditions.

Advances in high precision Ca isotope ratio measurements using TIMS

CLAUDIA BOUMAN*, DIETMAR TUTTAS, MICHAEL DEERBERG AND JOHANNES SCHWIETERS

Thermo Fisher Scientific, Hanna-Kunath-Str. 11, 28199 Bremen, Germany.
(*correspondence: claudia.bouman@thermofisher.com)

Ca isotopes are used in various disciplines within Earth Sciences, e.g. paleoceanography, geochronology and biogeochemistry. Precise and reproducible measurements of Ca isotopes are among the most challenging measurements within TIMS. Most important factors influencing the precision and reproducibility are sample loading, choice of double spike, instrumental mass fractionation and mass spectrometer performance. Advances in mass spectrometry have been made with the introduction of the TRITON *Plus*.

The TRITON *Plus* has innovative features that enable high precision Ca isotope ratio measurements for all Ca isotope ratios. First of all, the TRITON *Plus* enables simultaneous collection of 40Ca up to 48Ca without zoom due to the extended mass dispersion. Also, the instrument can house different ohmic resistors (10^{10}, 10^{11} and 10^{12} Ohm). This is especially useful for isotope systems with a large dynamic range, such as Ca, where the abundance of the major isotope is almost 97%. If smaller samples are analysed, the low-noise 10^{12} Ohm amplifiers are advantageous, since they show up to a factor of 3 improvement in signal/noise ratio over the standard 10^{11} Ohm current amplifiers.

In this contribution, we present basic performance features for the TRITON *Plus* with regard to Ca isotope ratio measurements, as well as precision and reproducibility for different sample sizes.

Alteration of oil by gas: Experiments in fused silica capillary capsules

J. BOURDET[1]*, P.J. EADINGTON[1], R.C. BURRUSS[2] AND I.-M. CHOU[2]

[1]CSIRO, CESRE, 26 Dick Perry Ave., Kensington, 6151, WA, Australia (*julien.bourdet@csiro.au)
[2]US Geological Survey, 956 National Center, Reston, VA 20192, USA

Reservoir case studies showed that the fluorescence of oil inclusion assemblages of current or palaeo-gas zone has patterns that are not seen in zones that have only been invaded by oil [1, 2]. It is suspected that a fraction of the oil is retained in the pores when oil is drained by gas and that molecules from this residual oil partionned in gas.

To attempt to reproduce the alteration of oil by gas, or gas-washing, we sealed small amounts of crude oil (59º, 42º or 33º API) and excess pure gas (methane, ethane, propane) in fused silica capillary capsules (FSCCs, [3]), with and without water. The UV-visible fluorescence spectra of oil phase(s) enclosed within the FSCCs were measured at temperatures of 20 to 100 ºC, and Raman and FT-IR spectra of the gas and oil phases were measured at 20ºC. With ethane and propane, the 33°API oil formed a new immiscible fluorescent liquid phase with fluorescence that is more blue than the initial oil, which became more yellow or disappeared or more blue when semi-solid residues formed. No or less solid residues formed in FSCCs without added water. Experiments with 59°and 42° API oil do not show immiscible hydrocarbon liquids. The fluorescence of those crude oils displays a yellow shift in presence of gas. Solid residues are minor.

We interpret for the residual oil (1) the decrease of fluorescence at short wavelengths (red-shift) as due to partitioning of low molecular weight aromatic molecules into the new immiscible liquid phase and/or vapour phase; (2) the decrease of fluorescence response at long wavelengths (blue-shift) as due to loss of high molecular weight aromatics by precipitation of solid residues; (3) the increase of fluorescence response at short wavelengths (blue-shift) as due to desorption of aromatics and resins from asphaltene. Water has effects on the precipitation of semi-solid residue and stability of oil phase in the lowest API gravity oil.

These results are consistent with the attributes of oil inclusions trapped in palaeo-oil zones that were displaced by gas and support the concept of gas-washing of residual oil.

Conditions of metal-silicate segregration in the parent bodies of iron meteorites

BERNARD BOURDON

Laboratoire de Géologie de Lyon, CNRS, UMR 5276, Ecole Normale Supérieure de Lyon, France

While there has been extensive work on the conditions of core formation on Earth, little work has focused on the conditions of core formation in the parent bodies of iron meteorites. A major obstacle to addressing this question is that the bulk compositions of the parent bodies are unknown and the iron meteorites do not represent directly the metallic liquid that segregated from silicates. Rather the iron meteorite compositions reflect various degrees of crystallization and fractionation of metallic iron. In some cases, there can be more than one liquid making the modelling more difficult.

By making the assumption that the bulk composition of the parent bodies was chondritic for the refractory siderophile elements, one can obtain a rough estimate of the size of the core and then estimate the corresponding oxygen fugacity of the parent body. In addition, using experimental determinations of the partition coefficients between metal and silicate, one can reconstruct the temperature and pressure conditions of metal-silicate segregation for various parent bodies. Using this approach, one can also estimate the abundance of volatile siderophile elements in the parent bodies of magmatic iron meteorites.

Due to the large number of assumptions made in this modelling, one can only obtain estimates for the oxygen fugacities, pressures and temperatures during core formation of the iron meteorite meteoroids. In the case of the IIIAB meteorites, the oxygen fugacity is close to IW-1.1 while it is IW-0.8 for the IVA magmatic iron parent body, which confirms the more oxidized nature of these parent bodies compared with the Earth (IW-2). In the case of the IVA irons, the best match is obtained for a volatile depleted bulk composition and the conditions of metal segregation has to be less than 1 GPa with a temperature ranging between 1600 and 1800 K. The siderophile element abundance of IIIAB requires a slightly higher temperature range and similarly low pressure.

Molecular dynamics simulations of the electrical double layer on smectite clay surfaces

IAN C. BOURG AND GARRISON SPOSITO

Earth Sciences Division, Lawrence Berkeley National Lab, Berkeley, CA, USA (*correspondence: icbourg@lbl.gov)

We report new molecular dynamics (MD) simulation results elucidating the structure of the electrical double layer (EDL) on smectite surfaces contacting mixed NaCl-$CaCl_2$ electrolyte solutions in the range of concentrations relevant to pore waters in ocean sediments and in geologic repositories for CO_2 or high-level radioactive waste (0.34 to 1.83 mol_c dm^{-3}). Our simulations used methodologies known to correctly describe the structure and diffusion coefficients of water and solutes in smectite interlayer nanopores [1]. Our results confirm the existence of three distinct ion adsorption planes (0-, β-, and d-planes), often assumed in EDL models [2,3], but with two important qualifications: (1) the location of the β-, and d-planes are independent of ionic strength or ion type and (2) "indifferent electrolyte" ions can occupy all three planes. Charge inversion occurred in the diffuse ion swarm because of the affinity of the clay surface for $CaCl^+$ ion pairs. Therefore, at concentrations ≥ 0.34 mol_c dm^{-3}, properties arising from long-range electrostatics at interfaces (electrophoresis, electro-osmosis, co-ion exclusion, colloidal aggregation) will not be correctly predicted by most EDL models. Co-ion exclusion, typically neglected by surface speciation models, balanced a large part of the clay mineral structural charge in the more concentrated solutions. Water molecules and ions diffused relatively rapidly even in the first statistical water monolayer, contradicting reports of rigid "ice-like" structure for water on clay mineral surfaces.

Quantifying weathering and erosion rates using cosmogenic nuclides.

D.L. BOURLES, R. BRAUCHER AND L. SIAME

CEREGE, UMR 6635 CNRS-Aix-Marseille Université, BP 80, 13545 Aix-en-Provence Cedex 4, France

Quantifying chemical weathering and physical erosion rates, whose sum corresponds to denudation rates, is of great importance across a wide range of environmental science disciplines Until recently, this has nevertheless been difficult over millenial timescales. Accumulating within mineral grains exposed to cosmic ray secondary particles in the uppermost few meters of the Earth's surface, *in situ*-produced cosmogenic have provided opportunities to quantify on such timescales not only the mineral grains exposure duration near the surface, but also the rates of the processes bringing them to the surface and removing them from above it.

Corresponding to their build-up in the suitable mineral over thousands of years, the cosmogenic nulide concentrations measured in rocks, sediments or soils are relatively insensitive to short-term fluctuations and thus allow quantifying natural, long-term weathering and erosion rates. More, they permit to evidence landscapes that are not at natural steady state because affected by natural hazards (landslides) or by anthropogenic activities. Cosmogenic nuclides thus provide reliable methods to measure long-term average denudation rates in a wide range of settings and to point out any perturbations that may have disturbed them.

Through the presentation of pertinent case studies from notably Brasil, Taïwan and Africa, the following general types of denudation-related problems will be addressed: (i) denudation rates from rock surface samples; (ii) denudation rates from vertically mixed continental sediments; (iii) spatially averaged denudation rates.

Magma recharge and eruption processes at Volcán Llaima (Andean Southern Volcanic Zone, 38.7°S)

C. BOUVET DE MAISONNEUVE[1]*, M.A. DUNGAN[1], O. BACHMANN[2] AND F. COSTA[3]

[1]Earth Science Section, University of Geneva, 1205 Geneva, Switzerland (*correspondence: caroline.bouvet@unige.ch)
[2]Earth and Space Sciences, University of Washington, Seattle, WA 98195-1310
[3]Earth Observatory of Singapore, Nanyang Technological University, Singapore 639798

Volcán Llaima (38.7°S) is one of the most active volcanoes in Chile with over 50 eruptions since 1640. Periods of eruptive activity are generally characterized by a combination of violent Strombolian explosions and voluminous lava flows. A previous study based on whole-rock, mineral, and olivine-hosted melt inclusion compositions of basaltic-andesitic magma erupted during three different episodes revealed shallow magma storage (2-3 km depth) as mush (>50 vol% crystals) in multiple dike-like reservoirs. Further characterization of the olivine compositions and comparison of the lava and tephra yield information on magma recharge time scales and eruption triggering. Multi-element zoning patterns (Fe, Mg, Mn, Ca, Ni, Cr, Ti, Co, Sc, V, Y, Al, P) were measured by LA-ICP-MS in olivine crystals from tephra. Coherence in the zoning patterns between various traverses and crystals from the same eruption allow us to reliably identify multiple magma replenishment events and the time scales at which they occur. Most elements record the latest recharge event, which took place between 100 and 600 days before eruption, while others (e.g. V, Ti, and Sc) also preserve compositional oscillations in the crystal core which we interpret as older recharge events. Comparison of the lava and tephra reveal higher crystallinities (~50 vol% vs. ~30 vol%) and a greater fraction of more evolved (mush-derived) crystals in the lava than in the tephra. This suggests that shifts in eruptive style at Volcán Llaima are strongly affected by the ratio of volatile-rich magma recharge to resident mush. When this ratio is low, the crystallinity of the erupted magma is high, which implies that (1) the resistance to flow is large, and (2) a permeable volatile network is achieved early, thereby promoting volatile-loss and diminishing the magma buoyancy. When the fraction of recharge magma is large, the crystallinity of erupted magma is lower and bubbles will tend to couple with the magma, entraining it rapidly toward the surface and producing a Strombolian eruption.

The first 10 million years of the Solar System

A. BOUVIER

Arizona State University, School of Earth and Space Exploration, Tempe, AZ 85287, USA (correspondence: audrey.bouvier@asu.edu)

The initial conditions of the solar nebula and subsequent formation and evolution of the protoplanetary disk can be constrained using chronological and isotopic studies of meteorites and samples returned from space missions. Chronology of early Solar System processes at a sub-My resolution is based on the long-lived U-Pb and short-lived (e.g., ^{26}Al-^{26}Mg) radiogenic systems. The precision of isotopic dating has dramatically increased over the last decade with the development of new mass spectrometry techniques. The accuracy, nevertheless, relies on knowledge of the initial composition, the distribution of the isotope pairs throughout the nebula, possible late additions, and disturbances during planetary processes. The degree of heterogeneity of the solar nebula can be evaluated from isotopic variations found for some elements (e.g., Nd, Ni) in chondritic and differentiated meteorites. Recently, U isotopic variations measured in CAIs [1] revealed the presence of ^{247}Cm in the early Solar System and consequently required the adjustment of previous U-Pb dates. For example, the U-Pb and Al-Mg chronologies of the formation of CAIs relative to chondrules are important constraints for the lifetime of the protoplanetary disk but are discordant [e.g., 2,3]. This brings into question the use of some meteoritic samples as reference materials, and reinforces the need for high-precision U-Pb isotopic studies of planetary materials.

The presence of short-lived radionuclides (SLR) has implications for the astrophysical environment of the Solar System. It is essential to determine the initial abundances and distribution of SLR in the Solar System to understand their origin and transfer within the nebula and possibly the protoplanetary disk. In particular, the source(s) of ^{26}Al and ^{60}Fe in the Solar System need to be constrained more tightly. As the major initial radiogenic heat sources, these two isotopes played a crucial role in the formation and evolution of habitable planetary worlds. I will discuss the most recent advances in the chronology of primitive and differentiated meteoritic objects using the U-Pb and extinct radioactivities and how they affect our models for Solar System formation and planetary evolution.

The formation of the angritic crust

A. BOUVIER*, G.A. BRENNECKA, M.E. SANBORN AND M. WADHWA

Arizona State University, School of Earth and Space Exploration, Tempe, AZ, 87287-1404, USA. (*correspondence: audrey.bouvier@asu.edu)

Angrites are a small group of basaltic meteorites which record the early stages of planetary formation and differentiation [1]. They are comprised of two main textural subgroups reflecting different cooling and metamorphic histories: fine-grained 'quenched' angrites (e.g., D'Orbigny), and coarse-grained 'plutonic' angrites (e.g., Angra dos Reis) [1]. The recently recovered angrite Northwest Africa (NWA) 6291 is suggested to be paired with NWA 2999; both have larger modal abundances of metal and spinel compared to other angrites [2, 3]. NWA 6291 contains fine- (FG) and coarser-grained (CG) lithologies comprised of pyroxene, anorthite, olivine, and spinel.

We measured trace element abundances and the $^{238}U/^{235}U$ ratio in a whole-rock (WR) sample of NWA 6291 (WR1, washed in 0.05M HCl). We processed 7 acid-washed WR powders prepared from the FG and CG lithologies and 3 pyroxene separates from the CG lithology of NWA 6291 for Pb isotopic analysis. The weak leachates (L_{1-3}) and all Pb column matrices of subsequent leachates (L_{4-8}) and residues (R) were recombined respectively for U separation and isotopic analysis. Analytical details are provided in [4,5]. The REE pattern is LREE-depleted (La/Yb_N=0.6), with HREE abundances at ~4×CI. The Th/U is ~3.5. The $^{238}U/^{235}U$ =137.754 for WR1, =137.785 for the recombined L_{1-3}, and =137.744 for the recombined L_{4-8} and R (±0.026, 2SD); these values are similar to those for other angrites [6].

The Pb-Pb internal isochron age of NWA 6291 (calculated using its measured $^{238}U/^{235}U$) is 4560.1 ±1.1 Ma (MSWD=2), identical to that of NWA 2999 [7] using $^{238}U/^{235}U$ =137.75. The incompatible element depletion in both these angrites relative to other quenched and plutonic angrites is attributed to lack of phosphate. Their similarities confirm their pairing and suggest a new angritic subgroup, while their ages indicate that crust formation on the angrite parent body began ~5 Ma after CAI formation, and continued for a period of ~6 Ma thereafter [4,7,8].

Interaction of small organic molecules with the calcite surface

N. BOVET*, M. YANG, M.P. ANDERSSON AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*correspondence: bovet@nano.ku.dk)

Calcite ($CaCO_3$) is one of the most abundant salts in the Earth's crust. Its surface behaviour in the presence of liquids and gases controls its dissolution, precipitation, adsorption and desorption. To help understand these complicated phenomena, a fundamental understanding of surface/gas interaction is required.

In this work, we investigated the molecular interaction of small organic molecules with the {10.4} surface of calcite. X-ray photoelectron spectroscopy (XPS), a surface sensitive technique that allows quantitative and qualitative investigation of surfaces, and simulations using molecular dynamics (MD) and density functional theory (DFT) were applied to determine the geometry, coverage and bond strength of ethane, ethanol, t-butanol, carbon dioxide, acetic acid and glucose molecules on calcite.

A series of pristine calcite {10.4} surfaces, prepared by cleavage in vacuum, were examined with XPS while gases were leaked into the experimental chamber. We used the high resolution carbon 1s signal, which has significant energy shifts, to observe coverage of the organic molecules. We also measured the temperature of desorption for each species to estimate its bonding strength.

The results show that CO_2 molecules form the weakest bond with calcite, with a desorption temperature of –130 °C. Glucose forms the strongest bond among the molecules studied and does not desorb even at 560 °C. We also observed that all the molecules formed a compact layer on the surface, except ethane, which does not adsorb at all in our experimental conditions, exhibiting no affinity with calcite. The MD and DFT calculations parallel the experimental results, indicating that CO_2, alcohols and acetic acid form a well ordered monolayer on calcite.

We are using the information about the bonding of simple molecules on calcite to interpret interaction of more complex organic molecules, such as those that play a role in biomineralisation, adsorbing from solution and inhibiting calcite growth and recrystallisation.

Mineralogy and geochemistry of a potential CO_2 sequestration reservoir and seal system, Illinois Basin, USA

B.B. BOWEN[1]*, T. LOVELL[1], R. NEUFELDER[1], J. RUPP[2], J. BROPHY[3] AND R. LAHANN[2]

[1]Department of Earth and Atmospheric Sciences, Purdue University, West Lafayette, IN 47907 (*correspondence: bbowen@purdue.edu)
[2]Indiana Geological Survey, Bloomington, IN 47405
[3]Department of Geological Sciences, Indiana University, Bloomington, IN 47405

Increasing atmospheric CO_2 concentrations have resulted in numerous studies into methodolgies for sequestering antropogenic CO_2 in the subsurface. Demonstrations of geologic CO_2 sequestration in the Illinois Basin are targeted at the basal Cambrian Mount Simon Sandstone as the potenital reservoir and the overlying Eau Claire Formation as the primary seal. Characterizing the mineralogy and geochemistry of these formations is an essential step towards predicting how these units will perform as a storage reservoir and seal respectively. Ongoing investigations are focused on characterizing the mineralogical and geochemical composition of these formations utilizing core analysis, microscopy, x-ray diffraction, reflectance spectroscopy, stable isotope geochemsitry and major and trace element whole rock geochemical analysis. Minerals identified in the Mount Simon Sandstone include monocyrstalline and polycrystalline quartz, k-feldspar, illite, kaolinite, goethite, hematite, and calcite with minor zircon, muscovite, and biotite. The amount and spatial context of the mineral phases vary with depth and across the basin. Some of the minerals, such as k-feldspar and the iron oxides, occur as overgrowths and grain coatings, putting them directly in contact with pore-fluids. Principle mineral phases identified in the Eau Claire Formation include: quartz, k-feldspar, plagioclase feldspar, illite, glauconite, dolomite, ankerite, calcite, chlorite, pyrite, goethite, and hematite. The suite of minerals identified in both of these units includes both detrital grains and multiple generations of authigenic precipitates that suggest a burial history that has included multiple episodes of fluid-rock interactions. Detailed analysis of the geochemistry of specific mineral phases (e.g., stable isotopes, trace elements, etc.) can be used to determine the nature of the fluids that have interacted with these rocks in the past. These analyses help to constrain the role of fluids in the evolution of these formations, the current reactivity of the minerals present, and the potential changes that could occur with the introduction of CO_2 into the pore fluids.

Impacts and feedbacks: Are the PETM and Eocene hyperthermals relevant to future global change?

GABRIEL J. BOWEN

Purdue University, West Lafayette, IN 47907, USA (*correspondence: gabe@purdue.edu)

After more than two decades of study, significant uncertainty remains regarding the causes and mechanisms underlying Early Paleogene transient “hyperthermal” climate events such as the Paleocene-Eocene thermal maximum and Eocene Thermal Maximum-2. Despite a lack of consensus on key details such as the trigger for these events and sources of carbon to the ocean and atmosphere, these events are frequently invoked as being among the paleoclimate case studies most relevant to understanding our climate future. Given all the uncertainty, it’s fair to ask whether our current level of understanding of these events really has relevance to the study of the anthropogenic climate era.

I will make the case that by focusing on the impacts and feedbacks associated with Eocene hyperthermal events researchers have been able to demonstrate several key patterns that are of relevance to informing and testing models of future anthropogenic climate change. The foundation for this inference is the unequivocal result, supported most strongly by records of widespread deep-sea carbonate dissolution, that the PETM and other hyperthermals are distinguished first and foremost by the massive addition of CO_2 to the exogenic carbon cycle. Despite uncertainties regarding the source and amount of this CO_2, we can view the subsequent sequence of events for any hyperthermal as a realization of CO_2-driven global change.

Important impacts and feedbacks associated with hyperthermals have been identified in at least four different systems. First, observations have largely supported existing models for the centennial-to-millennial-scale dynamics of the carbon cycle in response to massive CO_2 release. Second, estimates of pCO_2 change have been used to suggest high equilibrium climate sensitivity relative to most IPCC models. Third, there is increasing evidence for continental-scale water cycle change that is broadly consistent with the predictions of global climate models. Fourth, to the degree it has been studied these events have been demonstrated to have widespread, if not always deleterious, impacts on the biota. Although many details remain to be resolved, our current state of knowledge of Early Paleogene hyperthermals enables tests, and should support refinement, of models for anthropogenic global change.

IsoMAP: A web-GIS workspace for modeling isotope ratios in the environment

GABRIEL J. BOWEN[1], JASON B. WEST[2], LAN ZHAO[1], CHRIS C. MILLER[1], TONGLIN ZHANG[1], ZHONGFANG LIU[1], HYOJEONG LEE[1], AND AJAY B. KALANGI[1]

[1]Purdue University, West Lafayette, IN 47907, USA (*correspondence: gabe@purdue.edu)
[2]Texas A&M University, College Station, TX 77843, USA

Researchers have amassed a vast quantity of data on the stable H and O isotope ratios of environmental waters during the past 6 decades, and these data have supported the development of numerous paleoenvironmental, paleoecological, and paleoclimatic proxies. As new analytical instrumentation supports the gathering of water isotope data at increasing rates, these measurements promise to spawn new approaches to studying our contemporary environment. A key element in the development and interpretation of H and O isotope-based applications is the development of models for water isotope data to describe and predict relationships between these parameters and environmental variables.

In order to support widespread access to large water isotope databases and facilitate modeling of water isotopes and their propagation into hydrological and biological systems we have developed a web-GIS workspace called IsoMAP (Isoscape Modeling, Analysis and Prediction; http://isomap.org). IsoMAP consists of a set of Graphical User Interface that runs within the user's internet browser, server-side databases that host and serve isotopic and climatic monitoring data and GIS layers, and codes supporting the development and use of statistical and process-based models for environmental isotope ratio variation. Working through the GUI, users can select data and specify model parameterizations, submit and manage jobs, and visualize, download, or publish output including statistical descriptions of models and map predictions of the geographic variation in environmental isotope ratios.

Potential and demonstrated applications of the current version of IsoMAP include quantification of water isotope/climate relationships for different regions and time periods, evaluation of the stability or difference in isotope/climate relationships among regions and times, calibration of H- and O-isotope based proxies, and interpretation of H and O isotope data from biological and geological materials as a geographic source tracer. Future updates will provide additional functionality such as forward-modeling of H and O isotopes in plant leaf water and biological compounds.

Tracking the evolution of phase changes in ilmenites in microbial fossilization experiments: Understanding the role of microbes in diagenesis

D.M. BOWER[1], A. KYONO[2] AND A. STEELE[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington,Washington, D.C., 20015, (dbower@ciw.edu.asteele@ciw.edu)
[2]Division of Earth Evolution Sciences, University of Tsukuba, Tsukuba, Ibaraki 305-8572, Japan, (kyono@geol.tsukuba.ac.jp)

Ilmenite and related Fe-,Ti-oxides are ubiquitous components of beach sands and sedimentary rocks [1]. In many ancient sedimentary rocks, "fossil" microstructures that are used as biosignatures often contain mineral assemblages dominated by these metal oxides, and in some cases, are preserved along with trace amounts of graphitic carbon [2,3]. Passive microbial biomineralization occurs in a wide range of natural environments, and can dictate the types of minerals that precipitate [4]. Furthermore, complicated histories and atmospheric inputs also influence much of the mineralic makeup of the rocks present today. Thus, the assemblages in these rocks may not be the same as what was originally formed in the newly lithified sediments billions of years ago. To constrain the effects of microbial processes on diagenesis, phase changes in natural ilmenites (Fe_3TiO_4) were observed in the presence of microbes amd compared to those without microbes under laboratory controlled conditions of increasing temperatures. To identify the mineral phases in these samples, micro Raman spectroscopy, SEM, and XRD were used. Collectively, the results show a correlation bewteen Fe- and Ti-oxide phase changes and the presence of microbes under early diagenetic conditions (T<70ºC), where the precipitation of maghemite (γFe_2O_3) and magnetite (Fe_3O_4) starts to occur on the ilmenite surface. The preliminary results presented here are part of an ongoing collaborative study to understand the role of biological processes in diagenesis. In the process, mineralic biosignatures can be established as we continue to perfect analytical instrument techniques for future planetary life exploration missions.

Alkali metal and H_2O dynamics at clay-water interfaces: Lessons from NMR

GEOFFREY M. BOWERS*,[1] JARED WESLEY SINGER[2] AND R. JAMES KIRKPATRICK[3]

[1]Departments of Chemistry and Materials Engineering, Alfred University, 1 Saxon Drive, Alfred, NY, 14802. (*correspondence: bowers@alfred.edu)
[2]Department of Materials Engineering, Alfred University, 1 Saxon Drive, Alfred, NY, 14802. (jws4@alfred.edu)
[3]College of Natural Science, Michigan State University, East Lansing, MI, 48824. (rjkirk@msu.edu)

Many geochemical processes are highly dependent on the fundamental molecular-scale structure and dynamics of ions and H_2O at solid-water interfaces. We present here a detailed description of the behavior of alkali metal cations and H_2O in the interlayers and on external surfaces of smectite/H_2O pastes based on variable temperature nuclear magnetic resonance (VT NMR) spectroscopy.

Our new and previously published data show that alkali metal cations occupy multiple distinct binding environments in natural hectorite and that dynamic averaging of these sites is intimately linked to the dynamics of free and confined H_2O from -80°C to 50°C. For hectorite, K^+ and Cs^+ occupy two cation sites (likely 12-coordinate and 9-coordinate interlayer environments) that undergo rapid exchange above -20°C and -50°C, respectively [1, 2]. Companion ^2H NMR shows that exchange between K^+ environments is linked to the onset of diffusional exchange among confined and free H_2O populations [1]. Recent variable temperature ^{23}Na NMR data at 9.4 T and 21.1 T reveal two Na^+ sites in hectorite with distinct quadrupolar couplings. These two sites experience distinct dynamic behaviors (and no evidence of direct two-site exchange) that appear more strongly linked with the dynamics of specifically free H_2O. The dynamics of confined H_2O in the Na- and K-hectorites appear to be quite similar at temperatures < -20°C and reflect a combination of fast C2 symmetry jumps and exchange among positions in the ion hydration shell. Above -20°C there is diffusional exchange between confined and free H_2O populations for the Na- and K-hectorites. Differences in the residual ^2H quadrupolar splitting at these temperatures are likely due to differences in cation hydration energies and whether the cations prefer inner- or outer-sphere interactions with the clay surface.

Isotopically-zoned zircons: Records of fluid/melt flow in the lower crust, Kapuskasing Uplift

J.R. BOWMAN[1]*, D.E. MOSER [2], J.W. VALLEY[3], J.L. WOODEN[4], N.T. KITA[3] AND F.K. MAZDAB[5]

[1]Dept. of Geology and Geophysics, Univ. of Utah, Salt Lake City, UT, 84112, USA (*corr: john.bowman@utah.edu)
[2]Dept. of Earth Sciences, Univ. of Western Ontario, London, Ontario, CAN N6A 5B7, (desmond.moser@uwo.ca)
[3]WiscSIMS, Dept. of Geoscience, Univ. of Wisconsin, Madison, WI, 53706, USA
[4]U.S.G.S.-Stanford Ion Probe Laboratory, Stanford, CA, 94305, USA
[5]Dept. of Geosciences, Univ. of Arizona, Tucson, AZ 85721, USA

Ion microprobe (SHRIMP and CAMECA 1280) analyses document primary isotopic (Pb, O) and trace element zoning in zircon from lower crustal paragneiss in the granulite zone of the Kapuskasing Uplift, Archean Superior Province. Older and low-$\delta^{18}O$ (5.1 to 7.1‰) igneous cores are overgrown by metamorphic zircon rims (2.66±0.01 to 2.58±0.01 Ga in age) which have significantly higher but variable $\delta^{18}O$ values (8.4 to 10.4‰). Several individual rims are zoned, with $\delta^{18}O$ decreasing outward from >10‰ to values as low as 8.4‰ at rim edges. Rims fall into two geochemically distinct groups: Type 1 rims have lower $\delta^{18}O$ (8.4 to 9.4‰), higher Th/U (0.1 ave.) and lower U/Yb (6.9 ave.). Type 2 rims have higher $\delta^{18}O$ (9.4 to 10.4‰), lower Th/U (0.025 ave) and higher U/Yb (20 ave.). Garnets separated from leucosome and melanosome in this paragneiss have significantly different $\delta^{18}O$ values of 9.2 and 9.9‰ (laser fluorination), respectively. These $\delta^{18}O$ values are similar to the average $\delta^{18}O$ values of the type 1 and 2 zircon rims; this similarity suggests that type 1 and type 2 rims are equilibrated with the leucosome and melanosome domains, respectively. The $\delta^{18}O$ data indicate that the leucosome domain is not in isotopic equilibrium with the rock matrix, which supports leucosome formation by infiltration of lower $\delta^{18}O$ fluid/melt rather than by *in situ* partial melting.

In mafic gneiss adjacent to this paragneiss, metamorphic zircons (2.67±0.01 to 2.56±0.01 Ga) have variable $\delta^{18}O$ values from 7.6 to 11.3‰. A number of zircon rims are markedly zoned, with $\delta^{18}O$ values ranging from 11.1‰ down to values as low as 7.6‰ at rim edges. These variations in $\delta^{18}O(Zrc)$, coupled with some cases of disquilibium fractionation between zircon and garnet (up to 1.1‰), record multiple fluid/melt infiltration events involved in the geochemical evolution of this section of the deep crust.

[4]Oak Ridge National Laboratory, Oak Ridge, TN 37831

The fate of U released in the environment is determined by a complex array of complexation, adsorption, redox, and precipitation reactions. Reduction of soluble U^{VI} species to U^{IV} by direct or indirect bacterial activity often results in the precipitation of $U^{IV}O_2$ (uraninite) and has been explored as an immobilization strategy for subsurface U plumes. We will present results from a three year experiment in which the biogeochemical conditions in U-contaminated groundwater and sediments from a field site at Oak Ridge National Laboratory (U.S.A.) were allowed to evolve in diffusion limited reactors under iron- and sulfate-reducing conditions. The reactors were amended with ethanol at the water-sediment interface, mimicking the injection of electron donor during *in situ* subsurface remediation by biostimulation. Synchrotron x-ray absorption spectroscopy (XANES and EXAFS) was used to track *in situ* the spatial distribution, valence state, and speciation of U and Fe in the reduction zone propagating into the sediment, in parallel with measurements of solution phase [SO_4], [U], [ethanol], and pH. Results show rapid initial reduction of Fe^{III} and U^{VI} in the sediment near the interface, as well as redistribution of U^{VI} in the areas ahead of the reduction front. Sulfate removal from the solution phase and U^{VI} reduction throughout the sediment continued for two years. EXAFS spectroscopy demonstrated that U^{IV} in the reduced sediment was present as a non-uraninite U^{IV} species, similar to the non-uraninite U^{IV} species detected in sediment samples collected from the injection wells during field-scale biostimulation campaings at Oak Ridge National Laboratory. The immobilization of U^{IV} as a non-uraninite species in natural settings has important implications for the post-remediation stability of U plumes.

Sulfur speciation in lunar apatite

J.W. BOYCE[1,2]*, C. MA[1], J.M. EILER[1], Y. LIU[3], E. STOLPER[1] AND L.A. TAYLOR[3]

[1]Division of Geological & Planetary Sciences, Caltech, Pasadena, CA 91125 (*jwboyce@alum.mit.edu)
[2]Department of Earth & Space Sci., UCLA
[3]Department of Earth & Planetary Sci., Univ. of Tennessee

Apatite incorporates several volatile elements (including S, as SO_4^{2-}) and can provide a record of magmatic volatile evolution. Recent measurements of volatiles in apatite from Apollo sample 14053.241 revealed 300-450 ppm S. Although many lunar melts have sufficient S for sulfide saturation, the observed S content of lunar apatite is surprising because lunar samples (especially 14053) are highly reduced (≤ IW) and are thus expected to contain little SO_4^{2-}. One possibility is that there are micro-environments in late-stage lunar melts that are more oxidized than one would infer from conditions recorded by other components of these rocks. Alternatively, it may be that S^{2-} substitutes for F+Cl+OH in lunar apatite: S^{2-}–bearing apatite has been synthesized, but to our knowledge has not been observed in nature.

The Kα X-ray wavelength can be used to determine the relative amounts of S^{2-} and SO_4^{2-} in lunar apatite. Analyses were conducted at Caltech (JEOL 8200 with a 15 kV, 300nA, 15μm defocused beam, at 30 s/step, using PET crystals), referenced to FeS_2, $CaSO_4$, and SO_4^{2-}-rich Durango apatite.

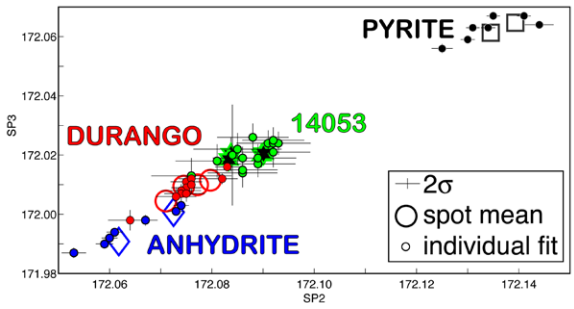

Figure 1: S Kα peak position (L-value) for two spectrometers.

The Kα peak of S in 14053 apatite is consistently shifted toward sulfide relative to both anhydrite (Δ = 29-44%) and Durango apatite (Δ = 19-24%; presumably containing all sulfur as sulfate) standards. This may indicate the first observation of a sulfide component in natural apatite. However, large uncertainties and apparent matrix effects (offset between anhydrite and Durango apatite) demand more data. Nevertheless, taking these data at face value indicates that lunar apatite includes both a S^{2-} and SO_4^{2-} component, in sub-equal proportions. The apparent SO_4^{2-} component in lunar apatite may indicate the presence of SO_4^{2-} in the late-stage lunar melt from which this apatite crystallized.

Lead and lead isotopes in the Atlantic and Indian Ocean: GEOTRACES data

E. BOYLE[1], Y. ECHEGOYEN-SANZ[1], K. FORNACE[1], J.-M. LEE[1], T. GAMO[2], H. OBATA[2] AND K. NORISUYE[3]

[1]Massachusetts Institute of Technology, Earth, Atm. & Planet. Sci., (eaboyle@mit.edu)
[2]University of Tokyo, Atm. & Ocean Research Institute, (gamo@aori.u-tokyo.ac.jp, obata@aori.u-tokyo.ac.jp)
[3]Kyoto University, Insitute for Chemical Research, (knorisue@inter3.kuicr.kyoto-u.ac.jp)

We will present data on the evolving anthropogenic Pb penetration into the Atlantic and Indian Oceans. In the North Atlantic Ocean, a few sites have multidecadal (Bermuda) and decadal data that show lead decreasing in the upper ocean in response to the phaseout of leaded gasoline; the decrease at depth depends on the ventilation time as shown by anthropogenic transient tracers (although Pb has been entering the deep Atlantic for at least the past 2 centuries, much longer than bomb nuclides and fluoro-compounds). The Atlantic Pb isotopic composition evolves as U.S. dominance is displaced by European Pb gas dominance; the southern Atlantic shows a distinct surface isotope composition. We will show a 10-station section in the Atlantic western boundary from 32degN to 25degS that shows N. Hemisphere Pb penetrating the S. Hemisphere dominantly with the Labrador Sea Water with some from the lower NADW. We will also show the Pb isotopic composition of these waters, including for the first time data on the scarce isotope Pb-204. We will also show a section of 8 stations from Lisbon to the Cape Verde Islands collected on the first US GEOTRACES North Atlantic Transect (2010). In the subtropics, the temporal Pb decrease due to Pb gas phaseout is reflected in this new data as compared to data from 1989 and 1999. In the tropical North Atlantic, thermocline Pb is low (<35 pmol/kg) reflecting the limited ventilation of this "shadow zone", but shows a maximum at about 700m depth. We have data from 11 stations from the Japanese Indian Ocean GEOTRACES cruise, from the Bay of Bengal and Arabian Sea into the Antarctic (18degN to 65degS). In response to later industrialization and a two-decade lag of Pb gas phaseout (and limited convection), anthropogenic Pb is higher in the surface waters of the Indian Ocean (40-80 pmol/kg) than in the present-day North Atlantic and North Pacific (20-30 pmol/kg), although Pb has not penetrated as deeply in the Indian Ocean (with little occurring below about 2000m, and some of the deep waters having extremely low Pb (~3 pmol/kg).

Modelling of hydrogeochemical processes in groundwaters of the North German Basin (NGB)

ELKE BOZAU AND WOLFGANG VAN BERK

TU Clausthal, Hydrogeologie, Leibnizstraße 10, D-38678 Clausthal-Zellerfeld (elke.bozau@tu-clausthal.de)

Modelling and forecasting quantitative hydrogeochemical changes in highly mineralised groundwaters is still a challenge. The extraction of deep groundwater for geothermal energy production from the NGB is affected by the precipitation of certain minerals, e.g. sulphates (Ba, Ca, Sr), carbonates (Ca, Fe), and silicate phases (SiO_2). These scalings often disturb the continuous production of geothermal energy and should be avoided in the technical sytems.

Groundwaters in deep aquifers of the NGB are dominated by Na^+ and Cl^-, or Na^+, Ca^{2+}, and Cl^-. The amount of total dissolved solids ranges from 100 to 300 g/l and increases with depth and temperature. Compared to surface groundwaters the deep groundwaters are enriched in a broad range of elements, including trace elements such as Ba, Pb, Sr, and Zn, and contain high amounts of dissolved gases (N_2, CO_2, H_2S, and CH_4).

An extended hydrogeochemical thermodynamic database for the well known and commonly used software PHREEQC has been developed to predict possible mineral precipitations during the use of highly mineralised groundwaters for geothermal energy production. Temperature (up to 200°C) and pressure (up to 500 bar) adaptations of the equilibrium constants were necessary. Pitzer parameters for the calculation of activity coefficients in waters of high ionic strength and solubility equilibria among gaseous and aqueous species of N_2, CH_4, and H_2S had to be implemented into the database.

In order to validate the implemented parameters the modelled mineral solubilities have been compared to experimental data gathered from the literature. First modelling results confirm the experimental data for the solubility of the minerals quartz, barite, anhydrite and calcite. However, there are problems with the solubility of several minerals at higher temperatures. Hence, evaluation and improvement of the thermodynamic database will be an ongoing process.

Acknowledgements. The presented data are results of the project "gebo" (Geothermal energy and high performance drilling research) financed by the Ministry of Science and Culture of the State of Lower Saxony and the company Baker Hughes.

An attempt to set the relation between chemical composition and microbiological activity in AMD reservoirs in the Łęknica region (the Muskau Arch, western Poland)

P. BOŻĘCKI AND G. RZEPA

Dept. of Mineralogy, Petrography and Geochemistry, Faculty of Geology, Geophysics and Environmental Protection, AGH - University of Science and Technology, Krakow, Poland (pbozecki@geol.agh.edu.pl)

The Muskau Arc is a large horseshoe-shaped glaciotectonic belt formed mainly during the Mid Polish Glaciation. Lignite deposits containing pyrite were excavated there to the early seventies. The abandoned mining areas were filled with acidic water, forming so-called "anthropogenic lakeland".

The aim of this study is to assess the impact of weather conditions and biological activity of selected microorganisms on the variability of chemical composition of acid mine drainage reservoirs. Water was sampled over one year period (from July 2009 to September 2010) from 11 selected locations. Water and ambient temperature, pH, Eh, EC, color, turbidity were determined in the field and samples were taken for major cations, anions and trace elements. In addition, 5 locations for microbiological research have been selected. These part consisted of qualitative determination of bacterial and fungal microflora in the waters with particular attention to microorganisms involved in the processes of iron transformation.

The results of the study show that most of the measured parameters have not only time but also spatial variability. The time variability results from seasonal changes in ambient condition as well as extreme weather events such as spring thaw and summer floods. One of the reasons for spatial variability is the variability in sources of water for distinct reservoirs. The results also show a positive correlation between :

- population size of *Acidithiobacillus ferrooxidans* bacteria and the concentration of such components as Fe and SO_4^{2-}.
- concentration of such components as Ca^{2+} and SO_4^{2-}, which may indicate that concentration level of these ions is closely linked with precipitation and dissolution of gypsum processes

This work was supported by MNiSW (project No. 0700/B/P01/2009/37) and AGH-UST (research project no. 11.11.140.158).

Sulfur isotope composition of the Bagirkacdere lead-zinc deposit, Biga Peninsula, Turkey

G. BOZKAYA

Cumhuriyet University, Department of Geological Engineering TR58140 Sivas, Turkey (gbozkaya@cumhuriyet.edu.tr)

Bagirkacdere lead-zinc deposit is one of the important deposits which are being mined on the Biga Peninsula. The vein type deposits are hosted by Triassic metamorphic rocks (Nilufer Unit of Karakaya Complex; [1]). The vein zones were emplaced within the meta-sedimentary rocks (phyllite, schist and marble) and are mainly concordant and partly discordant to foliation and/or schistosity planes. The mineralized zones contain galena, sphalerite, chalcopyrite, pyrite, marcasite, covellite, and specular hematite as ore minerals, with quartz and calcite as gangue minerals.

The $\delta^{34}S_{VCDT}$ values of galena range from -2.2 to 0.6 (average -1.07) ‰. The $\delta^{34}S_{VCDT}$ values of H_2S in equilibrium with sulphide minerals were estimated to be in the range of 2.4 to 0.14 ‰ (average 1.05‰) by evaluating the minimum and maximum $\delta^{34}S$ values of galena. For the calculation of $\delta^{34}S_{VCDT}$ values of H_2S, the average temperature of the hydrothermal fluids during the sulphide mineralization episode was assumed as 250 °C, which is obtained from the homogenization temperature measurements during fluid-inclusion studies, and the equations suggested by Li & Liu [2] was used. The $\delta^{34}S$ values of both sulphide and H_2S, which are close to 0‰, suggest a sulphur reservoir dominated by magmatic origin.

In addition, $\delta^{18}O$ and the δD data of the fluids, trapped quartz crystals, indicate that the hydrothermal fluids were completely originated from meteoric water [3]. The combined fluid inclusion and stable isotope data indicate that the reduced sulphur, depositing the sulphide minerals, was leached by heated meteoric waters during circulation within the igneous basement rocks.

Demir Kapija ophiolite: A snapshot of subduction initiation within a back-arc

M. BOŽOVIĆ[1], D. PRELEVIĆ[1], R.L. ROMER[2] AND M. BARTH[1]

[1]Uni Mainz, Mainz, Germany (bozovic@uni-mainz.de, prelevic@uni-mainz, barthm@uni-mainz.de)
[2]GFZ, Potsdam, Germany (romer@gfz-potsdam.de)

The Demir Kapija ophiolitic complex (Macedonia-FYROM) includes a mafic volcanic sequence (pillow lavas, diabases, and gabbros) that was intruded by intermediate to felsic and adakite-like rocks in an island arc setting.

The mafic volcanic sequence of the ophiolite complex formed in intra-oceanic back-arc setting. They are characterized by slightly increased LILE/HFSE, flat REE patterns, and radiogenic $^{143}Nd/^{144}Nd$ (up to 0.51272) and high TiO_2 contents, which reflect Pl+Ol+Cpx fractionation. The fractionation pattern between TiO_2 and MgO indicates that Ti saturation was reached and Ti-magnetite fractionated.

The intermediate to felsic and adakite-like intrusions are spatially and temporally closely related. The adakite-like volcanics show most of the features of typical adakites, i.e., low HREE, high Sr/Y, high LILE and LREE of whole-rock samples, as well as clinopyroxene major and trace element composition that are typical for adakite. The very high Th/La, Th/Yb and Ba/Yb ratios and the reduced $^{143}Nd/^{144}Nd$ values (around 0.51245) reflect contributions of sedimentary material to the mantle source of these melts. In analogy to adakites, these rocks are thought to be the product of slab melting in an unusually hot subduction zone. The intermediate to felsic volcanics show a broad range of SiO_2 content (51-75%) and more radiogenic Nd isotopic compositions than the adakite-like rocks. Their genesis is related to magma mixing of two different components; one is mantle derived, while the other one is a product of melting of an arc crust. The geochemistry of these rocks indicates that the melting of sedimentary rocks contributed to a variable extent to the source of these magmas.

During the Mid-Jurassic, opening of the short-lived Demir Kapija back-arc basin was initiated by slab roll back of the Western Vardar Ocean. Intra-oceanic subduction began within the collapsing ridge. As the subduced oceanic crust was young and hot, the thermal regime was favourable for slab melting and the formation of adakite-like rocks. Thus, the adakite-like rocks and the intermediate to felsic intrusions are related to the switch from an extensional to a compressional regime.

Testing crustal deformation and erosion-tectonic feedback models in the easternmost Himalaya using palaeo-Brahmaputra deposits

L. BRACCIALI[1,2,*], R.R. PARRISH[1], Y. NAJMAN[2] AND M.S.A. HORSTWOOD[1]

[1]NERC Isotope Geosciences Laboratory, British Geological Survey, Keyworth , Nottingham NG12 5GG, UK (*correspondence: laur@bgs.ac.uk)
[2]Lancaster Environment Centre, Lancaster University, Lancaster, LA1 4YQ, UK

Strain, uplift and exhumation of the Earth's surface impact on, and are impacted by, fluvial drainage evolution. An investigation of the latter therefore provides a key to understanding crustal deformation processes and erosion-tectonic-climate interactions. In the Himalaya, the unusual fluvial drainage configuration of the eastern syntaxial region has been interpreted either as distorted drainage resulting from crustal shortening (due to India-Asia convergence) and lateral extrusion of crustal material, or as the result of river capture events tectonically-induced by surface uplift. Determining if and when the Brahmaputra river captured the Yarlung Tsangpo is crucial to testing these models of crustal deformation. In addition, rapid fluvial incision potentially resulted in sufficient erosion by focused weakening of the crust, that deep seated ductile rocks were induced to flow upwards and be rapidly exhumed in the syntaxial region, providing a viable example of erosion-tectonic coupling. The first arrival of detritus carried by the Yarlung Tsangpo (draining the Jurassic-Paleogene Trans-Himalayan arc of the Asian plate) in the Neogene deposits of the palaeo-Brahmputra river in Bangladesh (that prior to capture would have drained the southern Himalayan slopes composed only of Precambrian-Palaeozoic Indian crust) should date the capture event, while input from the eastern syntaxis can be identified by the appearance of very young (<10 Ma) and rapidly exhumed mineral grains.

To address the river capture and the erosion-tectonic coupling hypotheses, U-Pb LA-MC-ICP-MS dating of detrital zircon grains (from palaeo-Brahmputra sediments as well as sands from modern rivers draining the Trans-Himalaya and Himalayan southern slopes) is integrated with microtextural analysis in a revised approach to the use of detrital zircon data as applied to provenance studies. In this ongoing multi-technique study, zircon data are complemented by the novel application of U-Pb dating to rutile detrital grains as well as by Ar-Ar dating of detrital white mica and zircon fission-track thermochronology.

Molecular tools for understanding biomarker compounds

ALEXANDER S. BRADLEY[1]* ANN PEARSON [2] AND CHRISTOPHER J. MARX [1]

[1]Department of Organismic and Evolutionary Biology, Harvard Univeristy, Cambridge MA 02138 USA (*correspondence: bradley@fas.harvard.edu)
[2]Department of Earth and Planetary Sciences, Harvard University, Cambridge MA 02138 USA

Hopanoids are pentacyclic triterpenoids found in some bacteria and widely used as organic geochemical proxies. A confident interpretation of this record requires an understanding of the function and distribution of these compounds among bacterial taxa. Recent analytical developments allowing the rapid identification of hopanoid structures [1] have made large strides towards this end. We complement this approach by performing three types of experiments: i) genetic experiments in a model organism (*Methylobacterium*) to identify genes involved in the synthesis of hopanoid side chains; ii) physiological experiments to understand the function of hopanoids, iii) replicate experimental evolution in the laboratory to understand how an organism might acquire adaptations to compensate for the absence of hopanoids.

Our studies have yielded results that have consquences for geochemical interpretation. By constructing genetic mutants, we have found that adenosylhopane is an intermediate in the synthesis of composite hopanoids in *Methylobacterium*, and this likely holds in all hopanoid-producing bacteria. This compound has previously been interpreted as a marker of terrestrial input to marine sediments [2], and this can be evaluated in light of our new understanding.

We have also found that the disruption of genes involved in hopanoid biosynthesis in *Methylobacterium* causes growth defects. The growth defect is particularly severe in a strain of *Methylobacterium* in which we disrupted hopanoid synthesis Experimental evolution of this strain in the laboratory has allowed this strain to overcome some of this defect. Other mutants, which can make hopanoid backbones but lack the ability to make either composite hopanoids or A-ring methylated hopanoids, have less-severe but still detectable growth defects. Examination of these phenotypes may cast light on the function of these molecules, which can be used to interpret the geochemical record.

Effect of different vegetation cover on throughfall chemistry

M. BRADOVÁ[1]*, V. TEJNECKÝ[1], L. BORŮVKA[1], K. NĚMEČEK[1], J. ZENÁHLÍKOVÁ[2] AND O. DRÁBEK[1]

[1]Department of Soil Science and Soil Protection, Faculty of Agrobiology, Food and Natural Resources, Czech University of Life Sciences in Prague, CZ-165 21 Prague 6 – Suchdol, Czech Republic (*correspondence: bradova@af.czu.cz)
[2]Department of Silviculture, Faculty of Forestry and Wood Sciences; Czech University of Life Sciences in Prague, CZ-165 21 Prague 6 – Suchdol, Czech Republic (zenahlikova@fld.czu.cz)

The monitoring of throughfall at the forest ground is a widely accepted approach for the estimation of trace-substance input in different forest types and in different regions [1, 2]. This study is focused on the evaluation of quantity of materials incoming into forest soil affected by acidification process under spruce forest (*Picea abies (L.) Karst)* and under beech forest (*Fagus sylvatica L.),* and describing the fluctuation of elements in precipitation within the monitoring period. Precipitation samples were collected at monthly intervals from April to October during the years 2008 - 2010 in the Jizera Mountains. Precipitation samples were quantified and analyzed for selected components (NO_3^-, SO_4^{2-}, Cl^-, F^-) and total amount of Na, Ca, K, and Mg. pH and conductivity of precipitation were measured. Statistical analyses like simple and multiple regression and correlation and multifactorial analysis of variance were used. Results of this work showed the elements, which flow into the soil under beech forest and under spruce forest, their preference transport way and amount of them.

Using opal and organic carbon as proxies for migration of the North African monsoon

L.I. BRADTMILLER[1]*, M.B. AWALT[1], D. MCGEE[2] AND P.E. DEMENOCAL[2]

[1]Macalester College, Saint Paul, MN, 55406, USA (*correspondence: lbradtmi@macalester.edu)
[2]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, 10964, USA

Marine and terrestrial records from northern Africa have greatly enhanced our understanding of both the causes and effects of climate change in the geologic past. Specifically, proxy records of changes in paleoproductivity yield information about upwelling strength, and therefore trade wind strength along the North African margin. Changes in wind strength, in turn, have been shown to correlate with changes in the relative aridity of the Sahel: periods of increased precipitation in the past were periods of weaker trade winds and decreased upwelling, and vice verse.

Records of opal flux over the past 18kyr illustrate the inverse relationship between precipitation and marine productivity, as periods of greater opal flux (increased wind-driven upwelling) correspond to periods of increased terrigenous flux (increased wind-borne dust flux). Paleoceanographic records have identified the African Humid Period (AHP; ~11 – 5.5 kyr) as a period of low dust flux and decreased opal flux consistent with a northerly shift in the ITCZ, increased precipitation and reduced upwelling. However, our current understanding of the causes and effects of the AHP is limited by the lack of upwelling/productivity data along a north-south transect of the African margin, as well as by a general lack of high-resolution data.

Here we present opal and organic carbon (C_{org}) records from a north-south transect of marine sediment cores on the northwest African margin. We observe decreased fluxes of opal and C_{org} in all cores at the onset of the AHP, although the magnitude of this response varies greatly from core to core. At the end of the AHP, opal and C_{org} fluxes increase, albeit not to pre-AHP levels. During both transitions the magnitude of flux change is greatest in the southernmost cores, which are closest to the region of maximum upwelling in the modern ocean. Current age models suggest that decreased fluxes of opal and C_{org} occur first in the southernmost core at the onset of the AHP, consistent with the hypothesis that these changes represent a northward shift in the ITCZ.

Chemical evolution of MORB: New insights from old crust

P.A. BRANDL*, M. REGELOUS AND K.M. HAASE

GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Schlossgarten 5, 91054 Erlangen, Germany (*correspondence: philipp.brandl@gzn.uni-erlangen.de)

The chemistry of mid-ocean ridge basalt (MORB) is studied almost exclusively using samples dredged from active spreading ridges. However, flows erupted at the ridge axis itself eventually make up the lowermost part of the extrusive section, and may not be representative of the entire oceanic crust. In contrast, samples drilled from old oceanic crust will include flows erupted both on- and off-axis, and also can be used to determine whether changes in MORB composition occur over the lifetime of an ocean basin. Despite this, few detailed studies of ancient MORB have been carried out.

We have analysed major element compositions of more than 400 fresh volcanic glasses from 35 DSDP-ODP drillsites in the Atlantic and Pacific, which range in age from 10 to 170 Ma. Trace element analyses of the same samples using LA-ICPMS are in progress.

In contrast to some previous studies, we find no significant difference in fractionation-corrected major element composition of Mesozoic and zero-age MORB in either the Pacific or the Atlantic. There is no indication that EMORB are concentrated in the upper parts of the oceanic crust, as would be expected if they were preferentially erupted off-axis. Instead, the youngest lavas (upper 100m) at a given drillsite tend to have relatively homogenous compositions, which could be explained if larger-volume flows flow further from the axis. If this is the case, then sampling MORB only from active spreading ridge axes may not give an entirely accurate picture of the average composition of the oceanic crust. It also means that direct comparison of lavas from slow- and fast-spreading ridges, which differ in axial topography and average flow volumes, will not be straightforward.

Quantifying rates and mechanisms of shale weathering across a continental-scale climosequence

SUSAN L. BRANTLEY, ASHLEE DERE AND TIMOTHY WHITE

The Pennsylvania State University, University Park, PA 16802; (*correspondence: sxb7@psu.edu)

Both ecosystems and humans are dependent on soil for nutrient and water cycling as well as food, making the loss of soil a major issue facing humanity. However, the rate at which soil forms has not been well quantified. To investigate rates of soil formation as a function of climate, a latitudinal climosequence of forested sites has been established in North America and Wales. The climosequence is bounded by a cold/wet end member in Wales and a warm/wet end member in Puerto Rico. In between, temperature and rainfall increase as sites extend south through New York, Pennsylvania, Virginia, Tennessee and Alabama. All sites, except Puerto Rico, are underlain by an organic-poor, iron-rich (Silurian-age) shale, providing a constant parent material from which soil is forming. Puerto Rico is located on chemically similar, but younger, shale. Soil sampling and geochemical analyses were completed similarly at all sites to allow direct comparisons and modelling of shale weathering. Independent Be^{10} estimates of erosion rates for a few locations along the transect are used to estimate residence times. Initial results show soil depth increases as a function of temperature, with shallow (~30 cm) profiles in Wales and Pennsylvania varying up to 630 cm deep in Puerto Rico. Depletion profiles of Na, a proxy for feldspar dissolution, are less than 20 % depleted at the surface in Wales and Pennsylvania, 50-60% depleted in Virginia and Tennessee, and 100% depleted at the surface in Puerto Rico. Using estimated soil residence times, apparent activation energies for Na depletion were calculated using different assumptions to range from 15-19 kcal mol^{-1}, values that are slightly higher than those reported for Na plagioclase dissolution in the laboratory. Overall, data collected from soils across the transect will promote a better understanding of how climate changes can impact soil formation rates.

CAPRAM mechanism development: Evaluation of prediction methods for aqueous phase rate constants and model results

P. BRÄUER[1]*, C. MOUCHEL-VALLON[2], A. TILGNER[1], B. AUMONT[2] AND H. HERRMANN[1]

[1] Leibniz-Institut für Troposphärenforschung, Permoserstr. 15, D-04318 Leipzig, Germany. (*correspondence: braeuer@tropos.de)

[2]LISA, UMR CNRS 7583, Universités Paris Est Créteil et Diderot, IPSL, 61 Av. du G[al] de Gaulle, 94010 Créteil cedex, France. (bernard.aumont@lisa.u-pec.fr)

Organic compounds are ubiquitos in the tropospheric multiphase system. With either large biogenic and athropogenic sources they play an important role and have thus become a major research topic within the last decades.

Modelling can provide a useful tool to explore the chemical and microphysical processes in the troposphere. However, detailed oxidation mechanisms exist mainly in the gas phase while they are very limited in the aqueous phase. Current studies aim to expand the aqueous phase mechanism CAPRAM 3.0i, which is the currently most comprehensive chemistry mechanism with 777 reactions and 380 species. However, the oxidation scheme is still incomplete for C3 and C4 organic chemistry and higher organics are missing at all.

The huge amount of organic species relevant in the troposphere makes it impossible to determine all the needed kinetic data experimentally. Therefore, estimation methods become necessary. Besides the construction of an up-to-date database of about 600 experimentally determined reaction rate constants of OH and NO_3 radicals with organics, estimation methods for the prediction of missing data have been evaluated. The evaluation led to a new oxidation schemes for C3 organic compounds added to the existing CAPRAM 3.0i mechanism. Furthermore, branching ratios were introduced for already prescribed OH reactions with organics. Model runs have been performed with the multiphase mechanism MCMv3.1 and the extended CAPRAM version for a meteorological scenario with non-permanent clouds under remote and urban conditions.

The addition of new C3 organic compounds led to the modified concentration profiles of many organic and inorganic species. For example, acid production is enhanced although contrations are still lower than measured in the field due to the missing implementation of the oxidation of higher organics. The introduction of branched OH attack to organics let to further refined results.

Bioavailability and toxicity of metals in an estuary contaminated by acid mine drainage

C.B. BRAUNGARDT[1]*, C. MONEY[2] AND E.P. ACHTERBERG[3]

[1]University of Plymouth, SoGEES, PL4 8AA, UK (*correspondence: cbraungardt@plymouth.ac.uk)
[2]AstraZeneca, Brixham TQ5 8BA, UK
[3]University of Southampton, NOC, SO14 3ZH, UK

Motivated by the need for a better understanding of the human impact on ecosystems (Water Framework Directive), we combined a bioassay (*Crassostrea gigas* larva) with high temporal resolution *in situ* metal speciation measurements to assess the temporal variability, biological availability and toxicity of dissolved metals in an estuary affected by historic (tin streaming) and contemporary (acid mine drainage) metal sources. Voltammetric *in situ* Profilers were deployed in the estuary for a tidal cycle to determine Cd and Cu species ('dynamic') in a size range (<4 nm) highly relevant for uptake by organisms [1]. Oyster larvae were exposed to discrete samples taken at regular intervals during the survey.

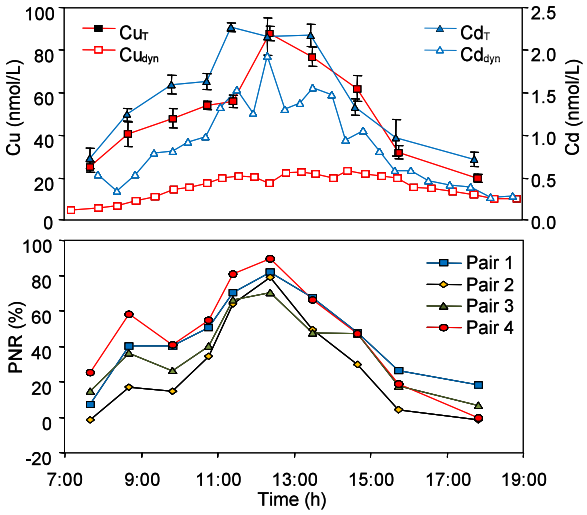

Figure 1: Dynamic (Cu_{dyn}, Cd_{dyn}) and total (Cu_T, Cd_T) metal concentrations and percent net response (PNR) of oyster larva.

Oyster larva responded to the highest dynamic Cu and Cd concentrations with maximum abnormal development (71-90% (Fig.1). Synergistic toxicity and model calculations suggest that bioavailable metal concentrations in this estuary are likely to severely compromise the ecosystem structure [2].

Biotite dissolution: The effect of organic ligands and pH

A.W. BRAY[1]*, S. BONNEVILLE[1,2], D. WOLFF-BOENISCH[3] AND L.G. BENNING[1]

[1]School of Earth and Environment, University of Leeds, Leeds, UK (*correspondence: a.bray@leeds.ac.uk)
[2]Département des Sciences de la Terre, Université Libre de Bruxelles, Brussels, Belgium
[3]Institute of Earth Sciences, University of Iceland, Reykjavik, Iceland

Traditionally mineral weathering studies are based on abiotic and, more recently, dissolution in the presence of living organisms. However, for biotite, a key nutrient bearing mineral (i.e., K), the piece of the puzzle linking abiotic [1] and biotic [2] dissolution rates - the effect of organic ligands - is still missing. Here we fill this gap via biotite dissolution experiments conducted with various organic ligands typical in soils or groundwaters to better quantify the full range of processes affecting rock weathing and soil formation.

Batch (pH = 2, 4, 6, 12 hrs) and flow-through (pH = 3.3 and 6, 96 hrs) experiments were carried out at 25°C with biotite with and without oxalic and citric acids and desferrioxamine-b (DFO-B) or a mixture of these. Aqueous Si, Al, Mg, K and Fe concentrations, analysed by UV-VIS, AAS, or ICP-MS, BET surface area and EMPA compositional analyses, were used to derive rate constants.

Our results show that the presence of organic ligands can enhance the dissolution rate of biotite by up to 2 orders of magnitude (Fig. 1). The degree of enhancement of the ligand promoted dissolution, compared to the abiotic dissolution, increases with increasing pH due primarily to the speciation and extent of surface complexation of the organic ligands.

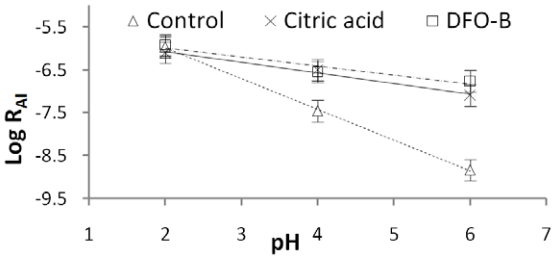

Figure 1. Log R_{Al}($mol_{(biotite)}$ m^{-2} h^{-1}) vs pH from the batch dissolution experiments (control = no organics). Rates were calculated from elemental release data (here Al) and normalised to the EMPA derived biotite stoichiometry.

Toward calibrating the paleosol carbonate CO_2 barometer for paleoVertisols

D.O. BREECKER[1], L.A. MICHEL[2], J. YOON[1], J.S. MINTZ[2], S.G. DRIESE[2] AND L.C. NORDT[2]

[1]Department of Geological Sciences, The University of Texas at Austin, 1 University Station C1100, Austin, TX 78712
[2]Department of Geology, Baylor University, One Bear Place 397354, Waco, TX 76798 USA
*Correspondance: breecker@jsg.utexas.edu

The concentration of CO_2 ($[CO_2]$) in soils during soil calcite formation must be known in order to accurately calculate ancient atmospheric $[CO_2]$ using the paleosol carbonate CO_2 barometer [1]. The average *S(z)* value ($S(z) = [CO_2]_{soil} - [CO_2]_{atmosphere}$) appropriate in the barometer has recently been estimated at 0.25% [2]. In the present study, we measured soil $[CO_2]$ in modern Vertisols (high shrink/swell clay content soils) in order to test the value of 0.25% and help calibrate the barometer for paleoVertisols which are commonly used to reconstruct ancient atmospheric $[CO_2]$.

We installed 7 soil gas wells in the Bkss horizon of modern Vertisols in a C_4 grassland at the USDA Riesel Watershed in Riesel, TX, USA. Soil $[CO_2]$ was measured in soil gas samples withdrawn from the wells on a monthly basis. The resulting time series currently extends from January 2010 through March 2011. Soil $[CO_2]$ varied seasonally and interannually during the period of study, reaching a maximum of 9.3% in June 2010 and a minimum of 0.13% in February 2011. Soil $[CO_2]$ was above 1% at every site during the winter of 2009/2010 when the soil was water-saturated and was below 1% at every site during the winter of 2010/2011 when the soil was dry and cracked. Soil $[CO_2]$ decreased rapidly from maximum values (~3-9%) in June 2010 to values as low as 0.2% in August 2010 as the soil warmed, dried and cracked. Without indpendent evidence for the timing of calcite formation, we cannot yet confidently quantify *S(z)* values appropriate for the barometer. However, the decrease of *S(z)* values below 0.25% during the summer when soil calcite is thought to form is consistent with the conclusions drawn by [2]. Our data suggest that soil $[CO_2]$ is strongly decoupled from temperature in Vertisols and is controlled by soil moisture and the opening and closing of soil cracks which act as gas transport conduits. Preservation of foraminifera skeletons from parent material in this soil suggest that calcite dissolution/reprecipitation is limited, even under seasonal changes in soil pCO_2 that span orders of magnitude.

Hydraulic-hydrochemical modelling of a geothermal reservoir in Indonesia

MAREN BREHME*, SIMONA REGENSPURG AND GÜNTER ZIMMERMANN

Helmholtz-Centre Potsdam, German Research Centre for Geosciences (GFZ), International Centre for Geothermal Research, Telegrafenberg, 14473 Potsdam, Germany (*correspondence: brehme@gfz-potsdam.de; regens@gfz-potsdam.de; zimm@gfz-potsdam.de)

The purpose of this study is to explain the hydraulic and hydrochemical connection between different surface and subsurface reservoirs at a geothermal site in Indonesia. By using an integrated model to determine hydraulic pathways through porous media as well as fault structures and connecting it to a chemical transport model, the effect of geology on the hydrochemical characteristics should be explained. The numerical simulator OpenGeoSys is used for modelling the thermo-hydraulic situation. Results will eventually be combined with hydrochemical PHREEQC calculations.

In November 2010 a geothermal plant has been visited and available hydraulic, geological, and hydrochemical properties were reviewed. Additionally, water samples from production wells, hot springs, and a lake have been taken and analysed. Physicochemical parameters were measured *in situ*.

At the investigated site three different fluid containing reservoirs have been identified at various depths with temperatures between 250 and 350 °C, which show each different hydrochemical characteristics: The deepest reservoir (2300 m) with a moderate pH of 5 is marked by silicium (Si) concentrations up to 350 mg/L and high chloride (Cl) concentrations of 430 mg/L The fluid in the most shallow (1000 m) reservoir above is highly acidic (pH 1). Still higher Cl (1550 mg/L), Si (1600 mg/L), and sulphate concentrations (460 mg/L) appear in this reservoir. Acid water (pH 2.6) was also observed in a nearby lake indicating a hydraulic connection to that reservoir. PHREEQC-calculations show an oversaturation of several minerals such as alunite, silicates e.g. kaolinite, Ca-montmorillonite, and quartz at temperatures between 25 and 45 °C. Therefore silicate mineral precipitation upon fluid cooling can be expected to occur in the wells, pipes or the reservoir, which would harm the plant components or even damage the reservoir in the long term.

Apparently three aspects are challenging for the model build-up: (I) a three level-reservoir with the connected acidic lake; (II) the oversaturation of silicates upon cooling; (III) the change in composition over time.

How small-volume basaltic magmatic systems develop: A case study from Jeju, Korea

MARCO BRENNA[1]*, SHANE J. CRONIN[1], IAN E. M. SMITH[2], ROLAND MAAS[3] AND YOUNG KWAN SOHN[4]

[1]Volcanic Risk Solutions, Massey University, Palmerston North, New Zealand, (*correspondance: m.brenna@massey.ac.nz)
[2]School of Environment, University of Auckland, Auckland, New Zealand
[3]School of Earth Sciences, The University of Melbourne, Parkville, Australia
[4]Dep. of Earth and Environmental Sciences, Gyeongsang National University, Jinju, Republic of Korea

Jeju is a volcanic field active since c. 1.8 Ma ago. Eruptive activity began with dispersed, basaltic, monogenetic, volcanism. Continuing monogenetic volcanism was later joined by more voluminous, alkali and sub-alkalic, evolved lava effusion events building a central composite edifice. Samples from older (>0.7 Ma) and younger (<0.2 Ma) monogenetic centres were analysed for whole-rock major elements, trace elements and Sr-Nd-Pb isotopic compositions. Early monogenetic centres are depleted in MgO, Cr and Ni reflecting considerable olivine fractionation. By contrast, younger monogenetic magmas fractionated clinopyroxene + olivine at deeper levels. Isotopes show little variation across the suite, but the younger monogenetic centres have generally lower $^{87}Sr/^{86}Sr$ and $^{208}Pb/^{204}Pb$ and higher $^{143}Nd/^{144}Nd$ than the older centres and sub-alkali lavas. Major and trace element and isotope data suggest a common, shallower source for older monogenetic magmas and sub-alkali lavas, in contrast to a deeper source for younger monogenetic magmas. We propose that mantle melting was initiated near the garnet to spinel transition at a depth of near 2.5 GPa, followed by extension of the melting zone to 3-3.5 GPa, with a concomitant increase in the volume of melt derived from the shallower part of the system to produce sub-alkali magmas, possibly related to accelerated heat transfer resulting from deepening of the melting zone, and/or increased mantle upwelling. A classical mantle plume model for Jeju is not viable due to physical constraints; however decompression melting is still responsible for magmatic activity in the area. Uplift of mantle blocks under Jeju occurred due to lubrication by shear zones created during the opening of the Sea of Japan/East Sea c. 15 Ma ago, and reactivated during rotation of the direction of subduction of the Philippine Sea plate c. 2 Ma ago. This is the first attempt to directly link subduction processes and intraplate volcanism on Jeju.

Volume control on magmatic evolution and eruption style transition, Jeju, Korea

MARCO BRENNA[1]*, SHANE J. CRONIN[1], IAN E. M. SMITH[2] AND YOUNG KWAN SOHN[3]

[1]Volcanic Risk Solutions, Massey University, Palmerston North, New Zealand, (*correspondance: m.brenna@massey.ac.nz)
[2]School of Environment, University of Auckland, Auckland, New Zealand
[3]Dep. of Earth and Environmental Sciences, Gyeongsang National University, Jinju, Republic of Korea

Jeju is a volcanic field active over the last c. 1.8 Ma. Eruptive activity began with dispersed, basaltic, monogenetic, volcanism. Continuing monogenetic volcanism was later joined by more voluminous, alkali and sub-alkali lava effusion events building a central composite edifice. From three deep cores (400-500 m) through the main edifice flanks, lava samples were analysed for major, trace-element and Sr-Nd-Pb isotope compositions. The low-volume monogenetic volcanoes erupted mainly primitive alkali basalts, whereas the larger-volume lavas have chemical variability spanning alkali basalt to trachyte compositions. The oldest erupted lavas form part of a high-Al alkali suite and evolved to Sanbangsan trachytes (SiO_2 c. 62 wt%). The topmost lavas show less Al_2O_3 enrichment and MgO depletion and hence form a low-Al alkali suite, which evolved to the Hallasan trachytes (SiO_2 c. 66 wt%). The similarities in the chemical evolution trends between low- and large volume magmas suggests similar magma sources and analogous crystal fractionation processes. This implies that the volume and proportions of parent melt was the dominating factor in determining the eventual course of magmatic activity. Based on the chemical trends, the proportions of partial melts must have increased in the middle and later stages of Jeju Island's formation. This may relate to increased uplift of mantle domains (or increased mantle convection) beneath the island, leading to accelerated decompression melting, compared to the early stages of activity. This resulted in the construction of the central composite edifice. Mantle upwelling was greater in the core of the system, resulting in the larger volume lava outpourings, compared the lower supply in distal parts of the field, resulting in low-volume monogenetic activity. These results have implications for hazard forecasting in monogenetic volcanic fields, with a first conclusion being that eruptions situated in the centre of the field may give rise to larger volume lava outpourings compared to those at the outer margins.

$^{238}U/^{235}U$ ratios of angrites: Adjusting absolute ages of anchors

G.A. BRENNECKA* AND M. WADHWA

School of Earth & Space Exploration, Arizona State Uni., Tempe, AZ (*correspondence: brennecka@asu.edu)

The use of short-lived chronometers is critical to our understanding of the high-resolution time sequence of events in the early Solar System. To map relative ages from short-lived systems onto the absolute time scale, they are "anchored" to the Pb-Pb ages of appropriate meteoritic materials. Previously reported high precision Pb-Pb dates of the basaltic angrite meteorites, some of which have been used extensively as anchors [1-2], have assumed a $^{238}U/^{235}U$ ratio (=137.88). However, the $^{238}U/^{235}U$ ratio has recently been shown to be variable in Solar System materials [3-6], requiring the reevaluation of these previously reported Pb-Pb ages. An adjustment to the Pb-Pb age of an anchor would consequently require a corresponding correction to the calculated "model" ages for any other meteoritic materials dated using that anchor and an extinct chronometer, such as the ^{26}Al-^{26}Mg, ^{53}Mn-^{53}Cr, or ^{182}Hf-^{182}W chronometers.

Here we report U isotope compositions of several angrites. Specifically, $^{238}U/^{235}U$ ratios were measured in whole-rock (WR) samples of the D'Orbigny, NWA 4801, NWA 4590, and NWA 6291 angrites. Additionally, phosphate separates from Angra dos Reis, pyroxene separates from D'Orbigny, and the leachate and residue from a separate acid-washed WR fraction of NWA 6291 were also measured. For D'Orbigny, two WR fractions and the pyroxene mineral separate yield identical (within 2SD errors) U isotope compositions. From these measurements, a $^{238}U/^{235}U$ ratio of 137.776±0.026 is determined, corresponding to a corrected Pb-Pb age of 4563.34±0.30 Ma (using the age previously reported by [2]). Furthermore, the $^{238}U/^{235}U$ ratios determined for WR samples of the angrites NWA 4590 (137.757±0.026), NWA 4801 (137.763±0.026), NWA 6291 (137.754±0.026), as well as for the phosphate separates of Angra dos Reis (137.791±0.042) are also identical (within 2SD errors) to those determined for D'Orbigny. Therefore, there is no detectable variation in the $^{238}U/^{235}U$ ratios measured in the angrite WR samples and mineral separates. This indicates that the angrite parent body was homogenous (at our current level of precision) in terms of its $^{238}U/^{235}U$ composition.

Simultaneous analysis of dissolved noble gases, SF_6 and CFCs in water

M.S. BRENNWALD[1]*, M. HOFER[1], AND R. KIPFER[1,2]

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland (*correspondence: matthias.brennwald@eawag.ch)

[2]Institute of Geochemistry and Petrology, Swiss Federal Institute of Technology (ETH), Zurich, Switzerland

Dissolved atmospheric noble gases, sulfur hexafluoride (SF_6) and chlorofluorocarbons (CFCs) are widely used as (transient) environmental tracers in water bodies. The concentrations of these trace gases in the water are determined by their partial pressure in the air, the gas equilibration at the water surface, the (partial) dissolution of air bubbles entrapped in the water ("excess air"), and the mixing within the water body.

In contrast to the noble gases, the partial pressures of SF_6 and CFCs in the atmosphere have increased strongly during the recent decades, e.g. due to release from industrial appliances. The SF_6 and CFC concentrations therefore contain direct information on the time when the water was last in contact with the atmosphere (water age), which is highly useful to study the mixing and deep-water formation in surface waters, the transport and mixing dynamics in groundwaters, and the geochemical origin and fate of other solutes and gases in aquatic environments (e.g. oxygen, methane, nutrients or contaminants).

For reliable water dating with SF_6 and CFCs, the relative gas contributions from air/water equilibration at the water surface and the formation of excess air to the total SF_6 and CFC concentrations in the water need to be quantified. However, the information required to disentangle these two components from each other is usually poorly constrained from the data available from the conventional analytical techniques.

A way forward to address this issue is to derive the required information from the noble-gas concentrations in the water. However, the analysis of SF_6, CFCs and noble gases in water usually involves the use of separate instruments and techniques in different and highly specialized laboratories. We therefore developed a new method and apparatus for the simultaneous analysis of He, Ne, Ar, Kr, Xe, SF_6, CFC-11, CFC-12, CFC-113, N_2 and O_2 in a single water sample. The apparatus is constructed using only standard and commercially available components. The method is based on vacuum extraction of the dissolved gases from the water. The sample gases are then separated into three fractions. He and Ne is quantified by static mass spectrometry, the remaining gases are quantified by gas chromatography.

U-Th-Ba elemental fractionation during partial melting of crustal xenoliths and its implications for U-series disequilibria in continental arc rocks

RAUL BRENS*[1] AND ROSEMARY HICKEY-VARGAS[2]

[1]Earth & Environment, Florida International University, Miami, FL, USA. (*correspondence: RaulJr00@hotmail.com)
[2]Earth & Environment, Florida International University, Miami, FL, USA. (hickey@fiu.edu)

Understanding U-series isotopic disequilibria of partially melted crust is integral for determining the effect crustal assimilation has on the U-series signature of magmas. The U-series isotopes are too low in abundance to determine by any microbeam technique. Therefore, in this work, U, Th and Ba (as a proxy for Ra) elemental abundances were gathered on the quenched glass in partially melted crustal xenoliths of granitic composition using microbeam techniques. The crustal xenoliths, which are from basaltic volcano Mirador in Chile, are old (Miocene), and can be assumed to be at secular equilibrium, whereas melting occurred during eruption of Mirador in 1979. Any recent fractionation of U from Th or Th from Ra (Ba) by partial melting will result in isotopic disequilibrium. A comparison of the ratios Ba/Th and U/Th in the partial melts with those of the whole rock reveal how much fractionation has occurred during partial melting.

An EPMA was used to locate and analyze glass pockets in the samples, through BSE images. Laser ablation ICP-MS was used to analyze U, Th and Ba in the quenched partial melts and solution ICP-MS was used for the whole rocks.

The SiO_2 content in measured glass samples was between 54% and 75%, Al_2O_3 (13% - 27%), K_2O (0.2% to 7%). Measured Ba/Th (glass/whole rock) are between 0.2 to 51 and Th/U (glass/whole rock) range from 0.3 to 7, with the majority Ba/Th between 1 to 51 and Th/U 0.3 to 1. Different ratios of U, Th and Ba compared to the whole rock substantiate fractionation via partial melting. Thus, assimilation of partial melts of crust can play a role on U-series isotopic disequilibria, which is commonly observed in continental arc magmas. Accessory minerals show variable effects as 'restite', with allanite having a large Th excess and zircon having U excess, these are foremost accessory minerals responsible for the fractionation. Potential U-series disequilibria impacts on magma through melt extraction from country rock or incomplete homogenization during assimilation is discussed.

Mineralizing fluids of the barite-fluorite mineralization at the S edge of the Thuringian Basin, Germany

M. BREY[1], J. MAJZLAN[1], R.J. BAKKER[2] AND W. PROCHASKA[2]

[1]Friedrich-Schiller Universität, Institut für Geowissenschaften, Burgweg 11, D-07749, Jena, Germany (maria.brey@uni-jena.de)
[2] Department Applied Geosciences and Geophysics, Montanuniversity, 8700 Leoben, Austria

Numerous small deposits and occurrences of barite-fluorite mineralization are developed along the southern edge of Thuringian sedimentary basin. It is a series of Upper Permian and Triassic strata (Zechstein, followed by Buntsandstein, Muschelkalk, and Keuper). The Tertiary tectonic activity uplifted the marginal portions of the today's basin where the pre-Permian rock complexes are exposed. The studied mineralization consists mostly of barite, calcite, dolomite, and locally quartz for Kamsdorf and mostly of barite and fluorite in Trusetal and Gehren. The primary fluid inclusions in barite from Kamsdorf show a wide range of salinities between 8-22 wt% $CaCl_2$ eq, the primary inclusions in fluorite from Gehren and Trusetal have about 24 to 27 eq wt% $CaCl_2$ eq. Th measurements range between 85°C to 160°C in barite and between 80°C to 130°C in fluorite. Chemical analysis of fluids extracted from fluid inclusions in fluorite and barite show compositions dominated by Na and Ca. The Cl/Br ratio in the fluorite samples is 260-340 and in barite between 150-240, always lower than in seawater (650). Raman analyses of the vapor phase inside an inclusion suggest traces of N_2 in fluorite and CH_4 in barite. Fluorite samples were analysed for rare-earth elements and two types of REE distribution patterns were found. Type 1 is characterized by high amount of light REE without any Ce anomaly and a steep decrease towards Lu. Type 2 has significantly lesser amount of LREE, a weak Tb/Dy anomaly, and a depletion in HREE. The most fluorite samples belong to the type 2.

The paragenesis of the primary minerals and the physical-chemical properties of the fluids can be explained by large-scale fluid circulation and mixing at the edge of the Thuringian basin and the adjacent Variscan crystalline basement, mostly likely during the late Mesozoic.

This work is a part of INFLUINS, a research project funded by the German Federal Ministry of Education and Research (BMBF) whose financial assistance is gratefully acknowledged.

Integrating multi-scale experiments and modeling to couple biotic weathering at nano and global scales

JONATHAN W. BRIDGE*[1], LYLA L. TAYLOR[2], STEVEN A. BANWART[1] AND THE WEATHERING SCIENCE CONSORTIUM TEAM[1]

[1]Kroto Research Institute, The University of Sheffield, Sheffield, UK (*correspondence: j.bridge@sheffield.ac.uk)
[2]Department of Animal and Plant Sciences, The University of Sheffield, UK.

Soil mycorrhizal fungi act through chemical interactions at nanometer scale to dissolve minerals and transport weathering products to plant symbionts through metre scale mycelial networks [1]. Soil development occurs at regional scale over millenia (ka) and coupling between ecological, geological and atmospheric systems is apparent over evolutionary (Ma) timescales [2]. We hypothesise that biologically-driven weathering reactions at molecular scale persist through scale transitions to exert strong controls on soil formation and atmospheric CO_2 evolution that occur over much larger temporal and spatial scales.

To test this we have applied an integrated suite of observations at scales from nanometre to decimetre using common minerals, fungi and physical and chemical conditions. Our experiment results demonstrate that fungal hyphae-grain contact leads directly to mass loss from mineral grains over time [3]. Cell exudates and nanoscale cell-mineral interaction forces progressively modify mineral surfaces and alter the pore microenvironment, conditioning subsequent biotic and abiotic weathering mechanisms. Crucially, these processes are directed by mycorrhiza towards minerals which yield the best nutrient supply for plants [1].

Here, we describe the development of numerical models for key nano-scale weathering processes coupled to stochastic, agent-based simulations of hyphal growth at the micron to cm scales which permit quantitative analysis of the dynamic interactions between plant carbon energy supply and soil mineral weathering rates, mediated by mycorrhizal fungi. These profile-scale data are aggregated in a continental scale process-based model [2,4] and tested for representation of the global carbon cycle at evolutionary timescales by comparing with proxy data for paleoenvironmental conditions [5].

Strontium incorporation into carbonate granules secreted by earthworms

LOREDANA BRINZA[1]*, J. FRED W. MOSSELMANS[1], PAUL F. SCHOFIELD[2], PAUL D. QUINN[1] AND MARK E. HODSON[3]

[1]Diamond Light Source, UK, (Loredana.Brinza@diamond.ac.uk)
[2]Natural History Museum, London, UK, (pfs@nhm.ac.uk)
[3]University of Reading, Reading, UK, (m.e.hodson@reading.ac.uk)

Earthworms secrete significant quantities of calcium carbonate in the form of granules (0.5mg $CaCO_3$/g worm/day), which can also contain other metals depending on the soil content (Pb, Mn, Mg). This may affect metal bio-availability and impact upon element bio-geo-cycling. We have examined Sr incorporation into the granules produced by earthworm *Lumbricus terrestris* cultivated in Sr containing soil. These granules contained up to 3.5% Sr with a positive correlation between Sr concentration in pore water and Sr in the granules. Sr-μXRF maps of the granules show Sr enrichment within the outer region of the granules. These both suggest that the mechanism of Sr incorporation is either adsorption onto or co-precipitation during granule growth.

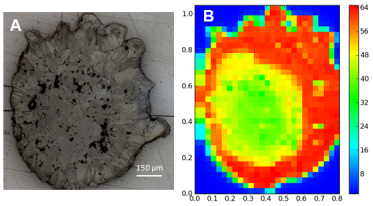

Figure 1. Slice of a calcium carbonate granule produced by ***Lumbricus terrestris*** incorporating 1.2% strontium: (A) Zeiss microscope image; (B) Sr-μXRF map: axis are in mm and the colour bar indicates: blue - low Sr and red - high Sr.

Analysis of Ca-μXANES and Sr-μEXAFS suggests that most Sr substitutes for Ca in the rhombohedral calcite structure rather than producing the orthorhombic carbonates. The results significantly improve our understanding of Sr sequestration within bio-synthesized carbonate granules in the context of its biogeochemical cycle. In terms of earthworm tolerance to Sr, earthworms showed significant mortality at soil bulk concentrations above 1000ppm.

Evaluation of surface complexation parameters for Eu^{3+} on muscovite and orthoclase

S.M. BRITZ[1]*, U. NOSECK[1], V. BRENDLER[2] AND M. STOCKMANN[2]

[1]GRS Braunschweig, D-38122 Braunschweig, Germany (*correspondence: susan.britz@grs.de)

[2]Helmholtz-Zentrum Dresden-Rossendorf, D-01328 Dresden, Germany

Sorption on mineral surfaces of sediments is an important retardation process for radionuclides to be considered in safety assessments for radioactive waste repositories.

This study deals with sediments of the overburden at Gorleben site that are mainly composed of tertiary and quaternary sands and clays [1]. A bottom-up approach is chosen to describe the sorption of Eu^{3+} (as homologue for trivalent actinides) on each single mineral phase of a representative sediment. Orthoclase and muscovite are important constituents of the sediment significantly contributing to the overall distribution coefficient.

The scope of the study is the assessment of surface complexation parameters by applying the geochemical speciation model PhreeqC, Version 2.17 which is coupled with the parameter-estimation code UCODE_2005. Since relevant data were missing for the sediment constituents orthoclase and muscovite batch experiments are performed for the parameter estimation. Establishing solid/liquid ratios of 1/20 and 1/80 the minerals are suspended in 0.01 M $NaClO_4$. Subsequently pH values ranging between 6 and 9 are employed in the suspensions over a period of several weeks. Eu^{3+} concentrations of 10^{-5} M, 10^{-6} M, 10^{-7} M, and 10^{-8} M are applied, whereat a chemical equilibrium between Eu^{3+} and the mineral is reached within 24 h.

PhreeqC and UCODE are used to acquire protolysis constants via a diffuse double layer model from measured titration curves. In the second step the basic required parameters, i.e. logK-values for selected surface reactions, the surface site density, and the specific surface area are iteratively determined by fitting the experimental data.

To simulate Eu-sorption on a representative sediment (10% muscovite, 10% orthoclase, 80% quartz) the derived surface complexation model is applied to a corresponding experimental data-set. Results show good reproduction of the data, hence, backing up a robust parameter set.

Molecular fossils and the late rise of eukaryotes and oxygenic photosynthesis

JOCHEN J. BROCKS

Research School of Earth Sciences, The Australian National University, Canberra ACT 0200, Australia.

Hydrocarbon biomarkers are the molecular fossils of natural products such as lipids and pigments. They can yield a wealth of information about early microbial ecosystems and are particularly valuable when preserved in > 1 billion-year-old (Ga) sedimentary rocks where conventional fossils are often lacking. Therefore, in 1999, the detection of traces of biomarkers in 2.5 to 2.7 Ga shales from Western Australia [1, 2] was celebrated as a breakthrough. The discovery, which was later confirmed by several independent studies, led to far-reaching conclusions about the early evolution of oxygenic photosynthesis [2] and ancestral eukaryotes [1]. However, here we present new data based on the carbon isotopic composition of solidified hydrocarbons [3] and the spatial distribution of liquid hydrocarbons within the original 2.5 and 2.7 Ga shales [4] that demonstrate that the molecules must have entered the rocks much later in Earth's history and therefore provide no information about the Archean (>2.5 Ga) biosphere or environment.

The elimination of the Archean biomarker data has immense implications for our understanding of Earth's early biosphere. 2α-methylhopanes have been interpreted as evidence for the existence of cyanobacteria at 2.7 Ga, about ~300 million years before the atmosphere became mildly oxygenated in the Great Oxidation Event (GOE; between 2.45 and 2.32 Ga). Now, the oldest direct fossil evidence for cyanobacteria reverts back to 2.15 Ga, and the most ancient robust sign for oxygenic photosynthesis becomes the GOE itself. Moreover, the presence of steranes has been interpreted as evidence for the existence of ancestral eukaryotes at 2.7 Ga. However, without the steranes, the oldest fossil evidence for the domain falls into the range ~1.78-1.68 Ga. Recognition that the biomarkers from Archean rocks are not of Archean age renders permissive hypotheses about a late evolution of oxygenic photosynthesis, and an anoxygenic phototrophic origin of the vast deposits of Archean banded iron formation.

The Great Artesian Basin (GAB) is one of the largest artesian groundwater basins in the world, underlying more than one-fifth of the Australian continent. The water is stored in a multi-layered confined aquifer system. Earlier studies using different dating methods showed a wide range of water ages up to more than 400 000 years [1,2]. As the GAB aquifers constitute the major water source in this semi-arid to arid region their careful management is of great importance.

Study area of this project is the western margin of the GAB as part of the project "Allocating water and maintaining springs in the Great Artesian Basin" of the Australian National Water Commission. We aim to obtain a full record of palaeoclimate data over the last 30 kyr by analysing groundwater samples for dissolved noble gases and stable isotopes. Noble gas studies have proven to be a valuable tool for determining palaeotemperatures all over the world [3]. By examining the excess air component estimations of palaeohumidity can be made [4].

^{3}He, ^{4}He, Ne, Ar, Kr and Xe concentrations are measured using mass spectrometry. For dating mainly ^{14}C and ^{4}He, in some cases other radioisotopes, will be used. Radiogenic ^{4}He concentrations increase with distance along presumed flow lines. First results for noble gas temperatures of recent groundwaters correspond well to the mean annual air temperature in the study area (21.7°C).

The rapid emplacement of the Val Fredda Complex, Adamello batholith, N. Italy

C.A. BRODERICK[1]*, U. SCHALTEGGER[1], D. GÜNTHER[2] AND P. BRACK[3]

[1]University of Geneva, Earth Sciences, Switzerland (*corresponence: Cindy.Broderick@unige.ch)

[3]ETH Zürich, Earth Sciences, Switzerland

Recent advances in U-Pb zircon geochronology have revealed the complexities of pluton construction, by multiple injections on 10-100 ka to Ma timescales [1, 2]. Using high precision U-Pb dating we are potentially able to determine timescales of magma generation, crystallization and emplacement within the crust. The potential exists to better understand magma forming processes with detailed high precision U-Pb dating and trace element analyses of zircon and titanite, combined with Hf isotope analysis of zircon.

The focus of this study is on the Val Fredda Complex (VFC) in the southern tip of the Adamello batholith, N. Italy. The VFC shows complex relationships among mafic melts that were injected into solidifying felsic magmas. Single zircon crystals, from the VFC, have been dated using CA-ID-TIMS, employing the ET2535 tracer solution for maximum precision and accuracy. The mafic units have apparent autocrystic zircons that indicate growth over a duration of 100 ka, with the majority of zircons crystallizing near the solidus, as indicated by ^{206}Pb/^{238}U zircon and titanite dates, both with permil uncertainties. Data from the VFC felsic units show more complex zircon populations, including xenocrystic, antecrystic and autocrystic zircons. Trace element ratios such as Y/Hf aide in our distinctions between autocrystic and antecrystic zircons. These felsic units have apparent autocrystic zircon growth over 100 to 200 ka, with zircons crystallizing near the solidus during the last 20 to 50 ka as indicated by titanite dates. Our data suggest that the oldest autocrystic zircon could be used to approximate the injection of the respective magma pulses into the host rock, whereas the youngest zircon and titanite could be used to approximate (final?) solidification. It appears that the five units from the VFC were injected into the crust between 42.58 Ma and 42.52 Ma and achieved the final solid state between 42.48 Ma and 42.42 Ma.

Sr isotope ratios determination by LA-MC-ICPMS in Rb rich samples: Online separation of Rb by electrothermal aerosol heating

R. BROGIOLI, L. DORTA, B. HATTENDORF AND D. GÜNTHER

Laboratory of Inorganic Chemistry, ETH Zurich, Wolfgang-Paulistrasse 10, 8093, Zürich, Switzerland

Rb/Sr geochronology using LA-ICPMS has successfully been demonstrated for solid samples where the Rb/Sr concentration ratio is lower than 0.02 [1] and 0.14 [2]. For samples with higher Rb content, the determination of Sr isotope ratios remains challenging because mathematical correction of the isobaric interference from ^{87}Rb leads to increased uncertainties in the results. Using electrothermal vaporization (ETV)-ICPMS, a method has been conceived by Rowland *et al*. [3] in order to selectively pre-vaporize Rb from a reference potassium feldspar sample (NIST SRM607) making the measurement of Sr isotope ratios possible for samples where the Rb/Sr ratio can be as high as 8.

In an earlier study we could demostrate that heating laser generated aerosols from a silicate glass reference material (NIST SRM610, Rb/Sr ~1) with a commercially available ETV unit (Perkin Elmer, HGA 600MS) to about 2000 °C, enables the reduction of the signal intensity of Rb by 99%, while the signal intensities for Sr remain practically unaffected [4]. The approach has now been used for Sr isotope ratios measuerments in NIST SRM 610 (Rb/Sr = 1), USGS BCR2G (Rb/Sr = 0.14) and $Li_2B_4O_7$ fused disks of NIST SRM607 (Rb/Sr = 8) using multicollector ICPMS coupled to the LA-ETV setup. The combination of electrothermal vaporization for interferences suppression and laser ablation for spatially resolved sampling of solids is expected to broaden the range of applications for Rb/Sr –geochonology since both, isotope ratios and elemental concentrations, can principally be determined under highly similar conditions when using either sequential LA-ICPMS approaches or a split-flow prior to ETV configuration with MC-ICPMS and single collector ICPMS operating in parallel [5].

Bioreduction of biotite and chlorite: Effects on mineral reactivity

D.R. BROOKSHAW*, R.A.D. PATTRICK, J.R. LLOYD AND D.J. VAUGHAN

School of Earth, Atmospheric and Environmental Sciences, and Williamson Research Centre for Molecular Environmental Science, University of Manchester, Manchester, M13 9PL, UK (*correspondence: diana.brookshaw@postgrad.manchester.ac.uk)

Interactions with mineral phases can dictate the mobility of contaminants in the subsurface. Electron transfer processes in particular have the potential to reduce redox-sensitive metals (including radionuclides) so as to form much less soluble and less mobile phases. This work concerns investigating the role that microorganisms can play in such electron-transfer processes, examining interactions involving two key phyllosilicates found in the sub-surface.

Biotite and chlorite are sheet silicate minerals containing both ferric and ferrous iron in their octahedral layers. The redox reactivity of these minerals when fresh, and after undergoing bioreduction, was studied. The model Fe(III)-reducing microorganism *Shewanella oneidensis* MR-1 was used in anaerobic batch experiments where reduction of structural iron was stimulated by addition of an electron donor. The bioreduced mineral was collected and washed before use in redox reactivity experiments.

Ferrous iron assays using the ferrozine method show that *S. oneidensis* MR-1 is able to reduce the bioavailable Fe(III) in both minerals, both in the presence and absence of an artificial electron shuttle and humic analogue (AQDS). Chromate (Cr(VI)) was used as a redox probe to explore mineral reactivity. Unaltered biotite and chlorite reduced up to ~15% of 1mM Cr(VI), compared to 82.8% for the bioreduced biotite, and 91.6% for the bioreduced chlorite. This demonstrates the importance of bioreduction in metal cycling, with the mineral surfaces conditioned to reduce the metals in solution. The amount of reduction suggests that the processes involve more than just the available Fe(II) surface atoms. Surface analysis (XPS) combined with XAS are being used to detemine the biologically induced mineralogical changes that are driving the reduction process.

The work is being extended to radionuclides, and the reduction of technetium (^{99}Tc). It is anticipated that the amount of reduction will be similar to that of Cr(VI) as Tc reduction is also a three-electron transformation (Tc(VII) to Tc(IV)).

Geochemistry and tectonic setting of Una-Una volcano, Sulawesi, Indonesia

S. BROOM-FENDLEY*, M.F. THIRLWALL, M.A. COTTAM AND R. HALL

SE Asia Research Group, Department of Earth Sciences, Royal Holloway University of London, Egham, Surrey TW20 OEX, UK (*correspondence: s.broom.fendley@gmail.com)

Una-Una is an isolated volcano in Gorontalo Bay, North Sulawesi situated in a complex tectonic setting. Previously, Una-Una has been linked to southward subduction of the Celebes Sea under the North Arm of Sulawesi or northward subduction linked to collision in East Sulawesi. These hypotheses have problems with the apparent depth to the Benioff zone and amount of continental underthrusting.

We present new geochemical and Sr, Nd & Pb isotope analyses of volcanic rocks from Una-Una (<~100 Ka) and the nearby Togian islands (~2 Ma). These are both alkaline or high-K calc-alkaline trachytes with elevated Sr, Pb and LILE and depleted HREE, Nb and Ta. Sr and Nd isotopes plot in the enriched quadrant on a Sr-Nd diagram and $^{207}Pb/^{204}Pb$ show a steep trajectory extending from Indian Ocean MORB. The isotopic trends and similar geochemistry indicate that the rocks are genetically related and have similar continental derived components. The elevated isotopic values require an ancient continental contribution to the source. Mixing trends between Sr and Nd isotopes show that contamination is not likely to have come from Celebes Sea sediment compositions and Indian Ocean pelagic sediment is more likely. Contamination could have occurred during Eocene-Early Miocene subduction of Indian Ocean lithosphere. Una-Una is not above a subducted slab, and is at least 200 km above any projected subduction zone. The age of volcanic rocks from the Togian Islands rule out subduction at the North Sulawesi trench as the slab would not have been deep enough.

We propose that Una-Una and the Togian Islands are the product of young extension of Gorontalo Bay due to slab roll-back. This provides a mechanism for upwelling of a pre-metasomatised mantle.

Assessing calcium isotopes as a dietary proxy for terrestrial vertebrates

J. BROSKA[1], T. TÜTKEN[2]*, S.J.G. GALER[3], P. HELD[1] AND K.W. ALT[1]

[1]Institut für Anthropologie, Johannes Gutenberg-Universität Mainz, 5099 Mainz, Germany

[2]Steinmann-Institut, Rheinische Friedrich-Wilhelms-Universität Bonn, Poppelsdorfer Schloß, 53115 Bonn, Germany (*correspondence: tuetken@uni-bonn.de)

[3]Max-Planck-Institut für Chemie, Abteilung Biogeochemie, Postfach 3060, 55020 Mainz, Germany

Vertebrates ingest calcium along with their diet, and during biomineralization the light calcium isotopes are preferentially enriched in the bioapatite of bones and teeth. Therefore, $\delta^{44/42}Ca$ should decrease systematically along a food chain, and display a trophic level effect (TLE). Since calcium isotope signatures of bones and teeth seem robust against strong diagenetic alteration, $\delta^{44/42}Ca$ is a promising proxy for reconstructing both past diets of extinct vertebrates and fossil food webs.

However, in order to be able to use $\delta^{44/42}Ca$ to elucidate the diet of extinct animals, a better understanding of $\delta^{44/42}Ca$ and TLE in modern ecosystems is paramount. With this in mind, we analysed $\delta^{44/42}Ca$ in more than 40 bones of 19 extant mammals with a broad range of well-characterized diets from savannah ecosystems in Africa. The Ca isotope data were obtained by TIMS using a ^{43}Ca-^{46}Ca double spike at MPI. Additional, established proxies for diet and trophic level such as $\delta^{13}C$ and $\delta^{15}N$ of collagen were also analyzed on the same specimens for comparison and to assess dietary differences and trophic level relationships.

A large variability in $\delta^{44/42}Ca$ was observed within each trophic level. Browsers and grazers, and some of the frugivores, had similar $\delta^{44/42}Ca$ values. A significant TLE difference in $\delta^{44/42}Ca$ of –0.36 was found to exist between herbivores (–0.53 ± 0.32‰) and carnivores (–0.89 ± 0.18‰). This TLE difference is smaller than the –0.65 that has been reported thus far, but appears to vary between different areas and geological substrates.

Carnivores with high amounts of bone consumption, such as leopards and hyenas, display the lowest $\delta^{44/42}Ca$, down to –1.2‰ (hyenas). In contrast, ant-eating insectivores, such as the aardvark and aardwolf, have the highest bone $\delta^{44/42}Ca$ (+0.03±0.27‰) observed for extant vertebrates thus far, being significantly higher than found for both herbivores and carnivores. Thus, $\delta^{44/42}Ca$ may potentially be a useful indicator of insectivory in fossil vertebrates.

Combining $\delta^{44/42}Ca$ with $\delta^{13}C$ and $\delta^{15}N$ allows us to refine our interpretation of diet of foodwebs significantly in extant and extinct vertebrates.

Effect of differentiation on Fe oxidation in arc basalts

MARYJO BROUNCE[1,2], KATHERINE A. KELLEY[1] AND ELIZABETH COTTRELL[2]

[1]Graduate School of Oceanography, University of Rhode Island, 215 S. Ferry Road Narragansett, RI 02882 USA
[2]National Museum of Natural History, Smithsonian Institution, Washington DC 20560, USA

The role of crustal differentiation processes in creating or modifying the relatively oxidized condition of arc basalts relative to mid ocean ridge basalts (MORB) is not well constrained. We present the first combined data set for major elements, dissolved volatile concentrations and $Fe^{3+}/\Sigma Fe$ ratios (determined by μ-XANES) in olivine-hosted basaltic glass inclusions from four Mariana arc volcanoes in order to examine how Fe oxidation varies with extent of fractional crystallization, degassing and contributions from the slab to the arc mantle source.

Glass inclusions span a variety of compositions and are consistent with multi-phase crystallization and degassing. A strong trend in Fe reduction accompanies magmatic degassing and inclusions with the highest MgO (>6.5 wt%) are consistently the most oxidized ($Fe^{3+}/\Sigma Fe>0.235$). The reduction trend suggests that redox exchange may occur during SO_2 degassing that redistributes e^- in the residual magma ($S^{2-}_{melt} \rightarrow S^{4+}_{vapor} + 6e^-$). We show that the high $Fe^{3+}/\Sigma Fe$ observed here cannot be created through extensive multi-phase fractionation (olv ± cpx ± plag) of a MORB-like primary melt ($Fe^{3+}/\Sigma Fe=0.16$ [1]). These observations support the hypothesis that the elevated $Fe^{3+}/\Sigma Fe$ of arc and back-arc basalts are due to differences in the source mantle. Primary melt compositions were reconstructed by restoring the most mafic inclusion compositions to equilibrium with Fo_{90}. A strong positive correlation exists between $Fe^{3+}/\Sigma Fe_{Fo90}$ and H_2O_{Fo90}, suggesting that slab derived fluids may contain an oxidized signature that contributes significantly to the oxidation state of basalts erupted at the Mariana arc.

Simultaneous reaction and creep in the KCl-KBr-H_2O system

J. BROUWER* AND A. PUTNIS

Institut für Mineralogie, Westf. Wilhelms Univ. Münster Corrensstr. 24, 48149 Münster , Germany
(* correspondence: J.Brouwer@uni-muenster.de)

As early as 1983 [1] it has been suggested that dissolution-precipitation creep rates may be affected by chemical reaction. However, for a long time research has focused mainly on creep of single phase mineral aggregates in order to understand the physics of stress-driven dissolution-precipitation creep [2,3,4]. More recent research has shown that background ions in solution may significantly effect surface kinetics and solubility both negatively and positively [5]. We present experiments on simultaneous reaction and dissolution precipitation creep in the system KBr, KCl, K(Br,Cl), H_2O.

When KBr and KCl are reacted in the presence of an aqueous fluid at room temperature a solid solution $K(Br_x, Cl_{1-x})$ will form. Creep rates of KBr and KCl in their respective aqueous solutions are compared with those of KBr and KCl in the solution of the other endmember, and with creep rates of mixtures of KBr and KCl in an aqueous solution that is in equilibrium with the solid solution that will form when reaction has gone to completion. These results provide in insight the complex combination of effects that reaction has on deformation, including changes in solid volume due to solubility differences between parent and product phases, changes in grain size and material properties, and changes in kinetics.

[4]Institut de Minéralogie et de Physique des Milieux Condensés (IMPMC), UPMC; Université Paris 7; CNRS; 4, Place Jussieu, 75252 Paris Cedex 05, France.

Electron transfer at mineral-water and mineral-microbe interfaces is a major biogeochemical process that can result in transformation of redox-sensitive minerals and adsorbed pollutant ions, capture (through adsorption and precipitation reactions) or release (through reductive transformation of the sorbent and desorption of surface complexes) of pollutant species, and major controls on element cycling. Over the past decade, a growing number of spectroscopic and imaging studies of the products of electron transfer reactions in model mineral-water systems have advanced our understanding of these reactions and their kinetics in the laboratory. Here, we will review a number of these studies, including abiotic reduction of As(V), Cr(VI), and Se(VI) on metal oxide surfaces, photocatalyzed As(III) oxidation on kaolinite and anatase surfaces, the role of reactive oxygen species and Fe^{2+} on the oxidation kinetics of As(III) on iron oxides, microbially mediated redox reactions of arsenic at iron oxide-water interfaces, and the role of exopolysaccharides in the reduction of nanoparticulate hematite by *Shewanella oneidensis* MR-1, and microbially mediated oxidation of metal sulfides. We will also present the results of several studies of complex environmental samples that illustrate the effects of electron transfer reactions in natural settings, including chromium reduction by magnetite, the effect of electrically insulating coatings on the Cr(VI) to Cr(III) reduction at the magnetite-water interface, Cr(III) oxidation by Mn-oxides, and arsenic redox reactions, including As(III,V) biomineral formation in an acid mine drainage environment.

Interfacial area measurements for robust models of multiphase flow in porous media

KENDRA I. BROWN[1], DORTHE WILDENSCHILD[1], WILLIAM G. GRAY[2] AND CASS T. MILLER[2]

[1]School of Chem/Bio/Env Eng, Oregon State University, Corvallis, OR 97331; (brownke@engr.orst.edu, dorthe@engr.oregonstate.edu)

[2]Dept of Env Science and Engineering, University of North Carolina, Chapel Hill, NC; (graywg@unc.edu, casey_miller@unc.edu)

Understanding the physics of natural flow systems that include *three* immiscible fluid phases in porous media is important to applications such as remediation of NAPL from the vadose zone, oil and gas recovery, and CO_2 sequestration.

Flow and transport in such systems are strongly influenced by the presence of fluid-fluid interfaces. Theoretical work based on conservation laws and the second law of thermodynamics has demonstrated the advantage of a different approach to modeling multiphase flow, accounting not only for traditional variables such as saturation and porosity, but that also incorporate specific interfacial areas, specific common curve lengths, and average curvatures, that are measures of the morphology and topology of the phase distributions.

This research expands previous work on two-fluid-phase systems to three-fluid-phase systems, and the particular focus is the generation of a pore-scale experimental data set that expresses the dependency of capillary pressures in the system on two saturations, as well as interfacial areas per volume. Synchrotron-based X-ray computed microtomography (CMT) is used to generate high-resolution images during drainage and imbibition, which are analyzed to measure the saturations and interfacial areas, and to calculate capillary pressures via meniscus curvature.

[4]University of Cambridge, Department of Earth Sciences, Downing Street, Cambridge, CB2 3EQ

[5]Berkeley Geochronology Center, 2455 Ridge Road, Berkeley, CA 94709

This study investigates changes in the rock magnetic properties of single crystals of ilmenite-hematite from the Ecstall pluton containing nm-sized magnetite crystals that formed as a result of reheating by the adjacent Quottoon plutonic complex. Measurements of hysteresis properties, low temperature remanence, room temperature IRM acquisition, and observations from magnetic force microscopy (MFM) and off-axis electron holography show that samples fall into 3 groups, which are defined by the presence of mineral microstructures documented in *Brownlee et al*. [2010], which are in turn related to distance from the Quottoon plutonic complex. Ilmenite-hematite grains from the two groups closest to the Quottoon plutonic complex contain nm-sized magnetite crystals within hematite and ilmenite lamellae. Reheating of the Ecstall pluton led to an increase in coercivity and overall magnetic intensity, as well as the development of mixed phase hysteresis. Though the potential for lamellar magnetism exists in all of these samples, off-axis electron holography results indicate that the magnetic signal is dominated by magnetite precipitates at intermediate distances from the Quottoon plutonic complex. Increased single grain coercivity may reflect further development of exsolution lamellae at very close distances to the Quottoon plutonic complex. These results indicate that reheating had a profound affect on the overall magnetic properties of the Ecstall pluton through the growth and modification of Fe-Ti oxide microstructures.

Fate of an Eocene HT metamorphic complex in a forearc location

E. BRUAND[1]*, D. GASSER[2] AND K. STUEWE[3]

[1]SEES, University of Portsmouth, Portsmouth PO1 3QL, UK (*correspondence: emilie.bruand@port.ac.uk)

[2]Department of Geosciences, University of Oslo, 0316 Oslo, Norway (deta.gasser@geo.uio.no)

[3]Department of Earth Sciences, Karl-Franzens Universität, 8010 Graz, Austria (kurt.stuewe@uni-graz.at)

The Chugach and St Elias mountains in southern Alaska are a peculiar and interesting region from many geological aspects. For example, this area encloses a high temperature Eocene complex (CMC) developed in a Late Cretaceous accretionary prism: such a high-thermal regime is uncommon in a subduction setting during the Phanerozoic. In addition, this investigated area is also currently the focus of intense research related to the coupling of surface processes (glacial erosion) and tectonics, since fast Neogene exhumation rates have been observed in areas of intense glaciation [1]. Therefore, in order to understand links between crustal thermal evolution, metamorphism, deformation and erosion in this area, it is crucial to obtain a detailed description of its PTdt-evolution through time. For this purpose, aspects of metamorphic petrology, geochemistry, structural geology and geochronology are combined and presented in this contribution to develop a crustal scale geodynamic model of this region.

The CMC is more than 300 km long, made up of metasediments associated with an amphibolite layer in its southern part. Detailed petrological work across several parts of this complex permits to discuss the uncommon presence of such a HT complex in a forearc location. Results highlight a pressure gradient from north to south and an interesting behaviour of the southern amphibolite belt that make up the suture between the CMC and the outboard accreted terrane. In addition, our dataset including detailed structural geology and geochronology suggests that fast burial and exhumation rates in this region do not only occur in the Neogene but also during the Eocene. Our new results assess that exhumation from depths of >20 km in parts of the complex were accompanied by erosion at the surface. Our data set documents a complex deformational and thermal history including accretion of sediments, subsequent vertical flattening leading to compressed isotherms, followed by dextral transpression, exhumation and erosion within a short time period of ca. 10-15 Ma.

Experimental quantification of plagioclase CSD during decompression of hydrous rhyodacite

C. BRUGGER-SCHORR AND J. HAMMER*

Dept. GG, Univ. Hawaii, 1680 East-West Rd., Honolulu, HI, 96822, USA (*correspondence jhammer@hawaii.edu)

Few experimental studies [1,2] constrain the link between crystal size distributions (CSDs) and known chemical, thermal, or barometric histories. We determine CSDs of plagioclase forming during decompression experiments on hydrous rhyodacite magma. Samples were annealed at 130 MPa, subjected to continuous decompression at either 2 MPa hr^{-1} or 0.5 MPa hr^{-1}, and then quenched at ~20 MPa intervals to provide snapshots of the system along the decompression path [3]. Crystal nucleation and growth rates derived from CSDs using standard assumptions are compared with values obtained using 2D measurements of the largest crystals (L_{max} methods) as well as bulk crystal populations (batch methods). The characteristic growth rate in the rapidly decompressed series is approximately five times faster than the growth rate in the slowly decompressed series. Because crystal growth rate depends on decompression rate, CSDs are incapable of revealing decompression timescales or magma ascent rates without independent knowledge of crystal growth rate.

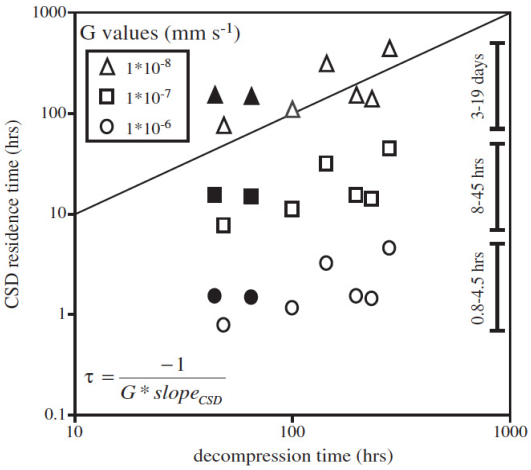

Figure 1: Residence time is computed using three published values of plagioclase growth rate. Only independent knowledge of G permits recovery of actual crystallization interval (1:1 line).

Bioapatite in mammalian teeth is readily preserved in continental sediments and represents an important archive for environmental reconstructions. Here we present electron microprobe data for fossil and modern molar enamel of Hippopotamids from different ecosystems in Eastern Africa, representing modern and fossil lacustrine (Lake Kikorongo, Lake Albert, and Lake Malawi) and modern fluvial environments of the Nile River system.

Fossil enamel from the saline Lake Kikorongo has a much higher MgO/Na_2O ratio (~1.11) than from the Neogene fossils of Lake Albert (MgO/Na_2O~0.4), which was a large fresh water lake. Similarly, the MgO/Na_2O ratio in modern enamel from the White Nile River (~0.36), which passes through several saline zones, is higher than that from the Blue Nile River (MgO/Na_2O~0.22). Thus, MgO/Na_2O is suggested be a fingerprint for environments where river and lake water have suffered strong evaporation.

Linear regression analysis reveals very tight physiological control on the MgO, Na_2O and Cl variations (R^2: 0.6-0.84) despite large concentration variations (40% to 300%) along sections perpendicular to the enamel-dentin junction (EDJ). MgO and Na_2O decrease from the EDJ towards the outer enamel rim, whereas Cl displays the opposite variation. Nevertheless, there are co-linear relationships among these elements which can be interpreted as binary mixing lines. Enamel crystallites precipitating during amelogenesis equilibrate with a continuously evolving fluid. During this process Na_2O and MgO behave incompatibly whereas Cl is incompatible to hydroxyapatite. This results in the formation of MgO, and Na_2O-rich, but Cl-poor bioapatite near the EDJ and MgO- and Na_2O-poor, but Cl-rich bioapatite at the outer enamel rim.

The relationship between $\Delta^{14}C$ and $\delta^{13}C$ of DIC in the LGM Ocean

S.P. BRYAN[1]*, S.J. LEHMAN[2] AND T.M. MARCHITTO[2]

[1]Dept. of Marine Chemistry & Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA (*correspondance: sbryan@whoi.edu)
[2]Dept. of Geological Sciences & INSTAAR, University of Colorado, Boulder, CO 80303, USA (scott.lehman@colorado.edu, tom.marchitto@colorado.edu)

Reconstructed atmospheric radiocarbon activities ($\Delta^{14}C$) during the last glacial period were higher than can be explained by ^{14}C production rates, seemingly requiring reduced ventiliation of the glacial deep ocean relative to the preindustrial ocean. Estimates of glacial deep ocean $\Delta^{14}C$ generally support this prediction; though large uncertainites exist in deep ocean paleo-$\Delta^{14}C$ reconstructions due to the paucity of records, generally low sedimentation rates in the deep ocean, bioturbative mixing of foraminifera of differing ages, and uncertain surface reservoir ages. Due to these uncertainties there is currently no consensus regarding the spatial extent or the degree of ^{14}C depletion in the glacial deep ocean. The lack of a strong decrease in $\delta^{13}C$ in the glacial deep Pacific Ocean has been used as an argument against the existance of a large ^{14}C-depleted water mass. However, the distributions of ^{14}C and ^{13}C of dissolved inorganic carbon are not strictly analogous. For example, in the modern ocean, differences in the depths of organic carbon remineralization vs water mass aging cause the slope of the relationship between $\delta^{13}C$ and $\Delta^{14}C$ to increase with water depth.

We explore the relationship between $\delta^{13}C$ and $\Delta^{14}C$ during the Last Glacial Maximum (~19-23 kyr BP) using a global compilation of published measurements. Despite the uncertainties listed above, there is credible evidence that deep waters in the North Atlantic, Southern Ocean and Eastern Equatorial Pacific were depleted in ^{14}C during the LGM. The decrease in deep Pacific $\Delta^{14}C$ with little associated change in $\delta^{13}C$ is equivalent to a steepening of the $\delta^{13}C$ - $\Delta^{14}C$ relationship. We suggest that this steepening may be explained by reduced organic carbon remineralization rates in the glacial deep Pacific and/or changes in preformed $\delta^{13}C$ and $\Delta^{14}C$ values. We discuss the evidence for such changes and the implications for reconstruction of the glacial ocean carbon cyle.

Rollback-enhanced decompression melting of a volatile-rich mantle: The ancient lavas of Mt. Etna

J.G. BRYCE[1]*, D. GRAHAM[2], J. BLICHERT-TOFT[3], B.B. HANAN[4], S. MILLER[1], J. BARKMAN[1], F.J. SPERA[5] AND G.R. TILTON[5]

[1]UNH Earth Sciences, Durham NH, USA (*julie.bryce@unh.edu, correspondence)

[5]UCSB Earth Sciences, Santa Barbara, CA, USA

Mount Etna, Europe's largest and most active volcano, sits above a complicated tectonic setting near the intersection of the Tyrhennian, African and Ionian plates. Geophysical evidence suggests that the large volumes of mafic lavas at Etna and the neighboring Hyblean plateau are due to enhanced melting caused by perturbations in mantle convection associated with the oversteepened Ionian slab. Here, we present new Sr-Nd-Hf-Pb data on ancient Etna basalts. We use these data, together with new major/trace element and literature data, to constrain the source lithologies responsible for early Etnean magmatism. Our sample suite includes basal tholeiites followed (at ~ 200 ka) by lavas of dominantly transitional and alkaline compositions. Major and trace element trends within the tholeiitic and alkaline series can separately be modeled by fractional crystallization, but processing through crustal magma bodies cannot satisfactorily explain the links between these two compositional series. Isotopic data are distinctive between the two groups, with the tholeiitic lavas bearing less radiogenic Sr ($^{87}Sr/^{86}Sr < 0.7032$) and Pb ($^{206}Pb/^{204}Pb < \sim 19.6$, $^{208}Pb/^{204}Pb < \sim 39.3$) when compared to the alkaline lavas ($^{206}Pb/^{204}Pb \sim 20$, $^{208}Pb/^{204}Pb > \sim 39.5$). Nd and Hf isotopic signatures define narrower ranges, with shifts of < 2 ε units across this compositional boundary and markedly more radiogenic compositions than modern Etna lavas. We interpret the isotopic data to signify mixtures of MORB mantle and enriched mantle (defined as where MORB and OIB mantle compositions generally intersect). Major element modeling using compositions of the most magnesian basalts from early Etna lavas, as well as those from the associated Hyblean plateau, indicates that these lavas represent melting from relatively fusible lithologies (volatile-rich peridotites and pyroxenites) with lower solidi than ambient asthenospheric mantle. The prevalence of fusible lithologies coupled with enhanced convection due to the unique tectonic setting, gives rise to the voluminous volcanism in the Etna /Hyblean region.

Thermodynamics of long-term metastable magnesium (chloro) hydroxo carbonates at 25°C

C. BUBE, M. ALTMAIER, V. METZ, D. SCHILD, B. KIENZLER AND V. NECK

Institute for Nuclear Waste Disposal (INE), Karlsruhe Institute of Technology, Herrmann-von-Helmholtz-Platz, 76344 Eggenstein-Leopoldshafen (bube@kit.edu, marcus.altmaier@kit.edu, volker.metz@kit.edu, dieter.schild@kit.edu, bernhard.kienzler@kit.edu)

The thermodynamics of magnesium (chloro) hydroxo carbonate phases is important to assess the geochemical conditions in carbonate-containing magnesium chloride-rich solutions for nuclear waste disposal scenarios in rock salt. Though Magnesite ($MgCO_3$) is known to be the thermodynamically stable solid in the Mg-Cl-HCO_3-CO_3-H-OH-H_2O system at room temperature, long-term metastable carbonates are observed to control the solution chemistry (Hydromagnesite ($Mg_5(CO_3)_4(OH)_2$:$4H_2O$) and Chlorartinite (Mg_2CO_3OHCl:$3H_2O$)). In the present study we focus on determining the phase transition between Hydromagnesite and Chlorartinite in order to estimate the equilibrium constant for Chlorartinite, which has not been reported so far.

Batch experiments with $MgCl_2$ solutions (0.25 to 4.5 M $MgCl_2$) and 0.05 M Na_2CO_3 are conducted over >3 years in Ar glove boxes. The pH_c ($-\log(m_{H+})$) is monitored with time and the respective precipitates are analysed with different methods (Raman, XRD, SEM-EDS, XPS). The equilibrium constant for Chlorartinite is calculated based on the equilibrium at the Hydromagnesite and Chlorartinite phase transition $Mg_5(OH)_2(CO_3)_4$:$4H_2O(s) + 3Mg^{2+} + 4Cl^- + 10H_2O(l) \Leftrightarrow 4Mg_2(OH)CO_3Cl$:$3H_2O(s) + 2H^+$. Calculations are done using the known $MgCl_2$-concentration, the measured pH_c and published solubility constants of Hydromagnesite. Under the given conditions, stability of Hydromagnesite is observed in solutions of less than 2.5 M $MgCl_2$, while Chlorartinite is found to exist in solutions with $MgCl_2$ concentrations higher than 3.2 M $MgCl_2$. In the intermediate solution of 2.8 M $MgCl_2$, both solid phases are detected with the analytical methods. Assuming a phase transition between 2.5 M and 3.2 M $MgCl_2$, the equilibrium constant for Chlorartinite is calculated as $\log K_{CA} = 13.15 \pm 0.36$ for reaction $Mg_2(OH)CO_3Cl$:$3H_2O(s) + 2\,H^+ \Leftrightarrow 2\,Mg^{2+} + HCO_3^- + Cl^- + 4\,H_2O(l)$, using the Pitzer approach for activity corrections. This equilibrium constant together with literature data allows for a comprehensive thermodynamic description of the system Mg-Cl-HCO_3-CO_3-H-OH-H_2O at room temperature.

Fluids in the upper continental crust

KURT BUCHER

Mineralogy Geochemistry, University of Freiburg, Germany (bucher@uni-freiburg.de)

The brittle upper continental crust consists predominantly of granite and gneiss. Fractures form an interconnected network of water conducting structures with an appreciable permeability also providing substantial fluid saturated fracture porosity.

The chemical composition of fluids in the fracture porosity of granite and gneiss changes with depth. Near the surface Ca-Na-HCO_3 waters dominate. With increasing depth water contains increasing amounts of alkalis and sulphate and grade into chloride-rich waters at greater depth. Total dissolved solids (TDS) of 10^5 mg L^{-1} are common at 5 km depth in most basement rocks. All reported deep fluids from the upper crust contain predominantly NaCl and $CaCl_2$. The brines vary from NaCl-rich in granites to $CaCl_2$-rich in mafic reservoir rocks such as amphibolites and gabbros.

In regions of the crust with strong topography, fluid flow is important and recharge water may have flushed the basement efficiently thereby removing old brine components from the granites.

Water samples from the new Gotthard Rail Base Tunnel of the Alps, from Norwegian road tunnels, from Korean granites and other localities represent this type of basement fluid. Analyzed fluids from up to 2.5 km depth differ from basement fluids from areas with less extreme topography in the following ways. Such waters have relatively low TDS of some 100 mg L^{-1} and are typically of the Na_2CO_3-Na_2SO_4 type. pH tends to be high and varies from 9 to more than 10. Low Ca and ultra-low Mg of such waters result from efficient deposition of secondary Ca-Mg-minerals as coatings on fracture walls. Reduction of CO_2 to amorphous carbon or further to CH_4 provides the oxidation capacity for sulphate production from primary rock sulphides. Ferrous iron silicate minerals (e.g. biotite) are oxidized to ferric oxides and hydroxides (e.g. hematite). Evidence for this mechanism is the presence carbon in sheared, water conducting granite and measurable quantities of methane in fracture water. Extreme local variations of redox conditions are reflected by the presence of pyrrhotite and other sulphides in a fracture system and anhydrite in nearby fractures of the same granite.

Geochemical signature of rocks of the neo-archean ultramafite-mafite mass in the Dzhugdzhur-Stanovoy Superterrane (the South-Eastern rim of the North-Asian craton)

I.V. BUCHKO[1]* AND S.D. VELIKOSLAVINSKY[2]

[1]Institute of Geology and Nature Management, Blagoveshchensk, Relochny, 1, Russia, (*correspondence: inna@ascnet.ru)
[2]Institute of Precambrian Geology and Geochronology, St.Petersburg, Russia

The first geochemical and geochronological data were obtained for the Neoarchean rhythmically stratified ultramafite-mafite massif in the Dzhugdzhur-Stanovoy superterrane of the south-eastern rim of the North-Asian craton.

The main petrochemical peculiarities of ultramafites and pyroxenites of the mass are the moderate increase in TiO_2 and FeO* contents at practically constant Al_2O_3, at a decrease of magnesia content from the earliest occurrences to the later ones. At the same time an increase in SiO_2, Al_2O_3 is typical for gabbro-anorthosites in the process of crystallization at a decrease of Mg# which is characteristic of high aluminiferous basalts. The duality of the petrochemical trends and the results of modeling suggest that crystallization of the rhythmically stratified ultramafites and gabbro-anorthosites occurred from two different melts corresponding in composition to pyrites and high aluminiferous basalts, respectively.

The conformity of spectra of REE and minor elements distribution are present. This lets us to conclude that the fusion of the both melts occurred from a single source that was close to Al non-depleted pycritoid in the intermediate magmatic chamber. It may be assumed that this ultramafite-mafite massif is an example of Arcean pycritoid magmatism.

The age of this massif is preliminary estimated as ~2.6 Ma (LA-ICP-MS method).

This study was supported by FEB RAS (Gr.No 09-II-SB-08-007).

Age relations, mineral-chemical and isotopic investigations on basaltic gem stone zircons from Eastern Germany

JÖRG BÜCHNER [1]*, OLAF TIETZ [1], WOLFGANG SEIFERT[2], AXEL GERDES[3] AND ULF LINNEMANN[4]

[1]Senckenberg Museum für Naturkunde Görlitz, D-02806 Görlitz, Germany (*correspondence: joerg.buechner@senckenberg.de)
[2]GFZ Potsdam, D-14473 Potsdam, Germany
[3]Geozentrum der Universität Frankfurt, D-60438 Frankfurt a. M., Germany
[4]Senckenberg Naturhistorische Sammlungen Dresden, D-01109 Dresden, Germany

In alkali basaltic rocks scarcely appear accessory minerals such as zircon and corundum. The origin of these mostly gem stone like mega-crystals is unknown and discussed controversial. Host magmas of the zircon mega-crystals are normally SiO_2 undersaturated (basanites and nephelinites).

In several localities we could observe some zircon mega-crystals and in a quarry in Saxony (eastern Germany) we collected about 40 crystals up to 15 mm in size *in situ* from the basanitic rock [1]. Zircons occur in agglutinates of lower crater facies of a scoria cone. The related lava flows are almost free of zircons and their Zr contents reaches up to 900 ppm [2]. There is a good correlation between Ar/Ar data of the basanites (30 to 31 Ma) and the zircon U/Pb data which show ages about 30.5 Ma.

First investigations indicate two different alkaline sources for zircons which origin possibly from syenitic, phonolitic or trachytic melts. This is evidenced by zircon-typology, mineral chemistry and analyses of mineral inclusions [3]. Preliminary *in situ* Hf-isotopic analyses of zircons indicate an origin from the lithospheric mantle.

The crystals show an intensive magmatic corrosion in alkalibasaltic rocks (including nephelinites), whereas zircons out of phonolites are mostly euhedral. Zircons in basaltic rocks have more or less evolved reaction rims, composed mostly of baddeyleit. Zr-contents in the rims of clinopyroxene phenocrystals decreases rapidly with the distance from the zircon inclusions. This indicates late entrainment of zircon crystals into the basanitic melt.

The age data of the zircons in relation to that of the host rocks as well as the mineral chemical and isotopic data imply a cogenetic development of both.

Petit spot-like volcanoes exposed in Costa Rica

D.M. BUCHS[1]*, S. PILET[1], P.O. BAUMGARTNER[1], M. COSCA[2], K. FLORES[1] AND A. BANDINI[1]

[1]IGP/IMG, University of Lausanne, Switzerland (correspondence: dbuchs@ifm-geomar.de)
[2]US Geological Survey, USA

The study of volcanism in the ocean is fundamental to better understand the dynamics of the Earth mantle and plate tectonics. However, our understanding of this volcanism is limited by difficulties to access the roots of ocean volcanoes and the ocean floor. Recent results in Panama shown that exposed accreted volcanoes can provide another way of understanding volcanism in the oceans [1].

Petit spot volcanoes found on the subducting plate off Japan are considered to reflect volcanism in response to plate flexure [2]. However, petit spot volcanoes are very small and it remains unclear if they are a common feature on the ocean floor; documenting new occurrences of petit spot volcanoes is a key multidisciplinary issue. We recognize here ancient petit spot-like volcanoes accreted in Costa Rica based on new geochemical, geological, ^{40}Ar-^{39}Ar, and biochronologic data.

Petit spot-like volcanoes acccreted in Costa Rica consists of tectonic stacks of volcano-sedimentary material that includes vesiculated pillow lavas, volcanic breccias and thick radiolarite beds. Igneous sills compositionnally similar to the lavas are common in the radiolarite beds. Major and trace element contents of the igneous rocks indicate an alkalic, moderately fractionated composition, and support very low degrees of partial melting in the garnet stability field. Normalized trace element patterns are very similar to those of petit spot volcanoes in Japan, and distinct from those of typical OIB, MORB and off-axis seamounts.

Step-heating ^{40}Ar-^{39}Ar dating on co-magmatic amphiboles gave two ~175 Ma ages of formation for the petit spot-like volcanoes in Costa Rica. Tectonostratigraphic and biochronologic data clearly document a ~110 Ma age of accretion, and indicate that the volcanoes did not formed close to a subduction zone or a mid-ocean ridge. Therefore, we propose that petit spot-like volcanoes may represent a ubiquitous feature on the ocean floor, which can form far from mid-ocean ridges and subduction zones. Possibly, petit spot-like volcanoes exposed in Costa Rica reflect tectonically-induced leaking of melts pre-existing at the base of the lithosphere.

Cross calibration of a Pb Multi Ion Counting array on TIMS

NADINE BUCHS, DIETMAR TUTTAS AND CLAUDIA BOUMAN*

Thermo Fisher Scientific, Hanna-Kunath-Str. 11, 28199 Bremen, Germany. (*correspondence: claudia.bouman@thermofisher.com)

Multicollector instruments using arrays of Faraday detectors are the first choice for high precision isotope ratio measurements. With decreasing sample sizes, the noise level of the Faraday detectors becomes the limiting factor for high precision isotope ratio measurements. The new TRITON *Plus* TIMS provides Multi Ion Counting with up to eight ion counters in addition to its variable multicollector array of nine Faraday cups. Classical large scale SEMs can be combined with the newly introduced compact discrete dynode electron multipliers (CDDs). The performance of these small electron multipliers is directly comparable to the classical large-scale SEMs. Both show identical stability and linearity. Also dynamic range and noise characteristics are equal for both ion counter types.

In case of Faraday detectors, precise cross calibration is guaranteed by the gain calibration and baseline measurements. In a Multi Ion Counting array, individual yield factors must be taken into account, but the stability of the yield factors needs to be assessed as well to obtain ultimate precision for isotope ratio measurements.

This study presents two strategies for precise cross calibation of all ion counting channels. The first one includes a calibration up-front; the second strategy involved an in-run calibration to control yield drift. Experiments were done on a TRITON *Plus* setup with four ion counting detectors to collect ^{204}Pb, ^{206}Pb, ^{207}Pb and ^{208}Pb. Internal correction for mass fractionation was done using ^{208}Pb/^{206}Pb.

Probing the Toba super-eruption: Oxygen isotope geochemistry of zoned quartz phenocrysts

D.A. BUDD[1]*, V.R. TROLL[1,4], E.M. JOLIS[1], F.M. DEEGAN[1], V.C. SMITH[2], M.J. WHITEHOUSE[3], C. FREDA[4], C. HARRIS[5] AND D.R. HILTON[6]

[1]Dept. of Earth Sci., CEMPEG, Uppsala University, Sweden (*correspondence: david.budd.0339@student.uu.se)
[2]Research Lab. for Archaeology, University of Oxford, UK
[3]Swedish Museum of Natural History, Stockholm, Sweden
[4]Istituto Nazionale di Geofisica e Vulcanologia, Roma, Italy
[5]Dept. Geol. Sci, University of Cape Town, South Africa
[6]Scripps Institute of Oceanography, UCSD, California, USA

The Toba caldera located in Sumatra (Indonesia) is the source of the largest volcanic eruption in the Quaternary [1]. We present oxygen isotope data for a suite of zoned quartz phenocrysts (n=8) erupted as part of the Young Toba Tuff (YTT), an eruption event of approximately 2800 km^3 some 75 ka ago [1, 2]. Oxygen isotope data has been obtained by SIMS (n=92) in combination with cathodoluminescence (CL) imaging in order to establish the role of shallow level processes such as magmatic fractionation, magma-crust interaction and crystal recycling occurring in the Toba magmatic system. The CL images exhibit defined patterns of magmatic zoning which broadly coincide with fluctuations in $\delta^{18}O$ values in the quartz crystals, allowing correlation of textural and compositional data. Measured $\delta^{18}O_{quartz}$ values range from 6.7 ‰ to 9.4 ‰, independent of position on crystal core or rim. Values for $\delta^{18}O_{magma}$ have been calculated from quartz phenocrysts (assuming $\Delta_{quartz\text{-}magma}$ is 0.7 ‰ at magmatic temperatures). The lowest magma value is 6.0 ‰, apparently reflecting a primitive isotopic signal [3]. The maximum calculated magma value is 8.7 ‰ and the average is 7.2 ‰, indicating multiple sources to the Toba system including a significant crustal component. These new data allow us to unravel the heterogeneous magmatic system at Toba volcano, involving an evolved but dominantly magmatic melt and crustal partial melts reflected in elevated $\delta^{18}O$ crystal zones. Several crystals, however, show gradually lower values towards the rims pointing to either input from a less evolved magma or, more likely, a low-$\delta^{18}O$ contaminant from the shallow volcanic edifice. The crystals therefore record a complex and heterogeneous origin of the YTT magma, comprising an evolved igneous component and several substantial crustal contributions to finally assemble the massive volume of the Toba eruption.

Microbial diversity and physiology of Alberta coal seams

K. BUDWILL[1]* AND S.P. KOZIEL[2]

[1]Alberta Innovates – Technology Futures, Edmonton, AB T6N 1E4, Canada (*correspondence: Karen.Budwill@albertainnovates.ca)
[2]Alberta Innovates – Technology Futures, Vegreville, AB T9C 1T4, Canada (Susan.Koziel@albertainnovates.ca)

We have begun to map, using 16S pyrosequenicng and traditional enrichment culturing techniques, the microbial diversity and metabolic activities of coal from different Alberta coal zones. Results have implications for optimizing the bioconversion of coal to methane and other products.

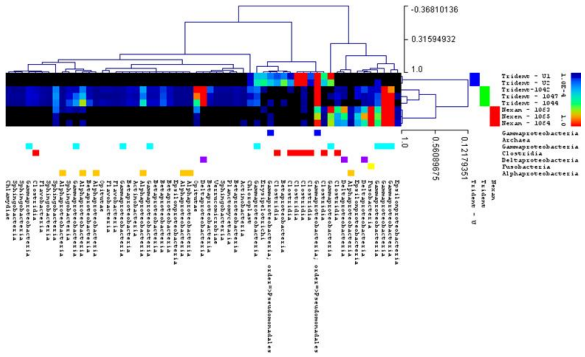

Figure 1: Hierarchical clustering tree (Linear Models for Microarray data significant taxons analysis) of 3 well sites from Mannville coal formation, Alberta.

Culture	μmol CH_4/mL culture
Coal + Tryptone	42.9
Tryptone only	11.7
Coal only	0

Table 1: CH_4 and CO_2 production at 55 days incubation in methanogenic cultures amended with 5 g coal and/or 0.05 g/mL tryptone.

Cluster analysis of microbial DNA sequences shows distinct microbial communities exist in Alberta coal deposits. The geochemical environment (e.g. salinity) likely influences community composition. Anaerobic culturing of the coal with 0.05 g/ml tryptone resulted in significant methane production and sequence reads related to *Methanobacter* increasing up to 30% from less than 1% of the total sequences detected in uncultured coal. GC-MS analysis of culture fluids provides evidence the microbial community uses coal as a carbon substrate in the presence of the nutrient.

Dynamics and evolution of the Earth's core and lowermost mantle

BRUCE BUFFETT

Earth and Planetary Science, University of California, Berkeley, CA 94720 USA (bbuffett@berkeley.edu)

Transport properties control many processes in the deep Earth. For example, the geodynamo is crucially dependent on electrical conductivity in the core. A typical estimate at relevant pressure and temperature is $5x10^5$ S m^{-1}, although this value is probably uncertain by a factor of two. At first glance a higher electrical conductivity might be expected to enhance the geodynamo. However, a higher electrical conductivity also implies a higher thermal conductivity, which suppresses the geodynamo. According to the Wiedemann-Franz law, an electrical conductivity of $5x10^5$ S m^{-1} corresponds to a thermal conductivity of 50 W K^{-1} m^{-1} at 4000 K. Approximately 8 TW of heat is carried by conduction toward the core-mantle boundary when the core is well mixed (i.e. adiabatic). This conductive transport represents a large fraction of the total core heat flow, suggesting that the transport due to convection is relatively small. Even modest changes in thermal conductivity can substantially alter the vigor of thermal convection. Present uncertainties in thermal conductivity permit widely varying estimates for the power available to drive the geodynamo.

Mass transport across the core-mantle boundary can also affect the dynamics and evolution of the core. Chemical disequilibrium between the core and mantle inevitably drives a flux of mass across the boundary, but the rate of transfer is limited by diffusion. Recent suggestions that the core is undersaturated in O and/or Si implies a flux of light elements into the core. Downward diffusion through the liquid core can produce a stratified layer 50 to 70 km thick if the flux of light elements from the mantle is sufficiently large. Dynamical arguments suggest that the residence time of material at the base of the mantle is 40 to 80 Ma. Steep chemical gradients in the mantle can drive a large mass flux, especially in the presence of partial melt or an interconnected ferropericlase phase. Local depletion of Si by transfer to the core would likely promote interconnection as the volume fraction of ferropericlase increases. Alternatively, a randomly oriented post-perovskite phase could permit a large flux. On the other hand, a large volume fraction of silicate perovskite at the boundary would likely suppress mass transfer. Differences in the mineralogy could have important implications for both the composition and dynamics of the core.

Net redistribution of ^{137}Cs over Australia

E.N. BUI AND A. CHAPPELL

CSIRO Land and Water, GPO Box 1666 Canberra, ACT 2601, Australia. (elisabeth.bui@csiro.au, adrian.chappell@csiro.au)

Cesium-137 (^{137}Cs), a radionuclide by-product of atomic testing, is a stratigraphic marker specific to the period of above-ground nuclear tests (1950s-70s), used to trace the movement of surficial material in terrestrial landscapes [1]. Its half-life is short (30.2 y) and its utility as a tracer will be of limited duration. We show here that its geographic pattern can shed valuable insight into contemporary geomorphic processes. We use geostatistics and estimates of net ^{137}Cs redistribution relative to a baseline reference fallout level to quantify and map topsoil erosion over Australia between 1950 and 1990. We show that net soil loss occurs in the main cultivated areas along the coastal regions of Western Australia, South Australia, Victoria, New South Wales, and Queensland. The most eroded area is in the Pilbara region of Western Australia, with median erosion rates > 6 t ha^{-1} yr^{-1}. The coincidence of net gain areas with eolian deposition in southeastern Australia suggests that the map is identifying wind-borne transport patterns. Eolian deposition in the Wet Tropics World Heritage Area supports the theory that dust is a major source of nutrients on ancient highly weathered soils where rainforests grow [2]. The potential for eolian deposition over the Wet Tropics is evident from an animation of MODIS imagery from the late September 2009 dust storm across Australia. However this is the first time that dust deposition over NE Australia has been substantiated.

To get insight into the fluid regime evolution during formation of Guli massif (Maymecha-Kotuy magmatic complex, Syberia) carbonatites we have studied C, N and Ar isotopic and elemental ratios in foure carbonatite samples by stepwise crushing method. Mineral separates representing different formation stages of the massif have been selected for the investigation: two early calcites (Cal) and a late stage dolomite (Dol) and siderite (Sid).

The early calcites are characterized by significantly lower CO_2 content and lower $\delta^{13}C$ values than the late Dol and Sid (-14.1, -13.6‰ and -9.0, -10.5‰ in average respectively). Fractionation during melt degassing (when system is closing) could lead to a higher CO_2 content with higher $\delta^{13}C$ values in the late minerals. But the results on C, N and Ar elemental compositions in the fluid inclusions have shown that C/N and C/Ar ratios also dramatically increase from the early to the late samples (C/N: from 7 in Cal to 210 in Sid and 2100 in Dol; C/Ar ; from 870 in Cal to 12300 in Sid and 159000 in Dol), which could not be caused by a simple magmatic fractionation. An additional source of CO_2 could appear at the late stages of the fluid-magmatic evolution of the massif. The data on C, N and Ar concentration variations in crushing steps support this assumption: well-defined correlations between concentrations of these elements in fluid inclusions are observed in the early Cal (i.e. all gases in the inclusions have the same elemental composition and concequently the same source). For the late Sid and Dol the situation is different: when N and Ar concentrations decrease with crushing steps, the C concentration is increasing, suggesting different sources for (N+Ar) and for most of CO_2. Moreover, $^{40}Ar/^{36}Ar$ ratios in early and late samples are quite different: 3680 in Cal and 657 and 549 in Sid and Dol, respectively. This suggests the air-like argon component to be dominated in fluids during formation of the late minerals. Thus, relationships between C, N and Ar concentrations as well as differences in C and Ar isotopic compositions in fluid inclusions of the early and late carbonatites suggest that at the late stages of Guli massif carbonatites formation an additional CO_2 source with havier carbon and atmosphere-like Ar have contributed to the system.

The expansion of metal stable isotope biogeochemistry into biomedicine

T.D. BULLEN* AND M-N. CROTEAU

US Geological Survey, Menlo Park, CA 94025, USA (*correspondence: tdbullen@usgs.gov, mcroteau@usgs.gov)

Numerous metals are essential nutrients for human health, while others are toxic even at extremely low concentrations in body fluids and tissues. Moreover, a variety of metals and most recently nanometer-sized metals are increasingly being used as components of diagnostic and therapeutic agents to study or treat diseases and metabolic disorders as well as for drug and gene delivery, tissue engineering and pathogen detection. Several of the metals studied in the field of biomedicine, including Li, Ca, Fe, Cr, Zn, Cu, Mo, Ni, Cd and Hg, have variable stable isotope composition in natural materials which can now be measured accurately. Application of stable isotope tracing techniques normally used to study biogeochemical systems could be invaluable to biomedical research. Metal stable isotopes can be used to understand processes such as metal transfer among body pools, and may uniquely identify the fate of toxic metals delivered to the body in different forms such as nanoparticles or aerosols. Initial work has focused on Ca and Fe stable isotope variations in humans, reflecting the importance of bone mineral balance and blood chemistry to human health as well as the advanced state of analytical techniques for the determination of Ca and Fe stable isotope compositions.

Both natural abundance and enriched stable isotopes can be used to provide increased understanding of metabolic processes and pathways at a mechanistic level. Natural abundance stable isotope variations between ingested and excreted metals may prove useful for determining the onset of and recovery from metabolic disorder or disruption of homeostasis. Enriched stable isotopes may be particularly useful for studying processes involving metals in the body, since only very small quantities of enriched tracer are needed in the exposure media in order to create a signal in body tissues and fluids above background levels. Carefully crafted laboratory experiments with lower trophic level organisms will help guide the application of these tools to biomedicine. Coupled with continual advances in mass spectrometry, expansion of metal stable isotope biogeochemistry into the field of biomedicine will be an exceptional research opportunity for the coming years. Involving experts from the medical and other professions in this work and learning their “language” will be essential for success.

Vertical distribution of Fe and S species in anoxic water column of Pavin Lake (France): Electrochemical evidence for nanoparticulate FeS

E. BURA-NAKIĆ[1]*, I. CIGLENEČKI[1] AND E. VIOLLIER[2]

[1]Ruđer Bošković Institute, Bijenička 54, 10 000 Zagreb, Croatia (*correspondence: ebnakic@irb.hr, irena@irb.hr)
[2]Université Paris Diderot – IPGP-UMR CNRS, Cas Courrier 7052, 75205 Paris Cedex 13, France (viollier@ipgp.jussieu.fr)

Recently it has been shown that anodic oxidation of Hg by FeS at around -0.45 V can be used as an analytical protocol for electrochemical determination of FeS nanoparticules in natural waters [1]. The proposed protocol was tested on anoxic samples of Pavin Lake (France) where anodic waves were observed at -0.45 V (vs. Ag/AgCl); these correspond to an electrochemical transformation of particulate and/or nanoparticulate FeS to HgS.

A vertical profile of S(-II) obtained by voltammetric measurements showed that through the whole Pavin Lake monimolimnion layer a majority (~70 %) of S(-II) is in the form of FeS nanoparticulates. Concentrations of dissolved Fe(II) in the Pavin Lake monimolimnion layer are extremly high (up to the 1 mM) supporting our previous conclusion that Fe(II) is controling the speciation and distribution of S(-II) between dissolved and particulate phases [2,3]. At the oxia-anoxia boundary (from 61 to the 64 m), electrochemical measurements indicate presence of colloidal Fe(III) and /or Fe(III) organic species [2].

Thermodynamic calculations predict precipitation of FeS with log Ks value between -3.6 and -3.8 in the Pavin Lake monimolimnion layer. In the upper part of monimolimnion layer most probably precipitation of greigite is proceeding.
It was shown that modification of an Hg electrode with surface formed FeS has significant influence on the voltammetric Fe(II) determination, since cathodic reduction of Fe(II) in such conditions is occuring both on bare (-1.4 V) and on FeS modified Hg surfaces (-1.1 V)[1]; Fe(II) may be underdetermined when only the -1.4 V peak is measured.

This research was suported by COGITO and UKF grant 62/10.

Inverse modelling of gas chemistry measurements

ALAIN BURGISSER, MARINA ALLETTI AND CLIVE OPPENHEIMER

ISTO-CNRS, 1A rue de la Férolerie, 45071 Orléans, France (burgisse@cnrs-orleans.fr; marina.alletti@cnrs-orleans.fr, co200@cam.ac.uk)

We illustrate the inverse modelling of gas chemistry measurements by using gas compositional data for both quiescent and explosive emissions from the lava lake at Erebus volcano, Antarctica. The multi-component degassing model used needs calibration with experimental data in order to partition correctly the volatile species between their gaseous and dissolved forms. Solubility experiments were made on phonolite lava from the lake for H_2O, and data from the literature were reformatted to obtain the fugacity-based solubilities of CO_2 and S.

The degassing model is based on the hypothesis that the gas phase is buffering the system and controls the balance of volatile species. Two types of calculations are performed, depending on whether the measured gas was in equilibrium with the surrounding melt at the lake surface (case 1), or was emitted in isolation from the lava contained in the lake (case 2). The inversion procedure starts by calculating the equilibrium composition of all the species assumed to coexist at atmospheric pressure. This is not straightforward, as the species that are best measured at the vent and those best constrained in the model do not always match. At Erebus, such discrepancy occurs for H_2S, which is simulated but not measured, and OCS, which is measured but not simulated. Compression is then performed by assuming mass conservation of the volatile elements, either applied to the mixture of melt and gas (case 1), or only to the gas (case 2).

Model results are projections at higher pressures (up to 3 kbar) of the gas composition measured at the surface. At Erebus, we find that the difference between the gas emitted explosively and that emitted passively can be explained by a common source situated at depths corresponding to as little as 300 bars pressure. While quiescent, the lake is either degassing in fully open system, or by the means of a convective system restricted between the surface and depths equivalent to 60 to 300 bars. Additional constraints on the magmatic system are obtained by comparing the simulated melt volatile contents with those measured in melt inclusions. We will discuss the limitations of the main model assumptions (chemical equilibrium, gas buffering of the redox state, and temperature effects).

Electrical resistivity imaging of a deep coal mine discharge

W. BURGOS[1]*, M. FITZGERALD[2], L. LARSON[1], L. HERWEHE[2], K. SINGHA[2], AND M. GOOSEFF[1]

[1]Dept. Civil Environ. Eng., Pennsylvania State University, University Park, PA 16802, USA (*correspondence: wdb3@psu.edu, lnl5053@psu.edu, mng2@psu.edu)

[2]Dept. of Geosciences, Pennsylvania State University, University Park, PA 16802, USA (mxf218@psu.edu, lmh5193@psu.edu, ksingha@psu.edu)

The biogeochemistry of iron cycling in acidic environments is quite complex where aerobic surface sediments and anaerobic subsurface sediments are often separated by only a steep redox gradient. The hydrodynamic conditions in these systems affect geochemical conditions that in turn affect microbial community structure. Hydrodynamic conditions can be observed directly at the surface, however, identification of e.g. areas of "fast" vs. "slow" flow are more difficult in the subsurface. To characterize flow paths and hyporheic exchange in the surface and shallow groundwater at an acid mine drainage (AMD) site, we used electrical resistivity imaging (ERI) at a stream emanating from a large abandoned deep coal mine in Cambria County, Pennsylvania. Because of the high conductivity (2,000 μS/cm) of the emergent AMD, we added clean fresh water (30 μS/cm) as a tracer to visualize the spatial and temporal distribution of the hyporheic exchange. Two-dimensional imaging of stream-groundwater exchange was collected from three locations in the study reach using three electrode transects across the stream. We were able to identify the location and spatial extent of a large artesian spring of AMD that contributed significant flow to the stream. Concurrent measurements of in-stream and in-well water chemistry were in good agreement with the inverted models of electrical resistivity. We believe this is the first report of a dilution tracer coupled with ERI for 2-D imaging of hyporheic extent in an acidic stream environment.

Uranium valence cycling with iron-rich phyllosilicates

W. BURGOS[1]*, F. LUAN[1], M. BOYANOV[2], K. KEMNER[2] AND H. DONG[3]

[1]Dept. Civil Environ. Eng., Pennsylvania State University, University Park, PA 16802, USA (*correspondence: wdb3@psu.edu, ful6@psu.edu)

[2]Biosciences Division, Argonne National Laboratory, Argonne, IL 60439, USA (mboyanov@anl.gov, kemner@anl.gov)

[3]Dept. Geology, Miami University, Miami, OH 45056, USA (dongh@muohio.edu)

Iron-bearing phyllosilicate minerals are widely distributed in soils and sediments and often account for about half of the iron in soil. These minerals help establish the physical/hydrogeological conditions of subsurface redox transition zones because of their small size and limited hydraulic conductivity, and disproportionately buffer the redox conditions through the transition zone because they provide a large solid-phase reservoir of Fe(III)/Fe(II) (e.g., they are less susceptible to reductive dissolution as compared to oxides). We previously demonstrated that metal-reducing bacteria preferentially reduce soluble U(VI) over structural-Fe(III) in phyllosilicates; uraninite ($U^{IV}O_2(s)$) is rapidly reoxidized by phyllosilicate-Fe(III) (allowing U to serve as an electron shuttle); but at some thermodynamic endpoint, corresponding to an elevated concentration of structural Fe(II), phyllosilicate-Fe(III) can no longer oxidize uraninite. To better characterize this thermodynamic endpoint we conducted a series of abiotic experiments with synthetic uraninite and specimen phyllosilicate minerals, and with synthetic uraninite and clay-sized fractions from sediments collected from redox transition zones. We conducted these experiments using the unaltered clays (highest Fe(III) contents) and chemically-reduced clays (incremental increases in Fe(II) contents) to evaluate both kinetic and thermodynamic behaviour of their reactions with uraninite. Identical experiments were conducted where uraninite was replaced with non-sorbing, colorimetric redox indicators to quantify the reduction potential of the clays. Reaction products were characterized by U L_{III}-edge and Fe K-edge EXAFS spectroscopy and by TEM-electron energy loss spectroscopy.

Mixing of radiocarbon from high latitude oceans through the atmosphere and ocean during the last deglaciation: Results from Iceland and the Drake Passage

ANDREA BURKE[1,2]*, LAURA F. ROBINSON[2] AND NICKY J. WHITE[3]

[1]MIT/WHOI Joint Program (*correspondence: aburke@whoi.edu)
[2]Woods Hole Oceanographic Institution, 360 Woods Hole Rd. Woods Hole, MA. 02543 USA.
[3]Bullard Laboratories, Madingley Rise, Madingley Road, Cambridge, CB3 0EZ, UK

Radiocarbon is a sensitive tracer of carbon cycle processes over the last ~40 kyr. We present new radiocarbon reconstructions from U-Th dated deep-sea corals from the Reykjanes Ridge off Iceland. These results are compared to radiocarbon reconstructions from deep-sea corals in the Southern Ocean and published radiocarbon records from benthic foraminifera to further our understanding of the transfer of carbon between different reservoirs during the last glacial period and deglaciation.

Our dataset from Iceland comes from solitary and colonial corals collected by dredge from water depths ranging between 770 to 1680 m. U-Th ages of these corals range from modern to 40 ka. During the last glacial period at ~35 ka, radiocarbon reconstructed at 1680 m water depth was ~100‰ more depleted from the contemporaneous atmosphere than it is today. However at the Bolling-Allerod and throughout the Holocene these sites were better ventilated, with radiocarbon offsets from the contemporaneous atmosphere similar to those observed in this region today (~70‰).

Radiocarbon reconstructions from Iceland and the Southern Ocean do not show extreme radiocarbon depletions of the magnitude oberved in some intermediate-depth deglacial records (e.g. [1]). A comparison of $\Delta^{14}C$ records to other proxy data suggests that these large depletions cannot be explained by a common water mass (e.g. Antarctic Intermediate Water), since mixing of this water mass would dissipate any extremely depleted radiocarbon signature. However, the radiocarbon depletions that we do observe throughout the glacial ocean are large enough to explain the atmospheric drop in $\Delta^{14}C$ over the 'Mystery Interval' if we allow some direct transfer of carbon from the deep ocean to the atmosphere, such as through the Southern Ocean.

Speciation of contaminant metals in red mud from Ajka, Hungary

I.T. BURKE[1]*, W.M. MAYES[2], C.L. PEACOCK[1], A.P BROWN[4], A.P. JARVIS[3] AND K. GRUIZ[5]

[1]Sch. Earth & Environ. and [4]Sch. Process, Environ. & Materials Eng., University of Leeds, UK (*correspondence: I.T.Burke@leeds.ac.uk)
[2]Centre for Environ. & Mar. Sci., University of Hull, UK.
[3]Sch. Civil Eng. & Geosci., Newcastle University, UK.
[5]Dept Appl. Biotechnol. & Food Sci., University of Technology and Economics, Budapest, Hungary.

The catastrophic failure of the sludge dam at the Ajkai Timfoldgyar Zrt alumina plant in Hungary on the 4th October 2010 resulted in the release of 700000 m^3 of caustic metalliferous red mud. Red mud leachate is hyperalkaline (pH 13) and has elevated concentrations of metals and metalloids such as Al (1000 ppm) As, V, and Mo (4 - 6 ppm). The red mud itself has elevated concentrations of As, V, Cr, Co, Ni and U (100-1000 ppm). These contaminants persist in water and sediment samples for up to 100 km downstream of the source. The long term effects of the red mud spill on the environment remain largely unknown, especially with respect to the behaviour of the toxic elements present. Here we describe the results of experiments using sequential extraction, electron microscopy and X-ray absorption spectroscopy techniques to characterise the occurrence of metal(loids) within the red mud.

SEM and TEM analysis of red mud material sampled from the dyke breach at Ajka was composed primarily of 10-100 nm haematite particles occurring as 100-700 nm aggregates and 1-4 μm sodium aluminosilicate particles. Transported samples also contain 10-40 μm silt particles, presumably entrained from local soils and sediments. In EDS analysis Cr, Ti, Al, Si, and Mn were associated with aggregates of nano-crystalline (~ 5 nm) haematite. Discrete 2-10 nm Ce-rich particles were also present. At Ajka, acid dosing and gypsum addition were extensively used to lower pH and precipitate soluble Al, As, V and Mo. Sequential extractions performed on transported red mud deposits determined that 70-90 % As and V are present in residual hard-to-leach phases. The remaining 10-30 %, however, occurred in weak acid / hydroxylamine HCl leached phases, which may represent the presence of freshly precipitated metal(loid) containing phases. XAS analysis of red mud samples and leachate precipitates focused on determining As and V speciation in both the labile and refractory phases present. This baseline information will help in predicting the likely environmental mobility, fate and the long term hazards from metal(loid) contamination associated with the spill.

Nucleosynthetic Mo and W isotope anomalies in Murchison leachates

C. BURKHARDT[1]*, T. KLEINE[2], N. DAUPHAS[3], F. OBERLI[1] AND R. WIELER[1]

[1]Institute of Geochemistry and Petrology, ETH Zurich, CH-8092 Zurich (*correspondence: burkhardt@erdw.ethz.ch)
[2]Institute for Planetology, University of Muenster, D-48149 Muenster
[3]Origins Laboratory, The University of Chicago, IL 60637, USA

Nucleosynthetic isotope anomalies at the bulk meteorite scale exist for several elements (e.g., Ti, Mo, Ru) and most likely reflect incomplete mixing of diverse presolar components in the solar nebula [e.g. 1]. These isotope heterogeneities contrast with uniform and terrestrial isotope composition for other elements (e.g., Hf, W, Os [2]). Constraining why planetary-scale nucleo-synthetic isotope anomalies exist for some elements but not for others can provide clues to understanding the early evolution of the solar nebula. To address this important issue we obtained Mo and W isotope data for acid leachates of the Murchison chondrite. About 16 g of Murchison was sequentially digested using acids of increasing strengths. Aliquots of these leachates were previously analysed for Os isotopes [3]. Here, in addition, the acid-resistant residue was completely digested after fusion with a laser.

The Mo and W isotope data, obtained by MC-ICP-MS at ETH Zurich, reveal large anomalies that correlate with each other as expected from nucleosynthetic theory [4] and can be accounted for by variable amounts of s-process Mo and W. A regression of ^{182}Hf-decay corrected W data in ε^{182}W-ε^{186}W space yields an initial ε^{182}W consistent with the solar system initial value [5]. The Mo and W anomalies do not correlate with Os isotope anomalies reported for the same samples [3], indicating that Mo and W are hosted in different carriers than Os. This can explain why planetary-scale isotope anomalies exist for Mo but not for Os. Furthermore, the well-correlated Mo and W isotope anomalies in the Murchison leachates combined with the observation that planetary-scale isotope anomalies exist for Mo but not for W suggests that Mo and W are hosted in distinct but chemically similar carriers. The different patterns of planetary-scale nucleo-synthetic anomalies thus seem to reflect the presence of distinct generations of presolar dust that have been homogenized to different degrees.

Oxygen fugacity-dependence of zircon-melt trace element partitioning

A.D. BURNHAM[1,2]* AND A.J. BERRY[1,2]

[1]Department of Earth Science and Engineering, Imperial College London, SW7 2AZ, UK (correspondence: a.burnham08@imperial.ac.uk)
[2]Department of Mineralogy, Natural History Museum, London, SW7 5BD, UK.

A common feature of terrestrial igneous zircons is a marked excess of Ce over La and Pr, and a deficit of Eu relative to Sm and Gd. This Ce anomaly is attributed to the presence of Ce^{4+}, and this Eu anomaly attributed to the presence of Eu^{2+}; all other REE occur exclusively as M^{3+}. Therefore, the magnitude of these anomalies may record the oxygen fugacity (fO_2) at which the magma crystallised. It is often unclear, however, whether the Eu anomaly reflects directly the Eu oxidation state ratio of the melt from which the zircon crystallised, or whether the Eu content of the melt was depleted by fractional crystallisation of plagioclase (or other Eu^{2+}-bearing minerals) prior to zircon growth. The present study presents the first systematic data on the dependence of zircon-melt REE partitioning on fO_2.

Synthetic zircons were grown at 1 atmosphere from a flux-free melt of 'natural' composition, over a range of 14 log units in fO_2 (IW-4 to QFM+6). The resulting crystals were characterised by cathodoluminescence and analysed by secondary ion mass spectrometry (SIMS) and laser ablation ICP-MS for P, Sc, Ti, Y, REE, Hf, Th and U.

Increasing fO_2 results in the Ce and Eu anomalies becoming more and less pronounced, respectively. There is a narrow fO_2 range over which both anomalies were observed; however the two anomalies do not covary in the same manner as natural samples. Therefore, either partitioning depends strongly on temperature and/or melt composition, or most natural samples suffer removal of Eu from the system before zircon saturation. The Ce and Eu data will be combined with direct determinations by XANES (X-ray absorption near edge structure) spectroscopy of the effects of fO_2, temperature and melt composition on the redox state ratios of Ce and Eu.

The partitioning of Sc, Y, other REE and Hf is fO_2-independent, as expected. The presence of P in the melt does not affect partitioning. Ti partitioning remains constant, indicating that Ti^{3+} (likely to represent 10-20% of Ti at the most reduced conditions studied) shows similar partitioning behaviour to Ti^{4+}. The U/Th ratio of zircon varies systematically over more than one order of magnitude with fO_2.

Mantle controls on the geochemistry of Kīlauea lavas erupted over the last millennium

D.H. BURNS[1], A.J PIETRUSZKA[1], M.D. NORMAN[2], J.P. MARSKE[3], M.O. GARCIA[3] AND J.M. RHODES[4]

[11]Department of Geological Sciences, San Diego State University, San Diego, CA 92182-1020, USA
[2]Research School of Earth Sciences, Australian National University, Canberra ACT 0200, Australia
[3]Department of Geology and Geophysics, University of Hawaii, Honolulu, HI 96822, USA
[4]Department of Geology and Geography, University of Massachusetts, Amherst, MA 01003, USA

Lavas from Kīlauea Volcano display rapid geochemical variations on a time scale of decades to centuries. The wall of Kīlauea Caldera at Uwekahuna Bluff exposes a 135-m thick sequence of recent prehistoric lavas (erupted mostly between AD 900-1400) and tephra from an explosive eruptive sequence at the volcano's summit (the Uwekahuna Ash). This stratigraphic section allows us to re-create a detailed temporal record of the mantle controls on the geochemical evolution of Kilauea lavas erupted over the last millennium. Previously [1], we analyzed the Pb, Sr, and Nd isotope ratios and major-element abundances of a series of 24 successive lava flows from the upper portion of Uwekahuna Bluff. The $^{206}Pb/^{204}Pb$ and $^{87}Sr/^{86}Sr$ ratios of these lavas were found to converge with prehistroic Mauna Loa lavas of the same age. This observation was attributed to the rapid passage of a small-scale compositional heterogeneity through the melting regions of both volcanoes. Here we present a detailed geochemical study (major- and trace-element abundances, and Pb, Sr, and Nd isotope ratios) of four glass separates from the Uwekahuna Ash and the remaining 38 lavas exposed lower in the Uwekahuna Bluff, along with trace-element abundances for the upper 24 lava flows from Uwekahuna Bluff. These prehistoric lavas and glasses display a small, but systematic, temporal variation in ratios of highly over moderately incompatible trace elements (e.g. La/Yb) that correlates with fluctuations in the Pb and Sr isotope ratios. These correlations suggests that the lithology of the mantle source controls the degree of partial melting at Kīlauea. The origin of these differences in source lithology will be explored using the major- and trace-element abundances of the lavas.

Mechanisms of deep crustal subduction and exhumation: Insights from numerical modelling

EVGUENI BUROV

ISTEP, UMR 7193 UPMC-CNRS, Case 129, T46-00 e2, University of Pierre et Marie Curie, 4 Place Jussieu, 75252 Paris (evgenii.burov@upmc.fr)

The dynamic processes leading to syn-convergent crustal subduction and consequent exhumation of high pressure low and high temperature rocks in continental collision zones remain poorly understood. Using results of thermo-mechanical thermodynamically coupled numerical models, we here discuss different possible mechanisms of crustal subduction and exhumation. To reach that goal, oceanic subduction-continental subduction and collision is modelled using a forward viscous-elastic-plastic thermo-mechanical models and synthetic petrology models allowing to trace P-T-t paths, generated out of numerical simulations, and compare them with natural P-T-t paths. Different collision scenarios, as function of the convergence rate and thermo-rheological profile are also discussed. It is shown that crustal subduction may occur only at very specific conditions in terms of crustal rheology, structure, subduction rate and thermal regime. It is also noteworthy that the models predict strong variations in the exhumation rates during the subduction-collision stage, and indicate that UHP rocks are likely to be exhumed at the earlier stages of continental subduction. Several additional mechanisms related to strain localization due to strain softening, metamorphic reactions, heat dissipation and fluids are also discussed. A particular attention is paid to the role of surface processes, sedimentary content and inherited structures. The experiments also show that the dynamic pressure in the subduction channel is unlikely to deviate by more than ± 10% from the lithostatic approximation. The models are applied to a number of regions such as the Alpes, Zagros and Hymalaya showing each time a significant difference in the mechanisms of subduction and exhumation.

GEO-CARS: 3-D, chemically selective imaging of fluid inclusions with multimodal nonlinear optical microscopy

R.C. BURRUSS[1]*, A.D. SLEPKOV[2], A.F. PEGORARO[2] AND A. STOLOW[2]

[1]USGS, Reston, VA 20191 USA, (*correspondence: burruss@usgs.gov)
[2]National Research Council of Canada, Ottawa, Ontario, Canada (Aaron.Slepkov@nrc-cnrc.gc.ca; Adrian.Pegoraro@nrc-cnrc.gc.ca; Albert.Stolow@nrc-cnrc.gc.ca)

3-D images and spectra of methane-rich fluid inclusions have been recorded for the first time with coherent anti-Stokes Raman scattering (CARS) and associated nonlinear optical methods (second harmonic generation, SHG, and two-photon excitation fluorescence, TPEF). Laser scanning confocal microscopy (LSCM) with CARS was developed for biomedical imaging of lipids [1] (based on C-H stretching vibration) suggesting that we could image CH_4 in fluid inclusions. The CARS microscope uses a single ultrafast laser source that simultaneously generates additional nonlinear imaging modes (SHG and TPEF) [1]. All three signals are generated in the same focal volume and collected on separate detectors, creating high-resolution 3-D images with complimentary information such as evidence of aromatic hydrocarbons (TPEF) and sub-micrometer crystallographic disorder and internal surfaces in host minerals (SHG), in addition to the chemically-specific Raman spectral information from CARS at 2100 to 4500 cm^{-1}.

CARS images and spectra of CH_4-rich inclusions in sedimentary, igneous, and metamorphic rocks provide new information on methane in the crust. 3-D images of CH_4 and water clearly identify aqueous inclusions with CH_4-rich vapour bubbles that coexist with one-phase CH_4-rich inclusions. In crude oil inclusions, CARS spectra of CH_4 are clearly separated from fluorescence emission of the oil, allowing us to record, for the first time, the pressure sensitive peak position of CH_4 [2] in oil inclusions for input to PVT models of oil migration. Healed microfractures are visible in SHG allowing identification of distinct generations of CH_4-rich inclusions associated with specific fracture orientations. Some CH_4-rich inclusions in metamorphic and igneous rocks show TPEF signals that indicate the presence of aromatic hydrocarbons associated with CH_4. We believe this work demonstrates the broad potential of multimodal nonlinear optical microscopy and spectroscopy to provide new insight to the geochemistry of carbon in the crust and upper mantle.

The role of microbial sulfidogenesis in shaping iron-sulfur-arsenic interactions within floodplain soils

EDWARD D. BURTON*, SCOTT G. JOHNSTON AND RICHARD T. BUSH

Southern Cross GeoScience, Southern Cross University, Australia; (*correspondence: ed.burton@scu.edu.au)

Introduction and objectives

Dissimilatory SO_4^{2-}-reducing bacteria play a key role in shaping the biogeochemical behaviour of Fe and As in floodplain wetland soils. These bacteria gain metabolic energy by coupling the anaerobic oxidation of organic C or H_2 with the reduction of SO_4^{2-}. This results in the generation of sulfide, which can interact via a series of often competing and complex reactions with both Fe and As. Here we discuss our recent research aimed at unraveling the role of microbial sulfidogenesis in shaping Fe-S-As interactions within flooded soils. More specifically, we examine how the onset of sulfate-reduction in floodplain soils can drive transformations in Fe mineralogy and cause associated changes in As mobility.

Methodological approach

To address this issue, we have employed a multi-scale approach spanning (1) field-scale investigations that include an essential integration of hydrological, geomorphological and geochemical observations, (2) a series of controlled advective-flow experiments with a pure culture of a sulfate-reducing bacteria (*Desulfovibrio vulgaris*) and (3) relatively simple batch-type incubations with a natural assemblage of anaerobic microorganisms.

Results and discussion

Aqueous sulfide is a powerful and facile reductant of Fe(III) that can drive the rapid reductive dissolution of poorly ordered ferric (hydr)oxides, such as ferrihydrite and schwertmannite. In the case of these poorly-ordered phases, the resulting production of Fe(II) can drive rapid formation of goethite – an Fe mineralogical transformation that appears to significantly retard As mobility. Under strongly sulfidogenic conditions, magnetite formation occurs preferentially along with the accumulation of Fe sulfide minerals.

Whilst sulfidogenesis initially causes pH-dependent release of Fe(II), sulfidogenesis can eventually sequester Fe via the the precipitation of Fe sulfide minerals. These minerals include mackinawite, greigite and pyrite – which appear to exhibit vastly contrasting affinities for As. Hence, the effect that Fe sulfide accumulation has on As mobility within floodplain soils is heavily dependent on Fe sulfide mineralisation rates.

Ancient lead trapped in the Earth's upper mantle

The isotope compostion of lead (Pb) the Earth's upper mantle (sampled by oceanic basalts) is far too radiogenic for evolution from chondritic (primitive solar system) material over 4.57 billion years, the so called 'Pb paradox' [1]. Loss of Pb to the core [2] or arrival in a late veneer [3], have both been proposed as mechanisms to account for this imbalance. Alternatively, recent Pb isotope data for orogenic peridotites suggests that such rocks could serve as a complentary reservoir of unradiogenic Pb [4]. However, orogenic peridotites may not be representative of the asthenopshere underlying present-day mid-ocean ridges, furthermore, it is unclear why such material is not sampled by oceanic basalts.

Here we show that sulphides trapped as inclusions in silicate minerals in abyssal peridotites from the North Atlantic ocean (ODP Leg 209; Site 1274A) preserve extremely unradiogenic Pb isotope compositions, some corresponding to an age of ca 1.8 billion years. These ages are indistinguishable from those preserved by Os isotopes in sulphides from the same abyssal peridotites [5], and demonstrate that both Pb and Os isotopes preserve an unequivocal record of ancient melt depletion in the sub-oceanic mantle. Therefore, at least, some of the Pb in the Earth's mantle is unradiogenic and complements the composition of oceanic basalts. That these sulphides contribute little of their Pb to the isotope composition of oceanic basalts may be due either to their entrapment in host silicate phases or else that they are generally present in refractory domains in the mantle that are little sampled by later melting events.

Fe isotope cycling in ferruginous and anoxic Lake Pavin (France) from water column to sediment

V. BUSIGNY[1], N. PLANAVSKY[2], D. JÉZÉQUEL[1], P. LOUVAT[1], G. MICHARD[1], E. VIOLLIER[1] AND T. LYONS[2]

[1]IPGP, 1 rue jussieu, 75005 Paris, France; (busigny@ipgp.fr)
[2]Earth Sciences, Univ. of California Riverside, USA

Fe isotopes are an emerging biogeochemical paleoproxy that can improve our understanding of the Fe cycle in early Earth's ocean and early microbial evolution. Sediments deposited during the Precambrian record a large range of δ^{56}Fe values, with an exceptional negative excursion (down to -3.5‰) between 2.9 and 2.3 Ga, a transition period believed to be marked by stratified redox ocean basins. The origin of this negative excursion is still debated but may be linked to a unique period of water column Fe cycling or a time of enhanced microbial Fe reduction in Fe-rich sediments.

Lake Pavin is a unique stratified aquatic system characterized by permanent anoxic and ferruginous deep water (from 60 to 92 m depth) topped by oxic shallow water (from 0 to 60 m), and can thus be regarded as a modern analog for Archean ocean. In the present work, we have studied Lake Pavin Fe isotope cycling along a profile in the water column down to the sediment in order to bring new insights into the record of ancient rocks. Four sediment cores were drilled and analyzed: (1) in the oxic zone, (2) at the oxic-anoxic boundary, (3) under the peak of H_2S production from SO_4^{2-} reduction and (4) at the bottom of the lake. In the water column, dissolved Fe concentration increases with depth from 2 μM at the oxic-anoxic boundary to 1200 μM at the lake bottom, with δ^{56}Fe increase from -1.67 to +0.31‰. The very negative δ^{56}Fe of the oxic-anoxic boundary reflects the residue of Fe oxidation and precipitation. The δ^{56}Fe increase with depth is interpreted as a coupling between (1) diffusion of Fe enriched in heavy isotopes from the bottom of the lake towards the oxic-anoxic boundary and (2) a combination of Fe reduction of downgoing Fe(III) particles and ferrous-ferric Fe interations. Analyses of bulk sediment show δ^{56}Fe values close to the purported detrital source (i.e. basalts with δ^{56}Fe ~ 0.20‰). In contrast, Fe sequential extraction in sediments shows a significant variation in δ^{56}Fe. Iron isotope mass balance calculation in both water column and pore waters of the sediment cores indicate that Fe isotope variability in iron sulfides reflects mostly Fe chemistry in the water column rather than isotopic fractionation during diagenetic processes or sulfide precipitation in the sediment.

Long-term versus short-term weathering fluxes in contrasting lithologies at the Luquillo Critical Zone Observatory, Puerto Rico

H.L. BUSS[1,2]*, A.F. WHITE[1], A.E. BLUM[3], M.S. SCHULZ[1] AND D. VIVIT[1]

[1]U.S. Geological Survey, Menlo Park, CA 94025, USA

(Bio)geochemical and physical weathering processes in tropical watersheds produce most of the solutes and sediments discharged to the oceans. Thus, relative to their area, tropical systems are disproportionately important in terms of weathering, erosion, and global CO_2 cycles. In addition to influencing stream and ocean chemistry and sediment loads, weathering processes exert control over chemical transport in soils and regolith (e.g., saprolite), soil and saprolite formation rates, mineral nutrient availability, and microbial growth rates. Currently, the volcaniclastic Río Mameyes watershed is being investigated as a comparison to the nearby, well-studied, granitic Río Icacos watershed in order to better understand the influence of lithology on weathering processes, weathering fluxes, and mineral nutrient availability.

Both watersheds are located in the Luquillo Critical Zone Observatory in Northeastern Puerto Rico and are characterized by similar humid, tropical climate; high annual rainfall, high year-round temperatures, tropical montane vegetation, and high relief. In both watersheds, thick (37+ m in places) saprolites blanket the ridges, but the majority of the chemical weathering occurs at the bedrock-saprolite interface. Long-term weathering fluxes are calculated from mass losses in the weathering profiles between the bedrock and the saprolite and from the age of the regolith surface (determined by cosmogenic nuclides or U-Th disequilibria). Short-term weathering fluxes are calculated from solute chemistries and infiltration rates and can be compared to watershed flux rates. Comparison of these three calculations for each watershed can be used to identify the changes in weathering regime and environment over time. Comparison of the two different watersheds demonstrates the influence of lithology on weathering fluxes on different timescales.

Defining a landscape for microbial electron transfer to extracellular minerals

JULEA N. BUTT[1]*, ANDREW J. GATES[1], SOPHIE J. MARRITT[1], MARCUS EDWARDS[1], THOMAS A. CLARKE[1], LIANG SHI[2], JAMES K. FREDRICKSON[2], JOHN M. ZACHARA[2] AND DAVID J. RICHARDSON[2]

[1]School of Chemistry and School of Biological Sciences, University of East Anglia, Norwich NR4 7TJ, United Kingdom (*correspondence: j.butt@uea.ac.uk)
[2]Biological Sciences Division, Pacific Northwest National Laboratory, Richland, WA, USA

The respiratory reduction of extracellular minerals poses a considerable challenge to microbes. Redox events associated with generating proton motive force across the inner membrane to drive ATP synthesis must be coupled to transfer of electrons to the extracellular matrix. In *Shewanella* multi-heme cytochromes support this translocation of electrons. The tetraheme containing protein CymA moves electrons from inner membrane quinols to the periplasm. Porin wrapped decaheme cytochromes provide a conduit for electron transfer across the outer membrane while additional cytochromes interface with the extracellular matrix. The redox activity of each of these cytochromes spans a distinct window of potential. Consequently when present together these cytochromes can provide both a reservoir to accommodate electrons arriving from quinol oxidation at the inner membrane and a variable driving force for delivering electrons to extracellular minerals.

Coevolution of early animals and environment

N. J. BUTTERFIELD

Department of Earth Sciences, University of Cambridge, Cambridge, UK CB2 3EQ (njb1005@cam.ac.uk)

Large scale coevolution of organisms and environment is conventionally viewed from the bottom up – with microbially driven biogeochemical cycles providing the ecological oportunity, and larger, more physiologically constrained organisms rapidly evolving in response. Nowhere has this approach been more popularly applied than in oxygen-limitation hypotheses aimed at the seemingly delayed appearance of large and/or predatory animals. In this presentation I consider the nature of biological/environmental coevolution through the Proterozoic-Phanerozoic transition.

There is no question that planetary environments and biogeochemical cycling changed dramatically through the the Ediacaran and early Cambrian, an interval also marked by the first significant appearance of macroscopic organisms in the fossil record. More significantly, fundamental shifts in the the composition and evolutionary dynamics of contemporaneous microfossils attests to the genuine absence of eumetazoans prior to the Ediacaran. If oxygen availability was a first-order constraint on animal evolution, then the critical threshold was crossed in the early Ediacaran. Evidence for earlier oxygen limitation comes from geochemical proxies for deep-water anoxia, though it is notable that these same signatures extend into early Palaeozoic strata – while evidence of significant surface water oxygenation extends well back into the Neoproterozoic.

Such geochemical expression is difficult to reconcile with oxygen limitation hypotheses – particularly in light of the modest oxygen demand of most animals, and the conspicuous monophyly of the Metazoa. As such, the delayed appearance of eumetazoans is more convincingly ascribed to the extraordinary complexity of gene regulatory networks underlying organ-grade multicellularity; i.e., internal rather than external constraints. Once these developmental schemes were established, however, they opened up a new universe of ecological, evolutionary and biogeochemical phenomena, ranging from bioturbation and faecal pellets to the coevolutionary forcing of biomineralization, large body size, eukaryotic dominated phytoplankton and fundamental shifts in oceanic structure. Unlike the exclusively bottom-up microbial world of the pre-Ediacaran, the Phanerozoic biosphere must also be viewed from the top down – with animals playing a key role in the construction and definition of environments.

Influence of secondary organic aerosols (SOA) on "Bromine Explosion" in smog-chamber experiments

J. BUXMANN[2]*, N. BALZER[1], J. OFNER[1], U. PLATT[2] AND C. ZETZSCH[1]

[1]Atmospheric Chemistry Research Laboratory, BayCEER, University of Bayreuth, Germany

[2]Institute of Environmental Physics, University of Heidelberg, Germany

(*correspondence: joelle.buxmann@iup.uni-heidelberg.de)

It is assumed that SOA slow down the catalytic bromine release via "Bromine Explosion" (auto catalytic release of reactive bromine from salt surfaces). Based on this theory a new experimental setup was developed, in which a substrate NaCl/NaBr=300:1 mixture was placed on a teflon pan located in an aerosol smog-chamber [1]. Direct observation of BrO is possible using an active Differential Optical Absorption Spectroscopy (DOAS) instrument [2] in combination with a multi-reflection cell. SOA was formed during the ozone-initiated oxidation of α-pinene, catechol and guaiacol, respectively [3].

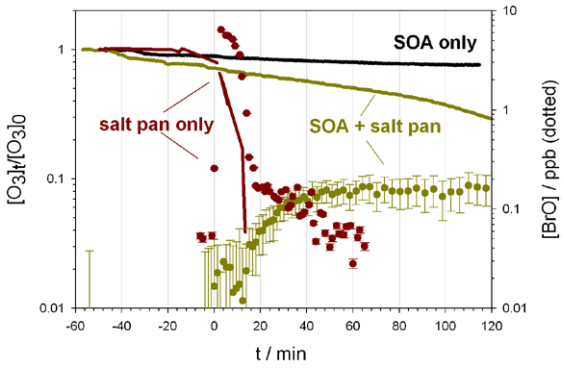

Figure 1: Time profile of O_3(lines) and BrO(dotted) during experiments with different initial composition: with salt pan as halogen source (red), with SOA only (black) and with both (green). At t=0 the solar simulator was switched on.

The experiments showed that the presence of SOA modifies the kinetics of halogen cycles in the gas phase: With salt pan only a complete ozone depletion was observed within first 10 minutes due to "Bromine Explosion" with up to 6ppb BrO. With salt pan and SOA the BrO formation showed a delay and its maximum mixing ratio of 150 ppt was one order of magnitude lower than without SOA.

Dissolved organic carbon and soil respiration release in undisturbed columns from SE Spain

A. BÜYÜKKILIÇ YANARDAĞ*, M. GÓMEZ-GARRIDO, M. D. ESTÉVEZ RODRÍGUEZ, I. H. YANARDAĞ AND A. FAZ CANO

Universidad Politécnica de Cartagena, Agrarian Science and Technology Department Research Group: Sustainable Use, Management and Reclamation of Soil and Water, Murcia/España (*correspondence: ab16@alu.upct.es)

When pig slurries (PS) are applied to agricultural fields at different rate, large amounts of carbon can be introduced into soils. Better knowledge land application of pig slurry is important to know influence on carbon in leaching experiment. This study assessed the leaching potential of carbon cycle after an intensive farm pig manure at rates of control, single, triple doses are applied and investigated 'how is the relation between leaching of dissolved organic carbon (DOC) and soil respiration in the laboratory leaching experiment in silty loam soil?'.

Leaching was carried out weekly using distilled water to simulate the monthly rainfall events in the study area. Experiment was carried out for 12 weeks rainfall. Soil solutions and CO_2 were analyzed in each week. The results showed that; DOC are changed between 1.1 and 24.3 ppm, DIC are changed 20.5 and 47.8 ppm, NT are changed 2.3 and 55.9 ppm. during leaching experiment. Soil respiration varied between 10 and 150 mg C-CO_2 kg^{-1} soil h^{-1} in the control, between 10 and 250 mg C-CO_2 kg^{-1} soil h^{-1} in single plots, between 10 and 450 mg C-CO_2 kg^{-1} soil h^{-1} in triple plots.

Dissolved Organic and Inorganic Carbon, Dissolved Nitrogen, are effected temperature, and pH in the leaching system. pH is a more important factor for DOC leaching than temperature. Soil respiration is not significantly affected by pig manure application even during the four weeks, which is found balance and hold C in the soil with application. In single doses plots, respiration values are strongly correlated with time and also this dose is the agronomic rate of N-requirement (170 kg N/ha/yr) [1]. Finally, single application doses to silty loam soils have positive effect on carbon to the atmosphere and ground water.

Inorganic and organic occurences from diagenesis of the Güvenç formation shales in the Adana basin, Turkey

A. BUYUKUTKU[1]* AND M. ALBAYRAK[2]

[1]Ankara University Engineering Faculty, Department of Geological Engineering, 06100 Besevler, Ankara, Turkey (*correspondence: butku@eng.ankara.edu.tr)

[2]General Directorate of Mineral Research and Exploration, Sogutozu, Ankara, Turkey (mustafa_albayrak@hotmail.com)

In the study, shale diagenesis of Güvenç Formation in Adana Basin was determined on the surface samples. Güvenç shales consist of organic matter (% 0.3-0.4) for hydrocarbon formation. X-Ray Diffractometer, Scanning Electron microscope equipped with an energy dispersive analyzer were used for detailed mineralogical, microstructural and elemental analysis for shale diagenesis. Fourier transform infra red spectroscopy (FTIR) was used for organic sample origin in the Güvenç Shales.

Diagenesis in the shales principally involves the progressive development of various types of cements in the following order: Calcite and feldspar formation, mixed layer smectite-illite and smectite-chlorite authigenesis, illite, chlorite authigenesis, quartz.

The C-H peak at 860 cm^{-1} shows the occurrence of aromatic groups (Fig. 1).

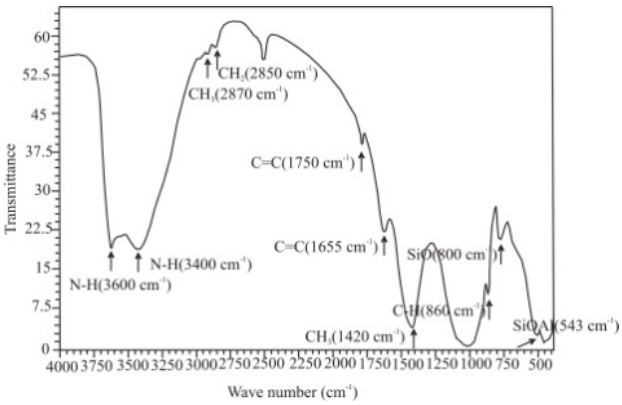

Figure 1: FTIR spectrum of the sample

Gallium oxide solubility in vapor and indicators of heterogeneous fluid filtration

A.YU. BYCHKOV, S.YU. NEKRASOV, I.YU. NIKOLAEVA AND S.S. MATVEEVA

Moscow State Universiy, Moscow,Russia (bychkov@geol.msu.ru)

The solubility of gallium and aluminum oxides in gas phase in the system Ga_2O_3 (Al_2O_3)-HCl-H2O was studied at 200-350ºC and pressure up to saturated vapor. The concentration of gallium increases with the increasing of HCl pressure. The formulae of gallium gaseous specie was determined as $GaOHCl_2$. The constant of gallium oxide solubility reaction was calculated at 200, 250, 300 and 350ºC. The concentration of aluminum in gas phase is insignificant in the same conditions. The possibility of gallium transportation in gas phase with small quantity of Al allow to separate this elements in hydrothermal processes with gas phase. The Ga/Al ratio can be used as the indicator of gas phase separation and condensation. The separation of gas and liquid phases was determined on greisen deposits by carbon isotope fractionation of carbon dioxide in fluid inclusion. The important feature of both ore mains is heterogenization and boiling of ore-forming fluids. Greisen ore bodies are formed as a result of strongly focused fluid flow in the T-P gradient fields. Gas and liquid phase separation specifies the vertical zonality of quartz type veins. The gas phase with the high gallium concentration is separated from a flow of liquid phase. Liquid phase react with the granites forming greisen metasomatites. Condensation of the gas phase in upper parts of massive produces the increasing of Ga/Al ratio in muscovite 3-5 times more, then in granites and bottom part of vein (from $2 \bullet 10^{-4}$ to $8 \bullet 10^{-4}$ mass ratio). The muscovite type veins has no separation between gas and liquid due to there thickness and small pressure gradient. There is no difference in Ga/Al ratio in muscovite from this veins. The Spokoinoe deposit is classified by mineralized dome type. The heterogenization of fluid occurs in H_2O-CO_2 system for water phase and carbon dioxide with temperature decreasing. Two-phase flow is separated in granite, forming greisen metosomatites. The Ga/Al ratio in rock increase up to 3 times to the upper part of metasomatitic zone. The Ga/Al ratio in muscovite can be applied for other hydrothermal systems for geochemical indicator of gas phase separation and condensation zone determination.

Geochemical evidence for lithosphere delamination beneath the central Rio Grande rift

B.L. BYERLY* AND J.C. LASSITER

Geological Sciences Department, University of Texas at Austin, Austin, TX, USA (* correspondence: benbyerly@utexas.edu)

Seismic studies have shown a low-velocity zone in the mantle that extends up to the Moho (~40km) beneath the central Rio Grande rift (RGR). Gao *et al*. [1] interpreted the low velocity zone to be the result of delamination of the original (≥100km thick) Proterozoic lithosphere and replacement with hot asthenosphere. However, hydration or melt infiltration of the lithosphere could also produce the observed low wave speeds. We have examined the geochemical signatures of spinel peridotite xenoliths hosted in alkalic basalts erupted near Elephant Butte, NM, USA in the central RGR in order to determine their chemical affinity (old continental lithosphere or young asthenosphere), and thereby test the delamination hypothesis.

Peridotite xenoliths from Elephant Butte can be divided into two distinct groups. One group is commonly fine grained and displays foliation. These are relatively fertile (3.5-4.5 wt.% Al_2O_3), have depleted Sr- and Nd-isotope signatures (e.g. $^{87}Sr/^{86}Sr \approx 0.7018$-$0.7025$), $^{187}Os/^{188}Os$ ranging from 0.124-0.130, and are LREE depleted with flat M-HREE. These signatures are similar to fertile abyssal peridotites, thought to represent the convecting upper mantle. In contrast, the other group are coarser grained, more refractory (~1.5wt. % Al_2O_3), display LREE enrichment, unradiogenic $^{187}Os/^{188}Os$ (~0.120), radiogenic $^{87}Sr/^{86}Sr$ (0.7041-0.7043) and lower modal abundance of CPX. These signatures are characteristic of Proterozoic SCLM. Two-phase pyroxene geothermometry of xenoliths from Elephant Butte shows no significant difference in temperature (~1000°C) between the two groups. Based on a local heat flow of 90mW/m^2 these temperatures correspond to a depth of ~45km.

The fertile xenoliths most likely represent convecting asthenospheric mantle that has recently replaced the lithosphere. The refractory xenoliths represent Proterozoic lithosphere which has undergone varying degrees of ancient melt depletion and metasomatism. This indicates that lavas from Elephant Butte are sampling the lithosphere asthenosphere boundary which lies at ~45km depth and that significant thinning of the lithosphere has occurred, consistent with the delamination hypothesis of Gao *et al*. [1].

Using bacteria to produce tailored magnetic nanoparticles

J.M. BYRNE[1]*, V.S. COKER[1], N.D. TELLING[2], G. VAN DER LAAN[1,3], D. J. VAUGHAN[1], R.A.D. PATTRICK[1] AND J.R. LLOYD[1]

[1]SEAES, Williamson Research Centre for Molecular Environmental Science, University of Manchester, M13 9PL, UK (*correspondence: James.Byrne@postgrad.manchester.ac.uk)

[2]Institute for Science & Technology in Medicine, Keele University, Stoke-on-Trent ST4 7QB, UK

[3]Diamond Light Source, Didcot, Oxfordshire OX11 0DE, UK

Magnetic iron oxide nanoparticles of the form $M_xFe_{3-x}O_4$ (M = Co, Zn, Cr, Mn etc.) are useful for a wide range of applications including targeted cancer therapies, remediation of contaminated ground waters and data storage devices. Many current production processes use chemical and mechanical methods which often use toxic reagents and are expensive. This work presents an alternative biotechnological approach, harnessing the reductive capabilities of the subsurface Fe(III) reducing bacterium *Geobacter sulfurreducens* which yields relatively large quantities of magnetite nanoparticles at ambient temperatures.

The intrinsic magnetism and small size of the nanoparticles are paramount to their commercial use, and must be optimised during production for specific applications. In this study, the incorporation of dopants including zinc and cobalt into the structure of the biomagnetite nanoparticles was studied, and changes in the magnetic and structural properties of the resulting iron oxide minerals quantified. We demonstrated a significant increase in the magnetic moment of the particles at 5K and room temperature by doping with relatively low quantities of zinc, whilst cobalt induced large increases in coercivity. The inclusion of dopants also significantly affected the size of the nanoparticle crystals, with decreases from ~20nm to 8nm observed as dopant concentration increased.

Analytical methods including x-ray absorption, (XAS and XMCD), SQUID magnetometry and Mössbauer spectroscopy were used to provide important information about the mineral structure and indications of where in the crystal the dopants were incorporated, i.e. tetrahedral or octahedral components of the magnetite. Such techniques are vital to better understand how to improve bioproduction methods in order to maximize the potential of biogenic nanoparticles.

Low-temperature Pt–Pd mineralisation: Examples from Brazil

A.R. CABRAL[1]*, B. LEHMANN[1] AND M. BRAUNS[2]

[1]Mineral Deposits, TU Clausthal, 38678 Clausthal-Zellerfeld, Germany
(*correspondence: alexandre.cabral@tu-clausthal.de)
[2]Curt-Engelhorn-Zentrum Archäometrie, 68159 Mannheim, Germany

Hematite-bearing Au–Pd mineralisation in Brazil commonly has a platiniferous component [1, 2]. Examples are Hg-bearing hongshiite, PtCu, and Pt_2HgSe_3, both from Itabira, Minas Gerais. These minerals occur in specular hematite-rich veins that cross-cut the ~0.6-Ga Brasiliano tectonic foliation of the host rock (itabirite). This vein mineralisation is called 'jacutinga'. The presence of barite in hongshiite and Na/K–Na/Li fluid–mineral geothermometers indicate that oxidising brines of evaporitic origin were instrumental to the Au–Pd–Pt mineralisation at a maximum temperature of about 350°C [3].

Platiniferous alluvia are found in the quartzitic domains of the Palaeo-Mesoproterozoic southern Serra do Espinhaço, Minas Gerais, north of Itabira. Alluvial palladiferous gold and specular hematite point to 'jacutinga'-like veins in the quartzite country rock in the Córrego Bom Sucesso area. We found high Pd/Ag ratios (~4–3700) in the alluvial palladiferous gold. Such ratios are thermodynamically restricted to very oxidising brines [4]. In addition, Córrego Bom Sucesso is famous for its botryoidal Pt–Pd aggregates, reaching several millimetres across, which formed within the alluvium [1, 2, 5].

In northern Brazil, Au–Pd–Pt bonanza mineralisation triggered the gold rush that made Serra Pelada known worldwide. The near-surface mineralisation is hosted by weakly metamorphosed metasedimentary rocks of supposedly Neoarchaean age, but the bonanza ore is coeval with a Mn–Ba oxide, which has a Late Cretaceous $^{40}Ar/^{39}Ar$ age [6]. Fluid-inclusion microthermometric data from quartz and the mineral assemblage of Mn–Ba oxide and fine-grained specular hematite give evidence for very oxidising brines at temperatures between ~100 and 170°C.

[4]Centro de Desenvolvimento Mineral, VALE, Caixa Postal 09, 33030-970 Santa Luzia-MG, Brazil

Botryoidal aggregates of platinum (Pt) and palladium (Pd) from an alluvial deposit (Córrego Bom Sucesso) in Serro, Minas Gerais, Brazil, were likely the sample material from which Wollaston [1] isolated and identified Pd for the first time [2]. We recovered millimetre-sized botryoidal and rod-shaped grains of Pt and Pd from the alluvial deposit. Their arborescent morphologies indicate that the Pt–Pd aggregates formed *in situ* within the alluvium [2]. We carried out synchrotron radiation-induced X-ray fluorescence (SR-XRF) spectrometry on the Pt–Pd aggregates to determine iodine. We found high concentrations of iodine, in the range from 10 to ~120 μg/g [3]. Iodine is a strongly biophile element [4], which is enriched in peatlands by microbial activity [5]. Its high concentration in the Pt–Pd nuggets suggests that microbial activity took place during precious-metal fixation in the aqueous alluvial milieu. The Pt–Pd nuggets have an average thallium/selenium ratio of about 0.08, a value close to that for fluvial waters, suggesting that Pt and Pd were fixed from highly dilute solutions within the alluvium [6]. Inorganic and biogenic processes, i.e. electrochemical metal accretion [7] and bioreduction, are thought to have contributed to the growth of biogenic Pt–Pd nanoparticles that formed on organic templates such as humified plant remains.

Volatile and trace element abundances in HIMU melt inclusions

R.A. CABRAL[1]*, M.G. JACKSON[1], E.F. ROSE-KOGA[2], J.M.D. DAY[3] AND N. SHIMIZU[4]

[1]Department of Earth Sciences, Boston University, Boston, MA 02215, USA (*correspondence: racabral@bu.edu)
[2]Laboratoire Magmas et Volcans, Universite Blaise Pascal, CNRS, UMR 6524, IRD, R 163, Clermont-Ferrand, France
[3]Scripps Institution of Oceanography, La Jolla, CA 92037, USA
[4]Woods Hole Institute of Oceanography, Woods Hole, MA 02543, USA

Water distribution within the mantle influences magma chemistry and evolution, location and extent of melting, and volcanism over geological time. During subduction, oceanic crust has been suggested to transport significant quantities of water and other volatiles to post-arc depths [1]. Despite the important control water has over mantle characteristics and behavior, the amount of water that is retained within the descending slab is poorly constrained [2, 3].

One possible method for constraining the amount of surviving volatiles is to examine oceanic hotspot lavas that are thought to sample melts of subducted oceanic crust. It is hypothesized that subducted material can be returned to the shallow mantle in areas of mantle upwelling, where it is partially melted and erupted during hotspot volcanism. Lavas from Mangaia represent the HIMU (high-μ, or high $^{238}U/^{204}Pb$) mantle end member, which contains geochemical signatures associated with recycled oceanic crust.

Earlier work on olivine-hosted melt inclusions from Mangaia found the inclusions to host volatile-rich phases (e.g., amphibole, phlogopite, apatite, and carbonatite [4]), an observation that is consistent with Mangaian melt inclusions being volatile-rich. High volatile abundances, coupled with major- and trace-element compositions in melt inclusions that are consistent with HIMU source derivation, may indicate that subducted oceanic crust has retained a significant amount of water [1]. This would imply that dehydration during subduction of oceanic crust is not an efficient process.

Here, we will place new constraints on deep cycling of volatiles into the mantle through examination of olivine-hosted melt inclusions, and we will present the first ever volatiles data on HIMU end member glasses.

Mineralogy of stream sediments and soils of Santiago Island, Cape Verde

M.M.S. CABRAL PINTO[1,2]*, M.M.V. SILVA[2], R. HERNANDEZ[1] AND E.A. FERREIRA DA SILVA[1]

[1]Geobiotec Center, University of Aveiro, Portugal
[2]Geociences Center, University of Coimbra, Portugal (*marinacp@ci.uc.pt)

Santiago Island covers an area of 991 km^2 and is characterized by a rough relief. (up to 1392 m) and valleys with almost vertical slopes and large flat areas in the coastal zones. The climate is semi-arid, with torrential rains. The lavas occupy most of the island, the pyroclasts are subordinated and the quaternary sedimentary cover occurs in small areas. The mineralogical composition of the 70 stream sediments and 70 soil samples, collected from all geological formations of the island, was studied in the < 2mm fraction. The samples are dominated by primary silicate minerals, such as feldspar (15.0 to 35.4 %), pyroxene (7.8 to 37.4 %) and olivine (0.0 to 9.0 %), reflecting the mineralogical signature of the igneous rocks that support the island. Quartz, phyllosilicates (smectite, kaolinite, mica/illite), calcite, hematite, leucite, apatite, nepheline, magnetite, titanomagnetite, ilmenite, chromite, garnet, zeolites, siderite, opal, barite, titanite, zircon, halite, aragonite, dolomite, brucite larnite and chlorite were also identified. Higher proportion of feldspar and pyroxene were detected on stream sediments (27.3 % and 25.6 %, respectively), than the soils (24.1 % and 17.0 %, respectively). The soils have higher relative proportion of quartz (24.5 %), phyllosilicates (16.1 %), calcite (2.8 %) and hematite (9.6 %) than stream sediments (12.2 %, 14.5 %, 0.8 % and 9.0 %, respectively). These differences are due to pedogenetic processes and wind-transported materials that affect the soils. Soil and stream sediments that cover formations affected by intense weathering are enriched in phyllosilicates and hematite and impoverished in pyroxene and olivine.

Contrasting mechanisms for two pulses of garnet growth at Stillup Tal, Tauern Window, Austria

MARK J. CADDICK[1], ETHAN F. BAXTER[1,2] AND ANTHONY D. POLLINGTON[2,3]

[1]ETH Zürich, 8092 Zürich, Switzerland
[2]Boston University, Boston MA, 02215, USA
[3]University of Wisconsin, Madison, WI, 53706, USA

Growth of *ca*. 110 cm^3 sub-spherical garnet crystals in a shear zone in the Austrian Tauern Window required *ca*. 7.5 Myrs, with the vast majority of this growth occurring in two distinct pulses [1]. These pulses are characterised by growth rates at least 5 times higher than the 'ambient' rate experienced during the *ca*. 2 Myr inter-pulse hiatus, and during the final stages of crystal growth. Here we explore possible mechanisms for such short crystal growth bursts, testing their viability in terms of an Alpine history, and using the available constraints to calibrate an exhumation velocity.

The first growth pulse occurred early in the preserved garnet history (inner 2 cm diameter of the crystal core) and is well resolved to no more than a few hundred thousand years duration (likely much less). A thermodynamically constrained garnet growth model [2] and a complex suite of mineral inclusions suggest that this records growth over a relatively limited range of P and T, at > 35 km depth and temperatures several 10s of degrees above the garnet-in reaction. A sharp Mn decrease within this growth phase likely reflects Rayleigh fractionation, but otherwise both garnet composition and its mineral inclusion assemblage are effectively constant. This supports the hypothesis that a kinetic trigger initiated and accelerated garnet growth at this time, with a distinct network of radiating fluid inclusions (absent outside the crystal core) attesting to fluid abundance [1].

A second phase of accelerated growth is more poorly resolved to no more than 1.5 million years (again, probably much less). Characteristic changes in all measured divalent cations imply that both this rapid crystal overgrowth and the slowly-grown crystal segment that preceeded it grew during *ca*. 5 kbars decompression and 50-100 ˚C heating. Results are consistent with equilibrium growth along a *P-T* trajectory that traversed fields of relatively constant mineral assemblage and then intersected a set of mineral reactions that accelerated garnet growth. Both slow garnet growth *after* the first pulse and rapid growth in the second pulse are thus possible without recourse to additional kinetic mechanisms or substantial increases in heating or decompression rate.

The characteristics of organic matter adsorbed on clay minerals and its significance in carbon cycling

CAI JINGGONG[1]*, JI JUNFENG[2], LU LONGFEI[1], DING FEI[1] AND CAI YUANFENG[2]

[1]State key laboratory of marine geology, Shanghai, 200092, China (*correspondence: jgcai@tongji.edu.cn)
[2]State Key Laboratory of Mineral Deposits Research, Nanjing; 210093,china

The protection of organic matter (OM) via adsorption on clay minerals is well recognized in recent years, however, the quantity and occurrence of OM adsorbed on different kinds of clay minerals may be not the same. As a result, smectite and illite were selected to synthetize with OM which are positive (HDTMA), negative (SDS) and neutral (0p-10) OM in various CEC. The amount, stability and occurrence of OM combined with different kinds of clay minerals were studied and their evolution distinction in the carbon cycling was discussed as well.

The result shows that the total organic carbon (TOC) absorbed on both the smectite and illite is 5-20%, and increasing with the CEC. Moreover, the TOC of positive OM absorbed on the smectie or illite is higher than the other kinds of OM. After 6 months at room temperature, the TOC absorbed on semectite decreases slightly(5-20%), whereas the TOC absorbed on illite decreases sharply to less than 2%. In a programming heating experiment, the TOC of smectite-complexes was 7% at the temperature of 300°C, and decreased to 2% as the temperature up to 500°C; however, the TOC of illite-complexes decreased to below 2% at 100°C. These results suggest that the stability of the complexes combined with smectite and illite is distinctively different. The diagnostic peaks of the smectite-complexes, including the d001 reflection peak on XRD, the methyl vibration peak and water vibration peak on IR, were changed in a programming heating, which indicate that the OM was not simply absorbed on the surface of smectite but also into the interlayer space. However, the diagnostic peaks of the illite-complexes on XRD and IR were changed slightly, which indicate that the OM was simply absorbed on the surface of illite. The different occurrences of OM associated with smectite and illite must determine the fate of OM in the evolution, which is significant in carbon cycling study.

This research was supported by the NSFC (Grants 40872089 and 41072089) and the State Key Lab. of Marine Geology Fund,Tongji University (MG200902).

Contaminant transport modeling in the candidate VLLW disposal site

CAI XINGQI, WANG YONGLI* AND DUO TIANHUI

[1]Department of Geochemistry, Chengdu University of Technology, Sichuan Province (*correspondence: wangyl@cdut.edu.cn, tsaiseven@sina.com, dth4358@126.com)

This paper takes advantage of MODFLOW software to simulate the groundwater pollutant(Sr) migration in the candidate VLLW disposal site in the Tea ditch and its nearby living quarters.

Simulation results show that, when the VLLW are dumped in landfills, there's no significantly impact on the environment and the residents living quarters in the south in 200 years. Meanwhile, we also simulate the condition once this disposal site leakage occurs. And this suggests, after the leakage 5 years, Besides pollutant concentration observation Well-3 (OW3) not observed in obvious pollutants, the rest two were observed a evident value of the pollutant concentration, since then, pollutants spread to the whole proluvial fan gradually, there's no doubt that it has a significant influence on the proluvial fan and the resident nearby.

Alteration of arsenopyrite in sulphruic acid

YUANFEGN CAI[12] AND XIAOXIAO HU[2]

[1]State Key Laboratory of Mineral Deposits Research, Dept. of Earth Sciences, Nanjing University, Nanjing, China
[2]Scool of Earth Sciences and Engineering, Nanjing University, Nanjing, China (caiyf@nju.edu.cn)

Arsenic contaminants gives the huge threaten on humanbeings health and life.

A massive asenopyrite sample was cut into small pieces of cube with the size of about 3 mm to have a reference shape and size when studying the leaching process. The leaching is lasting one month at the temperature of 100, 150, 200, 250 and 300 ºC in sulphric acid with the concentration of 1, 0.1 and 0.001M. The arsenopyrite cube and acid was enclosed in a tefelon tube and wraped with steel vessel. Each cube was measured in size and weight previous and after the leaching process. Then, the cube relicit was cut into sections and was used to carry out morphological observation under both petrographical microscope and Scanned Electron Microscope (SEM), surficial chemical element identification with the use of X-ray Photoelectron Spectroscopy (XPS). And the liquid lechate was tested by ICP-AES.

Results show that the size of cube keeps almost same but the weight decrease with increase of the concetration of sulphruic acid. It suggests that some element was leached out from the arsenopyrite. The majority of arsenic is present in the liquid leachate. The XPS measurement from both surface and profile shows the signal of As disappeared or weakened after the leaching process by XPS, while its signal increased with the in crease of etching time when depth profile scan is carried out. The morphological obervations gives the fact that the leaching starts from the outmost surface of cube or the edge of cracks, large quantities of pores present in the product area, the boundary of product and arsenopyrite is distinct and sharp, no buffer area is present, and the relicit keeps the shape of cube.

Our study shows that the leaching process of arsenopyrite is controled by the coupled dissolution-precipitation process. The As ion was leaching out and the new product, most probable arsenic oxide, precipitated on the surface of cube or along the cracks. This may suggest that the contamination of suface water and groundwater from weathering of arsenopyrite or arsenic pyrite or other arsenic mineral is main geological cause, And it will bring the huge threaten to the crops, habitants and long tern side-effect to the biosphere.

Molecular scale origin of nuclear waste glass properties

G. CALAS[1], L. CORMIER[1], J.M. DELAYE[2], L. GALOISY[1], P. JOLLIVET[2] AND S. PEUGET[2]

[1]Institut de Minéralogie et de Physique des Milieux Condensés, UPMC; Université Paris 7; CNRS; 4, Place Jussieu, 75 Paris, France (georges.calas@impmc.upmc.fr)
[2]CEA Valrhô-Marcoule, DEN/DTCD/SECM, BP17171, 30207 Bagnols-sur-Cèze cedex, France (jean-marc.delaye@cea.fr)

Assessing the long-term behavior of nuclear waste glasses implies predict their performance, and more precisely their evolution under irradiation and during interaction with water. Structure-property relationships depending on the local and medium-range structure of borosilicate glasses of nuclear interest [1] exemplify structural features rationalizing properties observed during glass elaboration or under forcing conditions (alteration, irradiation). Structural data are correlated with numerical simulations to determine the local structure of glasses, with a special attention to the interplay between glass components [2]. During alteration, some elements, such as Fe, change coordination, as other such as Zr only change coordination in under-saturated conditions. This may explain the chemical dependence of the initial alteration rate and the transition to the residual regime, illustrating the molecular-scale processes during glass-to-gel transformation [3]. Determining molecular scale processes helps in the exploration of new compositions of nuclear glasses [4].

Under irradiation, various structural effects are observed, including coordination change, ion migration or disorder effects. These studies show that glasses with a simplified composition do not show the same behavior as more realistic glasses. Molecular dynamics (MD) simulations provide complementary information on elastic effects [5]. Recent direct evidence for B-coordination change under external irradiation, together with structural models derived from MD, sheds light on the structural mechanisms at the origin of radiation-induced modifications of glass properties, emphasizing the importance of the thermal regime in the cascade core. Molecular scale view of nuclear glasses provides a unifying view of the processes that define the properties of this important class of materials.

Occurrences of nickel in different host phases of a laterite deposit: An example from Berong, Philippines

M.Y. CALIBO*, C.A. ARCILLA, R.M. ONG, M.L.G. TEJADA AND J.P. RAFOLS

National Institute of Geological Sciences, University of the Philippines – Diliman, Quezon City, 1101 Philippines (*correspondence: merylyc@gmail.com)

Despite being globally widespread and relatively easy to mine, nickel laterite ores prove to be difficult to process. Beneficiation of Ni and other economically extractable elements along with it, greatly depends on the mixture of the feed material (silicate phases and oxide phases) which, in turn, is dependent on the mineralogy of the raw ore. The type(s), concentration and consumption of acid to be used in dissolution are controlled by the percentages of both gangue and host minerals trapping the Ni, whether by sorption or isomorphous substitution. A modified selective sequential extraction was designed to recover Ni from from its various host phases to optimize the beneficiation process using samples from different zones in a nickel laterite deposit in Berong, Palawan. This deposit is defined by, from top to bottom, an iron oxide-hydroxide zone, a transition zone made up of serpentine and iron oxides, a nickel-enriched serpentine zone, and a nickel-depleted serpentine zone, based on mineralogy and geochemistry. The occurrence of Ni as adsorbed and exchangeable cations, in carbonates, in amorphous iron oxides, within the structure of crystalline iron oxides and hydroxides, and in residual silicate layers within each of the zones was determined. Qualitative analysis of nickel in iron oxides, serpentine and talc using electron-probe microanalyzer supports the results of the extraction experiment. In limonite zones, dominated by goethite and other secondary iron oxides, > 90% of the total nickel reside in the crystal structure of Fe oxides. In the iron oxide – magnesium silicate transition horizon and in the nickel-enriched saprolite zone, respectively, > 80% and an average of 77% of the nickel are distributed in Fe oxides and within the octahedral layers of serpentine. The remaining Ni ions not taken up by these crystalline minerals are mostly associated with amorphous Fe oxides. An EPMA image, depicting relative abundance of Ni, Mg, and Fe in a section of weathered bedrock, implies that Ni is more closely associated with Fe than with Mg. An industrially significant output of this research is the finding that residual silicates, which take an enormous amount of acid to dissolve, need not be dissolved in order to optimize the beneficiation of nickel.

Geochemistry of eastern North American CAMP diabase dykes

S. CALLEGARO[1]*, A. MARZOLI[1], H. BERTRAND[2], L. REISBERG[3], M. CHIARADIA[4] AND G. BELLIENI[1]

[1]University of Padua, Department of Geosciences, Italy (*correspondence: sara.callegaro@unipd.it, andrea.marzoli@unipd.it, giuliano.bellieni@unipd.it)
[2]Laboratoire de Géologie de Lyon, UMR-CNRS 5570, Lyon, (herve.bertrand@ens-lyon.fr)
[3]CRPG (CNRS UPR2300), Université de Lorraine, France (reisberg@crpg.cnrs-nancy.fr)
[4]Université de Genève, Switzerland (Massimo.Chiaradia@unige.ch).

Swarms of diabase dykes and a few sills of the Central Atlantic magmatic province (CAMP) intruded the Piedmont area of the Appalachians and the coastal plains of eastern North America (ENA) between 202 and 195 Ma [1]. Based on field observations, an age progression can be defined from NW- to N- and NE-oriented dykes. The basaltic dykes are Mg, Cr-, and Ni-rich, which may only in part reflect accumulation of mafic minerals. Incompatible trace element contents are fairly homogeneous and generally low, e.g. La_{Ch}/Yb_{Ch} (0.54-2.39), typical of melts issued from a quite depleted shallow mantle-source. The incompatible trace element contents are not correlated with isotopic compositions of ENA dykes, which display a considerable spread in initial isotopic signatures, i.e. $^{87}Sr/^{86}Sr_{200Ma}$ (0.7043-0.7088), εNd_{200Ma} (-6.8-+2.1) and $^{206}Pb/^{204}Pb_{200Ma}$ (17.41–18.61). Pb isotopic compositions plot above the NHRL, at positive Δ7/4 (10-17) and Δ8/4 (19-73). Generally low $^{188}Os/^{187}Os_{200Ma}$ ratios (0.127–0.144), which argue for negligible amounts of crustal contamination, coupled with the large range of Sr-Nd-Pb isotopic compositions, suggest generation from a strongly heterogeneous mantle source, probably metasomatized lithosphere. The alternative, a deep enriched mantle source, is unlikely because the crystallization temperatures calculated [2] for high-Fo (up to Fo_{89}) olivines (ca. 1350 °C) are not supportive of a very hot (i.e. mantle-plume) origin (see also [3]). Considering the isotopic compositions of ENA lava flows, some dykes may have fed eruptions chemically similar to the Newark Preakness and Hook Mt. flows, i.e. the youngest flows from the Newark Supergroup basins, whereas none of the analyzed basaltic dykes yields geochemical compositions similar to the slightly older Orange Mt. basaltic flows.

The Eastern Equatorial Pacific (EEP) is thought to have exerted a strong control over glacial/interglacial CO_2 variations through its link to circulation and nutrient-related changes in the Southern Ocean. Changes in phytoplankton productivity and composition associated with increases in equatorial upwelling intensity and influence of Si-rich waters of Sub-Antarctic origin have been recently detected in ODP Site 1240 (0º 01.31'N, 86º 27.76'W; 2,921 mbsl) [1]. However, these changes do not seem to have been crucial in controlling atmospheric CO_2, as they took place during the deglaciation, when atmospheric CO_2 concentrations had already started to rise. New results from Nd isotopes in foraminifera shells of *Neogloboquadrina dutertrei* from the same intervals corroborate this interpretation. *N. dutertrei* preferentially dwells in the lower thermocline, at the core of the Equatorial Undercurrent (EUC). Therefore, changes in the Nd-isotopic composition of these foraminifera will reflect the composition of the EUC, which, in turn, reflects changes in the advection of Sub-Antarctic Mode Water and Antarctic Intermediate Water and the composition of the Southern Ocean end-member. Our evidence indicates that diatoms outcompeted coccolithophores at times when the influence of Si-rich Southern Ocean intermediate waters was greatest as recorded by low ε_{Nd} values (-2.8). This shift from calcareous to non-calcareous phytoplankton would cause a lowering in atmospheric CO_2 through a reduced carbonate pump, as hypothesized by the Silicic Acid Leakage Hypothesis. However, the concomitant intensification of Antarctic upwelling brought large quantities of deep CO_2-rich waters to the ocean surface. This process very likely dominated any biologically mediated CO_2 sequestration, and probably accounts for most of the deglacial rise in atmospheric CO_2.

Nickel isotopes, BIFs and the Archean oceans

V. CAMERON[1]*, D. VANCE[1] AND S. POULTON[2]

[1]BIG, Dept. of Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK (*correspondence: glxvc@bristol.ac.uk)
[2]School of Civil Engineering & Geosciences, Newcastle University, Newcastle upon Tyne NE1 7RU, UK

Trace metal isotopes provide vital clues to the Earth's biogeochemical evolution. Key to these efforts is the development and application of new isotopic systems of bioessential elements important to specific organisms or metabolisms or, as recorders of changing environmental conditions through time. Nickel (Ni) is primarily restricted to microorganisms and metabolisms that might have evolved in a much different Archean environment [1-3]. Methanogens and their particular metabolism, methanogenesis, purportedly fit the criteria for an ancient origin of evolution and many studies have shown the absolute requirement that these microorganisms have for Ni.

Recently, we published the first measurements of nickel stable isotopes from abiotic terrestrial materials and pure cultures of methanogens [4]. Terrestrial samples representing the mantle and crust displayed very little isotopic variability (average δ^{60}Ni of 0.15 ± 0.24‰, 2σ). In contrast, Ni isotopes were significantly fractionated by pure cultures of methanogens. The largest fractionation, δ^{60}Ni of -1.46 ± 0.08‰, was achieved by a methanogenic hyperthermophile. Our data suggest the biological cycling of Ni may be an important contributor of Ni isotopic variations in the rock record. Furthermore, biological fractionation of Ni has the potential to be a powerful new biomarker particularly in regards to the nature and impact of early life.

We have started evaluating our new Ni isotopic tool by applying it to the measurement of Ni stable isotopes in banded iron formations (BIFs). In order to characterize the Ni isotopic composition of the geochemical and biological environment of the primitive Earth, it is essential to first understand the state and changing conditions of the Archean oceans. Such information recorded within BIFs and other terrestrial materials is necessary to support our continued efforts to establish Ni stable isotopes as a functional and detectable biosignature.

The weathering of platinum from nuggets and platinum immobilisation by *Cupriavidus metallidurans*

G. CAMPBELL[1], F. REITH[2], L. MACLEAN[3] AND G. SOUTHAM[1]*

[1]Department of Earth Sciences, The University of Western Ontario, London, ON Canada N6A 5B7 (*correspondence: gsoutham@uwo.ca)
[2]School of Earth and Environmental Sciences, The University of Adelaide, CSIRO Land and Water, Waite Laboratories, Urrbrae, South Australia, Australia
[3]Canadian Light Source Inc., 101 Perimeter Road, Saskatoon, SK Canada S7N 0X4

Platinum nuggets, collected from a platiniferous and auriferous site near Fifield, New South Wales, Australia were examined to evaluate mineral dissolution-precipitation processes occurring at the nugget–'soil solution' interface. Nuggets possessed striations indicating mechanical transport with the soil environment and micrometer-scale dissolution pits corresponding to regions possessing soil materials (quartz, clays and organics) and acicular, iron oxides suggesting an oxidising weathering environment. The occurrence of 100 nm-scale, cubic minerals at the soil solution interface and comparably sized cubic dissolution 'pits' suggest that platinum weathering occurs via preferential dissolution of the 'bulk' platinum nugget (an Fe-Pt alloy). Examination of these cubic minerals using scanning electron microscopy in secondary electron and back-scattered electron (BSE) imaging modes, and using energy dispersive spectroscopy indicated that they are enriched with copper (i.e., a Cu-Pt alloy). Growth of platinum nuggets via secondary platinum mineral formation was not observed. *Cupriavidus metallidurans* cultures reacted with 0.5 and 5 mM platinum (IV) chloride, immobilised platinum from solution rapidly i.e., within minutes. EXAFS/XANES analysis of these reaction systems demonstrated that most of the Pt(IV) chloride complex was reduced to Pt(II) and that platinum binding shifted from chloride to primarily, amino functional groups. Using transmission electron microscopy, *C. metallidurans* was also found to precipitate nm-scale colloidal platinum when exposed to 5 mM platinum (IV) chloride; the formation of these colloids occurred within the bacterial cell envelope. Understanding the biogeochemistry of platinum, in particular weathering and formation of colloids has important implications within geologic settings, i.e., for platinum dispersal in relation to exploration geochemistry programs.

Kinetic modeling of microbial Fe(II) oxidation, Fe(III) hydrolysis, and mineral precipitation in acid waters

K.M. CAMPBELL* AND D.K. NORDSTROM

U.S. Geological Survey, Boulder, Colorado, 80303, USA
(*correspondence: kcampbell@usgs.gov)

Acidophilic Fe(II)-oxidizing microorganisms are widespread in acidic mine-impacted waters and are the primary drivers for Fe(II) oxidation at low pH. The resulting changes in Fe chemistry have profound effects on trace element redox cycling and mobility in the environment. Sorption, precipitation, or redox activity of Fe(III)-containing mineral phases control the mobilization or sequestration of metal(loids) of concern in natural waters. Although Fe(II) oxidation is microbially-mediated, biogeochemical predictions for an acidic, Fe(II)-rich natural water require a coupled biotic-abiotic process model.

We present experimental and model results from a series of batch experiments conducted at four initial Fe(II) concentrations (10, 50, 100, and 159 mM), three initial pH values (2.0, 2.5, and 3.0), and inoculated with a pure strain of *Acidithiobacillus ferroxidans* isolated from acid rock drainage near a molybdenum mine. The pH, aqueous Fe(III), Fe(II), direct cell counts, and solid phase precipitates were monitored over the course of the experiments. For all inital Fe(II) concentrations except 10 mM, the pH increased initially, due to the acid-consuming stoichiometry of Fe(II) oxidation, but then decreased due to the combined effects of Fe(III) hydrolysis and precipitation of schwertmanite ($Fe_8O_8(OH)_6SO_4$) and/or jarosite ($KFe_3(SO_4)_2(OH)_6$). The Fe(III) concentration in the 10 mM Fe experiments was too low to precipitate jarosite, and only an increase in pH from Fe(II) oxidation was observed. The amount of pH increase due to Fe(II) oxidation was greatest at an initial pH of 2 for all initial Fe concentrations. The final pH in all bottles at 50 mM, 100 mM, and 159 mM Fe was very similar (pH 2), regardless of inital pH, because of equliibrium with mineral precipitates, primarily jarosite. Since the decrease in pH was due to both hydrolysis and precipitation, the kinetics of Fe(III) hydrolysis were measured in a separate experiment. PHREEQC, a geochemical model with the ability to incorporate multiple kinetic expressions, was used to simulate the experimental results by including kinetic expressions for microbial Fe(II) oxidation, Fe(III) hydrolysis, and jarosite precipitation. In addition, we compared various proposed kinetic formulations for microbial Fe(II) oxidation from the literature to our experimental results.

C, Sr isotopes in cap carbonate and and *Ce anomaly* in BIFs of Jucurutu Formation, Seridó Belt, NE, Brazil

M.S. CAMPOS[1], A.N. SIAL[1]*, C. GAUCHER[2], V.P. FERREIRA[1], ROBERT FREI[3], R.C. NASCIMENTO[4] AND M.M. PIMENTEL[5]

[1]NEG-LABISE, Dept. Geol. UFPE, Recife, 50670-000, Brazil (*correspondence: sial@ufpe.br)
[2]Facultad de Ciencias, Universidad. de la Republica, Montevideo,Uruguay (gaucher@chasque.com)

[4]Inst. Geography and Geol., Univ. Copenhagen, Denmark
[5]Inst. Geoc., Univ. Fed. Rio G. do Sul, Porto Alegre, Brazil

BIFs associated with Neoproterozoic glaciations are an important pillar of the Snowball Earth hypothesis and are regarded as accumulation of Fe^{+2} in ice-capped anoxic ocean. BIFs at Jucurutu (Mina do Bonito), Florânea (Cabeço da Mina) and São Mamede (Riacho Fundo) towns, Seridó Belt (itabirite and Fe ores, amphibole-itabirite, and tremolite schist) are overlain by Jucurutu marbles. Micro-drilled carbonate samples from the Jucurutu Formation exhibit $\delta^{13}C$ values as low as -12‰ in the first meter, followed by mantle values (-6 to -4‰) and then by positive values up section (+4 to +10‰). Surprisingly, $\delta^{13}C$ values for carbonates that overlie itabirites at Riacho Fundo and at Cabeço da Mina are all positive. Perhaps, the difference of C isotope behavior between basal carbonates at Mina do Bonito (negative), and Riacho Fundo and Cabeço da Mina (positive) reflect, perhaps, topographic control during deposition.

C-isotope stratigraphy for carbonates of the Jucurutu Formation support their deposition as cap carbonate. Negative $\delta^{13}C$ values are followed upsection by positive values. Sr isotope ratio for Jucurutu carbonates (~0.7074) approach Sr isotope ratios for Sturtian II cap carbonates (e.g. Maiberg, Pedro Leopoldo, Mirassol D´Oeste among others) between 740 and 635 Ma.

Negative Ce anomaly values (<0.10) result from Ce depletion or fractionation with metallic oxides, therefore, it indicates oxidizing conditions of the ocean water [1]. On the other hand, positive values (>0.10) reflect anoxic conditions of the ocean water. The values of Ce/Ce* in the BIFs vary from 0.54 to 2.46, indicating extremely anoxic environment, which seems to support the hypothesis of deposition of BIFs in an ocean capped by ice.

Kaolinite as a sorbent for As natural contamination

B. CAMPREDON, C. HUREL AND N. MARMIER

LRSAE – Sci. Fac., University of Nice Sophia Antipolis, Parc Valrose, 28 avenue Valrose, 06108 Nice cedex 2 France

The geological formation of the Mercantour basin is made of metamorphic rocks, granite, Permian argillite and sedimentary rocks, which can provide high arsenic concentrations in the riverine waters. In the Var (South of France) watershead high arsenic input were measured, and were attributed to the dissolution of the metamorphic rocks form the old massifs of Mercantour. This natural contamination may affect the geological environments, since the sediments are the main sinks of pollutants. When the environmental conditions are changed (hydrologic conditions, flow variation, pH, redox potential, etc.) the sediments can act as a source of contamination. In this study, kaolinite (a clayey material) was chosen as a potential binding agent for trapping the local excess of As. This adsorbent material was chosen on the basis of his natural occurrence in the studied watershead ecosystem.

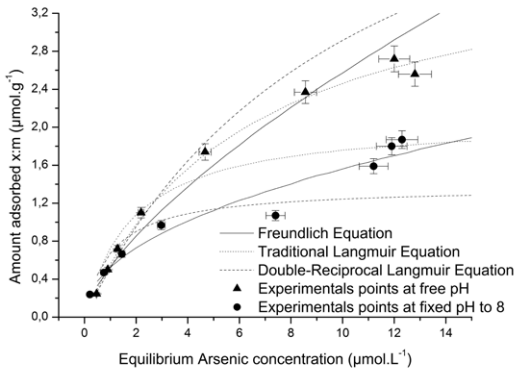

Figure 1: As adsorption on Kaolinite in $NaNO_3$ 0.1M and 13.3μM initial As concentration.

Adsorption of As on kaolinite was studied in various electrolytic conditions (concentration and composition), various solid to liquid ratios and various pH conditions (figure 1). The results were modeled considering empirical models and mechanistic models (surface complexation).

Changes in organic aerosol composition with aging inferred from aerosol mass spectra

M.R. CANAGARATNA[1,*], N.L. NG[1], J.L. JIMENEZ[2], P.S. CHHABRA[3], J.H. SEINFELD[3] AND D.R. WORSNOP[1]

[1]Aerodyne Research, Inc, Billerica, MA, USA (*correspondence: mrcana@aerodyne.com, ng@aerodyne.com, worsnop@aerodyne.com)

[2]CIRES & Department of Chemistry and Biochemistry, University of Colorado, Boulder, CO, USA (jose.jimenez@colorado.edu)

[3]Department of Chemical Engineering, California, Institute of Technology, Pasadena, CA, USA, (puneet@caltech.edu, seinfeld@caltech.edu)

The Aerosol Mass Spectrometer (AMS) provides real-time quantitative mass concentrations of non-refractory species in ambient aerosols. Factor analysis of ambient AMS organic aerosols (OA) spectra has been used to characterize the evolution of OA composition due to photochemical processing. A large database of ambient OA components has been analyzed with the "triangle" plot [1], in which f_{44}, ratio of m/z 44 (mostly CO_2^+ from acid-derived groups) to total signal in the component mass spectrum, is plotted against f_{43} (mostly $C_2H_3O^+$ from non-acid oxygenates). Examination of ambient oxidized organic aerosol (OOA) components in the triangle plot indicates that the relative acid group content and similarity of OA components increase with aging. A new parameterization of the H:C of OA components in term of f_{43} allows for further transformation of this data into the Van Krevelen diagram (H:C vs. O:C) [2]. Ambient OOA components also map out a triangular space in Van Krevelen diagram, showing a range of H:C at lower oxidization which decreases with increasing oxidation. The average slope (ΔH:C/ ΔO:C) that describes the transformation between the less and more aged OOA components is ~-0.5. This slope is consistent with the additions of both acid *and* alcohol functional groups without fragmentation, and/or the addition of acid groups with C-C bond breakage. The importance of acid formation in OOA evolution is consistent with increasing f_{44} in the triangle plot with photochemical age. The simple triangle and Van Krevelen plots for laboratory SOA formed in chamber experiments are also investigated.

The many flavors of oxygen-minimum zones past and present

DONALD E. CANFIELD

NordCEE and Institute of Biology, University of Southern Denmark, University of Southern Denmark, Campus vej 55, 5230 Odense M, Denmark

Oxygen-deficient oxygen minimum zones (OMZs) are concentrated today in only a few regions of the global ocean. They are truly anoxic and despite their limited areal extent, they are sites of globally-significant rates of nitrogen loss as N_2 gas. While this loss was traditionally ascribed to canonical heterotrophic denitrification, recent work has demonstrated that most nitrogen loss is, instead, channeled through the anammox (anaerobic ammonia oxidation) process. Active nitrogen cycling was thought to inhibit sulfate reduction, explaining the lack of sulfide into these oxygen-free waters. New results show, by contrast, that these waters likely support an active, but cryptic, sulfur cycle, where sulfide produced by sulfate reduction is actively oxidized through nitrate reduction. Metagenomic results confirm the presence of microbial sulfur-cycling communities, and through their activities, these organisms may contribute to significant amounts of organic matter mineralization in OMZ water and to the ammonia driving anammox. Accumulating evidence suggests that in the past, oxygen minimum zones supported chemistry quite different from those found today. Many instances of both sulfidic and ferrugenous OMZs, extending well into the Precambrian, have now been described. We are still challenged to understand the circumstances responsible for the development of these different styles of OMZ water chemistry. However, the different flavors of OMZs through time must reflect the evolving chemistry of the coupled ocean-atmosphere system through time, and how this has controlled the variable expression of the different microbial populations known to inhabit OMZs today.

The alteration and the fluid inclusion characteristics of the Çavdır (Burdur) copper mineralization, SW Turkey

Z. CANSU[1]* AND H. EMRE[1]

Istanbul University, Department of Geological Engineering, 34230, Istanbul, Turkey
(*correspondence: zynporu@istanbul.edu.tr)

Çavdır (Burdur) copper mineralization, located in southwestern Turkey, occurs in the gabbros of the Lycian Allochthon. The mining district has a few meter wide vein systems that contain malachite±azurite, plus minor chalcopyrite, bornite, iron minerals such as goethite, hematite and magnetite in quartz gangue. The strike of major ore-bearing veins is N 30º to 45º E that are nearly paralel to the major fault in the study area. The veins are accompanied by extensive alteration.

Qualitative clay analysis were made to define alteration minerals and kaolinite, smectite, illite, zeolite, chlorite group minerals, cristobalite were determined by X-Ray Diffractometer method.

Microthermometric measurements were done on fluid inclusions of the quartz gangue. Fluid inclusions are two phased L+V (liquid+vapour) and NaCl-H_2O in system. Mean homogenization temperature is measured as 283ºC, the mean salinity is calculated from the equation %NaCl= [(-1,78x Tm_{ice})-(0,0442xTm_{ice}^2)-(0,000557xTm_{ice}^3)] [1] as %8 NaCl equivalent and the mean density is found as 0,82 gr/cm^3 by plotting % NaCl equivalent versus Th (ºC) [2].

These alteration and microthermometric datas connote an epithermal system. In the light of the acquired datas, it is suggested that the mineralization occurred in the effect of tectonic control and the heated ground water by the crust tickening (because of the emplacement of the Lycian thrust sheets) and geothermal gradient mobilized copper minerals from parental rocks.

Zircon U-Pb chronology and geochemistry of Late Paleozoic-Early Mesozoic intrusive rocks in eastern segment of the northern margin of the North China Craton, NE China and its tectonic implications

H.H. CAO, W.L. XU *, F.P. PEI AND F. WANG

College of Earth Sciences, Jilin University, Changchun 130061, China (caohua9871@163.com; (*correspondence: xuwl@jlu.edu.cn)

Chronological and geochemical data of Late Paleozoic-Early Mesozoic igneous rocks in the Kaiyuan-Panshi area, NE China, provide insights for the Late Paleozoic-Early Mesozoic tectonic evolution in the eastern segment of the northern margin of the North China Craton (NCC). LA-ICP-MS zircon U-Pb dating results indicate that the Late Paleozoic-Early Mesozoic magmatisms can be subdivided into three stages, i.e., the middle Permian (~270 Ma), the late Permian-early Triassic (259~249 Ma), and the late Triassic (~222 Ma).

The middle Permian magmatisms consist chiefly of garnet-bearing monzogranites. Their SiO_2-high and Al-rich geochemical feature suggest that they could have formed under a setting of crustal thickening.

The late Permian-early Triassic intrusive rocks are composed mainly of the gabbro, monzodiorite, monzonite, monzogranite, and syenogranite. Chemically, they belong to a calc-alkaline series and are characterized by enrichment in LILEs and depletion in HFSEs and P. Combined with the contemporaneous high-Mg andesites in the adjacent area, we propose that they could have formed under an active continental margin setting.

The late Triassic igneous rocks are composed of pyroxene-peridotites and olivine-pyroxenite with cumulate texture. Combined with the existence of coeval A-type granites and mafic-ultramafic rocks in the adjacent area, it is suggested that they could form under an extensional environment.

Taken together, we propose that the collision and subduction between the continent (NCC) and the island arc could happen in eastern segment of northern margin of the North China Craton from the middle Permian to early Triassic, and that a post-orogenic extension environment occurred in the study area in the late Trassic.

This research was financially supported by research grants from the Natural Science Foundation of China (Grant 41072038) and the Geological Survey of China (Grants 1212010611806 and 1212010070301).

Difference of organic matter in the Early Cambrian Ni-Mo-bearing black rock series in the Zunyi city of South China: Implications for the origin of the deposits

JIAN CAO*, CHUNHUA SHI, KAI HU, SHANCHU HAN, LIZENG BIAN AND SUPING YAO

State Key Laboratory for Mineral Deposits Research (Nanjing University); School of Earth Sciences and Engineering, Nanjing University, Nanjing, 210093 (*correspondence: jcao@nju.edu.cn)

The Ni-Mo polymetallic mineral deposits in the Zunyi city of South China is likely the most representative case of such deposits worldwide, and thus have received large research attentions during recent years. The issue is disputable as the origin of the deposits has been reported to be of sea water or hydrothermal sources. In this work, we mainly reported the difference of organic matter between the metallic and non-metallic intervals, and further addressed the origin of the deposits.

Analytical results from petrography, organic and elemental geochemistry showed that biogenic and organic matters occur widely both in the metallic and in the non-metallic intervals, indicating important effects on the formation of the deposits. The matters vary in abundance, type and maturation between the metallic and non-metallic intervals. For example, the organic matter abundance and maturity of the metallic interval are both the highest in the section. In addition, a special organic matter in elliptical shape was only observed in the metallic interval. The mineral element may be sourced either from sea water or from hydrothermal water. In particular, the sea water and hydrothermal water may be the dominant source for Mo and Ni, respectively. The mineralization of Mo and Ni is relatively early and late, respectively. Based on these results, a new mineralization model was tentatively established.

Geochronology and geochemistry of Xingdi No. 1 intrusion in Kuluketage, NW China: Tectonic implication for Xingdi mafic-ultramafic rock belt

XIAOFENG CAO[1,2], XIANG GAO[1], XINBIAO LÜ[1,2]*, YUEGAO LIU[1], SHENTAI LIU[1] AND CHAO CHEN[1]

[1]Faculty of Earth Resources, China University of Geosciences, Wuhan 430074, China (*correspondence:Lvxb_01@163.com; cao079@qq.com)

[2]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

The Xingdi No. 1 mafic-ultramfic intrusion is the largest in the Xingdi mafic-ultramafic belt with an exposed area of ca. 20 km^2 and intruded into the Paleoproterozoic basement. Gabbro is the major rock type and there is minor olivine pyroxenite. Sm-Nd geochronometry of the gabbro gives an isochron age of 761.2±31.2 Ma. It is the same with the intrusion age of Xingdi No. 2 pluton (760±6 Ma). The gabbro is systematically enriched in large ion lithosphere elements (LILE), light rare earth elements (LREE) and depleted in high field strength elements (HFSE) and heavy rare earth elements (HREE). The studied rocks are characterized by low whole-rock and mineral $\varepsilon Nd_{(t)}$ values (–7.8 to –7.1) and elevated $(^{87}Sr/^{86}Sr)_i$ values (0.7066–0.7073). These geochemical characteristics, together with the presence of the abundant hornblende, biotite, bladed biotite enclosed in amphibole, and crescent-shaped Paleoproterozoic wall-rock enclosed within the intrusion are key features of magma mixing in the source or assimilation during its emplacement. The rocks have Zr/Y ratio of 3.81–13, which fall in the area of within-plate basalt area. As the Xingdi No. 1 and No. 2 plutons formed at the same period and display similar geochemical characteristics, we propose that they formed within the same tectonic setting and derived from the same origin, but No.1 experienced higher extent of evolution and contamination. On the basis of previous studies, the Neoproterozoic tectonic and magmatic events in Kuluketage comprise syn-collisional granite around TC (ca. 1.0–0.9 Ga), post-collisional K-rich granite and alkaline mafic-ultramafic intrusions (ca. 830–800 Ma) and rifting-related mafic-ultramafic plutons, dykes and bimodal volcanic rocks (ca. 774–744 Ma).

This work is founded by 305 Project of State Science and Technology Support Program (Grant No. 2007BAB25B04).

CO_2 sequestration in deep aquifers: Insights into future hazards from a natural analog (Campi Flegrei, Italy)

R. CAPOBIANCO[1]*, R. ESPOSITO[1], R.J. BODNAR[1], G. CHIODINI[2] AND J.D. RIMSTIDT[1]

[1]Virginia Tech, Blacksburg, VA 24061, USA (*correspondence: rcapobi@vt.edu)

[2]Istituto Nazionale di Geofisica e Vulcanologia, sezione di Napoli, Osservatoria Vesuviano, 80124 Napoli, Itally

Among the major challenges facing the world today are climate changes and the alteration of Earth's surface geochemistry that are occurring as the result of release of anthropogenic CO_2 into the environment. Geologic sequestration of CO_2 in deep aquifers is an approach to reducing CO_2 emissions to the atmosphere that has recieved much attention recently [1]. The largest of the sequestration projects currently underway, the In Salah Project (Algeria) injects approximately 1 Mt of CO_2 per year [2]. A large coal-fired powerplant emits over an order of magnitude more CO_2 than this; for example, the Scherer plant (GA, US) emitted about 25 Mt in 2010 [3].

Campi Flegrei is a natural analog for large-scale CO_2 sequestration in confined saline aquifers. At Campi Flegrei active magmatism at depth is releasing large amounts of CO_2 that migrate upward into a confined saline aquifer at depths of about 2-3 km. Campi Flegrei is estimated to have injected 63 Mt of H_2O and CO_2 during the crisis of 1982-1984, corresponding to a total volume increase of $5.7*10^7$ m^3 or $2.85*10^7$ m^3/y [4]. This is similar to the volume ($2.4*10^7$ m^3) that would be occupied by the annual CO_2 emissions from the Scherer plant at the T&P conditions of interest in a geologic sequestration scenario. We predict that large-scale sequestration of CO_2 as a supercitical phase will have consequences similar to those observed at Campi Flegrei – seismic activity, bradyseism, and release of CO_2 rich fluids from the aquifer to the surface. These effects may be mitigated to some extent through careful management of the reservoir during and following injection.

VSI study of biotite dissolution at acidic pH and 25-50˚C

C. CAPPELLI[1]*, J. CAMA[2], F.J. HUERTAS [1]

[1]Instituto Andaluz de Ciencias de la Tierra (IACT), CSIC-UGR, Avenida Fuentenueva s/n., 18002 Granada, Spain (*correspondence: chiaracappelli@ugr.es)

[2]Institute of Environmental Assessment and Water Research (IDAEA), CSIC, Jordi Girona 18-26, 08034 Barcelona, Catalonia, Spain

Generally, the dissolution rates of the phyllosilicates that comprise the mica group (e.g. muscovite, biotite and flogopite) were obtained from experiments in which ground powders were used, and the calculated rates were normalised either to total or edge surface area, derived from BET measurements. Using the vertical scanning interferometry (VSI) technique we attempt to compute biotite dissolution rates from quantifying surface normal retreat of the cleavage (001) surface at pH 1 and 25, 40 and 50 ºC. The advantage of these measurements is that allows us to obtain biotite dissolution rates from mineral surface retreat, and thus avoiding the need to normalize the dissolution rates with externally measured surface areas.

Single biotite fragments of approximately 100 mm^2 were placed in 250 mL of 0.1 M HNO_3 solution (pH 1) and 25, 40 and 50 ºC for almost two weeks. During this time span the cleavage surface was examined by VSI after 4, 7 and 13 days. On the one hand, dissolution features were observed on the cleavage surface, and on the other hand, the dissolution rates were computed from surface retreat compared to a non-reacted reference surface.

The calculated biotite dissolution rates, with an average error of ~10 %, were 2.5×10^{-8}, 1.1×10^{-8} and 0.3×10^{-8} mol m^{-2} s^{-1} at 50, 40 and 25 ºC, respectively, which are higher than those calculated from the total mineral surface area, although rates normalized to total surface area may have little relevance for micas, since reactive sites probably are concentrated on edge surface [1]. VSI examinations of the reacted cleavage surface show that biotite dissolution was controlled by preferential surface edge dissolution.

The calculated activation energy of the biotite dissolution at pH 1 from the rates obtained at 25, 40 and 50 ºC is 14.35 kcal mol^{-1} (R^2 = 0.997), which is similar to that of biotite dissolution at very acidic pH [2].

Spin transition in Fe-bearing perovskite: Implications for the lower mantle

RAZVAN CARACAS

CNRS, ENS Lyon, UMR5276, Lyon, Frence

Using lattice dynamical calculations based on density functional perturbation theory we are able to disentangle a part of the complex phase diagram and spin behavior of the $(Mg,Fe)SiO_3$ perovskite (pv). To do this we investigate the dynamic stability of Pbnm $FeSiO_3$ pv and show the existence of unstable phonon modes. We track the eigen-displacements of the phonons modes to find low-spin and intermediate spin states. On solid-state physical basis we explore a set of hypothetical structures with various spin configurations and considerably lower enthalpy than the parent orthorhombic Pbnm structure. We show that the spin evolves along a high-spin to mixed high- and intermediate spin to low-spin transition sequence. We also analyze the thermal behavior of both high-spin and low-spin phases and we discuss a first thermal phase diagram.

We show that the elastic moduli and the bulk seismic wave velocities are weakly affected by the spin transition. However, the intrinsic differences in seismic anisotropy between the high-spin and low-spin phases of Fe-bearing pv coupled with lattice preferred orientation that can develop during mantle flow lead to distinct seismic signatures between the top and the bottom of the lower mantle [1]. These signatures are detectable by seismic observations and they need to be taken into account in tomographic studies of the Earth's lower mantle.

Finally, we find that the electronic gap widens during crossover to the low-spin phase. This has a direct influence on the electircal conductivity and agrees qualitatively with in situ measurements [2].

Fe-rich stalactites from Libiola mine: Mineralogical and geochemical features

C. CARBONE[1]*, E. DINELLI[2], P. MARESCOTTI[1] AND G. LUCCHETTI[1]

[1]DIP.TE.RIS, University of Genova, Corso Europa, 26, Italy (*corrrespondence: carbone@dipteris.unige.it)
[2]Dip. di Scienze della Terra e Geologico-Ambientali, Alma Mater Studiorum - Università di Bologna, Italy

The aim of this work is to characterize the mineralogy of different-shaped Fe-rich stalactites as well as to investigate the physico-chemical parameters of the associated mine and drip waters. The mineralogy has been investigated by means of reflected and transmitted light microscopy, XRPD, SEM-EDS, EPMA-WDS, and TEM-EDS analyses. Mine and drip waters have been sampled for chemical analyses. Water temperature, electrical conductivity, alkalinity by acidimetric titration, pH, and Eh were determined in the field during sampling. In the laboratory, waters have been analyzed for: Mg, and Ca by AAS, Na and K by AES Cl, SO_4^{2-}, and NO^{3-} by ion-chromatography, Si, Fe, minor and trace elements by ICP-OES. Three different types of stalactites were distinguished on the basis of their morphology: 1) "soda straw"-, 2) "deflected"-, and 3) "coned shaped"-stalactites. Mineralogical results showed that all the samples are characterized by poorly crystalline Fe-rich phases associated to goethite with different degree of crystallinity. Nevertheless, there are significant differences either in their texture and chemistry. The "soda straw" stalactites are enriched in Cu and Zn and evidenced botroydal to mammellonar textures; the "deflected" stalactites are enriched in Ni and showed concentric layering characterized by sheaves of radiating fibers; the "coned shaped" stalactites are enriched in Cu, Zn and Ni and evidenced a concentric layering maked by the alternance of botroydal/mammellonar and fibrous-radiating textures. Geochemical investigations evidenced that the composition and physico-chemical parameters of mine and drip waters are in any case different from the other AMD occurrences in the mining area [1, 2]. All water samples contain Cu, Ni, and Zn to appreciable levels, and the physico-chemical conditions are consistent with stability of ferrihydrite, which however tends to transform to goethite upon ageing. Few of the mine waters plot close to the metastability field of schwertmannite.

1998-2010 more than ten years of soil CO_2 flux measurement at Solfatara of Pozzuoli (Campi Flegrei, Italy)

C. CARDELLINI[1]*, G. CHIODINI[2], S. CALIRO[2], D. GRANIERI[3], R. AVINO[2], F. FRONDINI[1].

[1]Università di Perugia, Perugia, Italy (*correspondece: geochem@unipg.it)
[2]INGV sez. Napoli, Napoli, Italy
[3]INGV sez. Pisa, Pisa, Italy

With a flux of deeply derived fluids of ~5000 t/d and an energetic release of ~100 MW Solfatara of Pozzuoli is one of the largest studied volcanic-hydrothermal system of the world. Since 1998, CO_2 flux surveys where performed using the accumulation chamber method: i) over a large area, including the volcanic apparatus and its surroundings, ii) at fixed points inside the crater and ii) by two automatic stations. The monitoring of CO_2 fluxes allowed to recognize both "long-term" and "short-term" variations in the degassing of the Solfatara system. The main "long-term" CO_2 flux variation consisted in the expansion of the area interested by anomalous soil CO_2 degassing which doubled since 2003. This variation mainly occurred external to the Solfatara cone in correspondence of a major fault system NE-SW oriented and was correlated with the occurrence in 2000 of relatively deep, LP seismic events, which were interpreted as the indicator of the opening of an easy-ascent pathway for the transfer of magmatic fluids towards the shallower domain hosting the hydrothermal system. The input of these magmatic fluids has been highlighted by the changes in the chemical and isotopic compositions of fumarolic fluids. "Short-term" variations of CO_2 flux were recorded by both automatic stations and at fixed measurement points. A marked peak of the mean CO_2 fluxes of fix points inside the crater occurred in 2000, probably connected with the 2000 seismic crises. In 2006 an evident anomaly was registered outside the crater. This anomaly was interpreted as due to shallow permeability changes along the NW–SE fault, induced by an earthquake swarm of October 2006. The physical feasibility of the interpretations of these variations was assessed by physical-numerical simulations of the gas along a "faulted" hydrothermal system. The relevant changes observed at Campi Flegrei since 2000 have to be taken in to consideration for the interpretation of the behaviour of this dangerous volcano.

[5]Centro de Geociéncias, Universidad Autónoma de México, Queretaro, México.

Magmatic fluxes in continental arcs have shown to include major flare-ups episodes during their evolution. These episodes reflect catastrophic events which may be connected to major plate tectonic reorganizations. U-Pb zircon crystallization from plutonic rocks (30 U-Pb LA-ICP-MS) and detrital zircons (ca. 2000 U-Pb LA-ICP-MS detrital zircon analysis) from northern Colombia have revealed the existence of two major continental magmatic flare ups in the Middle Jurassic (ca. 190-180 Ma) and the Paleogene (60-45 Ma). Their tectonostratigraphic relations suggest that these two episodes are related to different periods of subduction initation along the Pacific margin of South America. The older is related to an extensional type subduction formed after the break-up of Pangea, whereas the younger Paleogene reflect subduction initiation after arc- continent collision in the Late Cretaceous. These tectonic correlations suggests that the early episodes of subduction in continental margins are responsible for the compositional modification of significant segments of the continental crust.

Pre-eruptive history and longevity of felsic magma in Iceland illuminated by *in situ* U-Th dating and trace-element analysis of zircon from historical eruptions

T.L. CARLEY[1]*, C.F. MILLER[1] AND J.L. WOODEN[2]

[1]Vanderbilt U., Dept. of Earth and Environmental Sciences, Nashville, TN, USA (*correspondence: tamara.l.carley@vanderbilt.edu, calvin.miller@vanderbilt.edu)
[2]Stanford U. USGS-SUMAC SHRIMP Lab, Stanford, CA, USA (jwooden@stanford.edu)

We are investigating zircons from silicic volcanic rocks from recent (primarily historical) eruptions in different tectonic regions of Iceland: Torfajokull ~7500 and ~3100 BP and 871 and 1477 AD (rift-tip); Hekla 1104 AD (transitional to rift); and Oraefajokull 1362 AD (off-rift). Precise knowledge of these eruption ages, combined with relatively high precision U-Th disequilibrium ages of zircon (*in situ* SHRIMP-RG) that date crystal growth, permit us to elucidate longevity of and processes within these felsic magma systems. While zircon age distributions from individual eruptions are variable, all display evidence for extensive growth that predates eruptions by >10 k.y. Seventy percent of Hekla and Torfajokull ages are older than 10 ka, with 60% of model ages falling at 10-30 ka and reaching a maximum of 50 ka. The predominance of older ages, the general paucity of <10 ka ages, and observation of near-eruption age crystallization of major phases (e.g., Torfajokull [1]) suggests that these zircons experienced a history separate from that of magma in which they erupted. Zircon morphology (presence of rounded centers and grain boundaries), compositional zoning (core-to-rim complexities in Ti, Hf concentrations) and U-Th ages together point to growth at relatively low temperatures, subsequent storage in a subvolcanic, silicic mush or recently solidified rock, and entrainment by the hotter erupting magma. While Oraefajokull zircons are dominantly <10 ka, grain morphology and trace-element zoning suggest a similarly complex history. The erupted materials were likely ascending magmas that entrained a pre-existing zircon cargo.

Alkalic magmas and the diversity of mantle compositional variation

RICHARD W. CARLSON

Department of Terrestrial Magnetism, Carnegie Institution of Washington, 5241 Broad Branch Road, NW, Washington, DC 20015 USA, (rcarlson@ciw.edu)

As very small degree melts, mafic-alkalic magmas are sensitive tracers of small-scale compositional heterogeneity in the mantle. Some alkalic magmas contain trace element and isotopic signatures indicative of sources dominated by components derived from subducted sediments. Excellent examples of this end member are the alkalic magmas of Italy. In the north, mantle sources for these magmas contain tens of percent subducted sediment whereas in the south, the sources are just overprinted by small volume fluids released from the subducting plate. Many mafic-alkalic and carbonatitic magmas, however, have isotopic compositions that overlap values seen in intraplate oceanic basalts. Along with key OIB-like trace element ratios (e.g. Ce/Pb, Th/Ta) this suggests that these magmas simply represent very low degree (<1%) melts of "normal" mantle. Within this group, there are examples of regional isotopic differences that suggest lithospheric sources. For example, group I kimberlites from South Africa have εNd > +4 whereas similar composition kimberlites from Brazil have εNd < -4. The isotopic compositions of these kimberlite groups, however, also overlap the range seen in slightly older regionally-associated flood basalts, the Karoo and Parana, respectively. This may suggest sources in lithospheric mantle that was metasomatized by melts from compositionally distinct sublithospheric mantle. Mafic-alkalic magmas from Montana have OIB-like trace element characteristics, but extreme isotopic compositions (e.g. εNd often < -15) indicating source metasomatism some 1.8 Ga prior to the Cenozoic magmatism. Low $^{187}Os/^{188}Os$ in potassic ultramafic magmas (kimberlites, katungites, meimechites) point to peridotitic sources whereas more radiogenic Os in Na-rich varieties (e.g. kamafugites, nephelinites) suggest pyroxene-rich sources. Mafic-alkalic magmas appear most commonly in "thermally-limited" settings where melting cannot proceed to high enough degrees to make basalt. Such settings include areas where adiabatic ascent is inhibited by thick lithospheres (cratons, early stages of continental rifting), marginal to plumes in the early and late stage of ocean island formation, the final stages of a dying subduction zone, or in areas of rigid lithosphere where heating can only be accomplished by conduction from below. This marginal melting regime enhances the contribution from easily fusible metasomatic components in the source if they are present.

Implications of a non-chondritic primitive mantle for chemical geodynamics

RICHARD W. CARLSON[1] AND MATTHEW G. JACKSON[2]

[1]Department of Terrestrial Magnetism, Carnegie Institution of Washington, 5241 Broad Branch Road, NW, Washington, DC 20015 USA, (rcarlson@ciw.edu)

[2]Department of Earth Sciences, Boston University, 675 Commonwealth Ave. Boston, MA 02215 USA, (jacksonm@bu.edu)

Among the compositional components identified in the mantle, most attention has been devoted to those components produced by continental and oceanic crust production and recycling. "Primitive mantle" appears in most models of mantle compositional variation, but usually in the abstract sense in that few, if any, samples of oceanic basalt have all the characteristics expected for a melt of the model primitive mantle that is assumed to have chondritic relative abundances of the refractory lithophile elements. For example, the high $^{3}He/^{4}He$ component may sample a reservoir preserving primitive mantle noble gas characteristics, but at the same time generally has positive εNd and often has Pb isotopic composition plotting well to the right of the Geochron. PREMA, for "prevalent mantle" was coined by Zindler and Hart (1986) early in the investigation of mantle isotopic variation as the most common isotopic component seen not only in ocean island basalts but in both continental and oceanic large igneous provinces and as a component in many intraoceanic island arc lavas. This component largely vanished from the discussion of mantle compositional variation in part because its origin was unclear – it could not be primitive mantle because it did not have chondritic Nd or Hf isotopic composition and it might just be some "most likely" mixture between depleted mantle and enriched recycled components. The elevated $^{142}Nd/^{144}Nd$ of all post-Hadean igneous rocks on Earth, however, suggests that primitive mantle has Nd, and by inference Sr and Hf, isotopic compositions in the realm of what traditionally has been called depleted mantle. We use the trace element characteristics of Baffin Island and Ontong-Java lavas that have isotopic compositions closest to those expected for the non-chrondritic primitive mantle to examine how this reservoir was produced early in Earth history. We also explore the consequences of a non-chondritic primitive mantle for such issues as the relative fraction of DMM and PREMA in the current mantle and the role of the primitive mantle in the origin of the massive volcanism associated with large igneous provinces.

In silico, physiological, and proteomic cost-benefit analysis of resource-limited microbial growth

ROSS P. CARLSON*, REED L. TAFFS AND JAMES FOLSOM,

Deparment of Chemical and Biological Engineering, Montana State University, Bozeman, 59717 USA, (rossc@erc.montana.edu)

Evolutionary selection has produced fit microbes with robust and often redundant metabolic network functionality. Maintaining and regulating network redundancy represents a substantial resource burden especially in nutrient limited environments and therefore needs to be off set by fitness advantages. A genome enabled *in silico* methodology was developed and experimentally tested which quantifies molecular-level, resource allocation tradeoff strategies that permit competitive cellular functioning under a continuum of nutrient availabilities. The approach decomposed a metabolic network into a complete listing of non-divisible, mathematically-defined biochemical pathways which were then used to identify all potential strategies for investing limiting resources like iron and nitrogen into the genome encoded metabolic machinery. The tabulated enzymatic resource investment requirements for each distinct biochemical pathway were examined in concert with the pathway's efficiency at converting substrate into biomass. The analysis identified the most competitive molecular-level tradeoffs between pathway resource requirements and metabolic efficiency; allocating limiting resources to perform one function well came at the cost of performing another metabolic function well. *In silico* predictions were evaluated experimentally using physiological and proteomic data collected from iron- or nitrogen-limited *Escherichia coli* chemostat cultures. Experimental chemostat data was consistent with *in silico* theory and illustrated that under iron- and nitrogen-limited conditions *E. coli* regulates its metabolism to invest the limiting resource competitively at the cost of optimal biomass yields on electron donor. The study highlights a fundamental evolutionary and metabolic design paradigm for competitive network structure and control.

Solubility as a determinant of rates of intergranular diffusion in metamorphic rocks

W.D. CARLSON

Department of Geological Sciences, University of Texas at Austin, Austin TX 78712 USA (wcarlson@mail.utexas.edu)

Rates of intergranular diffusion in metamorphic rocks are principally determined not by temperature, but instead by the properties of the intergranular medium, particularly those properties that govern the solubility of the diffusing species.

Quantitative comparison of length scales and time scales for metamorphic reaction in natural examples reveals extremely large variations in rates of intergranular diffusion for Al among systems with different H_2O activities. For instance, at 600 °C the effective diffusion coefficient for Al ($m^2 \cdot sec^{-1}$) is $10^{-18.8}$ in fluid-saturated systems, $10^{-22.5}$ in hydrous-but-fluid-undersaturated systems, and $10^{-25.4}$ in anhydrous systems. Thus even at constant temperature, Al diffusivities can range across 6 to 7 orders of magnitude depending on the character of the intergranular medium.

In fluid-saturated systems, garnet zoning—which monitors the length scale of chemical equilibration during growth—shows that intergranular solubilities controlled by characteristics of the fluid itself (H_2O/CO_2 ratios, availability of ligands for complexation, pH) can exert greater influence on diffusivities than temperature. As a case in point, the nature of compositional zoning in garnet from Harpswell Neck, Maine, varies markedly from cores to rims. For Mn, Fe, and Mg, many crystals have irregular, patchy distributions in their cores that give way to smooth, concentric zoning in their outer rims. In contrast, zoning of Ca and Y is comparatively smooth and concentric throughout these crystals. Rims of all crystals share equivalent concentrations of all elements. Raman spectrometry of fluid inclusions demonstrates that growth of garnet cores took place in the presence of a CO_2-rich fluid, whereas growth of garnet rims took place in the presence of an H_2O-rich fluid. Thus the patterns of garnet zoning imply that low solubility for Mn, Fe, and Mg and high solubility for Ca and Y in a CO_2-rich fluid restricted the length-scales of equilibration for the former and expanded them for the latter during the growth of garnet cores; transition to an aqueous fluid with relatively high solubility for all elements then led to rock-wide equilibration for all during growth of garnet rims. Differential solubility of cations in fluids of variable composition is therefore a fundamental control on rates and scales of intergranular diffusion.

Structural changing control of potassium saturated smectite at high pressures and high temperatures: Application for subduction zones

L.C. CARNIEL, R.V. CONCEIÇÃO AND N.DANI

Geoscience Institute, UFRGS, Porto Alegre – RS, Brazil. (larissa.colombo@ufrgs.br rommulo.conceicao@ufrgs.br norberto.dani@ufrgs.br)

The lithospheric mantle is characterized by pressure ranges from ~ 2.0 and ~ 7.7 GPa and a specific mineralogy and composition. This region can be re-hydrated and re-enriched in incompatible elements (eg. potassium) through subduction processes that bring pelagic material, composed of clay minerals and other phyllosilicates, into these regions. These minerals act as carriers of water and incompatible elements, re-enriching the lithospheric mantle as they are destabilized. Then, simulating conditions of high pressure and temperature in potassium enriched smectite would help to check the stability field of this mineral and its transformations during the process of subduction. This research focuses on the construction of a phase diagram of smectite, previously saturated with potassium at different temperatures and pressures. We performed experiments in smectite under pressures between 2.5 and 4.0 GPa and at different temperatures (400°C to 700°C). From our results, we conclude that at 2.5 GPa pressure, which is about 75 km depth in the mantle, the clay mineral transform into a new phase at 500° C that correspond to the illite. At higher pressures, we conclude that at 4.0 GPa pressure, equivalent to 120 km depth, the same transformation occurs at 400°C. Such results aid new information to understand the dehydration of pelagic sediments in a process of subduction, and the mobility of some incompatible elements in such tectonic setting.

Elasticity and anelasticity of relaxor ferroelectrics

M.A. CARPENTER[1]*, J.F.J. BRYSON[1], E.H. KISI[2], S.M. FARNSWORTH[2] AND G. CATALAN[3]

[1]Dept. of Earth Sciences, Downing St., Cambridge CB2 3EQ (*correspondence: mc43@esc.cam.ac.uk)

[2]School of Engineering, The University of Newcastle, Callaghan NSW 2308, Australia

[3]Campus Universitat Autònoma de Barcelona, ICREA, Bellaterra 08193 Spain

The elastic behaviour of ferroelectric and relaxor ferroelectric materials makes an interesting contrast with that observed in association with ferroelastic phase transitions in minerals, though the same basic principles apply. Softening of the bulk and shear moduli of polycrystalline samples occurs in the high temperature structure as a consequence of dynamical effects, there are marked elastic anomalies associated with the phase transition, and anelastic losses arise due to mobile transformation microstructures. Distinctive features of relaxor ferroelectric perovskites are frequency-dependent softening and acoustic losses associated with freezing of polar nanoregions (PNR's), together with a large degree of softening of shear elastic constants due to condensation of static PNR's in the stability field of the paraelectric phase. The latter occurs ahead of the transition to a long range ordered ferroelectric structure. These distinctive features have been investigated by Resonant Ultrasound Spectroscopy (RUS) measurements of polycrystalline $Pb(Mg_{1/3}Nb_{2/3})O_3$ (PMN) and single crystals of $0.955Pb(Zn_{1/3}Nb_{2/3})O_3$-$0.045PbTiO_3$ (PZN-PT). In PMN the pattern of the elastic compliance as a function of temperature mirrors the real part of the dielectric constant and the inverse mechanical quality factor mirrors tanδ, showing that a key aspect of PNR formation is the development of local strain fields. In PZN-PT, there is a large difference in the shear elastic constants between poled and unpoled crystals in the stability fields of the rhombohedral and tetragonal phases and well into the stability field of the cubic phase. This signifies that the PNR's themselves develop a stable microstructure which can be polarised and which gives rise to acoustic losses in much the same way as a conventional ferroelectric microstructure. Central to all this behaviour, as with other types of phase transitions, including order/disorder, displacive, magnetic transitions and changes in spin state, is the coupling of strain with some primary order parameter or with microstructure.

Evaluating sources and transport of zinc and cadmium and their complexing ligands in the Atlantic and Pacific Oceans

G. CARRASCO[1]*, L.A. DUFFAUT-ESPINOSA[2], P.L. MORTON[3] AND J.R. DONAT[4]

[1]Earth, Atmos. and Planet. Sciences Dept., MIT, Cambridge, MA, USA. (*correspondence: gcarrasc@mit.edu)

[3]Earth, Ocean and Atmos. Sciences Dept., Florida State University, Tallahassee, FL, USA. (pmorton@fsu.edu)
[4]Chemistry and Biochemistry Dept., Old Dominion University, Norfolk, VA, USA. (jdonat@odu.edu)

Introduction and Methods

Using Anodic Stripping Voltammetry [1], the complexation and chemical speciation of Zn and Cd has been determined in the water column in the Western North Pacific, the Equatorial South Atlantic as well as in the Elizabeth River and the Chesapeake Bay waters and benthos. Using a novel mathematical interpretative tool (Titration Data Interpreter) that allows for precise, non-biased ligand parameter optimization of the Gerringa linearization [2], the speciation of these two metals data was calculated.

Discussion

The results obtained in these oceanic regions indicate marginal seas and other pointed sources provide both metals and strong ligands, combining riverine, terrestrial, marine and anthropogenic matter, as recent literature suggests [3-7]. The ligands are transported and decay with time along water masses in both Atlantic and Pacific Oceans, implying connections to ligands produced the water formation regions [3,7,8] and from estuarine origin. A consortium of strong ligands complexes these two metals, affecting their chemical speciation in surface, intermediate and deep waters. The ramifications of this phenomenon on the close and remote upwelling of potentially limiting concentrations of bioavailable Zn and Cd will be discussed.

Amino sugar and amino acid degradation and transformation in two lakes with different redox state

D. CARSTENS[1,2]*, K.E. KÖLLNER[1,2], H. BÜRGMANN[1] AND C.J. SCHUBERT[1]

[1]Swiss Federal Institute for Aquatic Science and Technology (Eawag), 6047 Kastanienbaum, Switzerland (*correspondence: doerte.carstens@eawag.ch)
[2]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zürich, 8092 Zürich, Switzerland

Transformation and degradation processes of organic matter in aquatic systems play a key role in the global carbon cycle. Although lakes seem to store carbon efficiently, little is known about organic matter degradation in these systems. In order to study the fate of organic nitrogen compounds in lacustrine systems under different redox conditions, Lake Brienz (oligotroph, fully oxic) and Lake Zug (eutrophic, stratified oxic/anoxic) were investigated. Profiles of particulate amino sugar and amino acid concentrations were measured in the water column of both lakes as well as in the first centimeters of the sediments by gas chromatography. Decreasing carbon normalized amino sugar yields with increasing water depth indicated enhanced degradation of amino sugars compared to the bulk organic matter in both lakes. Under oxic conditions the degradation was more pronounced. The amino sugar composition of the particulate organic matter revealed a replacement of planktonic biomass by heterotrophic mircoorganisms from the upper water layers towards the lake bottom. The contribution of bacteria to the organic carbon was estimated using the amino sugar muramic acid, which is unique to bacteria as part of their cell wall. In the oligotrophic lake 0.8-11% of the organic carbon derived from bacteria and in the eutrophic lake this contribution was 0.3-5%. These findings underline that bacteria are not only drivers of organic matter degradation in lacustrine systems but also a significant source of organic matter themselves.

On the mass independent fractionations of O, Hg, Si, Mg and Cd during open-system evaporation or thermal decomposition

P. CARTIGNY[1]*, J.M. EILER[2], P. AGRINIER[1] AND N. ASSAYAG[1]

[1]Stable Isotope Laboratory of IPG-Paris, France. (*correspondence : cartigny@ipgp.fr)
[2]Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA 91125, USA.

Many experiments in which an element or a mineral is evaporated or thermally decomposed under vacuum are known to consistently display unexpected behaviors. These include too low rates of evaporation, smaller (i.e. closer to 1) than predicted fractionation factors, and an inconsistent behavior of the stable isotope ratios of a given element (i.e. mass-independent fractionation). This applies to many elements including O, Hg, Si, Mg and Cd.

We present interpretations for a series of earlier observations, including experiments by Miller *et al*. (2002) in which mass-independent O isotope fractionations are produced during thermal decomposition of carbonates [1], and the finding of Estrade *et al*. (2009) showing an unexpected slope in a plot of Δ^{199}Hg vs Δ^{201}Hg (close to 1.2 instead of 2.4) during open-system evaporation of Hg [2].

These and related results can be explained if a fraction (usually a few to several tens of percent) of the evaporated compounds actually forms (or re-equilibrate) under conditions of isotope equilibrium, the remaining fraction obeying kinetic fractionation of its stable isotopes. This is the mixing of the that results in the appearance of mass-independence, rather than the action of a novel isotope effect having non-cannonical mass law.

Howardite noble gases as indicators of asteroid surface processing

J.A. CARTWRIGHT[1], D.W. MITTLEFEHLDT[2], J.S HERRIN[2] AND U. OTT[1]

[1]Max Planck Institut für Chemie, J.-J.-Becher-Weg 27, 55128 Mainz, Germany (julia.cartwright@mpic.de)
[2]NASA/Johnson Space Centre, Houston, Texas, USA.

Introduction and Research Objective:

The HED (Howardite, Eucrite and Diogenite) group meteorites likely originate from the Asteroid 4 Vesta [1] - one of two asteroid targets of NASA's Dawn mission [2]. Whilst Howardites are polymict breccias of eucritic and diogenitic material that often contain "regolithic" petrological features, neither their exact regolithic nature nor their formation processes are well defined [3-4]. As the Solar Wind (SW) noble gas component is implanted onto surfaces of solar system bodies, noble gas analyses of Howardites provides a key indicator of regolithic origin. In addition to SW, previous work by [5] suggested that restricted Ni (300-1200 μg/g) and Al_2O_3 (8-9 wt%) contents may indicate an ancient well-mixed regolith. Our research combines petrological, compositional and noble gas analyses to help improve understanding of asteroid regolith formation processes, which will play an intergral part in the interpretation of Dawn mission data.

Methodology:

Following compositional and petrological analyses [4,6], we developed a regolith grading scheme for our sample set of 30 Howardites and polymict Eucrites [4]. In order to test the regolith indicators suggested by [5], our 8 selected samples exhibited a range of Ni, Al_2O_3 contents and regolithic grades. Noble gas analyses were performed using furnace step-heating on our MAP 215-50 noble gas mass spectrometer.

Discussion of Results:

Of our 8 howardites, only 3 showed evidence of SW noble gases (e.g approaching $^{20}Ne/^{22}Ne \sim 13.75$, $^{21}Ne/^{22}Ne \sim 0.033$ [7]). As these samples display low regolithic grades and a range of Ni and Al_2O_3 contents, so far we are unable to find any correlation between these indicators and "regolithic" origin. These results have a number of implications for both Howardite and Vesta formation, and may suggest complex surface stratigraphies and surface-gardening processes.

Magnetic susceptibility of sands from a river beach for forensic applications

Á. CARVALHO[1], H. RIBEIRO[1], A. GUEDES[1,2], H. SANT'OVAIA[1,2], I. ABREU[1,3] AND F. NORONHA[1,2]*

[1]Centro de Geologia da Universidade do Porto (CGUP), Portugal

[2]Departamento de Geociências, Ambiente e Ordenamento do Território da Faculdade de Ciências da Universidade do Porto, Portugal

[3]Departamento de Biologia da Faculdade de Ciências da Universidade do Porto, Portugal (*fmnoronh@fc.up.pt)

Soil studies are often undertaken in forensic investigation because its particles are normally tranferred to the surfaces in contact with them, providing important information. Soil is composed by organic and inorganic materials and its history is reflected in its bio-physicochemical characteristics, including low-field magnetic susceptibility (MS). MS is defined as the ratio of the material magnetization (per unit mass) to the weak external magnetic field, and in soils, it is directly proportional to the quantity, composition and grain size of minerals in the sample (which can be diamagnetic, paramagnetic or ferromagnetic species).

In order to investigate the variability of this property in Areinho, a fluvial river beach in Porto region (Northern Portugal), twenty four samples were collected along a transect perpendicular to the river side and prepared for magnetic susceptibility analysis. MS was measured on 1g of dry bulk samples, applying them an external magnetic field of 300 A/m, and a Kappabridge model KLY4S of Agico balance equipped with the Sumean software was used. Before each measurement the equipment was calibrated. The MS of Areinho sands is low with values ranging between $0.68x10^{-8}m^3/Kg$ and $18.09x10^{-8}m^3/Kg$ which is an agreement with its mineralogical composition. All measurement results were reproducible. From this study we conclude that MS protocol is suitable for the analysis of sands with the advantage of being fast and non-destructive.

Radionuclides in uranium milling tailings and environment remediation

F.P. CARVALHO, J.M. OLIVEIRA AND M.MALTA

Instituto Tecnológico e Nuclear, E.N. 10, 2686-953 Sacavém, Portugal (carvalho@itn.pt)

The environmental and public health risks posed by legacy uranium mine sites and milling tailings in Portugal was assessed in order to allow for decision making regarding environmental remediation and for radiological protection measures of the population.

Most of old uranium mine sites did not pose noticeable ionizing radiation and contamination risks to the environment and population, especially the sites operated as open pits and without *in situ* chemical operations. The mines where *in situ* ore leaching with sulfuric acid was operated and the ore milling tailings are the sites with higher ambient radioactivity and contamination with radioactive and stable metals [1]. Over some waste piles the radiation dose attained 30 mSv y^{-1}, higher than the annual limit for members of the public, 1 mSv y^{-1}. Confinement and coverage of these uranium waste piles was necessary and allowed for reducing radon exhalation, dispersal of radioactive materials in soils, and abatement of surface runoff and radionuclide leaching with acid drainage. *in situ* formation of H_2SO_4 in waste piles still generates radioactive leachates in underground mines and in milling tailings that require continued treatment. Irrigation of agriculture plots in the mine areas with mine drainage and water from contaminated wells is the main pathway to transfer radionuclides, especially ^{226}Ra, into locally grown vegetables and into the food chain [1,2].

Milling tailings with high radioactivity must be confined to reduce dispersion of radionuclides and exposure of biota and the public. Water from rivers that received past discharges of acid mine drainage have contaminated sediments that may require removal. Mine drainage and underground waters in the area of former mines shall be monitored to avoid exposure of the public to acid, metals and radionuclides. Withouth suitable monitoring and abatement measures, radiological exposure of members of the public may be many times about radiation exposure legal limits.

Geochemistry of groundwater from Graciosa Island (Azores): A contribution to the hydrothermal system conceptual model

M.R. CARVALHO[1], P.M. CARREIRA[2], J.M. MARQUES[3], G. CAPASSO[4], F. GRASSA[4] AND J.C. NUNES[5]

[1]Universidade de Lisboa, Faculdade de Ciências, Depart. Geologia/CeGUL, Portugal
[2]Instituto Tectonológico e Nuclear, Lisboa, Portugal
[3]Instituto Superior Técnico, Lisboa, Portugal
[4]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Palermo, Palermo, Italy
[5]Universidade dos Açores & INOVA Inst., Azores, Portugal

Graciosa island is located in the Azores Archipelago, along the so-called Terceira Rift, a major tectonic structure that makes the NE boundary of the Azores Plateau. In general terms, it includes a basaltic plataform on the NW and a silicic poligenetic volcano with caldera on the SE, the Graciosa Caldera Volcano. This volcano has produced significant tephra falls, pyroclastic flows, lahars, and lava flows, both of basaltic s.l. and trachitic s.l. composition.

The hydrothermal system shows fumarolic emissions inside the volcano caldera and thermal springs located along the shoreline. This system is exploitated in a thermal building through shallow and deep (110 m) boreholes, near the coast.

In Graciosa two types of Na-Cl groundwater systems can be identified: 1) a cold one emerging at springs and exploited by wells for public water supply, and 2) a hydrothermal system with temperatures around 40-44 ºC. The cold groundwaters have pH higher than 7 and different degree of mineralization, according to the proximity to the sea. The thermal waters show mixing with seawater, pH varying between 6.20 and 6.94, 166 mg/L of SiO_2, and significant concentration of metals, such as Mn, Fe, Co, Ni, Cu and Zn. The thermal water mineralization varies strongly, showing EC from 8.87 mS/cm (shallow water) to 47.4 mS/cm (deeper water). The higher mineralized water is rich in CO_2(g), with 2130 mg/L of total dissolved CO_2. Geothermometers application reveals aquifer temperature ≈ 167 ºC and immature/mixed waters, not reaching complete equilibrium with reservoir rock.

The geochemistry of the thermal waters indicates the occurrence of seawater/host rock interaction processes at high temperature and slightly acid conditions, favored by CO_2(g) input, and a different degrees of mixing with cold and shallow groundwaters.

Geochemistry of S-type granitic rocks from the Valongo area (Northern Portugal)

P.C.S. CARVALHO[1]*, A.M.R. NEIVA[1], M.M.V.G. SILVA[1] AND F. CORFU[2]

[1]Geoscience Centre and Department of Earth Sciences, University of Coimbra, 3000-272 Coimbra, Portugal (*correspondence: paulacscarvalho@gmail.com)
[2]Department of Geosciences, University of Oslo, PB1047 Blindern, N-0316, Norway

Variscan peraluminous granitic rocks crop out at the eastern limb of the Valongo anticline, located about 18 km at east of Oporto, in the Dúrico - Beirão region, northern Portugal and Central Iberian Zone of the Iberian Massif.

The medium- to coarse-grained porphyritic biotite>muscovite granite (G1) intruded Ordovician and Silurian metasediments and produced a contact metamorphic aureole. The medium-grained porphyritic biotite ≈ muscovite granodiorite (G2) intruded the earlier granite and the contact is by faulting. The fine-grained porphyritic biotite>muscovite granodiorite (G3) intruded the other two granitic rocks. Granite G1 and granodiorite G2 are late-D3, whereas granodiorite G3 is post-D3. The U-Pb ages for zircon and monazite, obtained by ID-TIMS, are 309.6±1.0 Ma for G1, 307.0 ± 3.2 Ma for G2 and 305.1± 0.4 Ma for G3 and 587 Ma for inherited zircon cores from G2 and G3. Variation diagrams show that G3 has higher TiO_2, total FeO, MgO, CaO, Zr, Ba, Th, Ce contents and lower SiO_2, Li, Rb contents than G1 and they define independent trends. G2 is not related to G1. Granite G1 and granodiorite G3 have similar $(^{87}Sr/^{86}Sr)_i$ of 0.7085, εNd_T -6.64 (G1) and -6.92 (G3) and $\delta^{18}O$ 11.36 ‰ (G1) and 10.90 ‰ (G3). Therefore, they are derived by partial melting of the same metasedimentary materials, containing Neoproterozoic detritus, but G3 results from a higher degree of partial melting than G1. Granodiorite G2 results from a distinct granitic magma and is derived by partial melting of metasedimentary materials containing Neoproterozoic detritus, as it has $(^{87}Sr/^{86}Sr)_{307}$ of 0.7080, εNd_{307} of -7.06 and $\delta^{18}O$ of 11.31 ‰. The three granitic rocks are of S-type.

Systematic variations in argon diffusion in feldspars

W.S. CASSATA[12], P.R. RENNE[12] AND D.L. SHUSTER[12]

[1]Berkeley Geochronology Center, USA
[2]University of California, Berkeley, USA

Feldspars are commonly used in $^{40}Ar/^{39}Ar$ studies to constrain the thermal evolution of meteorites, mountain belts, intrusive magmatic bodies, and a host of other Earth and planetary processes. Although the kinetics of Ar diffusion in K-feldspars have been extensively researched, comparably little work has been published on plagioclase feldspars, despite their being the primary host of potassium in most chondritic, lunar, and Martian meteorites and many terrestrial igneous bodies. Similarly, little is known of the potential effects of composition and structural state on Ar diffusion kinetics, or the extent to which diffusion might be anisotropic.

In this study, ~100 step-heating diffusion experiments were conducted on feldspars that range in composition from nearly pure orthoclase to nearly pure anorthite, with the bulk of the samples being plagioclase feldspars. These experiments reveal systematic variations in diffusive behavior that appear to be closely related to composition and microstructure. For example, plagioclase crystals having compositions between An_{50} and An_{90} typically yield Arrhenius arrays with pronounced upward curvature between 600 and 800 °C, the opposite of that commonly observed on Arrhenius plots from K-feldspars inferred to have multiple diffusion domains. Plagioclase crystals with compositions $<An_{50}$ yield linear Arrhenius arrays that give way to downward curvature between 600 and 1000 °C, where the temperatures at which linearity ceases appear to depend on the composition of the sample and the heating schedule. Brecciated and microstructurally complex plagioclase crystals exhibit Arrhenius arrays consistent with multiple diffusion domains. Preliminary experiments on cleavage flakes indicate that diffusion may be faster in the [001] crystallographic direction than [010], and additional experiments are underway to confirm this finding. Activation energies for plagioclase and K-feldspars span a large range, from ~160-300 kJ/mole.

Arrhenius plots for Ar diffusion in plagioclase appear to reflect a confluence of intrinsic diffusion kinetics and structural ordering-disordering that occurs during prolonged step-heating. These data indicate that Ar diffusivity is intimately related to composition and microstructure in plagioclase. As such, there is no broadly applicable set of diffusion parameters that can be utilized in thermal modeling. Sample-specific data are required.

Tracking the magmatic evolution of an island arc volcano: Insights from a high-precision Pb isotope record of Montserrat, Lesser Antilles

M. CASSIDY*, R.N. TAYLOR, M.J. PALMER AND J. TROFIMOVS

National Oceanography Centre, Southampton, University of Southampton, Waterfront Campus, European Way, Southampton SO14 3ZH
(*correspondance:m.cassidy@soton.ac.uk)

It is rare to have a chance to examine the magmatic evolution of an island arc volcano over a period of millions of years. The volcanic succession exposed on Montserrat provides such an opportunity, extending from the 2 Ma andesites of the Silver Hills complex through to the youngest dome collapse of the Soufrière Hills volcano (February 2010). In this study we present new trace element, Sr, Nd and high-precision double spike Pb isotope data taken through Montserrat's time sequence. As well as from subaerial locations, we have collected samples from marine sediment cores, as significant volumes of pyroclastic material have ended up in the Caribbean Sea.

Each of Montserrat's volcanic groups; South Soufrière Hills (SSH), Soufrière Hills, Centre Hills and Silver Hills, can be clearly discriminated using trace element and isotopic parameters. Furthermore, the SSH can be divided into two suites: A and B, combining trace elements and Pb isotopes.

The trends in trace elements and isotopes suggest some variability in fluid and sediment addition over time. The SSH in particular has a greater slab fluid signature as indicated by elevated Pb/Ce, but less sediment addition than the other volcanic centres. $^{206/204}Pb$ against $\Delta 7/4$ and $\Delta 8/4$ diagrams show that Montserrat falls along two differing trends, one defined by the SSH volcanic region and the second trend defined by the other volcanic regions on Montserrat (Silver Hills, Centre Hills and Soufrière Hills). Furthermore, the SSH volcanic centre differs noticeably in trace elements and isotope ratios. This demonstrates that the source which generated the SSH magmas is different to the source of the other volcanics on Montserrat. Both isotopic trends point to an enriched mantle source underneath Montserrat. Samples from the current period of activity will be discussed including the presence of mafic enclaves within the current eruption.

Metamorphic and geodynamic evolution of the high-grade units of Mundão – Sátão (Northern Portugal)

P. CASTRO[1], T. BENTO DOS SANTOS[1,2]*, C. MEIRELES[1], A.J.D. SEQUEIRA[1] AND N. FERREIRA[1]

[1]LNEG – Laboratório Nacional de Energia e Geologia, Portugal (*correspondence: telmo.santos@lneg.pt)
[2]Centro de Geologia, Universidade de Lisboa, Portugal

The Mundão – Sátão sector (N Portugal) is composed of syn- to post-D_3 Hercynian granitoids and by pre-Ordovician metasediments, belonging to the Schist – Greywacke Complex of the Iberian Central Zone. The metasediments comprise two low-grade sequences (chlorite to biotite zones), Ponte Chinchela and Nelas Units, separated by the exotic high-grade tectonometamorphic sequence of the Casinha Derrubada Unit (CDU) [1] that includes three tectonic slices separated by thrusts, from bottom to top: a) micaschists and mylonites with sillimanite; b) mylonites with porphyroclastic staurolite; and c) biotitic micaschists with garnet.

The CDU is a MP metamorphic sequence associated with the establishment of the metamorphic peak during D_2. Late retrograde evolution is evidenced by prismatic andalusite pseudomorphs after porphyroclastic staurolite, and andalusite + biotite coronas around staurolite rims. These textural evidence are coeval with the reorientation of staurolite prismatic crystals from sub-horizontal to sub-vertical and late incipient migmatization by decompression and crossing of the granite wet solidus curve during D_3 exhumation phase.

The observed petrological/geochemical features and the paragenetic evolution of the CDU high-grade rocks imply that this area is not a typical contact metamorphic sequence [2] or a complete Barrovian-type sequence arround an anatectic dome [3]. The new data points out the existence of net-tectonic control on the emplacement of the high-grade rocks at this sector and that the CDU is an incomplete Barrovian-type sequence from MT to HT, subsequently exhumed onto a low-grade metamorphic sequence. The evidence suggest that the tectonometamorphic evolution of the CDU rocks is consistent with a clockwise P-T-t path, involving: 1) a metamorphic peak at T ~ 600 – 700 ºC and P ~ 6 – 7 kbar; 2) significant decompression to 2 – 3 kbar; 3) rapid cooling as the result of thermal readjustment to higher crustal levels.

[5]Chemical & Materials Sciences Division, Pacific Northwest National Laboratory, Richland, WA 99352 USA

Biogeochemical iron cycling induces coupled electron transfer and atom exchange between aqueous Fe(II) and Fe(III) oxide surfaces [1-4]. Our recent work [5] has explored the molecular-scale structural transformations of hematite surfaces that result from this process. Under both acidic (pH 3) and neutral (pH 7) conditions Fe(II) induces layer-by-layer dissolution or growth of the hematite (110) and (012) surfaces. In contrast, the hematite (001) surface develops a <1 nm-thick discontinuous film that displays structural relaxations different from the underlying surface. This demonstrates that Fe(II) activates localized growth and dissolution independent of macroscopic Fe(II) adsorption.

We have further explored the effect of this process on the fate of the structurally-compatible trace element Ni. For both hematite and goethite we observe that aqueous Fe(II) induces the incorporation of adsorbed Ni into the iron oxide structure. In addition, pre-incoporated Ni is released into solution by Fe(II). The rates of release and incoporation are orders of magnitude slower than the rate of macroscopic Fe(II) adsorption but comparable to iron isotope equilibration [3]. We propose that Fe(II) catalyzes a thermodynamically-controlled redistribution of Ni among the mineral bulk, mineral surface, and aqueous solution. This work has implications for the validity of proxies for ocean composition on the early Earth and micronutrient and contaminant availability in soil, sedimentary, and aquatic systems.

Reworked Hadean crust in the ca. 3780 Ma Nuvvuagittuq supracrustal belt

N.L. CATES[1], S.J. MOJZSIS[1], K. ZIEGLER[2] AND A.K. SCHMITT[2]

[1]Dept. of Geological Sciences, University of Colorado, Boulder, CO 80309-0399 USA (cates@colorado.edu)
[2]Dept. of Earth and Space Sciences, University of California, Los Angeles, CA 90095-1567 USA

Variably deformed amphibolites and granitoid gneisses of the Nuvvuagittuq supracrustal belt (NSB) preserve lower $^{142}Nd/^{144}Nd$ ratios than the terrestrial standard. Expressed as negative $\varepsilon^{142}Nd$ values, the amphibolites also show a slight positive correlation in Sm/Nd. Combined ^{142}Nd and ^{147}Sm-^{143}Nd data were used [1] to produce a ca. 4280 Ma isochron; this could make the NSB amphibolites the oldest preserved terrestrial rocks by about 300 Myr. Alternatively, the $^{142}Nd/^{144}Nd$ signal may be inherited from crustal recycling of remnant ancient mafic lithosphere and hence it would have no bearing on the crystallization ages of the amphibolites.

Here we report U-Pb ages for detrital igneous zircons with rhythmically zoned rounded cores and later metamorphic overgrowths, extracted from NSB fuchsitic quartzites. We show that they are statistically indistinguishable from other ~ 3800 Ma zircon ages obtained for transecting felsic gneisses [2, 3]. The zircon-bearing fuchsitic quartzites show: i) Elevated whole-rock Cr (>150 ppm) contents, and rounded chromites with mantling Cr-muscovite, inconsitent with orthogneiss compositions; ii) Enriched $LREE_{CN}$ and mantle-normalized multi-element compositions inconsistent with NSB chemical sediments (BIFs), but nearly identical to quartz-biotite schists (metaconglomerates) which also host mass-independently fractionated sulfur isotopes; iii) Major and trace elements, including elevated REE, Nb and Ti contents that are neither compatible with a silicification origin of NSB amphibolites, nor with hydrothermal quartz veinings; and iv) Oxygen isotopes consonant with a sedimentary origin.

It is thus improbable that amphibolites of the NSB represent relict genuine Hadean mafic crust captured in a supracrustal belt that can be no older than 3780 Myr. Comparison of detrital and igneous zircon ages from multiple lithologies in the NSB show that its initial development took place in under 20 Myr in the Eoarchean. However, our results do underscore the notion that recycling of volumetrically significant relict Hadean mafic crust continued to play a role in Eoarchean crustal processes, in accord with data in [1].

Colloidal control on the distribution of major and trace elements in a small mountain stream (Malaval catchment, Massif Central, France)

C. CATROUILLET[1], C. DE BARDON DE SEGONZAC[1], O. POURRET[1] AND M. STEINMANN[2]

[1]HydrISE, LaSalle Beauvais, 60026 Beauvais cedex, France (olivier.pourret@lasalle-beauvais.fr)
[2]UMR 6249 Chrono-Environnement, Univ. Franche-Comté, 25030 Besançon cedex, France (marc.steinmann@univ-fcomte.fr)

Organic and/or inorganic colloids play a major role in the mobilization and speciation of trace elements in river waters. Environmental physicochemical parameters (pH, Eh, T, ionic strength…) are the controlling factors of colloidal mobilization. Ultrafiltration experiments using small ultracentrifugal filter devices were performed at different pore size cut-offs (30 kDa, 10 kDa and 3 kDa) to study the colloidal control on partitioning of major and trace elements in stream water [1]. Six sites were sampled in the Malaval stream catchment from upstream to downstream (Massif Central, France [2]) during two sampling campaigns (September 2009 and June 2010) and analyzed for major and trace elements, and organic carbon. In addition to evolution with distance, the modification of the colloidal pool by water mixing at two confluences of the Malaval stream with tributaries was also studied.

The main results of the present study are the following: most elements behave coherently through time and their speciation evolves with distance from source. Based on principal component analysis and hierarchical ascendant classification performed on the whole ultrafiltration dataset, three groups of elements with a specific chemical behavior can be distinguished: (i) a dissolved group (Na, Mg, Si, K, Ca, Rb, Sr), (ii) a reactive group (Al, Fe, Y, Pb, Cu, Ni, As, U, Zr) and (iii) an intermediate group (Co). In addition to this statistical approach one trace element of each group (Sr, Co and Nd) has been studied in more detail on ultrafiltrated sample fractions (0.2 μg/L, 30 kDa, 10 kDa and 3 kDa). The results suggest that (i) the alkalines and alkaline earths are present as dissolved species, whereas (ii) rare earth elements and some metallic elements are bound to colloidal material. However, (iii) a few elements, like cobalt, have an ambivalent behavior: in some samples they behave like the first group and in others like the second group.

Effects of Laschamp excursion on cosmogenic isotope production

A. CAUQUOIN[1]*, J. JOUZEL[1] AND G. M. RAISBECK[1,2]

[1]IPSL / LSCE, UMR CEA-CNRS-UVSQ, CEA Saclay, 91191 Gif-sur-Yvette, France
(*correspondence: alexandre.cauquoin@lsce.ipsl.fr, jean.jouzel@lsce.ipsl.fr)
[2]Centre de Spectrométrie Nucléaire et de Spectrométrie de Masse, IN2P3-CNRS-Université de Paris-Sud, Bât. 108, 91405 Orsay, France (raisbeck@csnsm.in2p3.fr)

The Laschamp excursion is a period of reduced geomagnetic field intensity occurring 40.7 ± 1.0 ky ago [3] During this period, cosmogenic isotope production was affected not only directly by the reduced magnetic field, but also due to an increased sensitivity to solar activity. The latter occurs because a larger fraction of the lower energy interstellar galactic cosmic ray particles, normally excluded by the magnetic field, is able to reach the earth's atmosphere when the geomagnetic field is reduced. The overall result is a period of increased cosmogenic isotope (^{10}Be,^{14}C) production having considerable structure.

The aim of this study is to estimate, using high resolution (decadal) profiles of ^{10}Be in ice cores from both Antarctica and Greenland as a proxy for production, input into a 10-box carbon cycle model, the expected influence of the Laschamp event on the concentration of ^{14}C in the atmosphere between 37.5 and 45.5 ky BP.

Several cases were tested, from modern carbon cycle (pre-industrial) to severely reduced surface-deep ocean exchange flux [1]. We find that the atmospheric Δ^{14}C due to increased production during this period varies from 180 to 300 ‰. This is considerably smaller than the ~500 ‰ modelled by Hoffmann *et al*. [2] between 44-41 ky, which they attribute mainly to increased production. We believe the main difference is their use of an inadequate approximation for production as a function of geomagnetic field intensity. Hoffmann *et al*. also deduced an ~500 ‰ increase in atmospheric Δ^{14}C from measurements in stalagmites. If such an increase did indeed occur, we conclude that a substantial fraction must have resulted from a redistribution of the carbon cycle.

Environmental geochemistry of nickel in stream sediments in Pernambuco State, Brazil

R. CAVALCANTE, E. A. M. LIMA, M. FRANZEN AND S. S. COSTA

CPRM - Geological Survey of Brazil
(correspondence*: rogerio.cavalcante@cprm.gov.br, enjolras.lima@cprm.gov.br; melissa.franzen@cprm.gov.br)

The studied area covers the whole Pernambuco State, where they were collected 1162 samples of stream sediments to nickel (Ni). Analyses for environmental geochemistry have been achieved by the concentration ratios of metal and the average content in Brazilian standards [1].

The drainage sediments were analyzed by ICP-MS in fractions <80 mesh. Statistical analysis of dispersion of data obtained and toxicological reference [1] provided level above which the Ni may be considered anomalous.

The study shows Ni contents below the background, and environmentally consistent with the average (18 ppm) below which is not predictable adverse effects on biota. With the exception, there are three main areas with few values exceeding the limit proposed by [1]: (i) western 40-75 ppm Ni; (ii) center 43-54 ppm Ni; e (iii) east 50-80 ppm. The above data may correspond to normal values, backgrounds rocks of the area and may not represent anthropogenic pollution.

[2]Botany and Plant Science, School of Natural Sciences, Ryan Institute, National University of Ireland Galway, Galway, Ireland.

[3]Institute of Atmospheric Sciences and Climate, National Research Council, Bologna, 20129, Italy.

Marine aerosol enrichment by biogenic organic matter (OM) has been linked to phytoplankton activity [1], thus having a strong seasonal impact on both the Earth's albedo and climate. In addition to a seasonal cycle, sea-spray generation and its enrichment with OM is a very dynamic process producing regular OM plumes over N.E. Atlantic [2]. Plankton-enriched seawater contains a complex mixture of dissolved and particulate organic carbon components (POC and DOC) producing both water soluble and insoluble organic aerosol species [3, 4]; this warrants detailed laboratory studies aimed at establishing a link between observed ambient aerosol OM and its very primary form.

Laboratory studies using the microalgal species *Emiliania huxleyi*, *Leptocylindrus danicus* and *Cylindrotheca closterium* were performed using on-line and off-line analytical techniques, a sea spray production chamber and an ageing chamber with day-light and ozone. Under controlled conditions a sea spray highly enriched in OM was produced with levels similar to Facchini *et al*. [3]. HR-ToF-AMS, ^{1}HNMR and HTDMA techniques confirmed OM composition of highly hydrocarbon-like, water insoluble OM characteristic of unsaturated lipids exhibiting low hygroscopic growth factor. Freshly produced OM, while largely insoluble, was far less oxidised (less sugars) than the OM reported by Facchini *et al*. [3]. Processing with light and ozone continued to support primary origin of ambient OM.

Mineralogy and geochemistry of zeolites of pyroclastic deposits in Northwestern of Tuzgölü Basin (Turkey)

MUAZZEZ ÇELIK KARAKAYA* AND NECATI KARAKAYA

Selçuk Universitesi Muh.-Mim. Fakültesi Jeoloji Müh. Böl. Konya, 42079, Türkiye (mzzclk@hotmail.com)

The Early Miocene volcanic rocks in the Kulu (Konya)-Haymana (Ankara) area were classified as andesitic-dacitic lavas and pyroclastics, and in some cases as trachytic and trachyandesitic. The zeolitic tuff layers are interbedded with bentonite layers and rarely silica lenses or thin layers. Plagioclase crystals, glass shards, and volcanic rock fragments altered to zeolites and smectite in tuff of the volcanic rocks. Clinoptilolite/heulandite, erionite/offlerite, analcime, and chabazite and rarely phillipsite and mordenite occur with other authigenic minerals, e.g. Fe- and Mg-rich smectite, K-feldspar. Gypsum, calcite, dolomite, and hexahydrite were also found in the some altered tuffs and clay layers. The zeolite minerals grow up as crypto- to microcrystalline aggregates after dissolved glass fragments in cavities and represent most of the matrix in the altered tuffs.

Nine K-feldspar, twelve plagioclase and sixty nine zeolite minerals were analyzed by microprobe. Zeolite analyses were made on single crystal and crystal clusters of heulandite, clinoptilolite, erionite, and chabazite. The structural formulae of the feldspar were calculated as $(Si_{2.98}Al_{1.03})(K_{0.67}Na_{0.27}Ca_{0.01})$ and $(Si_{2.67}Al_{1.31})(K_{0.05}Na_{0.60}Ca_{0.28})$, respectively, and the zeolite minerals as $[(Si_{28.7}Al_{7.3})(Mg_{1.5}Ca_{0.9}Sr_{0.1})(K_{1.0}Na_{1.3})]$, $[(Si_{29.6}Al_{6.4}Fe_{0.1})(Mg_{1.0}Ca_{1.0}Sr_{0.1})(K_{0.8}Na_{0.9})]$, $[(Si_{28.3}Al_{8.2})(Mg_{1.7}Ca_{0.3}Sr_{0.1})(K_{2.0}Na_{1.2})]$, and $(Si_{9.88}Al_{2.18}Fe_{0.01})(Mg_{0.2}Ca_{0.6}Sr_{0.03})(K_{0.3}Na_{0.17})]$, respectively. Clinoptilolites are mostly high-silica Ca-rich heulandites having intermediate composition between heulandites and clinoptilolites. Si/Al ratios of heulandites (3.70-4.20) and clinoptilolites (4.30-5.30) are similar to heulandite group minerals and their divalent/monovalent cation ratios range from 0.41 to 5.75 and 0.44 to 3.6, respectively. The structural (Na+K) content is higher than that of (Ca+Ba+Sr) in all heulandite group minerals and erionites. Mean Si/Al ratio of erionites is 3.40 and divalent/monovalent cation ratios are between 0.42 and 1.25. Zeolite minerals, e.g. analcime, chabazite, erionite, and phillipsite, and saline minerals such as gypsum, calcite, dolomite and hexahydrite were precipitated in a closed alkaline and saline environment. High proportions of alkali cations would indicate that highly alkaline pH values are likely in pore water in the tuff.

Acid gases speciation in H_2S-CO_2-Portland Cement-H_2O system

J. CENTENO

PDVSA Intevep, Los Teques, Venezuela,
(*correspondence: centenojs@pdvsa.com)

This study presents the interactions of H_2S and CO_2 with the cementitious material used in the oil wells construction to determine the speciation of these chemicals in a closed system conditions at high temperatures and pressures. Using a charge balance was possible to determine the mass of each of the species involved in the chemical balance of the system and make the corresponding mass balance. H_2S and CO_2 are aggressive agents and their action against the cementitious material is influenced by the characteristics of cement, porosity, permeability, type of hydration products, partial pressure of CO_2 and H_2S, temperature and composition of formation water, in particular is important to consider the salinity. The CO_2 attack is preferential on portlandite [Ca $(OH)_2$] present in cement and its initial impact is minimal on calcium silicates; deteriorates the outer surface of cement and migrates through the matrix affecting its internal structure. Chemical attack of samples was performed in a closed system under high temperature and pressure (ATAP), with known concentrations of CO_2 and H_2S, establishing conditions under which is progressively increased aggressiveness of the attack (approximately up to 38 atm CO_2 16 atm H_2S). Each test series includes the following time intervals: 20, 40, 80 days. The mass balance allowed calculating the concentrations of sulfide (HS^-) and bicarbonate (HCO_3^-), according to the following expressions:

$$[HS^-] = pH_2S10^{-7}\left(2[Ca^{2+}]+[Na^+]+[K^+]-2[SO_4^{2-}]\right)$$

$$[HCO_3^-] = 2[Ca^{2+}]+[Na^+]+[K^+]-[HS^-]-2[SO_4^{2-}]$$

The main conclusion suggests an inhibitory effect of CO_2 on the solubility of H_2S.

Lignin decomposition in paddy soils as affected by redox conditions

C. CERLI[1]*, Q. LIU[2], A. HANKE[1], K. KAISER[3] AND K. KALBITZ[1]

[1]Institute of Biodiversity and Ecosystem Dynamics, Earth Surface Science, University of Amsterdam, 1098 XH Amsterdam, The Netherlands (*correspondence: c.cerli@uva.nl; a.hanke@uva.nl, k.kalbitz@uva.nl)

[2]Institute of Soil Science, Chinese Academy of Sciences, 210008 Nanjing, China (qliu@issas.ac.cn)

[3]Soil Sciences, Martin Luther University Halle-Wittenberg, 06120 Halle (Saale), Germany (klaus.kaiser@landw.uni-halle.de)

In submerged soils, lignin constitutes a major portion of the total organic matter (OM) because of hampered degradation under anoxic conditions. Paddy soils management involves alternating redox cycles with periodic changes in soil solution chemistry and microbial metabolism. Such an environment might promote both degradation and preservation of lignin, affecting the overall composition and reactivity of total and dissolved OM.

We sampled two soils either subjected to cycles of anoxic (rice growing period) and oxic (harvest and growth of other crops) conditions since 700 and 2000 years. We incubated suspended Ap material, sampled from the two paddy plus two corresponding non-paddy control soils under oxic and anoxic condition, for 3 months, interrupted by a short period of three weeks (from day 21 to day 43) with reversed redox conditions. At each sampling time (day 2, 21, 42, 63, 84), we determined lignin-derived phenols (by CuO oxidation) as well as phospholipids fatty acids contents and composition. We aimed to highlight changes in lignin decomposition as related to changes in microbial community composition.

In well-established paddy soils relative short (3 weeks) changes in redox conditions had no effect on lignin decomposition or oxidation state. Also, lignin was not altered during oxic incubation. Since fungi represented only small portion of the microbial biomass in the studied soils, they were obviously not capable to cause much degradation, even under favourable conditions. On the contrary, 3 months of anoxic conditions resulted in a decrease in lignin-derived phenols. This decrease was likely not a result of degradation but of (partial) dissolution and/or pH-induced changes of the surface properties of Fe and Mn hydrous oxides causing the release of mineral-associated lignin-derived phenols. Thus, we speculate, that oxidised lignin fragments produced during the (oxic) dry period do not remain in the soils but leach with water drainage during the flooding period.

Model calculations of scale forming minerals of high enthalpy geothermal waters in Turkey

ZIYA CETINER[1] AND YONGLIANG XIONG[2]

[1]Canakkale 18 Mart University, Department of Geological Engineering, 17010, Canakkale, Turkey (ziyac@comu.edu.tr)
[2]1404 North Country Club Circle, Carlsbad, New Mexico, USA (yongliangxiong@yahoo.com)

Located on the active Alpine-Himalayan Orogenic Belt, Turkey's geological and neo-tectonic evolution had been dominated with active faults and volcanisms which are the leading causes of substantial geothermal resources. Such resources are widespread throughout the country and are indentified with three distinctive geothermal regions based on their tectonic settings. Of which, high enthalpy resources, suitable for geothermal power production, are mainly located in the western part of the country along the major graben and associated fault systems. These include Denizli-Kızıldere (242°C), Aydın-Germencik (232°C), Manisa-Kavaklıdere (213°C), Aydın-Pamukören (187°C), Canakkale-Tuzla (175°C), Aydın-Salvatlı (171°C) and Kütahya-Simav (162°C) [1]. Low and moderate enthalpy sources exist in the Middle and Eastern Turkey along North Anatolian Fault Zone because of volcanism and fault formations.

The total geothermal potential in Turkey is estimated to be about 31,500 MWt. Most of the geothermal development in Turkey has been initiated by MTA (General Directorate of Mineral Research and Exploration of) since 1962. A law allowing geothermal sources discovered by the MTA to be used by commercial organizations was introduced in 2007. Moreover, legislation concerning renewable energy was brought in at the end of 2010. These new laws have led to increased efforts to explore profitable geothermal electricity and to use the heat directly.

In this study, geochemistry of the medium to high enthalpy geothermal waters suitable for electrical energy production has been critically reviewed and the solubilities of potential scale-forming minerals including silica polymorphs and carbonates at various temperatures have been calculated by using EQ3/6, for determining the optimum operation conditions in power generation.

Geochemical tracing of water-rock interactions in the Ringelbach granitic research catchment (Vosges, France)

F. CHABAUX , T. SCHAFFHAUSER, B. FRITZ, B. AMBROISE AND P. STILLE

LHYGES, Université de Strasbourg/EOST, CNRS, France (fchabaux@unistra.fr)

For constraining the nature of water-rock interactions occuring within granitic watersheds a geochemical and isotopic (Sr, U) study of all springs within the Ringelbach granitic research catchment (Vosges, France) has been undertaken, following the approach classically developped in the Lab [1]. This study also includes the analysis of water samples collected in two 150-m deep boreholes, which permit the evaluation of (a) water flux and composition in the deeper part of the watershed and (b) deep weathering processes within the granitic bedrock. At the scale of a single spring, important geochemical variations are observed over the year. Such variations cannot be accounted for by a simple mixing scenario of rainwater contributing in variable quantities to the chemical composition of these waters. For each considered spring, the geochemical variations have to be interpreted as the contribution of two different weathering fluxes with changing intensities over the hydrological cycle. At the scale of a same slope a systematic geochemical variation of the spring waters is observed according to their emercgence altitude along this slope. These chemical changes affect both the elementary and U activity ratios but not the Sr isotope ratios. This indicates that geochemical variations are not simply controlled by mixing processes between waters having interacted with different lithologies. Furthermore, geochemical variations observed in subsuface waters (springs) cannot be explained by a contribution of deep waters (boreholes). All together these data suggest that the main parameter explaining geochemical variations of water samples collected within the Ringelbach catchment is the water pathway of the waters within the watershed. Modeling approaches confirm and constrain the importance of this parameter in the control of geochemical characteristics of surface waters (Schaffhauser *et al*., this issue).

Biogeochemical characterization of Mercury (Hg)-contaminated sediments at the Bunikasih Gold mine, West Java Province, Indonesia

SITI KHODIJAH CHAERUN[1,2]*, SAKINAH HASNI[1], EDY SANWANI[3] AND D. BARRIE JOHNSON[4]

[1]Laboratory of Mining Biotechnology and Enironmental Bioengineering, School of Lifesciences and Technology, Institut Teknologi Bandung, Ganesha 10, Bandung 40132, West Java, Indonesia (*correspondence: skchaerun@gmail.com)
[2]Centre for Life Sciences, Institut Teknologi Bandung
[3]Department of Metallurgical Engineering, Faculty of Mining and Petroleum Engineering, Institut Teknologi Bandung
[4]School of Biological Sciences, Bangor University, UK

The objective of this study was to investigate the biogeochemical characteristics of mercury (Hg)-contaminated sediments at the Bunikasih Gold Mine, West Java Province, Indonesia in order to provide a basic and initial description of biogeochemically sediments at this contaminated site for bioremediation purposes. Sediments contained elevated total Hg concentrations of 28 – 61 ppm. XRD analysis revealed the presence of quartz and berlinite minerals, indicating that mercury contained in sediments was not in mineral form of mercury but in other form. SEM-EDS analysis indicated the presence of Si (30 – 44%), Al (0.6 – 8%), O (45 – 51%), and C (3.5 – 7%). Ten heterotrophic bacteria that were resistant to $HgCl_2$ (25 ~ 550 ppm) were isolated from the Hg-contaminated sediments. 16S rRNA gene sequence analysis identified the bacteria as strains of *Pseudomonas koreensis*, *Pseudomonas putida*, *Pseudomonas fulva, Stenotrophomonas maltophilia* and *Aeromonas sobria*.

The findings of this study provide evidence of heterotrophic bacteria associated with Hg-contaminated sediments as well as provide the first information of phylogenetically-diverse Hg-resistant bacteria in the Hg-polluted sites of Indonesia. Such information may prove highly useful for developing in situ bioremediation of Hg-contaminated sites in Indonesia.

Interactions of Eu(III) and Cm(III) with celestite and strontianite: Precipitation kinetics and uptake mechanisms characterisation

A. CHAGNEAU[1,2], K. HOLLIDAY[1], M. SCHMIDT[1], T. STUMPF[1] AND T. SCHÄFER[1,2]

[1]Karlsruhe Institute of Technology (KIT), Institute for Nuclear Waste Disposal (INE), D-76344 Eggenstein-Leopoldshafen, Karlsruhe, Germany
[2] Freie Universität Berlin, Institute of Geological Sciences, Hydrogeology Group, 12249 Berlin, Germany

The present work focuses on the characterization of lanthanides and actinides interactions with celestite ($SrSO_4$) and strontianite ($SrCO_3$). Precipitation kinetics studies of the minerals were performed in batch type and mixed-flow reactors experiments, in presence and absence of Eu(III) and Cm(III) in solution. It is shown that the presence of Eu(III) and Cm(III) as trace elements (up to 4.5×10^{-4} mol L^{-1}) have no effect on the precipitation rates, which are dependant on the initial saturation index.

TRLFS analyses shown a clear incorporation of the Eu(III) and Cm(III) into the mineral structures, with a minor surface component for the strontium sulfate. Similar studies were earlier performed on aragonite, calcite ($CaCO_3$) and gypsum ($CaSO_4$) in the same experimental conditions. Incorporation was observed for aragonite and only surface complexation for the calcium sulfate, while both mechanisms were observed for calcite. Therefore, the ligand strength was expected to play an important role in the uptake mechanisms. The present work focused on two minerals isostructural with aragonite, demonstrating the importance of the lattice parameters in the uptake mechanisms as well. Moreover, the presence of Eu(III) and Cm(III) as incorporated species has no effect on these lattice parameters.

The Eu(III) and Cm(III) affinity coefficients for the $SrSO_4$ and $SrCO_3$ structure as well as the strontianite and celestite precipitation rates as a function of the oversaturation (SI) were determined. This information is prerequisite to develop a reactive transport model able to predict the behavior of these elements in a porous media under chemical perturbation.

Enhanced growth of *Acidovorax delafieldii* 2AN during nitrate-dependent Fe(II) oxidation in continuous-flow systems

A. CHAKRABORTY[1], J. SCHIEBER[2], E.E. RODEN[3] AND F.W. PICARDAL[1]*

[1]School of Public and Environmental Affairs, Indiana University, Bloomington, IN 47405 USA (*correspondence: picardal@indiana.edu)
[2]Department of Geological Sciences, Indiana University, Bloomington, IN 47405 USA
[3]Department of Geology and Geophysics, University of Wisconsin, Madison, WI 53706 USA

It is not clear if microbial, NO_3^- -dependent, Fe(II) oxidation (NDFO) is energetically beneficial to cells or if it is primarily a fortuitous, side-reaction, involving both abiotic and enzymatic reactions during heterotrophic growth. Although recent batch experiments by others have suggested that NDFO may provide an energetic benefit through a mixotrophic physiology, it is not known if long-term growth yields can be enhanced by Fe(II) oxidation, and if this enhancement can be realized at environmentally relevant Fe^{2+}, NO_3^-, and organic C concentrations. *Acidovorax delafieldii* 2AN was incubated anoxically in batch reactors using a bicarbonate-buffered, artificial groundwater medium containing 5-6 mM nitrate, 8-9 mM Fe(II) and 1.5 mM acetate. A novel, continuous-flow culture system was also used to evaluate growth on low concentrations of substrates, e.g. 100 μM nitrate, 20 μM acetate and 50-250 μM Fe(II).

In batch reactors, almost 90% of the Fe(II) was oxidized with concomitant reduction of NO_3^- and complete consumption of acetate. However, cells became encrusted with Fe(III) (oxy)-hydroxides, lost motility and formed aggregates. Encrusted cells could neither oxidize more Fe(II) nor utilize further additions of acetate. In batch experiments using chelated iron [Fe(II)-EDTA], aggregated and encrusted cells were not produced and further additions of acetate and Fe(II) could be oxidized. This suggests that the cell encrustations prevent substrate entry into the cell or otherwise render cells physiologically inactive. In the continuous-flow system, the growth yield of *A. delafieldii* 2AN was always greater in the presence of Fe(II) than in its absence and ESEM examination showed that encrustation was minimized. This suggests that cell encrustations may be an artifact of the high concentrations of Fe(II) and NO_3^- used in batch cultures. Our results provide evidence that, under environmentally relevant concentrations of Fe(II) and NO_3^- , NDFO can enhance growth without the formation of cell encrustations that may limit viability in batch culture.

Kimberlites, flood basalts and mantle plumes: New insights from the Deccan Large Igneous Province

N.V. CHALAPATHI RAO[1,2]* AND B. LEHMANN[2]

[1]Centre of Advanced Study in Geology, Banaras Hindu University, Varanasi-221005, India (*correspondence: nvcr100@gmail.com)
[2]Mineral Resources, Technical University of Clausthal, Adolph-Römer-Straße 2A, 38678 Clausthal-Zellerfeld, Germany (lehmann@min.tu-clausthal.de)

A temporal and spatial relationship between small-volume, volatile-rich and highly potassic continental melt fractions, such as kimberlites and related rocks, and large-volume continental flood basalts exists in several Large Igneous Provinces (LIPs). Many of these LIPs are also widely regarded as products of mantle plume-lithosphere interactions. The small-volume melts either immediately pre-date or post-date or even are co-eval with the main flood basalt event. The overlap of ages between the flood basalts and the kimberlites very likely reflects a cause and effect relationship via mantle plumes.

Recently discovered end-Cretaceous diamondiferous kimberlites (orangeites) in the Bastar craton of central India which are synchronous with the flood basalts, carbonatites, lamprophyres and alkaline rocks of the Deccan LIP provide an opportunity to re-evaluate the role of mantle plume-lithosphere interactions in the generation of these disparate magmas. The geographical zonation of the kimberlite-lamprophyre-carbonatite-alkaline rock spectrum in the Deccan LIP is inferred to reflect variable thickness of the pre-Deccan Indian lithosphere with a thinner lithosphere along the known rift zones of northwestern and western India and a thickened lithosphere underlying the Bastar craton of central India. This heterogeneity is thought to have controlled the volume of melt generation and melt ascent, as well as the ultimate alkaline magma type.

These findings are supported by the regional lithospheric thickness map, generated from converting seismic shear wave velocities into temperature profiles, which depicts that the present-day lithosphere beneath the Bastar craton is thicker than that in western and NW India where the centre of the Deccan plume-head was located. Thermal weakening of the sub-Bastar craton due to mantle plume-lithosphere interaction at the end-Cretaceous resulting in a thin-spot is suggested to have controlled the Deccan-related mafic dyke emplacement in the Bastar craton

A new *Gallionellales* isolate: A model system for comparative studies of Fe-oxidizer physiology and biomineralization

CLARA S. CHAN*, SEAN T. KREPSKI AND GAURAV SAINI

Dept. of Geological Sciences, University of Delaware, Newark, DE 19716 (*correspondence: cschan@udel.edu)

The Fe-depositing bacterium *Gallionella ferruginea* was first described in the early 19th century based in part on its twisted ribbon-like stalk, which has since been widely used in its identification. In 1993, Hallbeck *et al*. [1] reported the 16S rRNA sequence of a stalk-forming isolate. Recently, researchers have isolated several Fe-oxidizing bacteria (FeOB) related to *Gallionella*; however, none produce biomineral structures that typically comprise Fe microbial mats, so we have made relatively little progress characterizing and linking FeOB physiology, biomineralization, and mat formation. Towards these goals, we have isolated a novel stalk-forming FeOB, strain R-1, from a freshwater Fe seep in Delaware, USA. R-1 is a neutrophilic, obligate Fe-oxidizing Betaproteobacterium. Despite strong morphological similarity to *G. ferruginea* [1], this isolate shares only 93.6% 16S rRNA gene sequence similarity. It is more similar (94.0-94.4%) to *Sideroxydans* isolates [2,3], which do not produce morphologically-distinct minerals. Its phylogenetic distance from other *Gallionellales*, especially its distance from *G. ferruginea* shows the high diversity of FeOB in this order.

R-1 is remarkably similar to the marine Zetaproteobacterial Fe-oxidizer *Mariprofundus ferrooxydans* PV-1, presenting an opportunity for comparative study. Both organisms are obligate FeOB isolated from Fe mats. R-1 oxidizes ~1-2x10^{-14} mol Fe/cell, comparable to PV-1 (0.9x10^{-14} mol Fe/cell). Like PV-1, R-1 cells are relatively Fe-free, with a fibrillar, ribbon-like Fe and polysaccharide-rich stalk, binding multiple lectins. We postulate that the R-1 stalk plays similar roles to that of PV-1, especially as a mechanism for removing Fe(III) waste from the cell [4]. TEM studies have shown that cell surface structure differs from PV-1, which may imply different surface chemistry. We have been investigating surface characteristics by atomic force microscopy, electrophoretic mobility, hydrophobicity tests, and probing by charged nanoparticles. Results to date suggest that both R-1 and PV-1 surfaces have near-neutral charge, which helps explain how cells avoid encrustation.

Evaluation of relationships used to model sea surface iodide concentrations

R.J. CHANCE[1]*, A.R. BAKER[1], L.J. CARPENTER[2] AND T. JICKELLS[1]

[1]School of Environmental Sciences, University of East Anglia, UK (*correspondence: r.chance@uea.ac.uk)

[2]Department of Chemistry, University of York, YO10 5DD, UK

Sea-to-air exchange supplies reactive iodine to the atmosphere, where it contributes to tropospheric ozone depletion and particle formation, and allows the dispersal of radioactive iodine discharges. A major contributor to this process is the reaction of ozone with iodide at the air-sea interface. Sea surface iodide concentrations range from 5 to 200 nM, varying with latitude and proximity to the coast; the controls on this distribution are not well understood. Recent attempts to quantify the contribution of the ozone–iodide reaction to large scale ozone deposition [1,2] have modelled sea surface iodide concentrations using observed relationships between iodide and nitrate [3] or chlorophyll [4].

Here, we present new iodide measurements from the tropical eastern Atlantic and the Southern Ocean, incorporate these into a preliminary global surface iodide climatology and use this to evaluate the two different modelling approaches. We find that neither model was able to fully explain the observed global iodide distribution. We propose the compilation of a global iodide climatology which can be used to rigorously test models and new hypotheses concerning the marine biogeochemical cycle of iodine. If spatial resolution is sufficient, such a database might also be used directly in modelling studies.

Carcass Island: A new site for the observation of Southern South American dust in the western Falkland Islands

R.J. CHANCE AND A.R. BAKER*

School of Environmental Sciences, University of East Anglia, UK (*correspondence: alex.baker@uea.ac.uk)

Dust originating in Southern South America (SSA) is probably the largest source of mineral matter and its associated trace elements to the remote South Atlantic and Atlantic sector of the Southern Ocean. Antarctic ice core records show very large variations in dust supply over glacial – interglacial timescales, which may be related to changes in atmospheric pCO_2 and temperature proxies.

Our understanding of the current strength and transport of SSA dust sources is very poor however, partly because persistent cloud cover makes remote sensing observations in the region difficult, but also due to a lack of observations of surface level dust concentrations along transport pathways.

In September 2010 we established a new site for the collection of SSA dust on Carcass Island (51°15'S, 60°35'W) in the western Falkland Islands, as part of the UK contribution to the GEOTRACES programme. Weekly aerosol samples were collected at the site between September 2010 and April 2011, using a high-volume sampler under the control of a wind sector monitor ("clean" sector 220-310 degrees, relative to true north). The collector was mounted at the top of a short (~3m) aluminium scaffolding tower near the crest of a small ridge approximately 400m from the shore. The nearest settlement is >3km downwind of the site. During site visits rain samples were also collected either at the aerosol site or settlement.

Samples will be analysed for their soluble and total trace metal content and major ions (including macronutrient) chemistry. We intend to operate the site in future years.

This contribution will describe the Carcass Island site in detail and we hope to be able to present preliminary results from the first year of sampling.

High-pressure Mössbauer Spectroscopic study of Lohawat (Howardite) meteorite up to 9GPa

USHA CHANDRA[1], POOJA SHARMA[1] AND G.PARTHASARATHY[2]

[1]High Pressure Physics Lab., Department of Physics, University of Rajasthan,Jaipur 302055 ; (chandrausha@hotmail.com)

[2]National GeoPhysical Research Institute(CSIR), Uppal Road, Hyderabad 500606 (gpsarathy@ngri.res.in)

The effect of high-pressure on Lohawat(Howardite) Meteorite which fell at Lohawat village in Jodhpur was studied using Mössbauer spectroscopic technique with diamond anvil cell and 4:1 methanol:ethanol mixture as hydrostatic pressure medium[1]. The main minerals detected in the meteorite were orthopyroxenes and plagioclase with little amount of olivine. Ambient Mössbauer study showed ferrosilite with Fe^{2+} in two inequivalent octahedral sites M1 and M2 [2]. Both the sites behave differently under pressure.At 2.8 GPa, a sudden decrease in Mössbauer parameters (quadrupole splitting and isomer shift) indicate transformation of high spin Fe^{2+} to low spin configuration. The trend of decrement continues up to 5.6 GPa where isomer shift reaches a low of -0.14 mm/s . Further increase in pressure reverses the trend and at 8.4 GPa the value becomes +0.05mm/s. The observation of low spin Fe^{2+} configuration in pyroxene is unusual , not observed in terrestrial samples. Such a behaviour resembles post-peovskite character which occurs at ~ 120 GPa [3]. The presence of low spin Fe^{2+} phase at low pressure of ~ 2GPa indicates the defects generated in the system under shock impact. The results thus obtained are also supported by high pressure electrical resistivity measurements.

We acknowledge CSIR, New Delhi; PLANEX (ISRO), Ahmedabad for Financial support and Prof. R.P.Tripathi for providing the meteorite sample.

Phosphorus in olivine from Italian potassium-rich lavas

S.R. CHANEVA*, I.K. NIKOGOSIAN, M.J. VAN BERGEN AND P.R.D. MASON

Department of Earth Sciences, Utrecht University, the Netherlands
(*correspondence: simonachaneva@gmail.com; iniki@geo.uu.nl; vbergen@geo.uu.nl; mason@geo.uu.nl)

Phosphorus in igneous olivine is promising as a petrogenetic proxy and as a sensitive indicator of crystal growth histories [1,2]. To explore its applicability in solving outstanding issues concerning Italian K-rich magmatism, we analyzed a collection of well characterized forsterite-rich olivines, along with their Mg-rich melt inclusions (MI) for P contents. The wide compositional range of the basaltic samples (from high to low-K) and the regional coverage of volcanic centres (between the Roman Province and Vulture) enabled us to detect variations in magmagenetic conditions that control the behaviour of phosphorus.

Phosphorus concentrations in the olivines were determined by EPMA (15kV, 100nA, extended counting times) and by LA-ICPMS, along with standard major and trace element analyses that included homogenized MI. Intra-crystal variations were explored in rim-to-rim traverses by EPMA, following a procedure optimized for P. Detection limits were 40±20 ppm for both techniques, based on the analyses of a series of reference materials. The measured olivines cover an overall range in P between 40 and 230 ppm, despite their consistent forsterite-rich nature (Fo>87). The olivines from the medium to low-K series (M-LKS) contain less P (<70 ppm, except for Campi Flegrei where <230ppm was found) than those from the high-K series (HKS) which reach a maximum of 130 ppm. Corresponding MI from M-LKS and HKS samples contain up to 0.7 and 1.9 wt.% P_2O_5, respectively.

The P contents in olivine tend to increase with K_2O and P_2O_5 contents in the melt, and show regional systematics, suggesting that they signal variations in mantle source composition and/or mode of melt extraction. On the other hand, some M-LKS melts with similar P contents crystallized olivines with significantly different contents, indicating that P in the melt may not be the only control of uptake by olivines. Additional factors to be considered include growth rate [1] and coupled substitutions (e.g., with Al, Cr, Ti). Also, profiles in selected olivines show P depleted zones around MI, which questions the supposed immobility of P in olivine.

Atmospheric CO_2 levels have fluctuated greatly during the Phanerozoic [1]. Although many organic and inorganic factors affected atmospheric CO_2 levels, plants have played an important role in CO_2 fluctuations. Recently, most paleobotanists accept an Early Cretaceous origin for angiosperms and support that angiosperms underwent a rapid ecological radiation in middle-late Cretaceous [2]. Because high concentrations of Cretaceous atmospheric CO_2 underwent a long-term decline, several hypotheses suggested that the origin and radiation of angiosperms and atmospheric CO_2 levels are closely related [3].

The recent discovery of *Schmeissneria* from the middle part of the Jurassic Haifanggou Formation provided evidence that the origin of angiosperms could predate the Early Cretaceous [4]. Because previously reported ages for the Haifanggou Formation are scattered and the uncertainties of these ages were fairly large, our on-going work aims to establish high-precision $^{40}Ar/^{39}Ar$ ages for volcanic ashes from the Haifanggou Formation.

Our preliminary results indicate that *Schmeissneria* is older than 160 Ma. The age results will provide a robust geochronological calibration for the oldest angiosperm and will improve our knowledge of the link between atmospheric CO_2 and the rise and the radiation of angiosperms.

[2]Guangzhou Institute of Geochemistry, Chinese Academy of Science, Guangzhou 510640, Guangdong China;

Products of designations of origin was used to describe a product originating in that specific place, region, or country, if the quality or characteristics of which were essentially or exclusively due to a particular elements geochemical factors, and the production, processing and preparation of which took place in the defined specific place, region, or country [1-3].

Select products of designations of origin Kaempferia Galangal from YangChun, Guangdong Province, China. The plants and soil profile samples were collected and the element content, element speciation, and lead isotope ratio were determined. Through the multivariate statistical analysis to ascertain the characteristic elements and multielement group, and provide evidence for establishing the elements- isotope fingerprints of product identification system. Fourteen trace elements in soil and galangal samples were measured to explore the feasibility of characteristic elements as the fingerprinting marker of products of origin. The results showed that there was a significant correlation between the contents of trace elements in soil and galangal. Trace elements yield a good inheritance between soil and galangal. Mg, Mn, Zn, Sb, Fe, Cu and Sr were the characteristic elements of Galangal by weight analysis. The geochemical tracer method could be used in research the effect of regional geochemical background on the products of origin.

Lead isotope ratios analysis result showed that the sources of lead in the soil profile and Galangal was very stable, lead isotope ratios of Galangal was very close to the distribution characteristics of soil region. $^{206}Pb/^{208}Pb$ -$^{206}Pb/^{207}Pb$ showed significant correlation further proves the product with soil were homology. Lead isotope could be used as the criterion of fingerprint identification of products of designations of origin.

Weathering fluxes from time series sampling of the Irrawaddy and Salween Rivers

HAZEL CHAPMAN[1]*, MIKE BICKLE [1], SAN HLA THAW[2] AND HRIN NEI THIAM[2]

[1]Earth Sciences, University of Cambridge, Downing St. Cambridge CB2 3EQ, UK (*hjc1000@cam.ac.uk)

[2]Department of Meteorology & Hydrology, 50 Kaba-Aye Pogoda Rd, Mayangon 11061, Yangon, Myanmar

The Irrawaddy and Salween rivers in Myanmar Burma have water fluxes ~70% of the Ganges-Brahmaputra river system. Together these systems are thought to deliver about half the dissolved load from the tectonically active Himalayan-Tibetan orogen [1]. Previously very little data was available on the dissolved load and isotopic compositions of these rivers.

Here we present time series data of 171 samples collected fortnightly at intervals throughout 2005 to 2007 from the Irrawaddy and Salween at locations near the river mouths, the Irrawaddy at Myitkyina, the Chindwin, a major tributary of the Irrawaddy and a set of 28 small tributaries which rise in the flood plain of the Irrawaddy between Yangon and Mandalay. The samples have been analysed for major cation, anion, Sr and $^{87}Sr/^{86}Sr$ ratios. The new data indicates that the Irrawaddy has an average Na concentration only a third of the widely quoted single published analysis [2].

The catchment of the Salween extends across the Shan Plateau in Myanmar through the Eastern syntaxis of the Himalayas and into Tibet. The Irrawaddy flows over the Cretaceous and Tertiary magmatic and metamorphic rocks exposed along the western margin of the Shan Plateau and the Cretaceous to Neogene Indo-Burma ranges. The chemistry of the waters reflects these differences with the $^{87}Sr/^{86}Sr$ compositions of the Salween and Upper Irrawaddy (between 0.713 and 0.718) significantly higher than the downstream Irrawaddy (0.709 to 0.711) and the Chindwin (0.708 to 0.710). The Irrawaddy and the Chindwin exhibit lower $^{87}Sr/^{86}Sr$ and Na/Ca ratios during and immediately post-monsoon, interpreted to reflect higher weathering of carbonate at high flow (c.f. [3]). The Salween exhibits higher $^{87}Sr/^{86}Sr$ ratios but lower Na/Ca ratios during the monsoon, interpreted to reflect higher inputs from the upper parts of the catchment in the Himalayas.

Complexation studies of EDTA with ^{99}Tc analogue rhenium

PAUL M. CHAPMAN, CLAIRE L. CORKHILL AND MARÍA ROMERO-GONZÁLEZ

Cell-Mineral Research Centre, Kroto Research Institute, The University of Sheffield, S3 7HQ, UK
(*correspondence: pmchapman2@sheffield.ac.uk)

Technetium-99 (^{99}Tc) is one of the important waste products formed during the nuclear fuel cycle. In oxidising conditions, ^{99}Tc exists as the highly mobile pertechnetate anion ($Tc(VII)O_4^-$), which has widespread environmental implications. When present in anoxic environments and in the presence of reducing species, it is expected that an insoluble solid oxide, $Tc(IV)O_2$, will form. Complexation of Tc(IV) with man-made and naturally occurring ligands is expected to increase environmental mobility.

The purpose of this investigation was to use a novel technique, Raman spectroscopy, to determine the complexation of rhenium, a non-radioactive analogue for ^{99}Tc, with ethylenediaminetetraacetic acid (EDTA) under oxic and anoxic conditions. EDTA is a common nuclear waste co-contaminant and has functional groups representative of much larger natural organic molecules.

In oxic and anoxic conditions, perrhenate ($Re(VII)O_4^-$) and EDTA were combined with HCl to attain pH values of 3.7, 6.5 and 10.3. Raman spectroscopy showed that the EDTA and perrhenate remained unchanged (e.g. 971cm^{-1} peak characteristic of the Re-O bond in a perrhenate anion was observed) at all pH values, indicating that no complexation had occurred.

Under highly acidic (pH 0.6) and anoxic conditions, *in situ* reduction of Re(VII) in the presence of EDTA resulted in an orange-yellow colour solution and a UV-VIS peak at 450nm, indicative of the formation of a Re(IV)-complex. Changes in the Raman spectrum of this solution also indicated complexation shifts of a CN stretch (to 1112cm^{-1}) and a COO^- vibration (to 1332cm^{-1}). Other Raman bands of the Re-EDTA complexes were also investigated for complexation shifts and binding mode information.

It has been shown that rhenium complexes to EDTA by *in situ* ligand reduction under very low pH conditions. Binding through the carboxylate and nitrogen groups of a tetradentate EDTA ligand to a mono-oxorhenium core is proposed. It is hypothesised that ^{99}Tc could complex under less harsh conditions in presence of ligands, which would prevent the formation of the precipitate $Tc(IV)O_2$ and hence increase the environmental mobility of ^{99}Tc.

H_2-rich fluids issued from the Kulo Lasi volcano, a new active hydrothermal field recently discovered in the South-West Pacific

J.L. CHARLOU*, J.P. DONVAL, C. KONN, V. GUYADER, Y. FOUQUET AND THE SCIENTIFIC PARTIES

Ifremer c/Brest, Laboratoire de Géochimie et Métallogénie, BP70, 29280, Plouzané
(*correspondance: charlou@ifremer.fr)

A lot of Back-arc basins (Fidji, Lau, Manus,…) investigated in the last 20 years revealed an intense hydrothermal activity. A new active vent field was recently discovered off-shore the Futuna island in an unexplored area during a French cruise (September 2010) from hydrothermal anomalies detected in the seawater column. High-temperature fluids were collected by the submersible Nautile from active vents located on a volcano (Kulo Lasi caldeira). The fluids exhibit temperatures of 343°C, pH of 2.36, low H_2S content (1-3 mM), variability in chlorinity (485 to 735 mM) and are enriched in Mg and SO_4. Mixing lines of elements vs Mg clearly reveal three types of fluids, all controlled by phase separation. Mg and SO_4 data in fluids also show a magmatic influence. Silica measurements show that the reaction zone is at a relatively low depth (~700 m). The fluids are poor in H_2S and CH_4 but enriched in CO_2 and H_2 and also contain a lot of organic compounds (see Konn *et al*., this meeting). The enrichment in CO_2 is explained by magmatic degassing from arc-magmas very rich in CO_2 compared to ridge-magmas, as previously shown in many active sites in back-arc basins. The generation of H_2 is explained by cristallization of the ascending magmatic basalt and by interaction of hot lava with seawater possible during the hydrothermal circulation. The Kulo Lasi fluids are compared to other fluids previously studied in various back-arc basins.

Oxygen dynamic in the Eastern South Pacific OMZ

JOSE CHARPENTIER[1]* AND OSCAR PIZARRO[2]

[1]Oceanographic center for the Eastern-South Pacific, COPAS, University of Concepción, Casilla 160-C, Concepcion, Chile (*correspondence: jcharpentier@profc.udec.cl)
[2]Department of Geophysics, Faculty of Physical and Mathematical Sciences, University of Concepción, Casilla 160-C, Concepcion, Chile (orpa@profc.udec.cl)

The eastern South Pacific holds one of the largest and most intense oxygen minimum zones (OMZ) of the world. This region also sustains a very high productivity and a unique ecosystem constrained by low oxygen concentration. To analyze the temporal evolution of the OMZ and relevant processes related to its biogeochemistry a monthly, ship-based, oceanographic time series have been maintained over the continental shelf off central Chile (~36.5º S) since 2002 [1]. During the last 2 years moored instruments have been added to this initiative including an ADCP to measure currents in the water column, and sensors of temperature and oxygen. Additionally several oceanic glider sections have been carried out along the same region.

Dissolved oxygen over the continental shelf is very low (typically lees than 0.5 mL L^{-1}) immediately below the mixing layer. Its temporal variability shows a marked seasonal pattern, mainly driven by upwelling events that predominate during austral spring-summer. The mechanism by which upwelling drives mid-water anoxia is not well known, but is greatly related to the supply of fresh nutrients to the photic zone, and to the advection of low-oxygen water from the north. Winter oxygen concentrations are usually larger in the water column and are related to downwelling events and to the increasing of fresh water discharge. These phenomena related to the dissolved oxygen variability off central Chile are discussed in this work based on observational evidences.

Data from moored instruments shows an interesting pattern that suggests upwelling (and downwelling) events affect oxygen concentration in "pulses" that occur in a temporal scale of days. Oxygen budget for the upper and lower layer of the water column shows that biological oxygen production in the mixed layer during spring-summer is almost equilibrated by biological oxygen consumption. Preliminary modeling results of the oxygen dynamics are also discussed.

What real constraints do cherts bring on precambrian surface temperatures?

MARC CHAUSSIDON[1] , PHILIPPE LACH[2], FRANCOIS ROBERT[3], MARIE CHRISTINE BOIRON[3] AND BEATRICE LUAIS[1]

[1]CRPG-CNRS, Nancy Université, BP 20, 54501 Vandoeuvre-lès-Nancy, France (*correspondence: chocho@crpg.cnrs-nancy.fr).

[3]G2R-CNRS, Nancy Université, Boulevard des Aiguillettes, B.P. 70239, 54506 Vandoeuvre-lès-Nancy, France

The extent of surface temperature change during the Precambrian is one of the key questions for the evolution of the Earth and the development of life. Solar physics dictates that the luminosity of the Sun was 25-30‰ lower than today in the early archean [1, 2]. Archean surface temperatures above the freezing point of water, as indicated by marine sediments of that age, were likely the result of enhanced concentration of greenhouse gases and/or decrease in Earth albedo or both [3, 4]. The low $\delta^{18}O$ values discovered in archean cherts of presumably marine sedimentary origin can be interpreted as reflecting very high surface temperatures 55-85°C during this period [5 and refs therein]. Contradictory lower temperatures have been infered from cherts and from thermodynamic stability fields of other minerals [6, 4]. Studies of Si isotopic compositions of cherts [7] and of micrometer scale distribution of $\delta^{18}O$ and $\delta^{30}Si$ values [8] allow to add independant constraints on seawater temperature and to define quantitative criteria to assess the origin of cherts (sedimentary or not) and the preservation of their isotopic signature. In addition it allows to propose a way to correct the inferred seawater temperature from isotopic fractionation taking place during the formation of chert upon diagenesis. Germanium concentrations (the partitioning of Ge between quartz and fluid is temperature dependant) in precambrian cherts show a range from ≈ 0.1 to ≈10 ppm (this study) which adds potentially another dimension to constrain the silica cycle and seawater temperatures in the precambrian.

Ion microprobe high precision measurements of oxygen and magnesium isotopic compositions in extraterrestrial materials

MARC CHAUSSIDON AND CLAIRE ROLLION-BARD

CRPG-CNRS, Nancy Université, BP 20, 54501 Vandoeuvre-lès-Nancy, France
(*correspondence: chocho@crpg.cnrs-nancy.fr).

Two key isotope systems in cosmochemistry are oxygen isotopes (non mass dependent oxygen isotope variations, i.e. $\Delta^{17}O$, are ubiquitous in meteorites, especially in the high temperature components of chondrites) and Mg isotopes (^{26}Mg radiogenic excesses, i.e. $\delta^{26}Mg^*$, are due to the *in situ* decay of short-lived ^{26}Al with a half life of 0.73 Myr). Because of the presence of Al/Mg variations and of mineralogical variations in chondrites at the micrometer scale, ion microprobe is the only technique which offers the appropriate spatial resolution to unravel the $\Delta^{17}O$ and $\delta^{26}Mg^*$ systematic.

Recent developments using multicollectors ims 1270 and ims 1280 HR2 large radius Cameca ion microprobes allow to reach a precision (2 sigma error) better than 0.01 ‰ for $\delta^{26}Mg^*$ and better than 0.04‰ for $\Delta^{17}O$, for sputtered volumes of 20μm diameter and less than 1μm depth (in Mg-rich silicates and oxides).

Such high precisions transform the "traditional" O and Mg isotopes into "new" isotopic systems in meteorites. In the case of ^{26}Al for instance, the homogeneity of the distribution of ^{26}Al (which is a prerequisite to its use as a precise chronometer) can be quantified for the first time by comparing chondrules to the solar system Mg isotopic growth curve [1]. ^{26}Al model ages can be calculated in chondrules or in Al-free phases from their Mg isotopic composition [2]. These model ages in Mg-rich olivines from type I chondrules can be compared to high precision $\Delta^{17}O$ values to identify the origin of the olivines and to test whether they could be fragments of the mantles of planetesimals which differentiated very early in the disk [3].

Average Nd-Hf isotopic compositions and model age of the upper continental crust

C. CHAUVEL[1], M. GARCON[1], N.T. ARNDT[1], S. GALLET[2] AND B.M. JAHN[2]

[1]ISTerre, BP 53, 38041 Grenoble Cedex 9, France
[2]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan

Establishing the average chemical and isotopic composition of the upper continental crust as well as its model age is difficult due to the diversity in compositions and ages of this major Earth reservoir. Estimates exist for major and trace elements as well as for some isotopic systems, but not for the Nd-Hf isotopic couple. In 1999, Vervoort *et al.* [1] defined the Nd-Hf "crustal array" and showed that Nd and Hf are correlated in crustal rocks of various ages and origins, but they could not define an average value.

Here we estimate the average composition of upper continental crust using two complementary types of sedimentary materials: (1) loess because they represent well-mixed materials from large areas of upper continental crust; (2) beach placers because they concentrate heavy and resistant minerals such as zircon and monazite. We determined the Hf and Nd isotopic compositions on samples from various locations in Western Europe, Tajikistan, China, Argentina, Africa, USA and Australia.

The loess have remarkably uniform Nd and Hf isotopic compositions and the average value plots on the "mantle array" within the field of crustal materials. Placers have more variable compositions linked to the age of the drained area. Indeed, samples from Europe, South Africa, Eastern Australia and USA have compositions comparable to the loess, but the Western Australian placers have significantly less radiogenic values due to the presence of Archean terranes in the source area.

Combining the constraints provided by the loess and the placers, we suggest that the following Nd and Hf characteristics: $\varepsilon_{Nd} = -10.3 \pm 1.2$ and $\varepsilon_{Hf} = -13.8 \pm 4.2$. The corresponding model age is 1.75 Ga, a value in the young side of other estimates.

Mobility of rare earth elements during igneous rocks weathering and associated stream water transport (Malaval catchment, Massif Central, France)

L. CHAUX[1], T. ROUTIER[1], O. POURRET[1], M. STEINMANN[2] AND S. BONTEMPS[2]

[1]HydrISE, LaSalle Beauvais, 60026 Beauvais cedex, France (olivier.pourret@lasalle-beauvais.fr)

[2] UMR 6249 Chrono-Environnement, Univ. Franche-Comté, 25030 Besançon cedex, France

Rock alteration occurs within the critical zone at the interface between atmosphere, biosphere, hydrosphere and lithosphere. It is a major process within the global bio-geochemical cycle and contributes also to the evolution of landscapes. Chemical weathering dissolves partially or completely bedrock minerals to form weathering profiles, and dissolved ions are transported by surface and underground runoff to the oceans. In order to establish a link between the distribution patterns of the rare earth elements (REE) in stream water and bedrock, a detailed alteration study of the granitic, gneissic and basaltic bedrocks of a small mountain catchment was realized (Malaval catchment, Massif Central, France).

The mineralogy of fresh and weathered samples was determined by microscopy and XRD. Major and trace elements were determined by ICP-AES and ICP-MS. A comparison between the REE patterns of the more altered horizons of each profile and the < 0.22 μm water fraction of the Malaval stream has been realized in order to determine the influence of the different bedrocks on stream water chemistry [1]. Results suggest similar alteration mechanisms for granite and gneiss, which is mainly controlled by the dissolution of plagioclase leading to losses of Na_2O, CaO, SiO_2 and Al_2O_3. Mobilization of K_2O can be related to fracturing of K-feldpar, whereas the evolution of the REE patterns is mainly controlled by the distribution of zircon. In the alteration profiles on basalt, olivine is the first mineral to be altered into orange oxides leading to a mobilization of MgO. The transformation of plagioclase into clays is accompanied by losses of Na_2O and CaO. Lowered iron concentrations can be related to fracturing of pyroxene. A comparison between the REE patterns of the most altered horizons of the different weathering profiles suggests that water chemistry of the adjacent Malaval stream is mainly controlled by basalt weathering. In order to confirm this finding, sequential leachings have been performed on basalt samples and compared with stream water.

Spatial and temporal variability of fluid and gas chemical composition at the Lucky Strike hydrothermal vent site (Mid-Atlantic Ridge)

V. CHAVAGNAC, C. BOULART, C. MONNIN AND A. CASTILLO

Geosciences Environement Toulouse, 14 Avenue Edouard Belin, 31400 Toulouse, FRANCE (valerie.chavagnac@get.obs-mip.fr)

Numerous acidic submarine hydrothermal sites have been discovered, sampled and studied along the Mid-Atlantic ridge between 14ºN and 38ºN near the Azores hot spot. Most hydrothermal systems lie on basaltic substratum and only a few of them on ultramafic rock substratum. The Lucky Strike hydrothermal field was discovered in 1992 during the joint US-French FAZAR expedition on a volcanic segment at 37º50'N at 1700m water depth. The high-temperature hydrothermal fluids (up to 328ºC) have been collected in 1993 and 1994. The chemical composition of fluid and gas emitted at this site indicate variable chlorinities lower than seawater, low hydrogen sulfide, low metal concentrations and high gas contents. The distinct chemical end-members argue for a significant geographic control of the venting system and fluid chemistry is strongly affected by phase separation at depth.

The Lucky Strike hydrothermal field was visited during the BATHYLUCK and MOMARSAT cruises in 2009 and 2010, respectively, in order to assess the spatial and temporal variability of the hydrothermal fluid and gas chemical composition. Numerous fluid discharges on the western side the lava lake were collected as limited chemical were acquired thus far. A maximum temperature of 340ºC was measured at South Crystal. Based on the distribution of element concentrations, fluid chemistry is strongly affected by phase separation at depth as well as the geographic control of fluid plumbing system. Our results indicate that 3 different fluids are feeding the Lucky Strike field (1: Eiffel Tower, Montségur; 2: White Castle, Isabel, Cypress; 3: Y3, Nuno, Crystal, South Crystal, Sintra). The concentrations of CH_4 and CO_2 have increased since 1994 at Eiffel Tower, Sintra, Montségur and Y3, while the N_2 concentrations have all decreased significantly. The H_2 concentrations have stayed stable at Eiffel tower while increasing at Y3 but decreasing at Montségur. CH_4 is generated by water-rock interaction by Fischer-Tropsch caalysis of CO_2 reduction.

The noble gas and halogen composition of the hydrated oceanic crust

D. CHAVRIT[1]*, R. BURGESS[1], C. BALLENTINE[1], B. WESTON[1] AND D. TEAGLE[2]

[1]S.E.A.E.S, The University of Manchester, Manchester, UK (*correspondence: deborah.chavrit@manchester.ac.uk)
[2]National Oceanography Centre, University of Southampton, Southampton, UK

Mantle heavy noble gases have a remarkable similarity to those found in marine pore fluids [1,2]. This implies a significant contribution of these gases into the mantle recycled through subduction zones. In order to better constrain the quantity and character of noble gases available for subduction, we are reassing the major host phases of noble gases in pre-subducted material.

We have acquired, from different ODP sites, a sample suite that is representative of the altered oceanic crust. Noble gas (He, Ne, Ar, Kr and Xe) isotopes and abundances are being determined using crushing release measured with an upgraded VG5400 mass spectrometer.

Preliminary results from four altered basalts (ODP sites 504B and 1256D in the Southeast Pacific Ocean, respectively 5.9 and 15 Ma) show Ne to Xe isotopically identical to air. $^{3}He/^{4}He$ ratios are uniform at 6.82±0.42 (R/Ra). Heavy noble gas elemental ratios fall within a narrow range, with $^{130}Xe/^{36}Ar$ and $^{84}Kr/^{36}Ar$ ratios varying between seawater values and values enriched in Xe and Kr and indistinguishable from mantle values [1]. The range of $^{130}Xe/^{84}Kr$, varying by up to a factor 2.5, suggests that different trapping or fixation sites could control such compositions.

This is supported by an observed correlation of increase of the $^{132}Xe/^{36}Ar$ ratio relatively to $^{84}Kr/^{36}Ar$ with crushing step in the same sample, which does not seem related to air contamination. This could be representative of the different phases retaining different amounts of heavy nobles gases.

These measurements will be extended to include halogen determinations which are tracers of marine pore fluids and seawater interaction [2]. Analysing noble gases and halogens in basalts characterized by different alteration patterns and in gabbros and sediments will allow the identification of the noble gas host phases, as well as the controls of the seawater noble gases interaction with the oceanic crust.

Experimental constraints on magmatic wolframite

X. CHE[123], R.L. LINNEN[23] AND R.C. WANG[1]

[1]School of Earth Sciences and Engineering, Nanjing University, (xdche.nju@gmail.com)
[2]Dept. Earth Sciences, University of Western Ontario
[3]Dept. Earth & Enviromental Sci., Univ. of Waterloo

Wolframite is normally a hydrothermal mineral but at the Yaogangxian tungsten deposit, Hunan, China it also occurs as an apparent magmatic phase disseminated in a medium-grained two-mica granite. The magmatic wolframites are tabular crystals, hundreds of μm long, in planar contact with with magmatic K-feldspar and quartz. The major elements of magmatic wolframite are similar to hydrothermal crystals in quartz veins from the main zone of mineralization at the deposit. However, Zr, Nb, Ta and Mo are more abundant in magmatic wolframites compared to hydrothermal varieties.

The solubilities of synthetic hubnerite ($MnWO_4$) in flux-rich water saturated haplogranitic melts have been determined at 850° to 700°C and 2000 bars in order to test the magmatic hypothesis. The melts contain 1.1, 1.7 and 2.02 wt % of Li_2O, P_2O_5 and B_2O_3, respectively. Up to 6 wt% fluorine was added as AgF; the ASI of the melt is close to 1, but if Li is considered to be an alkali element, the melts are alkaline. Hubnerite solubility is weakly dependent on F. At 800°C the solubility products for hubnerite (*K*sp) range from $38x10^{-4}$ mol^2/kg^2 for a 0 wt% F melt to $69x10^{-4}$ mol^2/kg^2 for a 6 wt% F melt. Hubnerite solublity is strongly temperature dependent. *K*sp for a 6 wt% F melt decreases from $162x10^{-4}$ mol^2/kg^2 at 850°C to $17x10^{-4}$ mol^2/kg^2 at 700ºC. Another potential control on hubnerite solubility is $f_{O2.}$ The *K*sp is $38x10^{-4}$ mol^2/kg^2 at an f_{O2} near Ni-NiO, $53x10^{-4}$ mol^2/kg^2 using a Co filler rod and $69x10^{-4}$ mol^2/kg^2 using Ti filler rod (see [1] for approximate f_{O2} values). The weak variation of solubility with f_{O2} implies that the predominant oxidation state of W in the melts is +6, even at reduced conditions.

The above experimental solubilities are too high to support the magmatic wolframite hypothesis, however the melts in these experiments are alkaline and solubilities are lower in subaluminous compositions [2]. Because of the strong temperature dependence, magmatic wolframite may nevertheless occur in nature, but the melts should have crystallized at a low temperature and be subalkaline to peraluminous in composition.

Silica coatings on young Hawaiian basalts: Constraints on formation mechanism from silicon isotopes

S.M. CHEMTOB[1]*, J.A. HUROWITZ[2], Y. GUAN[1], K. ZIEGLER[3], J. M. EILER[1] AND G.R. ROSSMAN[1]

[1]California Institute of Technology, Pasadena, CA 91125 (*chemtob@gps.caltech.edu)
[2] Jet Propulsion Lab, Caltech;
[3] UCLA, Los Angeles, CA

Young basalts from Kilauea, on the big island of Hawai'i, frequently feature visually striking, white, orange and blue coatings, consisting of a 10-50 μm layer of amorphous silica, capped, in some cases, by a ~1 μm layer of Fe-Ti oxide [1]. The coatings provide an opportunity to study the early onset of acid-sulfate weathering, a process common to many volcanic environments. Silicon isotopes fractionate with the precipitation of clays and opaline silica, and have been demonstrated to be an indicator of weathering intensity [2,3]. Here we report *in situ* measurements of δ^{30}Si of the silica coatings and their implications for coating formation.

The analyzed coated basalt was collected from 1997 overflow lavas at the rim of the Pu'u O'o cone. The sample was mounted in cross section. Analyses were conducted on a Cameca 7f-Geo ion microprobe with a O^- primary beam (~30 μm spot) and two Faraday cups. The silica coating was measured against the Rose Quartz standard (RSQ). We tested whether the coating's amorphous structure introduced a matrix effect by analyzing quartz and fused glass of the same composition (Ge214). Measurements of those materials were the same within error, so although we have not ruled out other relevant matrix effects (e.g. water content), we accept RSQ as a viable standard for analyzing amorphous silica.

The silica coating was determined to have δ^{30}Si = -1.8 ± 1.0‰ (2σ). Hawaiian basalts have δ^{30}Si ≅ -0.5‰ [2], so the silica coatings are ~1‰ lighter than the substrate. The sign of this fractionation is consistent with previously reported values for secondary silica [2-4], and implies that, although the silica coatings have a residual/leaching morphology [1], Si was mobile during coating formation. Basalt dissolved in acidic solution, then a fraction of aqueous Si precipitated as amorphous silica; the remaining dissolved Si (tens of percent) was lost from the system. Ongoing work includes confirmation of the SIMS analysis by ICP-MS and replication of observed coating morphologies and isotopic properties in flow-through alteration experiments.

Origin of the late Mesozoic high-Mg diorites from the North China Craton: Petrological and Os isotopic constraints

B. CHEN*[1,2], C. WANG[2], A.K. LIU[2] AND L. GAO[2]

[1]College of Geology & Prospecting Engineering Program, Xinjiang University, Urumqi 830046, China (*correspondence: binchen@pku.edu.cn)
[2]School of Earth and Space Sciences, Peking University, Beijing 100871, China

The Mesozoic Tietongou & Jinling high-Mg dioritic plutons from the north China craton contain plagioclase (45-55%), hornblende (20-40%), Cpx (10%) and minor Opx, olivine, biotite, quartz, and accessory sphene, magnetite and apatite. The diorites (SiO_2 = 52-63%) show high MgO (9.2-3.5%), Sr (470-980 ppm), Ni (15-157 ppm), Cr (35-416 ppm) and Co (20-35 ppm), with I_{Sr} = 0.7052-0.7083 and $\varepsilon_{Nd}(t)$ = -4.5 to -15. The contradictory geochemical features of the high Sr and high compatible Ni, Co and Cr are reminiscent of the sanukitoids of late Archean times.

Traditionally, the Tietongou and Jinling high-Mg dioritic plutons were suggested by most workers to have originated from partial melting of the eclogitized Archean mafic lower crust delaminated to mantle depths due to crustal thickening, followed by interaction of the resultant dioritic melts with mantle peridotites during magma ascent, during which the melts gained additional MgO. However, our petrological and Os isotopic data suggest that the dioritic plutons formed from a process of magma mixing between basaltic magma and granitic crustal melt formed due to underplating of the basaltic magma in the lower crust. In this model, no crustal thickening and delamination of the lower mafic crust is required. Main arguments are as below. (1) Plagioclase shows compositional and textural disequilibrium, as revealed by the eroded calcic core (An_{78-60}) surrounded sharply by a mantle with much lower An contents (38-16), which is typical of magma mixing between mafic and felsic magmas. (2) Hornblende shows complex compositional zoning, with low TiO_2 zones (0.8%) surrounded by high TiO_2 zones (2.7%), suggesting an input of high temperature basaltic magma during magma evolution. This agrees with the complicated compositional zoning of Cpx. Opx is always rimmed by Cpx, indicating a reaction relationship. This, along with the presence of millimeter-scale relict aggregates of olivine + Opx, suggests that the dioritic plutons are actually mixture of melts plus xenoliths. (3) The dioritic plutons have Os isotopic ratios in the range 0.33-1.22. If the dioritic plutons were formed by interaction of the melts from the delaminated Archean lower crust with mantle rocks, the required proportions of the latter would be unreasonably high (30-85%). The Os isotopic data can be reasonably explained by our magma mixing model: the majority of the dioritic plutons were basaltic magma from an enriched mantle source, which mixed with subordinate crustal melts (9-35%) in the lower crust.

Hydrothermal circulation and post-obduction hydration & carbonation of oceanic lithosphere - $^{87}Sr/^{86}Sr$ and oxygen isotopic study of Oman ophiolite

C. CHEN*, C. ANDRONICOS, L.M. CATHLES AND W.M. WHITE

Department of Earth and Atmospheric Sciences, Cornell University, Ithaca, NY 14853
(*correspondance: cc839@cornell.edu)

We report whole-rock isotopic analyses on 33 samples collected from Nakhl, Sumail and Wadi-Tayin nappes of Oman ophiolite, sampling a transect from upper gabbros to the Moho Transition Zone. $^{87}Sr/^{86}Sr$ and $\delta^{18}O$ varied as follows: (1) upper gabbros: $^{87}Sr/^{86}Sr$ 0.7032~0.7080, $\delta^{18}O$ 2.4~6.3; (2) middle gabbros: $^{87}Sr/^{86}Sr$ 0.7031~0.7060, $\delta^{18}O$ 5.3~6.1; (3) lower gabbros: $^{87}Sr/^{86}Sr$ 0.7031~0.7064, $\delta^{18}O$ 3.4~6.7; (4) Moho peridotites and carbonates, $^{87}Sr/^{86}Sr$ 0.7035 ~ 0.7086, $\delta^{18}O$ 2.95 ~ 30.57. These data together with petrographic studies confirmed that the entire ophiolite section below sheeted dikes was subjected to >300°C hydrothermal alteration during its formation and that locally temperatures exceeded 500°C. High $\delta^{18}O$ and $^{87}Sr/^{86}Sr$ in excess of Cretaceous seawater (0.7079) clearly show that serpentinization and carbonation of the ophiolite have also occurred post-obduction. Four out of five samples with $^{87}Sr/^{86}Sr > 0.7079$ are from Moho Transition Zone: two samples magnesite rocks with $\delta^{18}O$ ~30, the other two are serpentinites with $\delta^{18}O > 7$. One tiger gabbro has $^{87}Sr/^{86}Sr$ of 0.7080 and $\delta^{18}O$ of 2.4. Leaching experiments show that the radiogenic Sr is not restricted to carbonate vein minerals. Thus original isotopic information is easily overprinted by the late stage processes if the peridotites are entirely altered into serpentinites or carbonates. On the other hand, gabbros, which have cracks filled with carbonates but not fully altered, can preserve hydrothermal alteration information during formation.

Atoll garnet in the Yukahe UHP eclogite: Evidence for melt/fluid activity during the eclogitic facies metamorphism

D.L. CHEN, L. LIU AND X.M. LIU

State key Laboratory of Continental Dynamics, NW Univ., Xi'an, 710069, PR China. (dlchen@nwu.edu.cn)

The typical mineral assemblage of the Yukahe eclogite from the North Qaidam in NW China is Grt+Omp+Phen+Rt+Coe. Garnets in the eclogite show two shapes of normal porphyroblast garnet and atoll texture garnet. In which, the normal garnet cores contain mineral inclusions of Pl, Amp, Ap, Zoi, Ep and Qz, and change into Omp, Phen and Rt in the mantles, the rims are clean with few inclusion. EMP analyses revealed a compositional zoning with a bell-shaped decrease of Spe and a bowl-shaped increase of Pyr content towards the rim and a small decrease of Pyr in the outmost rims. The atoll garnets commonly consist of a euhedral ring and a island/peninsula core of garnet, eclogite facies multiphase solid inclusions of Omp, Phen, Grt, Rt and Qz filled between the core and the ring. In a few cases the garnet core is totally missing and filled with a single Phen. The island cores contain the same mineral inclusions as those of in the normal garnet cores; the garnet rings, like the rims of the normal garnet, are clean without any inclusions. A successive compositional zoning with Spe content decrease and Pyr content increase were revealed from the core to the ring, similar to that of the normal garnets. Omp and Phen occur in the matrix and within the atoll have almost the same composition. EBSD analyses demonstrate that the island/ peninsula garnet cores or fractions inside atolls have crystallographic orientations identical to that of the atoll rings. LA-ICP-MS analyses indicate that Omps in both the matrix or within the atoll display the same REE patterns with a peak in MREEs and a pronounced depletion in both LREEs and HREEs. Whereas, the rings of the atoll garnet, ralitive to the core, show a distinct enrichment in MREEs and a visible depletion in HREEs. The mineral assemblage and their composition within atoll garnet are as same as that of the peak metamorphism of the Yukahe eclogite except for Coe, combined with the existing geochemical and chronological studies of leucosomes interbeded with the UHP eclogite body, it suggests that atoll garnets in the Yukahe eclogite formed under eclogite facies conditions during almost the peak metamorphism. It provides good evidence for melt/fluid activity during UHP metamorphism.

Provenance of early sedimentary sequences in the Tethyan Yunnan, SW China: Age and Hf isotope of early Archean zircons

F. CHEN [1], B.-X. LIU [1], S.-Q. LI [1] AND W. SIEBEL [2]

[1]CAS Key Laboratory of Crust-Mantle Materials and Environments, University of Science and Technology of China, Hefei 230026, China

[2]Institut für Geowissenschaften, Universität Tübingen, 72074 Tübingen, Germany

This study presents U-Pb ages and Hf isotopic composition of detrital zircons from Cambrian to Ordovician sedimentary rocks exposed in the Tethyan belt of western Yunnan, SW China. This orogenic belt belongs to the eastern Tethyan belt in SW Asia. It is composed of several micro-continents or continental block of different affinities.

The early Paleozoic sedimentary rocks, collected from the Baoshan block, contain detrital zircons of different crystallization ages ranging from about 3800 Ma to 550 Ma ($^{207}Pb/^{206}Pb$ age), but mostly clustering around 1.0 Ga and 2.4 Ga. About 10% zircon grains yield $^{207}Pb/^{206}Pb$ ages older than 3.0 Ga Ma, indicating significant sedimentary source(s) of early Precambrian crustal material. Initial εHf values of the detrital zircons vary from -34 to +15, while TDM values of zircons, calculated from Lu-Hf isotopic composition, range from about 1.0 Ga to 4.0 Ga with peaks around 1.8 Ga and 2.8-3.0 Ga. Their Nd isotopic composition of whole-rocks (TDM values from 1.8 Ga to 2.5 Ga) also imply significant put-in of old crustal material.

The Baoshan block is considered as the northern part of the Sibumasu microcontinent in the eastern Tethyan orogenic belt. From the analytical results of detrital zircons above, we propose that the sedimentary sources of the early Paleozoic sequences in the western Yunnan originated from Archean and Paleoproterozoic terrains most likely in India and NW Australia.

A study of the column bioleaching of Xianshan uranium ore

GONGXIN CHEN [1,2]*, JINHUI LIU [1] AND ZHANGXUE SUN [1]

[1]East China Institute of Technology , Fuzhou 344000 , China (*correspondence: gxchen@ecit.edu.cn)

[2]China University of Geosciences, Beijing 100083 , China

The samples of uranium ore were obtained from the U mine at Xianshan, Jinagxi Province (China). Quantitative chemical analysis showed that the uranium ore had a mediate carbonate content (CO_2~1.42%), that pyrite was the most important sulphur mineralization (~1.43%) and that the principal components were silicates. The most common uranium mineralization in the vein, pitchblende, appears as UO_2. The particle size of the ore is less than 10mm. Acidithiobacillus ferrooxidans, Leptospirillum ferrooxidans and Acidithiobacillus thiooxidans isolated from the mine waters of the Xianshan uriamium depoist were used in this bioleaching experiment.

The column was made of PVC with 300cm heigh and 80cm diameter. Once the column was fully charged, it was irrigated with 20g/L H_2SO_4 about 20 days to reach the correct degree of acidity, after which the inoculum was introduced and irrigation continued until the end of the experiment. Sample volumes of liquid were extracted periodically and the pH and redox potential (Eh) were measured. The U_30_8, Fe_{Total}, and Fe^{2+} content were also analyzed.

Mixed bacteria play an important role in the leaching process. In 120 days, the recovery of pyrite leaching is about 70%, and of uranium is up to 90%. Acid consumption is very low, about 6.8%. Results also show that U leaching and pyrite leaching are closely related during bioleaching. With the increase of pyrite leaching recovery, uranium leaching recivery is also increased. Due to some pyrite in U mine, biological leaching have good benefit to extract U from the ore compared with those traditional leachings such as heap leaching with acid and stirring tank leaching with MnO_2.

This study is financially supported by Foundation of Jiangxi Educational Committee for Youths (GJJ11155).

Precise determination of the Ca isotopic compositions by thermoionization mass spectromery

H.-W. CHEN[1]*, J.-C. CHEN[1], J.J. SHEN[1], D.-C. LEE[1] AND T. LEE[12]

[1]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan, ROC (*correspondence: haart@earth.sinica.edu.tw)
[2]Institute of Astronomy and Astrophysics, Academia Sinica, Taipei, Taiwan, ROC

High precision Ca isotopic measurements have been set up using the thermo ionization mass spectrometry (TIMS). With the improved sample loading technique, it is possible to sustain a Ca ion current of 1.5~3nA for more than an hour for high precision Ca isotopic measurements. Using this procedure, typical analytical precision (2σ) for $^{40}Ca/^{44}Ca$, $^{43}Ca/^{44}Ca$, $^{46}Ca/^{44}Ca$, and $^{48}Ca/^{44}Ca$ are 1.6, 0.31, 7.5, and 0.68 epsilon (ε; in parts per 10^4), respectively, after normalizing to $^{42}Ca/^{44}Ca = 0.31221$ [1]. Four separate runs are usually taken for individual sample to ensure the reproducibility of the isotopic measurements, and the analytical uncertainty (2σ) can be further reduced to 0.87, 0.13, 4.6, and 0.42ε for $^{40}Ca/^{44}Ca$, $^{43}Ca/^{44}Ca$, $^{46}Ca/^{44}Ca$, and $^{48}Ca/^{44}Ca$, respectively, if the data of all four runs are combined. With the improved analytical precision, in particular for the less abundant ^{43}Ca and ^{48}Ca, it is possible to re-examine the Ca isotopic heterogeneity in terrestrial and meteoritic materials, and to explore the preserved non-linear stellar nucleosynthetic signatures in meteorites and homogenization process in the early solar system.

Interaction of NOM and NZVI: Implication for NZVI's toxicity and reactivity in the environment

JIAWEI CHEN[1,2]*, ZONGMING XIU[2], GREGORY V. LOWRY[3] AND PEDRO J. J. ALVAREZ[2]*

[1]State Key Laboratory of Geological Process and Mineral Resources, China University of Geosciences, Beijing 100083, China (*correspondence:chenjiawei@cugb.edu.cn)
[2]Dept. of Civil & Environmental Engrg., Rice University, Houston, TX 77005, USA
[3]Dept. of Civil & Environmental Engrg., Carnegie Mellon University, Pittsburgh, PA 15213, USA

Nano-scale zero-valent iron (NZVI) particles are increasingly used to remediate aquifers contaminated with hazardous oxidized pollutants such as trichloroethylene (TCE). However, the high reduction potential of NZVI can result in toxicity to indigenous bacteria and hinder their participation in the cleanup process. Here, we report on the mitigation of the bactericidal activity of NZVI towards gram-negative *Escherichia coli* and gram-positive *Bacillus subtilis* in the presence of Suwannee River humic acids (SRHA), which were used as a model for natural organic matter (NOM). *B. subtilis* was more tolerant to NZVI (1 g/L) than *E. coli* in aerobic bicarbonate-buffered medium. SRHA (10 mg/L) significantly mitigated toxicity, and survival rates increased to similar levels observed for controls not exposed to NZVI. TEM images showed that the surface of NZVI and E. coli was surrounded by a visible floccus. This decreased the zeta potential of NZVI from -30 to -45 mV and apparently exerted electrosteric hindrance to minimize direct contact with bacteria, which mitigated toxicity. H_2 production during anaerobic NZVI corrosion was not significantly hindered by SHRA ($p > 0.05$), However, NZVI reactivity towards TCE (20 mg/L), assessed by the first-order dechlorination rate coefficient, decreased by 23% (from 0.0178 ± 0.0007 h^{-1} to 0.0137 ± 0.0004 h^{-1}). These results suggest that the presence of NOM offers a tradeoff for NZVI-based remediation, with higher potential for concurrent or sequential bioremediation at the expense of partially inhibited abiotic reactivity with the target contaminant [1].

Research on pretreatment of highly concentrated dye-printing wastewater using surplus sludge together with powder ash

JINGYING CHEN

Department of Civil and Environmental Engineering, East China Institute of Technolog, Fuzhou344000, China (cjy006@163.com)

The pretreatment craft is extremely essential in the processing of dye-printing waste water. Using surplus sludge together with the powder ash as the flocculants to pretreat highly concentrated dye-printing wastewater, which leads to the remarkable reduction of the discharge monitoring index in the wastewater — chroma, the suspended solid and the chemical oxygen demand.[1]

This article has conducted the experimental study uses surplus sludge together with the powder ash as the flocculants to pretreatment highly concentrated dye-printing waste water. The results show that through control the volume ratio of the surplus sludge and coal ash, static time and so on, when the volume ratio is the dye-printing waste water/Surplus sludge/coal ash =60: 1: 8, and the static time between 20 ~ 40 minutes, there is a remarkable reduction of the discharge monitoring index in the waste water–chroma and the chemical oxygen demand. The finding provides the experiment basis for reducing the consequent biochemical treatment loads effectively reducing the running cost for highly concentrated dye-printing waste water disposal exploring the industrialized technical designing direction and the way on using the waste to deal with the waste.

Mass-dependent fractionation and mass-independent fractionation of Hg isotopes in aqueous environment

JIUBIN CHEN[1,2], HOLGER HINTELMANN[2] AND XINBIN FENG[1]

[1]State Key laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, 46 Guanshui Road, Guiyang, GuiZhou 550002, China

[2]Chemistry Department, Trent University, 1600 West Bank Drive, Peterborough, Ontario, K9J7B8, Canada

Preliminary studies have demonstrated both mass-dependent fractionation (MDF) and mass-independent fractionation (MIF) of Hg isotopes in the environment (1) and the potential for their application in biochemistry and geochemistry. However, the majority of previous work has focused either on developing reliable MC-ICP-MS measurements or on monitoring isotopic variation of Hg in solid samples and in Hg-enriched synthetic solutions. Little has been reported for Hg isotope geochemistry in natural aqueous environment because of the very low Hg concentrations (several ng/L).

Precipitation samples and water samples from different aquatic systems (remote lakes, contaminated rivers, groundwater) were analyzed for Hg isotopic composition after pre-concentration using a new pre-concentration method (2). The results displayed evident MDF and MIF of Hg isotopes in natural aqueous environment. All samples displayed a total δ^{202}Hg variation of 2.42‰ (-1.68‰ to 0.74‰), with lower values for precipitation and lake waters and higher values for contaminated river waters. Unlike waters from contaminated rivers, precipitation samples displayed positive MIF of odd Hg isotopes, contrast to the predicted result from previous studies. Moreover, our results confirmed the observation of MIF of odd Hg isotopes (^{200}Hg) in precipitation samples (3), implying that the (atmospheric) process introducing the MIF for even Hg isotopes may be different from that producing MIF of odd isotopes in the aqueous environment. More research is required to fully understand the behavior of Hg isotopes in the hydrosphere.

The evidences of the Initial broken for the Shangdan Ocean: Geochronology and geochemistry of the Muqitan Formation, in North Qinling

JUN-LU CHEN, XUE-YI XU, HONG-LIANG WANG AND PING LI

Xi'an Center of Geological Survey(Xi'an Institute of Geology and Mineral Resource), CGS, Xi'an, Shaanxi 710054, China

The Muqitan ophiolitic mélange found within the Muqitan Formation near Muqitan region, the North Qinling Orogen. They mainly consist of amphibolite with minor meta-gabbro and meta-chert. Zircon LA-ICP-MS U-Pb dating yields an age of 762.5±4.6Ma for the amphibolites, interpreted as crystallization time, The amphibolites are characterized by low TiO_2 (0.57%~2.16%), relatively low K_2O/Na_2O ratios (0.06~0.55) and moderate-high Mg# (45.3~68.7). They are geochemically similar to low-Ti tholeiites. The Muqitan amphibolites have low REE contents, with differentiated LREE/HREE patterns and no Eu anomalies on the chondrite-normalized REE diagram, analogies to E-MORB. The amphibolites display an enrich elements Rb, Ba,Th, and La pattern, low ($^{87}Sr/^{86}Sr$)i ratios of 0.7038 to 0.7040 and high εNd(t) values of +4.1 to +6.9, suggesting a mantle origin, similar in composition to FOZO-like source. Their (Th/Nb)N, Nb/La and Ba/La ratio features indicate that these amphibolite have been experienced varying degrees of crustal contamination. All these data, combined with the regional geological features demonstrate that the Muqitan amphibolites are interpreted as remnants of the Shangdan ancient oceanic crust that would have formed during the inception of the oceanic open at ca. 762.5 ±4.6Ma.

Deposition and remobilization of oxidized multiwalled carbon nanotubes on silica surfaces: Implications for environmental fate and transport

KAI LOON CHEN* AND PENG YI

Department of Geography and Environmental Engineering, Johns Hopkins University, Baltimore, Maryland 21218 (*correspondence: kailoon.chen@jhu.edu, peng.yi@jhu.edu)

Carbon nanotubes (CNTs) are increasingly used in commercial and industrial applications because of their superior mechanical and electronic properties. With CNT-containing products already available in the market, it is inevitable that some CNTs will be released into natural aquatic systems. In order to predict the fate and transport of CNTs in surface water and groundwater systems, it is important to understand the interaction between CNTs and natural surfaces. In this study, we investigate the deposition and remobilization of oxidized multiwalled carbon nanotubes (MWNTs) on silica surfaces with a quartz crystal microbalance with dissipation monitoring (QCM-D). The distributions of oxygen-containing surface functional groups for two MWNTs are determined using X-ray photoelectron spectroscopy in conjunction with vapor phase chemical derivatization. Deposition kinetics of lowly oxidized MWNTs (LO-MWNTs) and highly oxidized MWNTs (HO-MWNTs) are compared in monovalent (NaCl) and divalent ($CaCl_2$) electrolytes. HO-MWNTs are found to be more stable to deposition than LO-MWNTs in the presence of NaCl. However, in the presence of $CaCl_2$, the attachment efficiency profiles of both MWNTs are comparable, which is possibly due to Ca^{2+} cations having a higher affinity to form complexes with adjacent carboxyl groups on HO-MWNTs than with isolated carboxyl groups on LO-MWNTs. Additionally, the deposited MWNTs can be released from silica surfaces when they are rinsed with low ionic strength solutions, indicating that the deposition of MWNTs is not always irreversible. The degree of nanotube release is observed to be dependent on the ionic strength and pH of rinsing solutions.

DIE model and compensation method applied in through-casing resistivity measurement

CHEN QING

CEEE of Huazhong University of Science and Technology, 430074Wuhan, China

Double-Injection-Electrodes (DIE) model and its compensation arithmetic method has been proven to be very useful for eliminating the errors caused by electrode-scale mechanical tolerances in formation resistivity measurement through metal case. In this paper, we found that even minor casing joint or casing corrosion may deteriorate the measurement accuracy. Based on theoretical analysis and self-adaptive goal oriented hp-Finite Element (FE) simulations, the compensation effects of DIE model were estimated. The calculated results from DIE model are always close to the real formation resistivity no matter the metal casing is ideal or not. Meanwhile, large errors occur in Single-Injection-Electrode (SIE) model, where the calculated formation resistivity may provide negative numbers when casing joint or casing corrosion exists. The Double-Injection-Electrode (DIE) model is predicted to have good compensation effects to many non-ideal situations with uneven metal casing besides electrode-scale mechanical tolerances.

Timing of dehydration melting and fluid flow during continental subduction-zone metamorphism in the Dabie orogen

REN-XU CHEN* AND YONG-FEI ZHENG

School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (chenrx@ustc.edu.cn)

Dehydration melting of UHP metamorphic rocks and the possible presence of supercritical fluid during continental subduction-zone metamorphism has been revealed by microscale observations of petrology and geochemistry. However, a direct geochronologic constraint on partial melting and fluid supercriticality is still lacking. This study reports for the first time the outcrop-scale occurrence of migmatite-like structure within UHP eclogite in the Dabie orogen. Leucocratic veins and their host rocks were investigated by means of petrology and zirconology. Metamorphically grown zircons from the veins yield consistent U-Pb ages of 215±4 to 218±4 Ma; zircon trace elements indicate that they crystallized in the presence of garnet or amphibole. Ti-in-zircon and Zr-in-rutile thermometers gave variable temperatures from 537 to 758°C. Thus the veining occurred in the stage of transition from HP eclogite-facies to amphibolite-facies retrogression during exhumation of the deeply subducted continental crust. On the other hand, based on the paragenesis and trace element composition of vein minerals, vein-forming fluids are mainly composed of SiO_2 + Al_2O_3 + CaO + K_2O + FeO + MgO + H_2O and enriched in LREE, HREE, HFSE, LILE, and Pb, Th and U. The enrichment of HREE and HFSE suggests that the fluids have very high capacity of dissolving water-insoluble elements, pointing to the possible presence of supercritical fluid. While the supercritical fluid is stable in the UHP regime, it would separate into a hydrous melt and an aqueous fluid during the decompression exhumation into the HP eclogite facies. As a consequence, the vein minerals rich in the trace elements would precipitate as a product of phase separation. Thus, the dehydration melting of UHP metamorphic rocks is considered as the prerequisite for local formation of supercritical fluid in the UHP regime, whereas the phase separation of supercritical fluid during the exhumation is suggested as the basic cause for differential partition of trace elements between rock-forming and accessory minerals in the veins. Therefore, the zircon U-Pb dates on the leucocratic veins provide a temporal constraint on the lower limit of local melting during the continental collision.

Fungal spore contributions to subtropical aerosol particles

S.-H. CHEN AND G. ENGLING*

Department of Biomedical Engineering and Environmental Sciences, National Tsing Hua University, Hsinchu 300, Taiwan (*correspondence: guenter@mx.nthu.edu.tw)

Primary Biological Aerosol Particles (PBAPs), as derived from pollen, fungi, bacteria, viruses, algae, and plant fragments, have recently been shown to contribute sizeable portions of atmospheric particulate matter (PM) on global scale, specifically in coarse mode particles [1, 2]. Fungal spores in particular constitute an important type of PBAPs [3, 4]. A new method for estimating PBAP contributions was introduced by Bauer and coworkers by utilizing molecular source tracers, i.e., the polyols arabitol and mannitol [5]. While conversion factors from ambient tracer concentrations to fungal spore mass have been determined for a continental location in Europe [4, 5], there are no reports to date regarding the tracer characteristics of different types of fungal spores in other areas and specifically in Asia.

Our recent investigations have shown that fungal spore content in coarse PM can be rather high in tropical regions with contributions up to 26% of organic carbon and up to 18% of PM_{10} [6]. Ambient conditions, such as temperature and moisture, influence biological activity, including fungal spore release rates. Moreover, fungi species in different locations likely have varying polyol content. Therefore, it is crucial to determine the absolute and relative abundance of individual polyol tracers in different fungi species (i.e., source samples), as well as the concentrations of these tracers in ambient PM as a function of environmental conditions.

In order to address these open questions, size-resolved PM samples were collected at various sites across Taiwan, including coastal, urban, rural and high-altitude sites. In addition, various types of fungi were cultured. The polyol tracers arabitol and mannitol, along with other carbonaceous species, were quantified in the ambient and source samples by high-performance anion exchange chromatography (HPAEC). New insights into the size-dependent composition of fungal spore tracers in subtropical PM and in specific fungi species will be presented here.

Hf-Nd isotope variations of late Cenozoic Arctic intermediate water reflect continental weathering

TIAN-YU CHEN[1], MARTIN FRANK[1] AND ROBERT F. SPIELHAGEN[1,2]

[1]IFM-GEOMAR, Leibniz Institute for Marine Sciences, Wischhofstrasse 1-3, 24148 Kiel, Germany (tchen@ifm-geomar.de; mfrank@ifm-geomar.de; rspielhagen@ifm-geomar.de)

[2]Academy of Sciences, Humanities and Literature, 55131 Mainz, Germany

The late Cenozoic glaciation history of the Arctic is important for understanding the global climate system and feedback mechanisms. However, such information from the Arctic basin itself is limited. The combined Hf-Nd isotope composition of past seawater in high latitudes has been suggested as a proxy for changes in intensity and regime of continental weathering due to fractionation processses as a function of weathering regime.Enhanced physical weathering during glaciations is expected to cause a more congruent release of Hf weathered from continental rocks. So far, there are, however, no records from the Arctic basin. We extracted combined seawater-derived Nd-Hf isotope compositions from the authigenic Fe-Mn oxyhydroxide fraction of two sediment cores recovered on Lomonosov Ridge (PS2185, ACEX), in order to reconstruct weathering regime and past circulation.

We produced ε_{Nd} (~-10.5) and ε_{Hf} (~0.4) signatures of AIW from the core-top sediments, which agree well with previously reported values directly determined on nearby water samples of AIW. Over time, Hf isotopes have in general become less radiogenic since 16 Ma, which is not observed for Nd isotopes. Similar to Nd isotopes, clear glacial-interglacial variations of Hf isotopic compositions were also observed in the late Quaternary, with more radiogenic Hf isotope signatures in glacial stages and less radiogenic Hf isotope compositions during interglacial stages. Unlike Nd isotope compositions of AIW, which are at present dominated by current inputs from the North Atlantic, Hf isotope signatures of AIW are apparently more influenced by input from local shelf sediments and surrounding rivers. Our interpretation for the long term Hf isotopic evolution is that they reflect progressively more congruent weathering of rocks of the continents surrounding the Arctic Ocean, associated with stepwise cooling of the Northern hemisphere. Glacial-interglacial variations of Hf isotopes also seem to have been controlled by the variable weathering regime as a function of climate and temperature changes.

(U-Th)/He geochronological evidence for rapid uplift of Tianshan orogenic belt since Miocene

CHEN WEN[1]*, SUN JINGBO[1], JI HONGWEI[2,1], LI JIE[2,1], YIN JIYUAN[1], GONG JUNFENG[1] AND LIU XINYU[1]

[1]Laboratory of Isotope Geology, Institute of Geology, CAGS, Beijing, 100037 China (*correspondence: chenwenf@vip.sina.com)

[2]China University of Geosciences (Beijing), Beijing, 100083 China

The Tianshan orogenic belt, lying across Central Asia, is an important part of the Central Asian Orogenic Belt, which formed by the continental collision between Siberia and Tarim plate in Late Paleozoic. Since Cenozoic, strong compression caused by the collision between Indian and European plates has led to intense uplift of pre-Mesozoic terrains in Tianshan Area. Analysis of growth strata and regional geological studies show that rapid uplift of the Tianshan in Late Cenozoic occurred younger than 10-7Ma, of which the existence of extremely thick Quaternary molasse sediments indicates that the uplift and denudation in a relatively high tectonic position occurred younger than 3Ma, paradoxically, most of the thermochronology data gained from the FT (Fission Track) is >20Ma [1], lack of data which is <7Ma.

Non-dilution ^{4}He content measurement technique is developed in the Helix MC multi-collector mass spectrometer in our laboratory [2], as well as the establishment of the (U-Th)/He dating experimental procedure. Apatite in granite、gabbro sampled from Tianshan orogenic belt are dated by (U-Th)/He method, obtained a series of ages around 5Ma-10Ma, which provide geochronological evidence for a rapid uplift event in Late Miocene-Pliocene in Tianshan orogenic belt.

Redox evolution of the late Neoproterozoic to early Cambrian ocean on Yangtze platform, China

X. CHEN[1,2]*, D. VANCE[2], H.-F. LING[1], C. ARCHER[2], G.A. SHIELDS-ZHOU[3] AND L.M. OCH[3]

[1]Department of Earth Sciences, Nanjing University, Nanjing 210093, China (*correspondence: imchenxi@gmail.com)

[2]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK

[3]Department of Earth Sciences, University College London, London WC1E 6BT, UK

The late Neoproterozoic-early Cambrian interval (663-521 Ma) witnessed a critical transition in the surficial Earth system. Although it is still debated whether physical or biological factors controlled this transition, the redox state of the atmosphere and ocean are generally considered to be a key factor in the cause and effect relationships. Here we present data for several redox tracers, including Mo isotope compositions, Fe speciation and Mo/TOC ratios in the organic-rich shales/carbonates from the Yangtze platform, Southern China.

The results suggest a key evolutionary transition either side of ca. 580-551 Ma. Between 663 and 580 Ma, Fe speciation data give high Fe_{HR}/Fe_T (> 0.38) with relatively low Fe_{Py}/Fe_{HR} (< 0.7). Both Mo concentrations and Mo/TOC ratios are low. δ^{98}Mo values are not far from the modern dissolved riverine input value of 0.7. Between ca. 551 and 521 Ma, Fe speciation begins to show more variation. Unprecedented enrichment of Mo also emerges as a characteristic of sediment and the range of δ^{98}Mo values show an extended range of variation.

The data suggest a still low atmosphere O_2 level during the early stage, resulting in low input of Mo and sulfate to the ocean. Sulfate deficiency and/or low productivity in the ocean induced ferruginous anoxia. Due to a low proportion of Mo output via the oxic sink and quantitative removal to sediments, no obvious fractionation of Mo was recorded. But a pronounced oxidation event initiated after (at least) ca. 551 Ma. Elevated atmosphere O_2 level and sulfate input to the ocean may have resulted in expansion of euxinic, suboxic, and oxic environments. Moreover, expansion of the ocean Mo reservoir also stimulated greater fractionation of Mo in anoxic/suboxic environments. δ^{98}Mo in euxinic sediments reached the modern value after ca. 530 Ma, marking the epilogue of this profound redox transition in the ocean, and coincident with the immediately following peak of metazoan radiation. This study is supported by NSFC grant 40872025.

Metasomatic pyroxenites and peridotites in the mantle wedge: Tracing the high Nb/Ta reservoir

Y. CHEN, K. YE, S. GUO AND J.B. LIU

State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geopgysics, Chinese Academy of Sciences, P.O. Box 9825, Beijing 100029, China (*correspondence: chenyi@mail.iggcas.ac.cn)

The Nb/Ta ratios in most silicate earth reservoirs are generally subchondritic (< 19.6±0.6), and thus a 'hidden' high Nb/Ta ratio reservoir is expected in the deep Silicate Earth. The core of the Earth [1] and the deep recycled eclogites [2] have been regarded as the candidates of the high Nb/Ta reservoirs. However, high-pressure experiments demonstrate that the melts/fluids released from the HP-UHP eclogite commonly have higher Nb/Ta ratios than the residue rutile-bearing eclogites [3-5]. Such melts and fluids with high HFSE and Nb/Ta ratios are expected to penetrate into the cold mantle wedge just above the subduction slab and result in significant metasomatism. However, the Nb/Ta ratios in the metasomatic cold mantle wedge are still unclear.

A relevant case study is represented by a mafic-ultramafic complex in Maowu, Dabieshan UHP belt, eastern China. It is mainly composed of orthopyroxenite and garnet orthopyroxenite, with minor garnet clinopyroxenite, garnet websterite, harzburgite and dunite. The Maowu pyroxenites are formed by interactions of refractory mantle wedge harzburgite or dunite with slab-derived fluid. Most of these metasomatic pyroxenites and peridotites contain Ti-clinohumite, which is the major Ti-Nb-Ta-bearing mineral in these rocks. The Ti-clinohumite is formed by the interaction between protolith olivine and a UHP (~5.5 GPa, 800 ºC) slab-derived fluid rich in Ti, Nb and Ta. The whole-rock Nb/Ta ratios in most fresh metasomatic pyroxenites and peridotites are superchondritic (20-28), however, the unmetasomatic harzburgite and dunite still have subchondritic Nb/Ta ratios (13-17). The Nb/Ta ratios in the Ti-clinohumite are similar to those of the whole rock. The superchondritic Nb/Ta ratios in the Maowu metasomatic pyroxenites and peridotites indicate that the cold metasomatic mantle wedge just above the subduction slab may be the potential "hidden" superchondritic Nb/Ta reservoir in the Silicate Earth.

Metamorphic growth and recrystallization of zircons in negative $\delta^{18}O$ metamorphic rocks: A combined study of U-Pb dating, trace elements, and O-Hf isotopes

YI-XIANG CHEN, YONG-FEI ZHENG AND REN-XU CHEN

School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (cyxz@mail.ustc.edu.cn)

A combined *in situ* SIMS and LA-(MC)-ICPMS study incorporating of U-Pb dating, trace elements, O-Hf isotopes was conducted on zircons from ultrahigh-pressure metamorphic rocks at Qinglongshan in the Sulu orogen, China. The results indicate that many zircons are actually different proportions of mixtures between residual cores and metamorphic overgrowths, with contrasts in $\delta^{18}O$ values, U-Pb ages, Th/U ratios and REE patterns. Generally, residual cores have U-Pb ages of middle Neoproterozoic, positive $\delta^{18}O$ values, high Th/U and $^{176}Lu/^{177}Hf$ ratios, high REE contents, and type magmatic REE patterns. They crystallized from positive $\delta^{18}O$ magmas in the middle Neoproterozoic. In contrast, newly grown domains show concordant Triassic U-Pb ages, negative $\delta^{18}O$ values, low Th/U and $^{176}Lu/^{177}Hf$ ratios, low REE contents, and REE patterns typical of metamorphic growth. The domains grew from negative $\delta^{18}O$ fluids that were produced by metamorphic dehydration of high-T glacial meltwater altered rocks. The large $\delta^{18}O$ variations between grains and intragrain domains indicate varying degrees of O isotope exchange between the residual cores and the negative $\delta^{18}O$ metamorphic fluids. Protolith magmatic zircons underwent three types of metamorphic recrystallization, with extents of modification depending on accessibility of the negative $\delta^{18}O$ fluids. Solid-state recrystallization still maintains the positive $\delta^{18}O$ values and other features of magmatic zircon except some extent of lowering in U-Pb ages. Dissolution recrystallization results in strongly negative $\delta^{18}O$ values, almost complete resetting of U-Pb ages and partial redistribution of REE systems. Replacement recrystallization causes variable negative $\delta^{18}O$ values, partial resetting of REE, and the U-Pb and Lu-Hf isotope systems. Therefore, this combined *in situ* study not only places robust constraints on genesis of metamorphic zircons, but also allows discrimination between the different types of zircons in eclogite-facies metamorphic rocks.

Stability of engineered nanoparticles under various environmental conditions: Measurements and modeling

YONGSHENG CHEN, WEN ZHANG, KUNGANG LI

School of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, Georgia, 30332 (yongsheng.chen@ce.gatech.edu)

To better understand and predict the environmental fate of engineered nanoparticles (ENPs) and their biological effects, characterization of their aqueous stability (e.g., aggregation and ion release) is important. In this study, we investigated and developed models to describe aqueous behaviors of serval selected ENPs. The ENPs include CeO_2, Ag, and quantum dots (QDs), which have broad commercial applications and toxicological relevance. The primary physicochemical properties of ENPs (i.e., morphology, size distribution and surface potential) were characterized by transmission electron microscopy (TEM), atomic force microscopy (AFM), dynamic light scattering (DLS), and zeta potential instrument. The aqueous stability was evaluated by studying the aggregation kinetics under different levels of salt, natural organic matter (NOM) and temperature by time resolved-dynamic light scattering (TR-DLS). Extended Derjaguin–Landau–Verwey–Overbeek (EDLVO) theory and the attachment efficiency (or inverse stability ratio) were both used to interpret the aggregation mechnisms. Moreover, we developed models by combining EDLVO with Arrhenius equation or von Smoluchowski's population balance equation to describe aggregation kinetics of ENPs. Particularly, the model derived from EDLVO and Arrhenius equation was also used to simulate the Ag^+ release kinetics and the influences of particle size, concentration, dissolved oxygen, and other environmental factors (e.g., temperature) on ion release kinetics. Finally, we investigated the oxidative dissolution of QDs under irradiation of ultravoliet (UV) light at 254 nm.. The effects of irradiation intensity, dissolved oxygen (DO), temperature, and surface coating on the dissolution kinetics of QDs were systematically investigated. Our results showed that the possible mechanism of the oxidative dissolution of QDs involved the formation of reactive oxidative species (ROS) on the surface of QDs under UV irradiation, and ROS may further oxidize the core-shell compositions of QDs and subsequently release the metal ions (Cd^{2+}, Se^{2+}, and Zn^{2+}). The knowledge gained from this study proivdes insight information about aqueous stability of ENPs, which lays out groundwork toward a better understanding of environmental impacts of ENPs.

Quantification non-linear flow and transport in fractures based on boundary layer theory and MIM

Z. CHEN, H. N. LI AND R. Z. LI

School of Resources and Environmental Engineering, Hefei University of Technology, Hefei, 230009, China (czhfut@gmail.com)

Solute transport in fractures or fractured media becomes a big issue in CO_2 geological sequestration, groundwater reservoir finding, oil exploiting, nuclear waste disposal and many other fields[1-4]. More and more attentions were drawn on solute transport in single rough fracture. Among which, Fickian Law is believed to be the "right" form of governing law, however, extensive evidences such as "early arrival" and "the long tail" show non-Fickian transport [5-6].

The roughness of the fracture and the non-linear flow were considered to be two important reasons for non-Fickian transport [7]. Application of boundary layer theory in describing the flow condition in fracture seems to be a choice in non-Fickian explanation by Qian *et al*. [8]. A viscous boundary layer existed near fracture wall and the flow velocity changed rapidly. A low velocity zone (or zero velocity in cavities caused by roughness) and a fast velocity zone exist based on boundary layer theory. As a simplification of the boundary layer dispersion problem in single rough fracture, the mobile-immobile (MIM) model may be applicable. MIM approah assign a mobile domain and a immobile domain for the transport. The mobile domain was used to approximate the region near the symmetry of the fracture and the immobile domain used in low velocity zone.

By fitting the experimental data of solute breakthrough curve (BTC) through a single rough fracture using MIM we found that MIM did an excellent work. The early arrival of peak value can be explained by the dispersion in fast velocity zone and the long tailing phenomenon can be explained by the delayed transport in low or zero velocity zone. Further work can be carried out on finding the relationship between the thickness of boundary layer and mobile water fraction coefficient in MIM.

Influence of sedimentary gas bubble ebullition on interfacial transport in permeable marine sands

C.H. CHENG AND M. HUETTEL*

Earth, Ocean, and Atmos. Science Dept., Florida State University, Tallahassee, FL, USA
(*correspondence: mhuettel@fsu.edu, chc09@fsu.edu)

In the uppermost centimeter of shallow, permeable sediments, photosynthesis by microalgae causes oxygen supersaturation, leading to the formation of oxygen bubbles. Ebullition is one of several processes that affect circulation and exchange of water into and out of the sediment, yet is not well understood. It occurs when these gas bubbles are released due to growth in size or waves and tide-induced pressure oscillations, and may enhance the release or exchange of solutes. In sandy, coarse-grained sediments bubbles occur mostly as small inconspicuous interstitial bubbles, in contrast to larger formations of free methane gas in deeper layers of muddy sediments. Laboratory ebullition experiments utilizing inert dye showed the effects of the sediment depth of ebullition and the volume of sediment affected by the bubble flow. Compared to sediment cores, where diffusion was the sole transport mechanism for the dye, flux in the ebullition experiments was enhanced 5-23 fold. Analyses of the sediment cores revealed a distinct pattern of pore water flow as a result of ebullition, where circulation that was effective in vertical and horizontal mixing of pore fluids. In field experiments using bromide as intert tracer, bubble ebullition caused an enhancement of pore water exchange and thus benthic pelagic coupling.

Water table fluctuations with soil temperature changes in a laboratory experiment

DONG-HUI CHENG

School of Environmental Sciences and Engineering, Chang′an University, Xi′an 710054, China (chdhbsh@chd.edu.cn)

A New Observation about Water Table Fluctuation

A phenomenon of the diurnal water table fluctuations with soil temperature changes was derived from a laboratory experiment on soil (eolian sand) evaporation. The water table rise with the soil temperature increase in daytime and it declined with the soil temperature decrease in nighttime. In 10-day time scale, the water table also exhibited the same variations with temperature changes. The influence of temperature on diurnal water table fluctuation was considered ignorable and only exhibited in long-term changes in previous studies [1,2]. However, our experiment results showed it is notable.

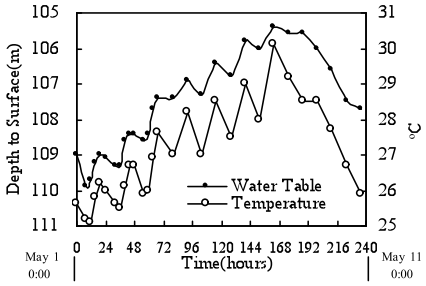

Figure 1: Water table fluctuations with soil tempeture changes

Discussions of Results

In our experiment, the groundwater evaporation was not effect on the water level due to the depth to water table (about 1.1 m) was much less than the extinction depth of water evaporation in the eolian sand media (about 0.5 m), as well as the barometric pressure change. Traditionally the water table fluctuations due to temperature changes were interpreted using the Muskat equation [3,4]. However, it only reasonable to explain the water tables rise due to temperature rise. The Influence of temperature on the soil capillary pressure of soi is probably main factor for water table fluctuation. a completely discussion of these results will be presented in the conference.

Erosion rate of yellow soil on pine hill in the Three Gorges reservior region using ^{137}Cs Technique

J. CHENG [1,2], Y. SHUANG[1,2]*, Z.Y. JIANG[1,2] AND H. LI[1,2]

[1]Chongqing Key Laboratory of Exogenic Minerallization and Mine Environment, Chongqing Institute of Geology and Mineral Resources, Chongqing 400042, China (*correspondence: shy0124@yahoo.com.cn)

[2]Chongqing Research Center of State Key Laboratory of Coal Resources and Safe Mining 400042, China

Soil erosion and degradation, as one of the major environmental problems man is confronted with, is becoming a hot spot in the study of soil and environmental Science. In recent years, radio-isotope tracer in soil erosion studies has become one of the hottest research topics in the field of soil Science. This research presents the ^{137}Cs tracer in the soil erosion rates in the Three Gorge Reservoir Region in Chongqing.

Two yellow soil profile samples which formed by the weathering of quartz sandstone of the Upper Triassic Xujiahe Fm were collected from the pine hill. Simplified mass balance model established by Zhang *et al* [1] is applied to overestimate the soil erosion rates.^{137}Cs of Section A (sits on upper section of the hill, with an incline of about 15 degrees) is mainly gathered in middle section (4-10cm). The ^{137}Cs inventories of the section is estimated to be 1099.8 Bq/m^2. The soil erosion rate on this section is 1009.92 t/km^2.a, in concordance with the result of Dong *et al* (2006)[2].

As to section B (sits on middle to lower section of the hill, with an incline of about 15 degrees), ^{137}Cs is mainly gathered in surface soil (2-6cm). The ^{137}Cs inventories and soil erosion rate values are 2139.8 Bq/m^2 and -190.937 t/km^2.a respectively, indicating slight accumulation happened before.

Combined with some previous results[2], it may be deduced that the soil erosion rates of this area might have little relationship to the soil type and soil forming rocks, but were greatly affected by topography, soil utilization way and vegetation.

This research project was financially supported by the Argo-geologic Survey in Zhong county Project from Chongqing Administration of Land, Resources and Housing.

Alteration of biochemical pools assemblage induced in *A. variabilis* by TiO_2 nanomaterials exposure

C. CHERCHI AND A.Z. GU*

Dept. of Civil and Environmental Enginering, Northeastern University, Boston, MA 02115 (*correspondence: april@coe.neu.edu)

In this study Fourier Transformed Infrared spectroscopy and Transmission Electron Microscopy were used to evaluate the ecotoxic impact of TiO_2 nanomaterials to the cellular reorganization of macromolecules in the nitrogen-fixing cyanobacteria *A. variabilis*. The increase in occurrence and intracellular levels of cyanophycin grana proteins (CGPs, Figure 1) reveal changes in the dynamics of cellular nitrogen storage and metabolism. The results also showed characteristic temporal re-allocation patterns after short and long-term exposure of the predominant chemical markers (lipids, nucleic acids, carbohydrates and proteins) with nTiO_2 dose-dependent trends.

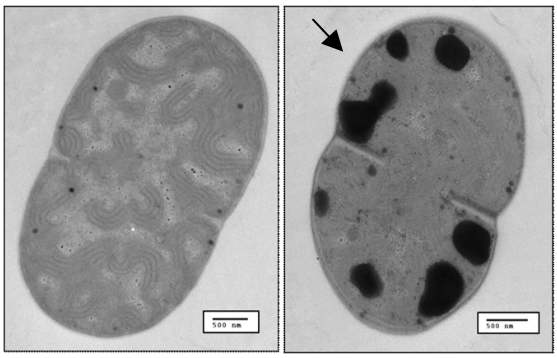

Figure 1: CGPs formation after cell exposure to nTiO_2 (right) compared to control (left).

In conclusion, this study reveals important insights into the metabolic strategies implemented by cyanobacteria under nTiO_2 exposure and anticipates at larger scale the impact on important biogeochemical processes, such as nitrogen cycle, and ecological food web dynamics.

Natural water contamination under chromite deposit mining

E.V. CHERKASOVA AND B.N. RYZHENKO

Vernadsky Institute of Geochemistry and Analytical Chemistry RAS, Moscow, Russia (ryzhenko@geokhi.ru)

For any chromite mining site there is a problem of ore waste burial. In our opinion for Aganozerskoe deposit (Russia, Kareliy) there are two possibilities for waste burial: to keep waste wet with water on the land surface or to put it in the nearest water reservoir (pool, lake). According to [1] the main factors which determine dissolution of minerals and migration of aqueous species are the following: (a) weight ratio of rock to water (R/W), (b) partial pressure of O_2 and CO_2 in the site atmosphere, (c) chemical and mineralogical compositions of the site rock, (d) temperature-pressure conditions of the water-rock system under study. Using these conclusions and computer simulation technique of water-rock systems the chemical reactions which are occurred between the rock minerals and water have been modeled to estimate the groundwater contamination.

The computer model of water - serpentinised ultramafic rock - atmosphere system that has been constructed is based on groundwater and rock chemical compositions of Aganozeskoe deposit. The system under consideration consists of H-O-Si-Al-Ca-Mg-Na-K-Ti-P-Mn-Cl-S-C-Cr-Zn-Ni-Co-V. The simulation code is HCh [2, 3]. The modeling shows that keeping waste wet on the land surface under the atmosphere oxygen access to the chromite ore and ore waste stores will result in chromite oxidation and aqueous chromium species migration in environment. The burial of ore waste in water pool decreases the influence of oxidizing dissolution of chromite. But it is necessary to keep the pool water isolated from landscape lakes. According to [4] the rate of oxidizing dissolution of chromite might be experimentally measured.

Lead isotope composition variations in sulfides from hydrothermal fields of the Mid-Atlantic Ridge: High-precision MC-ICP-MS isotope data

I.V. CHERNYSHEV, N.S. BORTNIKOV AND A.V. CHUGAEV[1]

IGEM RAS, Moscow, Russia (cher@igem.ru)

The high-precision MC-ICP-MS method of Pb-isotope analysis (±0.03%) with mass-bias correction to $^{205}Tl/^{203}Tl$ isotope ratio [1, 2 and others] have been applied for study of sulfides from 4 hydrothermal fields (HFs) in the southern part (12°58'–16°38' N) of Mid-Atlantic Ridge (MAR) spreading zone: Ashadze, Semenov, Logachev, and Krasnov.

Sulfide Pb-isotope ratios variation scale in the four studied HFs have been estimated: 0.04–0.09% for $^{206}Pb/^{204}Pb$, 0.02–0.04% for $^{207}Pb/^{204}Pb$, and 0.04–0.07% for $^{208}Pb/^{204}Pb$, while analytical error was ±0.03%. These variations are lower by a factor of 3–4 than was evident from the data previously obtained for HFs in MAR and Pacific Ocean by traditional TIMS, which are characterized by precision ±0.1-0.2%. Using high-precision MC-ICP-MS method we did not reveal dependence of the Pb-isotope composition on the type of HFs sulfide mineral and total Pb concentration in it.

The results provide the following regularities [3]. (1) At small (close to 0.03%) variations of the Pb-isotope composition of sulfides from individual HF, the latter differ significantly from each other by all isotope ratios. (2) Sulfides of HFs related to serpentinized peridotites have more radiogenic Pb-isotope composition by all isotopes (^{206}Pb, ^{207}Pb, and ^{208}Pb) in comparison to HFs occurring on tholeiitic basalts. (3) On the evolutionary Pb-Pb isotope diagrams the Pb-isotope compositions of HFs sulfides discretely plot in the area of MAR basalts and are located exactly along the NHRL. The Pb-isotope characteristics of sulfides from MAR HFs permit participation of two mantle sources of Pb (DMM and HIMU) in their formation with prevalence of the first of them. Sulfides of MAR HFs are similar to MORB by the total range of the Pb-isotope composition; because of this, the data obtained do not contradict the idea that hydrothermal solutions and then sulfides inherit the Pb-isotope composition from underlying rock series. As above represented data show convective cells provide exceptional homogenization of Pb isotope composition for individual HFs.

U-Pb and Th-Pb dating of apatite by LA-ICPMS

DAVID M. CHEW[1]*, PAUL J. SYLVESTER[2] AND MIKE N. TUBRETT[2]

[1]Department of Geology, Trinity College Dublin, Dublin 2, Ireland. (correspondance*: chewd@tcd.ie)
[2]Department of Earth Sciences and Inco Innovation Centre, Memorial University, St. John's, Newfoundland, A1B 3X5 Canada (psylvester@mun.ca, mtubrett@mun.ca)

Apatite is a common U- and Th-bearing accessory mineral in igneous, sedimentary and metamorphic rocks and ore systems. However, low U, Th and radiogenic Pb concentrations, elevated common Pb and the lack of a U-Th-Pb apatite standard remain significant challenges in dating apatite by LA-ICPMS.

This study has determined U-Pb and Th-Pb ages for seven apatite occurrences (Durango, Emerald Lake, Kovdor, Mineville, Mudtank, Otter Lake and Slyudyanka) by LA-ICPMS [1]. Analytical procedures involved rastering a 10µm spot over a 40×40µm square to a depth of 10µm using a Geolas 193nm ArF excimer laser coupled to a Thermo ElementXR single-collector ICPMS. These raster conditions minimized laser-induced inter-element fractionation which was corrected for using the back-calculated intercept of the time-resolved signal. A Tl–U–Bi–Np tracer solution was aspirated with the sample into the plasma to correct for instrument mass bias. External standards (Plešovice and 91500 zircon, NIST SRM 610 and 612 silicate glasses and STDP5 phosphate glass) along with Kovdor apatite were analysed to monitor U-Pb, Th-Pb and Pb-Pb ratios.

Common Pb correction employed the ^{207}Pb method, and also a ^{208}Pb correction method for samples with low Th/U. The ^{207}Pb and ^{208}Pb corrections employed either the initial Pb isotopic composition where known or the Stacey and Kramers model. No ^{204}Pb correction was undertaken because of ^{204}Pb interference by ^{204}Hg in the argon gas supply.

Age calculations used a weighted average of the common Pb-corrected ages and Tera-Wasserburg Concordia intercept age (both unanchored and anchored through common Pb). The samples yield ages consistent with independent estimates of the U-Pb apatite age, which demonstrates the suitability of the analytical protocol employed. Weighted mean age uncertainties are as low as 1-2% for U- and/or Th-rich Palaeozoic-Neoproterozoic samples [1].

Aqueous CO_2 solutions at silica surfaces and confined environments

ARIEL A. CHIALVO[1], LUKAS VLCEK[1] AND DAVID R. COLE[2]

[1]Oak Ridge National Laboratory, Oak Ridge, TN 37631, U.S.A. (chialvoaa@ornl.gov)
[2]Ohio State University, Columbus, OH 43210, U.S.A.

The CO_2 capture and sequestration in geological reservoirs have been considered as a potential approach to mitigate its release into the atmosphere and reduce its contribution to the greenhouse effect on climate change. The feasibility and safety of this process for long-term storage of CO_2 depends on the low hydraulic permeability of the caprock and its ability to hold the aqueous fluid in its porous structure, *i.e*., its interfacial and confinement properties.

Interfacial and confined fluids exhibit microstructural, dynamical, and thermophysical behavior that differ dramatically from their bulk counterparts. The immediate consequence is the inherent inability of current modeling approaches to capture the actual (aqueous-caprock) fluid-solid and fluid-fluid interfacial mechanisms underlying the geological CO_2 sequestration.

Here we present a molecular-based study of the microstructural and dynamical behavior of CO_2-aqueous solutions at silica surfaces and under extreme confinement, to address fundamental issues, including (a) how the degree of surface hydrophobicity affects the interfacial structure, (b) how the overlapping of interfacial structures affects the confined fluid composition (relative solubility), and (c) how to account for the effect of medium polarization on the species solubilities.

Toward those goals we developed (i) a synergistic approach to calibrate the CO_2-H_2O interactions for the accurate and simultaneous prediction of the compositions of the two phases in liquid (water_rich)-liquid (CO_2_rich) equilibrium at realistic well conditions [1]; and (ii) we applied a molecular dynamics protocol that allows the simultaneous study of the behavior of the aqueous system at interfaces and within confinement between silica surfaces, while the fluid remains in equilibrium with its own bulk at isobaric-isothermal conditions.

Carbon-isotope and Mercury Stratigraphies of the Frecheirinha Formation cap carbonate, Northeastern Brazil

L. CHIGLINO[1], A.SIAL[1] AND C. GAUCHER[3]

[1]NEG-LABISE, Departamento de Geologia, Universidade Federal de Pernambuco, Recife, Brazil (Sial@ufpe.br, leticia@ufpe.br)

[2]Facultad de Ciencias, Universidad de La República, Montevideo, Uruguay (gaucher@chasque.com)

The Frecheirinha Formation is a carbonate unit of the Ubajara Group in the the Middle Coreaú Domain, state of Ceará, Brazil. This formation is composed of basal marls followed by limestone-dolostones rhythmites and by stromatolitic limestone in the top. It overlies red to purple slates and, locally, itabirites of the Caiçaras Formation. The C-isotope pathway for the Frecheirinha Formation with negative $\delta^{13}C$~-6 ‰values in the base and positive values up to 3.7 ‰ in the top of the formation is compatible with pathways for cap carbonates elsewhere. On the contrary to other studied cap carbonates in northeastern Brazil (e.g. Sergipano and Seridó Belts and Rio Pardo Basin), no $\delta^{13}C$ value > + 3.7‰ has been recorded in the Frecheirinha Formation, and this raises the possibility of an Ediacaran age for this carbonate sequence. A preliminary Hg survey with carbonate samples from the Freicherinha Formation was carried out, aiming to use Hg as a proxy of volcanism intensity and CO_2 buildup during a possible snowball event. Typically, Hg contents have been analyzed only form basal marls and that show negative $\delta^{13}C$ values ~ -6‰. In this way, only carbonates deposited at the earliest stages of the aftermath of glacial events were analyzed. The highest mercury contents were over 10 times higher than background values (<1nng^{-1}).This suggest that CO_2 in the basal portion of this carbonate formation is mostly mantle-derived, transferred to the atmosphere by volcanism. The only age available for the Frecheirinha Formation (0.61 Ga) is based on poor Rb-Sr isochron for clay fractions of the Caiçara Formation [1]. The Mucambo pluton intruded these carbonates at 0.54 Ga [2]. These carbonates show $^{87}Sr/^{86}Sr$ values ~ 0.7075 which do not allow an unambiguous age assignment. Similar Sr-isotope values and associated itabirites without glacial features occur in the Ediacaran Arroyo del Soldado Group of Uruguay.

Compound-specific stable isotope analysis of amino acids as a novel tool for ecological food web study

Y. CHIKARAISHI, N.O. OGAWA, Y. TAKANO, M. TSUCHIYA AND N. OHKOUCHI

Institute of Biogeosciences, Japan Agency for Marine-Earth Science and Technology (ychikaraishi@jamstec.go.jp)

Knowledge of the trophic position (TP) of organisms in food webs allows understanding of biomass flow and trophic linkages in complex networks of ecosystems. Compound-specific stable isotope analysis (CSIA) of amino acids is a novel method with that enables TP estimates of organisms in food webs [1-4]. This approach is based on contrasting isotopic fractionation during metabolic processes between two common amino acids: glutamic acid (Glu) shows significant ^{15}N-enrichment of +8.0‰ during reactions (transamination, deamination) that cleaves the carbon-nitrogen bond, whereas phenylalanine (Phe) shows little change in $\delta^{15}N$ values (by +0.4‰) during conversion to tyrosine that neither forms nor cleaves the carbon-nitrogen bond [3]. In the previous studies [3,4] we established based a number of natural and laboratory grown organisms a general equation for estimating the TP of organisms by CSIA of amino acids:

$$TP = [(\delta^{15}N_{Glu} - \delta^{15}N_{Phe} + \beta)/7.6\ ] + 1$$

where β represents the isotopic difference between Glu and Phe in primary producers (–3.4‰ for aquatic cyanobacteria and algae, +8.4‰ for terrestrial C3, and –0.4‰ for terrestrial C4 plants). In the presentation, we briefly review this amino acid method and then show its application to various natural organisms in aquatic marine and freshwater as well as terrestrial food webs.

Self-assembly in natural organic matter: Lipid and amphiphilic components

G. CHILOM, J. SHORE AND J. A. RICE*

Dept. Chemistry & Biochemistrry, South Dakota State University, Brookings, SD 57007, USA (gabriela.chilom@sdstate.edu, jay.shore@sdstate.edu, *correspondence: james.rice@sdstate.edu)

Recent work has demonstrated that natural organic matter (NOM) in soils and sediments has a hierarchical or "structure within a structure" architecture [1,2]. The first-order structure results from the self-assembly of amphiphilic and lipid components to form a nanostructured composite material. The second-order structure is formed by the self-assembly of this composite with additional but nonamphiphilic components. The objective of this study is to investigate the dependence of NOM self-assembly on the concentration and nature of components in the first-order level of organization, which is assumed to initiate and control the final NOM structure. Composite materials isolated from four different environmental samples were analyzed by differential scanning calorimetry and multidimensional solid-state NMR spectroscopy. Variation of the excess heat capacity and the mobility and domain structures of composite materials with their composition was used to assess structural organization of these materials.

Emplacement of passive margin sediments into deep crustal hot zones of continental arcs: Interplay of tectonic and magmatic thickening in the formation of continental crust

E. J. CHIN[1], C.-T. LEE[1], D. L. TOLLSTRUP[2], L.-W. XIE[2], J. B. WIMPENNY[2] AND Q.-Z. YIN[2]

[1]Rice University, Houston, TX USA (ejc5@rice.edu)
[2]University of California, Davis, CA, USA

Both magmatic and tectonic processes cause thickening of continental arc lithosphere. In western USA, increased Farallon-North American plate convergence during the Cretaceous was accompanied by lithospheric thickening due to enhanced magmatism and tectonic shortening. Here, we use lower crustal metaquartzite (80% SiO_2) xenoliths in late Miocene basalts in the central Sierra Nevada Batholith, California to constrain how arc lithosphere thickens and matures. The xenoliths are equigranular in texture and contain >50% qtz, ~10% gt, <40% pl, trace TiO_2, Al_2SiO_5, and biot. High qtz mode, abundant detrital zircons, and oriented graphites suggest a supracrustal sedimentary protolith. However, last equilibration T using TitaniQ are 700-800°C. Thermodynamic modelling shows that coexistence of gt and pl for these bulk compositions limits equilibration P's to 0.6-1.6 GPa with GASP barometer giving 0.9-1.3 GPa. These P-T constraints indicate equilibration of the metaquartzites within a hot lower crust (18-45 km). All zircons have discordant U-Pb with variable upper intercept ages (1.7, 2.7, 3.3 Ga; consistent with Hf model ages) and common lower intercept age (100 Ma). Collectively, the above indicate that protoliths of the metaquartzites were Proterozoic to Paleozoic passive margin sediments of N. American affinity and that they were transported to lower crustal depths at ~100 Ma during the peak of Cretaceous arc magmatism. Underthrusting of N. American lithosphere beneath the arc could have transported these sediments to high P, but underthrusting alone cannot explain the xenoliths' high final temperatures. An extra heat source, imparted by deep lithosphere magmatic "hot" zones, is needed. Our results thus suggest a complex interplay between tectonics and magmatism that drives vertical growth and compositional evolution of continental arcs. Despite the common view that magmatic differentiation drives lower crust to become mafic and upper crust felsic, underthrusting can introduce felsic rocks into lower crust. Local density, rheologic and seismic inversions are thus expected.

[7]NOAA NCEP, Camp Springs, Maryland, USA

We present an investigation on multi-decadal changes of atmospheric aerosols and their effects on surface radiation using a global chemistry transport model along with the near-term to long-term data records. We focus on a 28-year time period of satellite era from 1980 to 2007, during which a suite of aerosol data from satellite observations, ground-based measurements, and intensive field experiments have become available. We analyze the long-term global and regional aerosol trends and their relationship to the changes of aerosol and precursor emissions and assess the role aerosols play in the multi-decadal change of solar radiation reaching the surface (known as "dimming" or "brightening") at different regions of the world, including the major anthropogenic source regions (North America, Europe, Asia) that have been experiencing considerable changes of emissions, dust and biomass burning regions that have large interannual variabilities, downwind regions that are directly affected by the changes in the source area, and remote regions that are considered to representing "background" conditions.

Oxygen optodes as fast sensors for eddy correlation measurements in aquatic systems

The aquatic eddy-correlation technique can be used to non-invasively determine the oxygen flux across the sediment-water interface by analyzing the covariance of vertical flow and oxygen concentration in a small measuring volume above the seabed. The method requires fast sensors that can follow the rapid changes in flow and the oxygen transported by this flow. In this paper, we demonstrate the suitability of fast optical oxygen sensors (optodes), in place of the traditionally used electrodes. Optodes have the advantage over electrodes of being less susceptible to signal drift, more durable under field conditions, less expensive, and repairable. Comparisons of the response times of optodes and electrodes to rapid oxygen changes showed that the optimized optodes had a slightly longer response time (164 ± 70 ms) than the microelectrodes (151 ± 60 ms) but were fast enough to capture the oxygen fluctuations that are relevant for the eddy correlation flux calculations. Side by side comparisons of benthic oxygen fluxes collected with both electrode-based and optode-based eddy correlation instruments in freshwater and marine environments showed good agreement between the measured fluxes. Over a 4 h mid-day measuring period, short term (15min) oxygen fluxes in the spring-fed Wakulla River (Florida) fluctuated between 52 and 401 mmol m^{-2} d^{-1} (average 165 ± 67 mmol m^{-2} d^{-1}), revealing the importance of local light and flow variations on the benthic oxygen exchange.

Oxidation of FeS by $Fe^{3+}_{(aq)}$

P. CHIRITA[1]* AND M.L. SCHLEGEL[2]

[1]University of Craiova, Calea Bucuresti 107I, Craiova Romania (*correspondence: paulxchirita@gmail.com)
[2]CEA, DEN/DANS/DPC/SCP/Laboratory for the Reactivity of Surfaces and Interfaces, F-91191 Gif-sur-Yvette, France (michel.schlegel@cea.fr)

The oxidative dissolution of iron monosulfides (FeS) releases toxic elements, such as heavy metals and arsenic, in natural solutions [1]. Also, partial oxidation of sulfur from FeS minerals produces sulfur-bearing compounds which may alter the redox properties of natural media [2]. Hence, it is important to understand the reactions between FeS minerals and oxidative solutions.

In this work we examine the kinetics and mechanism of oxidative dissolution of synthetic FeS in presence of $Fe^{3+}_{(aq)}$ by monitoring the pH, Eh and total dissolved Fe concentration ($[Fe]_{total}$) of oxidant solutions during their contact with FeS that lasted 4 hours. Note that concentrations of dissolved sulfur were too low to be reliably quantified. The experiments were performed in acidic media ($2 \leq pH \leq 3$), 25 ºC and $[Fe^{3+}_{(aq)}]$ spanning the $[10^{-4}; 10^{-3}]$ mol L^{-1} range.

The experimental data indicate that Fe^{3+} was removed from the solution at pH>2. A progressive increase in pH values and an Eh decrease within 4 h of reaction time were also observed. The reaction order of FeS oxidation with respect to $[H^+]$ is estimated to 0.65 at initial pH 3.0, and increases up to 1.0, when initial pH decreases [3], indicating that $[H^+]$ is an important parameter of FeS oxidation. In contrast, ferric iron concentration has only a small effect on FeS oxidative dissolution rate in studied $[Fe^{3+}_{(aq)}]$ range.

Taking into consideration present findings it can be stated that mechanism of FeS oxidation starts with the protonation of mineral surface [2]. Thereafter, the adsorbed protons accelerate Fe^{2+} release [3]. Finally, $Fe^{3+}_{(aq)}$ may adsorb at the surface and oxidize the sulfur moieties to insoluble species, presumable polysulfide ($S_n^{2-}{}_{(s)}$) and elementar sulfur ($S^0_{(s)}$).

The authors greatly appreciate support from IFA-CEA Program (Project C1-04).

Two competing processes in petrogenesis of basaltic magma conduits

SOFYA CHISTYAKOVA* AND RAIS LATYPOV

Department of Geosciences, University of Oulu, Oulu, FI-90014, Finland
(*correspondence: sofya.chistyakova@oulu.fi)

A recent geochemical study of dolerite dykes from many regions of the world has revealed that small dolerite dykes (<50 cm wide) representing shallow parts of basaltic magma conduits are remarkably zoned [1-5]. The zonation is compositionally anomalous since compatible and incompatible components behave in a manner inconsistent with predictions of fractional crystallization of basaltic magma. Here we put forward a novel concept interpreting the anomalous compositional trends in dolerite dykes as a result of competition between two petrogenetic processes with opposite effects on dyke composition. These are (a) the filling of dykes with magmas that become increasing more evolved with time and (b) *in situ* cumulate growth of these inflowing magmas against dyke sidewalls. The first process makes inward-solidifying rocks geochemically more evolved whereas the second process more primitive. The combined operation of these two competing processes results in intricate chemical profiles of dykes. Geochemical modelling indicates that all the observed patterns in distribution of compatible and incompatible elements in small dolerite dykes can be reproduced by variations in the relative contribution of these two petrogenetic processes. One important implication of this study is that compositional zonation of small dolerite dykes is indicative of an effective magma fractionation along sidewalls of the deeper parts of basaltic magma conduits.

Zircon U-Pb and Hf isotopic constraints on the magmatic and tectonic evolution in Iran

HAN-YI CHIU[1]*, SUN-LIN CHUNG[1], MOHAMMAD H. ZARRINKOUB[2], I-JHEN LIN[1], HSIAO-MING YANG[1], CHING-HUA LO[1], HAO-YANG LEE[1], KWAN-NANG PANG[1], SEYYED S. MOHAMMADI[2] AND MOHAMMAD M. KHATIB[2]

[1]Department of Geosciences, National Taiwan University, Taipei, Taiwan (*correspondence: hychiu@ntu.edu.tw, sunlin@ntu.edu.tw)
[2]Department of Geology, Birjand University, Birjand, Iran

This study reports new zircon LA-ICPMS U-Pb ages and Hf isotope compositions, coupled with whole-rock Ar-Ar age data and geochemical analyses, for magmatic rocks of Cenozoic age from the Urumieh-Dokhtar magmatic arc (UDMA) in Iran. The UDMA has been divided into three parts by latitude of ~35°N and ~31°N in this study. The northwestern UDMA show two distinct age periods: (1) the older period of 53-27 Ma exhibits zircon $\varepsilon_{Hf}(T)$ values from +11.8 to +1.8; and (2) the younger period of <11 Ma exhibits zircon $\varepsilon_{Hf}(T)$ values from +12.8 to +5.9 and reveals the same formation time as the collision-related volcanism in eastern Anatolia proposed by Keskin [1]. The central and southeastern parts of UDMA yield ages of 51-16 Ma with zircon $\varepsilon_{Hf}(T)$ values from +12.8 to -1.3 and ages of 45-5 Ma with zircon $\varepsilon_{Hf}(T)$ values from +15.7 to +1.1, respectively. The overall zircon $\varepsilon_{Hf}(T)$ values implicate that at least three significant episodes of mantle input occurred in the middle Eocene (~40 Ma), the early Oligocene (~30 Ma) and the late Miocene (~10 Ma). Zircons from the youngest magmatic rocks in central UDMA, however, show much negative $\varepsilon_{Hf}(T)$ values from +8.1 to -1.1, suggesting contamination of crustal materials has played an important role in the middle Miocene magmatism in this region. Furthermore, the pre-collisional, calc-alkaline magmatism in the UDMA appears to cease southeastward, that implies the diachronous collision occurred between Arabia and Eurasia and started in Armenia and northwestern Iran.

Optimization of a low-background liquid scintillation counter for the determination of ^{222}Rn and Uranium isotope in ground water

S.Y. CHO, K.Y. LEE, Y.Y. YOON AND K.S. KO

KIGAM, Daejeon 305-350, Korea (sycho@kigam.re.kr, kylee@kigam.re.kr, yyoon@kigam.re.kr, kyungsok@kigam.re.kr)

An analytical method for the measurement of the ^{222}Rn and Uranium isotope in water sample by liquid scintillation counting technique using LKB Wallac Quantulus 1220 liquid scintillation counter(LSC) equipped with pulse shape analyzer(PSA). We have optimized the pulse-discrimination capabilities of the detector to achieve the best α/β separation and the lowest detection limits possible. LSC was calibrated using the optimization of PSA with ^{241}Am and ^{90}Sr/^{90}Y as well as ^{226}Ra. The optimum PSA level for the measurement of ^{222}Rn was 100 when measuring a sample containing 8 ml water and 12 ml of Optiphase HiSafe™ 3 scintillation cocktail. By the analysis of ^{226}Ra standard, ^{222}Rn counting efficiency and precision were found to be 91.6 ± 3.6% and 2%, respectively. Detection limits of ^{222}Rn for 5 hours counting were counted to be 0.11 Bq/L.

A solvent extraction method was used for the measurement of uranium isotope in ground water samples. The effect of solution volume was not significant, the error being less than 5% for solutions ranged from 100 to 1000 mL at pH 2. The uranium extraction efficiency was found to be the maximum at pH 2 while the pH was varied from 0.5 to 10. We dispersed 20 mL of liquid scintillation for both solvent extraction and alpha/beta discrimination in one liter of water at pH 2. The extraction efficiency of uranium isotopes was near 96% according to the NIST standard. Using the method, the lower detection limit for uranium was determined to be 0.018 Bq/L, with the counting time of 300 min. The results of this study were also compared to those obtained by the conventional ICP-MS measurement. It is demonstrated that the suggested method is valuable to determine the optimum extraction and measurement conditions for uranium in ground water

The analytical method obtained from this work was also applied to the determination of ^{222}Rn and uranium isotopes in some ground water samples.

Hydrothermal copper mineralization in the Gyeongnam mineralized district, Korea

SANG-HOON CHOI

Chungbuk National Univ., Cheongju, Chungbuk, 361-763 Korea (cshoon@chungbuk.ac.kr)

Copper mineralization in the Gyeongnam district, which is located within the Cretaceous Gyeongsang basin, mainly occurs in hydrothermal polymetallic quartz and/or carbonate veins. These veins are all related to the Cretaceous Chindong granite. Generally, successive polymetallic ore mineralization in the district shows a simplified mineralogy progressing through: Fe-W-Mo, Cu, (Cu-)Zn-Pb with sulfosalts, and/or ferric mineralization. The early Gyeongnam hydrothermal system is characterized by high-salinity brine and/or CO_2-rich fluids. The vein mineralization initiated at high temperature (≈550℃) from fluids with high salinity (up to about 60 equiv. wt. % NaCl or NaCl+KCl) derived mainly from the granite source and/or CO_2-rich fluid by fluid unmixing coupled with boiling. The oxygen isotope data ($\delta^{18}O_{water}$ = 8.9 to 4.7‰ for the early mineralization) suggest that early hydrothermal fluids in the Gyeongnam hydrothermal system likely represent magmatic and/or meteoric water whose isotopic composition was controlled by exchange with a large volume of igneous (and metamorphic or sedimentary) rocks at near-magmatic temperatures. In the waning portion of the vein mineralization, the high-temperature, high-salinity fluids gave way to progressively cooler, more dilute fluids (down to ≈150℃ and ≈1 equiv. wt. % NaCl). There is a systematic decrease in calculated $\delta^{18}O_{water}$ values with decreasing temperature in the Gyeongnam hydrothermal system (from 5.0 to -9.9 ‰). These trends are interpreted to indicate progressive mixing of high-salinity, magmatic hydrothermal fluids with cooler and less saline meteoric groundwater. Equilibrium thermodynamic data combined with mineral paragenesis, and fiuid inclusion and isotope data indicate that copper minerals precipitated mainly within a temperature range of 350° to 250°C. During early copper mineralization at 350°C, significant amounts of copper (10^3 to 10^2 ppm) could be dissolved in weakly acid NaCl solutions. For late mineralization at 250°C, about 10^0 to 10^{-1} ppm copper could be dissolved. Equilibrium thermodynamic interpretation indicates that the copper in the Gyeongnam hydrothermal system could have been transported mainly as a chloride complex and the copper precipitation occurred as a result of cooling accompanied by changes in the geochemical environments (fs_2, fo_2, pH, etc.) resulting in decrease of solubility of copper chloride complexes.

Mineralogy and Geochemistry of the Yangyang IOA deposit, South Korea

SEON-GYU CHOI[1]*, JIEUN SEO[1], JUNG-WOO PARK[2], DONG WOO KIM[1]

[1]Department of Earth and Environmental Sciences, Korea University, Seoul 136-701, Korea (*correspondence: seongyu@korea.ac.kr, still4@korea.ac.kr, heskool@korea.ac.kr)

[2]Research School of Earth Sciences, Australian National University, Canberra ACT 0200, Australia (jung.park@anu.edu.au)

The Yangyang deposit is characterized by the occurrence of a distinctive type of iron oxide apatite (IOA) deposit such as a Kiruna-type deposit. Occurrence in iron mineralization is concordant to discordant layered, lenticular or massive, magnetite-biotite, magnetite-actinolite, and magnetite-apatite-biotite-pyrite ores, which are hosted by a stratum of metamorphosed subvolcanic-sedimentary unit enclosed within Paleoproterozoic gneiss complexes. The phosphorous content in the apatite-rich magnetite ore varies up to ca. 7.38 wt. % P_2O_5. However, the iron ores have about 40 to 90 wt. % Fe_2O_3 with significantly low titanium content (< 0.57 wt. % TiO_2) and V content (< 404 ppm V).

The dominant mineral constituents consist of magnetite, actinolite, biotite and fluorapatite with subordinate amounts of scapolite, albite, diopsidic pyroxene, pyrite and carbonates. Titanite, allanite, monazite and fluorite are distinctively found in a mineral accessory assemblage. Apatite grains contain Th-poor monazite, magnetite, and sulfide inclusions commonly, and exhibit patchy zoning in concentrations of REE and some trace elements such as Si, S, V, Zr, Y, Pb, Th, and U, suggesting that apatite undergoes hydrothermal overprint as observed in other IOA deposits of Kiruna area, Sweden, and Bafq district, Iran. Sulfides clearly overprint the oxide stage assemblages and consist of minor pyrite ± chaclcopyrite. Low Ti, V, Cr, Co and Ni contents in magnetite indicate that these magnetites are not magmatic origin (i.e., nelsonite). The halite-bearing fluid inclusion in apatite shows an evolving hydrothermal system from saline fluids. REE-rich fluorapatite and titanite in the Yangyang ore mean ages of 198±13 Ma and 226.1±5.3 Ma, respectively (U-Pb LA-ICPMS ages). The Yangyang iron deposit has been precipitated from iron oxide-volatile-rich magmatic-hydrothermal fluids, which is derived from slightly alkaline magma.

Lu-Hf and Sm-Nd isotope systematics of Korean spinel peridotites: A case for Nd-Hf decoupling

SUNG HI CHOI[1,*] AND SAMUEL B. MUKASA[2]

[1]Department of Geology and Earth Environmental Sciences, Chungnam National University, Daejeon 305-764, S. Korea (*correspondence: chois@cnu.ac.kr)
[2]Department of Earth Sciences, University of New Hampshire, Durham, NH 03824 (sam.mukasa@unh.edu)

We have determined the Hf and Nd isotopic compositions of spinel peridotite xenoliths in alkali basalts from Baengnyeong (BR) and Jeju (JJ) islands, South Korea, in order to constrain the timing of melt depletion events. Equilibration temperatures estimated by two pyroxene thermometry range from 780 to 950ºC, and 960 to 1010ºC for BR and JJ peridotites, respectively. The BR peridotite clinopyroxenes are characterized by extremely radiogenic Hf in association with isotopically less extreme Nd, resulting in strong Nd-Hf decoupling compared to the mantle array. This is in stark contrast to the observation of well-correlated isotopic compositions of Hf and Nd in the JJ peridotite clinopyroxenes, plotting along the Nd-Hf mantle array. The Hf abundances and isotopic compositions of the BR clinopyroxenes were less affected by relatively recent secondary enrichments that overprinted the LREE abundances and Nd isotopes, which caused decoupling of Nd-Hf isotopes. In the case of JJ peridotites, the Nd-Hf isotopic compositions are considered to have been re-equilibrated, probably because of efficient diffusion at relatively higher temperature than the BR peridotites.

Lu-Hf tie lines for clinopyroxene and orthopyroxene from four of the Korean peridotites have negative slopes on the Lu-Hf isochron diagram, yielding negative ages. This is interpreted as indicating recent isotopic exchange of orthopyroxene by reaction with metasomatic agents having low $^{176}Hf/^{177}Hf$ components. Secondary overprinting in orthopyroxene was facilitated by the fact that this mineral has considerably lower Hf concentrations than does the co-located clinopyroxene. BR lherzolite clinopyroxenes yield a Lu-Hf isochron age of 1.9 ± 0.1 Ga, which is independently supported by a model Os age (T_{RD}) of 1.8 Ga on a refractory BR peridotite. We interpret this age range to mark the time of stabilization of the mantle section beneath this area by major melt extraction. This Proterozoic melt removal coincided in time with widespread ca. 2.1 to 1.8 Ga tectonothermal events documented throughout the Korean peninsula.

Kinetics and mechanism of antigorite dehydration: Implications for subduction zone seismicity

M. CHOLLET[1], I. DANIEL[1], K. T. KOGA[2], G. MORARD[3] AND B. VAN DE MOORTÈLE[1]

[1]Université Lyon 1, ENS de Lyon, CNRS, UMR 5276, Laboratoire de Géologie de Lyon, France (isabelle.daniel@univ-lyon1.fr)
[2]Laboratoire Magmas et Volcans, UMR CNRS 6524, IRD – M163, Université Blaise Pascal Clermont-Ferrand, France
[3]MARUM, Center for Marine Environmental Sciences, Bremen, Germany
[3]Institut de Minéralogie et de Physique des Milieux Condensés, Paris, France

Properties of serpentine minerals are thought to influence the occurrence and location of intermediate-depth seismicity in subduction zones, which is often characterized by two dipping planes separated by ca. 30 km defining a double seismic zone. The seismicity of the lower plane is believed to be provoked by the dehydration of serpentine since the experimentally determined stability limit for antigorite matches hypocenters location. This requires that the fluid produced by dehydration is released much faster than the typical time-scale of ductile deformation mechanisms. Here we measured the kinetics of antigorite dehydration *in situ* at high pressure and high temperature by time resolved synchrotron X-ray diffraction in a closed system. Antigorite dehydrates in two steps. During step (1) it partially breaks down into olivine and a hydrous phyllosilicate closely related to the 10Å phase. The modal abundance of the intermediate assemblage is described by 66 wt% antigorite, 19 wt% olivine, 12 wt% 10Å phase. During step (2) at higher temperature, the remaining antigorite and the 10Å phase fully dehydrate. From the analysis of reaction progress data, we determined that the major release of aqueous fluid occurs during step (2) at a fast rate of 10^{-4} $m^3_{fluid}.m^{-3}_{rock}.s^{-1}$. This exceeds by orders of magnitude the typical time scale of deformation by ductile mechanisms of any mineral or rock in the subducting slab or in the overlying mantle wedge. These results suggest that the fast dehydration of antigorite may well trigger the seismicity at intermediate depth in subduction zones.

Distribution characteristics of Pt, Pd, and related traffic elements in dusts from Seoul, Korea

H.T. CHON[1]*, M. SAGER[2] AND H.Y.LEE[3]

[1]Department of Energy Resources Engineering, Seoul National University, Seoul 151-744, Korea (*correspondence: chon@snu.ac.kr)
[2]Austrian Agency for Health and Food Safety, A-1226 Vienna, Austria
[3]Korea Institute of Geosciences and Mineral Resources, Daejeon 305-350, Korea

The emission level and pollution characteristics of platinum (Pt) in dust, soils, and tree barks collected from Seoul metropolitan city was published for the first time in Korea (Lee and Chon, 2006). The previous study confirmed that an important source of Pt in roadside environment is automobile catalytic converter, and that it indicates a tendency to increase Pt levels in road dusts along with traffic volume. The study also suggested that not only traffic volume but also driving style have a great influence on Pt levels in road dusts.

In this study previous dust samples and some new collected dusts from Seoul were reanalyzed to determine Pt, Pd, and some traffic metal elements by ICP-MS and ICP-OES. The concentration levels of Pt and Pd were in the range of 0 – 444 (median 76) ng/g and 172 – 1,215 (median 609) ng/g, respectively, and remarkably high concentration of Pd and Pt in dust was found in the heavy traffic areas . Palladium also shows similar distribution trend with Pt that remarkably high concentration of Pd and Pt in dust was found in the heavy traffic areas. Distribution trend of some traffic elements such as Pb, Cr, Cu, Ni, Mo, Bi is also similar to that of Pt showing relatively high correlations (higher than r = 0.50) with Pt and Pd. Road dusts with high Pt and Pd levels were enriched in traffic related elements compared with road dusts from control suburb areas.

Geologic carbon-sulfur co-sequestration: Experimental investigation of a natural analogue, Madison Limestone, SW Wyoming USA

C. CHOPPING[1] AND J. KASZUBA[1,2]

[1]Department of Geology and Geophysics, University of Wyoming, Laramie, Wyoming 82071, USA (cchopp@uwyo.edu, john.kaszuba@uwyo.edu)
[2]School of Energy Recources, University of Wyoming, Laramie, Wyoming 82071, USA

SO_2 is a common impurity in effluent gasses of coal-fired power plants. Co-sequestering SO_2 and CO_2 can eliminate the need for pure CO_2 separations and related parasitic energy costs. For 50 million years, the Mississippian Madison Limestone in SW Wyoming has naturally contained a mixture of CO_2 (66%-95%), H_2S (5%) and other gases as well as sulfur complexes (SO_4^{2-} and HS^-) and minerals (anhydrite, pyrite, and native sulfur). These products of SO_2 disproportionation provide the opportunity to evaluate how a carbon-sulfur co-sequestration scenario evolves.

Hydrothermal experiments performed at 250 bars, 110°C evaluated brine-rock±supercritical CO_2 reactions between a Na-Cl-SO_4^{2-} brine (I=0.52 mol/Kg, 80 mmol/Kg SO_4^{2-}) and two different synthetic rock types (Do-Cc-Anh-Py and Do-Cc-Py). After CO_2 injection, dissolved CO_2 concentrations increased from 1.0 mmol/Kg to 1.1 mol/Kg. In situ pH decreased from approximately 7.5 to 4.8. Ca^{2+} and Mg^{2+} concentrations initially increased, but subsequent anhydrite precipitation decreased Ca^{2+} and SO_4^{2-} concentrations in both experiments. Fe^{2+} and Mn^{2+} metal mobilization increased from below detectable limits to 0.06 mmol/Kg in both experiments. Calcite dissolution, as evidenced by mineral pitting and etching, and anhydrite mineralization in the experiments are consistent with petrologic observations of Madison Limestone core. Ca^{2+} from dissolving calcite and dolomite reacts with SO_4^{2-} provided by SO_2 disproportionation to precipitate anhydrite. Anhydrite precipitation provides a mineral trap for sulfur, but may also clog available pore space.

Bio-inorganic interfaces in the critical zone

J. CHOROVER

Department of Soil, Water and Environmental Science, University of Arizona, Tucson, AZ 85721 (chorover@cals.arizona.edu)

At the particle scale, critical zone biogeochemical interfaces are heterogeneous and patchy. Patchiness results from the wide range in mutual affinities among primary bio-geo-chemical components that are continuously influent to terrestrial weathering systems (water, minerals, solutes, gases, cells). In addition, hydrologic events shift the disequilibrium state, generating short time-scale surface reactions, colloidal dynamics, and biotic/abiotic transformations that are superimposed on (and constrained by) long-term weathering history. A corollary is that the structure and reactivity of bio-inorganic interfaces are a function of the sequence of perturbations acting on the porous medium over an integrated soil residence time.

The complexity of critical zone systems raises challenging research questions that highlight the need to unravel these couplings and feedbacks: What products form when biochemical and geochemical components react in pore waters? How stable are these products to further biogeochemical transformation and how do they influence the evolution of interfacial structure in particles, aggregates, and porous media? How does this "architecture" dictate surface reactions and the bioaccessibility of carbon and/or contaminants? How does interfacial reactivity change over time and environment to control larger system (e.g., catchment) response?

These questions can be addressed by combining tools of analytical biogeochemistry with those of hydrology, geomorphology and ecology in bench-, meso- and field-scale experiments. One goal is to elucidate molecular- and pore-scale components and processes that are active contributors to observed meso- and field-scale phenomena (e.g., metalloid stabilization, carbon sequestration, catena structure formation, catchment hydrochemical response). Such studies require multi-faceted, interdisciplinary measurements in common systems and locations. Examples are presented from ongoing studies conducted at three scales (1) biomolecule-mineral surface reactions in aqueous suspensions, (2) metal(loid) transformation in phytostabilized tailings mesocosms, and (3) biogeochemical weathering fluxes in semi-arid catchments of the southwestern US.

Geochemical position of Pb, Zn and Cd in soils near a mine/smelter: Effects of land use, type of contamination and distance from pollution source

VLADISLAV CHRASTNÝ[1], ALEŠ VANĚK[2], MICHAEL KOMÁREK[3] AND MARTIN NOVÁK[1],

[1]Czech Geological Survey, Geologická 6, 152 00 Praha 5, Czech Republic

[2]Department of Soil Science and Soil Protection, Czech University of Life Sciences Prague, Kamýcká 129, 165 21 Praha 6, Czech Republic

[3]Department of Agro-Environmental Chemistry and Plant Nutrition, Czech University of Life Sciences Prague, Kamýcká 129, 165 21 Praha 6, Czech Republic

Contaminated agriculture and forest soil samples with mining and smelting related pollutants were collected in the Pb-Zn-Ag mining area near Olkusz, Upper Silesia to (i) compare the chemical speciation of metals in meadow and forest soils situated at the same distance from the point source of pollution (paired sampling design), (ii) to evaluate the relationship between the distance from the polluter and the retention of the metals in the soil, and (iii) to assess the effect of deposited fly ash vs. dumped mining/smelting waste on the mobility of metals in the soil. The smelting emissions intensively contaminated mainly the upper soil horizons, while the deposition of processing waste resulted in a contamination of the deeper parts of soil profiles. The maximum concentrations of Pb, Zn and Cd were detected in a forest soil profile near the smelter and reached about 25 g kg^{-1}, 20 g kg^{-1} and 200 mg kg^{-1} for Pb, Zn and Cd, respectively. Forest soils are much more affected than agriculture soils. However agriculture soils suffer from the downward metal migration more than the forest soils. Metal mobility ranges in the studied forest soils are as follows: Pb>Zn≈Cd for relatively circum-neutral soil pH (near the smelter), Cd>Zn>Pb for acidic soils (further from the smelter). The mobilization of Pb, Zn and Cd in soils depends on the persistence of the metal-containing particles in the atmosphere, and consequently on the mineralogical transformation controlled by the soil pH. Under relatively comparable pH conditions, the main soil properties influencing metal migration are total organic carbon (TOC) and cation exchange capacity (CEC).

Multi-isotopic constraints on contamination history, contaminant migration and structure of the F-Area acidic plume, Savannah River Site

JOHN N. CHRISTENSEN[1]*, MILES E. DENHAM[2], MARK E. CONRAD[1], MARKUS BILL[1] AND JIAMIN WAN[1]

[1]Lawrence Berkely National Lab., Berkeley, CA, USA (*correspondance: jnchristensen@lbl.gov) (msconrad@lbl.gov; mbill@lbl.gov; jwan@lbl.gov)
[2]Savannah River Natl. Lab., Aiken, SC, USA (miles.denham@srnl.doe.gov)

Seepage basins in the F-Area of the Savannah River Site were used from 1955 to 1989 for the disposal of low-level radioactive acidic (ave. pH ~2.9) waste solutions from site operations involving irradiated uranium and other materials used in the production of radionuclides. These disposal activities resulted in a persistent acidic groundwater plume (pH as low as 3.2) beneath the F-Area including contaminants such as ^{3}H, HNO_3, ^{90}Sr, ^{129}I and U that has impinged on surface water about 600 m from the basins. After cessation of disposal in 1989, the basins were capped in 1991. Since then, remediation consisted of a pump-and-treat system that was recently replaced by *in situ* treatment using a funnel-and-gate system with injection of alkaline solutions to neutralize pH.

In order to delineate the history of contamination and the current mobility and fate of contaminants in F-Area groundwater, we have undertaken a study of variations in the isotopic compositions of U ($^{234}U/^{238}U$, $^{235}U/^{238}U$, $^{236}U/^{238}U$), Sr ($^{87}Sr/^{86}Sr$), Nd ($^{143}Nd/^{144}Nd$) water ($\delta^{18}O$, δD) and nitrate ($\delta^{15}N$, $\delta^{18}O$) within the contaminant plume. The chemical and isotopic variations in the plume all delineate upper (0-15ft below water table) and lower (15-35 ft) zones within the upper aquifer. Together, the data suggest that the lower zone represents the effects of seepage from the basins during operation, while the upper zone represents mostly meteoric water contaminated by infiltration through the sub-basin vadose zone since closure/capping. Through U isotopic analysis, we have been able to detect recent migration as the plume expands laterally, with the greatest extent of U contamination near the top of the aquifer but decreasing with depth. Comparing the U isotopic compositions of groundwater samples collected within the plume two years apart tracks the migration of U from up-gradient portions of the plume. Nd isotopic compositions indicate that REE concentrations were controlled by progressive interaction between acid solutions and natural trace minerals in the sediments. Nitrate has an isotopic signature of processed waste, but no sign of nitrate bioreduction within the plume.

Vertical distribution of ^{236}U in the western equatorial Atlantic Ocean

M. CHRISTL[1]*, J. LACHNER[1], C. VOCKENHUBER[1], M. RUTGERS V. D. LOEFF[2], O. LECHTENFELD[2] AND I. STIMAC[2]

[1]Laboratory of Ion Beam Physics, ETH-Zurich, Switzerland, (*correspondence: mchristl@phys.ethz.ch)
[2]Alfred Wegener Institute, 27570 Bremerhaven, Germany

During the Pelagia Geotraces cruise PE321 in summer 2010 two depth profiles of ^{236}U were sampled in the western equatorial Atlantic Ocean (WEA) and subsequently analyzed at ETH Zurich using low energy accelerator mass spectrometry (AMS). These data represent the first ^{236}U-measurements in the open Atlantic Ocean.

^{236}U is almost exclusively produced by neutron capture on ^{235}U. While the natural background of $^{236}U/^{238}U$ is estimated to be in the 10^{-12} - 10^{-14} range anthropogenic $^{236}U/^{238}U$ ratios are much higher. For example, it can be estimated that as a consequence of the atmospheric nuclear bomb explosions about 1-2 tons of ^{236}U were blown into the atmosphere. Mixed with the upper few hundred meters of the Ocean this would result in $^{236}U/^{238}U$ ratios in the 10^{-9} range. Although the expected signal dynamics of $^{236}U/^{238}U$ in the environment is very large, currently only AMS-systems have the capability for a fast and quasi background free detection of $^{236}U/^{238}U$ ratios significantly below 10^{-9}.

At stations 39 and 40 of the PE321 cruise two depth profiles were sampled for ^{236}U (25 m. 2500 m, and 4250 m). The $^{236}U/^{238}U$ ratios decrease from about 10^{-9} at the surface down to about 10^{-10} in the Antarctic Bottom Water (AABW). The advective contribution of anthropogenic ^{236}U from the North Sea (from nuclear reprocessing plants) seems unlikely at this location. The most likely explanation for the elevated ratios in the AABW is the transport and the subsequent release of particle bound ^{236}U from the biologically active surface waters. Extrapolating from the calculated ^{236}U-inventories a total input of 1.5 - 2 tons of ^{236}U can be estimated for the global fallout. The inventory calculations are consistent with global fallout as the sole source for ^{236}U at the WEA. However, simple box model results show that very high U-export rates from the surface layer to the deep sea (>50 ng cm^{-2} yr^{-1}) would be necessary to reproduce the measured concentration profile.

Furthermore, a close correlation of salinity and ^{236}U was found, which is much steeper than the relation with natural U-isotopes in the open ocean. This indicates that, in contrast to natural U, ^{236}U has not yet reached steady state. Our results indicate that ^{236}U might have a large potential as a new conservative and transient tracer in Oceanography.

Sr isotopes ($\delta^{88/86}$Sr and ^{87}Sr/^{86}Sr) in cold seep environment of Niger and Nile Delta Fans

NAN-CHIN CHU*[1], EMMANUEL PONZEVERA[1], EMMANUEL FAVREAU[1], GERMAIN BAYON[1] AND YVES FOUQUET[1]

[1]IFREMER, BP70, Plouzané, 29280, France (*correspondence: nchu@ifremer.fr; eponzevera@ifremer.fr; gbayon@ifremer.fr; fouquet@ifremer.fr)

In cold seep areas, carbonates form as a result of the anaerobic oxidation of methane, which increases alkalinity in pore waters. Upon formation, cold seep carbonates incorporate dissolved alkali earth elements, such as Ca and Sr. The Ca and Sr isotopic compositions of authigenic carbonates and associated pore waters can hence provide information into fluid sources and biogeochemical processes at cold seeps. Over the last decades, radiogenic ^{87}Sr/^{86}Sr ratios in sediment interstitial fluids have been used for identifying deep fluid sources in seepage areas. However, recent studies have demonstrated that significant fractionation of stable Sr isotopes can occur in marine carbonates, which led to a revisited view of the oceanic budget [1].

Here, we report paired ^{87}Sr/^{86}Sr and $\delta^{88/86}$Sr values on a series of authigenic carbonate crusts and associated pore waters from fluid seepage areas of the Niger and Nile deep-sea fans. Sr isotopes were measured on a Neptune MC-ICP-MS using Zr for mass bias correction to acquire simutaneously radiogenic and stable (^{87}Sr/^{86}Sr and $\delta^{88/86}$Sr) values [2, 3]. Our results indicate that $\delta^{88/86}$Sr values for most carbonate samples exhibit very small fractionation relative to seawater or pore water signatures, contrary to biogenic carbonates that shows a 0.1‰/amu lower than seawater [1]. Exceptions are found for a few samples collected from mud volcano settings, which are characterized by distinctively low ^{87}Sr/^{86}Sr and $\delta^{88/86}$Sr values. We will discuss the Sr isotope systematics in comparison with other proxies.

What role did methane seeps play in the formation of the Doushantuo cap carbonate?

XUELEI CHU[1]*, JING HUANG[2] AND T.W. LYONS[3]

[1]Institute of Geology and Geophysics, CAS, Beijing 100029, China (*Correspondance: xlchu@mail.iggcas.ac.cn)
[2]Institute of Geology and Geophysics, CAS, Beijing 100029, China (jhuang@mail.iggcas.ac.cn)
[3]Dept. of Earth Sciences, Univ. of California, Riverside, CA 92521, USA (timothyl@ucr.edu)

Extremely negative $\delta^{13}C_{carb}$ values, less than -30‰, have been reported for the cap carbonate of the Ediacaran Doushantuo Formation (ca. 635 Ma) and used to support the hypothesis that methane hydrate destabilization contributed significantly to formation of the enigmatic cap carbonate and negative carbon isotope anomalies following Neoproterozoic ice ages (1, 2). Here, we show distinct differences between the methane-related carbonate and bulk cap carbonate.

Negative $\delta^{13}C_{carb}$ values of <-30‰ obtained from isopachous cements and recrystallized carbonate crusts have been found only in the Yangtze Gorges area (YGA), South China. These microsamples were reported from secondary, pore-filling carbonate minerals tied to methane seep activity, rather than reflecting the bulk composition of the cap carbonate. We investigated the Doushantuo cap carbonate at three localities, the Jiulongwan (inner-shelf, YGA), Zhongling (outer-shelf), and Long'e (basin) sections, and find that the $\delta^{13}C$ and $\delta^{18}O$ values for the cap vary from -2‰ to -10‰ and -5‰ to -12‰, respectively, and show a postive $\delta^{13}C$-$\delta^{18}O$ correlation, with a negative trend from the shallow to deep sites. Interestingly, all the microsampled $\delta^{13}C$ and $\delta^{18}O$ data from the methane-seep sections in the YGA (1, 2) show two distinct trends in the $\delta^{13}C$-$\delta^{18}O$ cross-plot, a positive correlation the same as the bulk cap carbonate and negative correlation attributed to methane oxidation. Similar to the Upper-Cretaceous Tepee Buttes in Colorado (3), the latter shows a nice relationship from early to late diagenetic carbonate phases – starting with very light, methane-dominated carbon.

We conclude that the methane-related carbonate can be distinguished clearly from the bulk Doushantuo cap carbonate by coupled C and O isotopes.

Multi-scale modelling of ions and water diffusion in clays

S.V. CHURAKOV

Paul, Scherrer Institute, Villigen-PSI, CH-5232, Switzerland (sergey.churakov@psi.ch)

Materials with low hydraulic permeability such as clays are major components in engineered and natural barriers for waste disposal sites. Migration of ions and water through such barrier systems over safety relevant times are predicted solving diffusion equation on continuum scale. Natural clay, however are highly heterogeneous in terms of porosity and mineralogical composition. These heterogeneities are manifested at different scales and consequently have strong influence on diffusion of solutes. To fully understand the mechanism of ion transport in clays the solute migration has to be addressed using complementary simulations and measurements capable of resolving the transport and chemical phenomena on different scales.

In clays, up to 50-70% of fluid accessible pore space is attributed to the interlayer and the diffuse double-layer porosity where solution properties, namely the mobility of ions and water, are strongly influenced by mineral surfaces. The transport through such nanopores is readily addressed by molecular simulations. At the sub-micrometer scale the individual interlayers are interconnected thought the macrospores. Molecular simulations with explicit solvent approach are not feasible at this scale anymore. Instead pore scale stochastic approaches are used to assess the influence of pore geometry and topology on the effective diffusion coefficient of the sample. Finally, state-of-the-art X-ray tomography measurements can provide 3D mineral distribution in a sample non-destructively at a resolution down to few micrometers. These data are directly used in transport simulations to reveal the consequences of mineralogical and textural heterogeneities in clays and their influence on the effective transport parameters of clay samples. Such a multi-scale treatment of transport phenomena using complementary modelling and measurement techniques is a necessary condition for accurate and reliable prediction of radionuclides migration over geological space and time domains.

Two step up-scaling of molecular diffusion coefficients in clays

S.V. CHURAKOV[1]*, TH. GIMMI[1,2] AND M TYAGI[1]

[1]Paul, Scherrer Institute, CH-5232 Villigen-PSI, Switzerland (*correspondence: sergey.churakov@psi.ch)

[2]University of Bern, CH-3012 Bern, Switzerland

Mass transport in rocks with low hydraulic conductivity such as clays originates from Brownian motion of molecules and ions in the solution and their interaction with the surface of the minerals. Up-scaling these molecular phenomena to the continuum scale, which is required for large-scale and long-time predictions, is particularly challenging because the considered scales differ by orders of magnitude. To address the up-scaling problem we developed a two-step simulation approach which enables us to derive macroscopic diffusion coefficients of water and ions for continuum equations from pore scale molecular diffusion coefficients [1]. Our starting point for the up-scaling procedure is local pore diffusion coefficients derived from molecular dynamics simulations for specific local environments, such as the interlayer or edge regions of clay particles. We then assign these local diffusion coefficients to different types of porosity of a model clay structure and obtain the structure-averaged effective diffusion coefficient of the sample by random walk simulations. Our model clay rock is composed of compacted grains of clay minerals. The space between the grain boundaries forms micro-pores. To generate such structures, a kinetic Monte Carlo method is employed on a grid to obtain closely packed grains of desired shapes, sizes and orientations. By varying the composition and geometrical properties of the clay model we have investigated the effects of mineralogical heterogeneities and of anion exclusion on the diffusion coefficients measured in laboratory experiments. Our up-scaling concept is general and can be used for up-scaling molecular diffusion coefficients for porous materials with almost arbitrarily complex structures.

Europium structural role in silicate glasses

M.R. CICCONI[1]*, G. GIULI[1], E. PARIS[1], W. ERTEL-INGRISCH[2], D.B. DINGWELL[2] AND P. ULMER[3]

[1] School of Science and Technology – Geology Division, University of Camerino, I (*correspondence: mariarita.cicconi@unicam.it)

[3]Institut f. Mineralogie und Petrographie, ETH Zürich, CH

Rare Earth Elements (REE) have demonstrated to be important geochemical indicators; in fact, the distribution of REE in igneous rocks are frequently used to constrain the mineralogy of the source materials, the degree to which magma composition has been modified by crystal fractionation, and to identify the mineral phases removed from the magma during differentiation. Moreover, the Eu redox ratio can be used to constrain the formation conditions within a very large range of oxygen fugacity down to few log units below the Fe/FeO buffer. The $Eu^{+2}/(Eu^{+2} + Eu^{+3})$ ratio is therefore very useful in the study of meteoritic material and in studying planetary evolution. A complete understanding of transition and REE elements is important for the geochemical and petrological interpretations of magmatic processes and partition properties between melt and crystals. To this aim, synthetic silicate glasses corresponding to compositions relevant for the Earth sciences were used to study the dependence of the redox states of Eu on the bulk melt composition and at different values of oxygen fugacity (from air to IW-2). The samples have been analyzed via Eu LIII-edge X-ray Absorption Spectroscopy (XAS) to study the Eu oxidation states and local environments. Eu LIII-edge XANES peak analysis allowed the quantitative assessment of Eu redox ratio. XANES spectra vary systematically with composition and with f_{O2} (log $f_{O2} \sim 0$ to –11.6) indicating changes in the Eu oxidation state. The intensity of the shoulders on the absorption edges were quantified and used to determine $Eu^{+2}/(Eu^{+2} + Eu^{+3})$ ratio. Moreover, the local environment of Eu was determined by EXAFS (Extended X-ray Absorption Fine Structure) analyses, highlighting the different Eu behaviour as function of the f_{O2}. This work has clearly demonstrated that for a better interpretation of the Eu anomalies observed in rocks and minerals, which are often used to constrain magmatic evolutions of igneous regions, the melt composition and the redox condition must be taken into consideration.

Nanoparticles in aqueous environments: Electrochemical, nanogravimetric, STM and AFM studies

I. CIGLENEČKI[1]*, E. BURA-NAKIĆ[1], M. MARGUŠ[1], I. MILANOVIĆ[1], N. BATINA[2], A. AVALOS-PEREZ[2] AND D. KRZNARIĆ[1]

[1]Ruđer Bošković Institute, Bijenička 54, 10 000 Zagreb, Croatia (*correspondence: irena@irb.hr)

[2]Laboratorio de Nanotecnología e Ingeniería Molecular, Área de Electroquímica, Depto. Qiumica, UAM-I, Mexico City, Mexico.

Electrochemical and piezo-nanogravimetric (EQCM) studies in combination with atomic force and scanning tunneling microscopy (AFM,STM) have been used for characterization and determination of chalcogenide nanoparticles in model solutions and natural samples. Different electrode surfaces (Hg and Au) were used to give more details relating to attachment, adsorption, deposition and interaction between selected nanoparticles and functionalized electrode surfaces.

Mercury electrodes preconcentrate some metal sulfide nanoparticles effectively, enabling their detection at submicromolar concentrations. Voltammetrically active metal sulfides are accumulated on Hg electrode surfaces by two mechanisms: a) adsorption of nanoparticles to an electrode where they undergo reduction at -0.9 to -1.35 V (vs. Ag/AgCl), and b) formation directly at the Hg electrode surface in supersaturated metal sulfide solutions; the latter produces an analytical artifact [1]. In the case of FeS nanoparticles, anodic oxidation of Hg by FeS at around -0.45 V is the operating mechanism for their determination in aqueous solution [2].

By following changes in resonance frequency accompanied with some changes in current produced during oxido-reduction processes, it is possible to characterize physico-chemical properties and to calculate the mass of nanoparticles deposited on the Au surface over a broad range of environmentaly relevant solution characteristics, including variation in ionic strength, composition and particle sizes. Particle deposition mechanisms are studied in relation to variations of particle charge, particle size and applied electrode potential, all with the aim to improve and develop new analytical methods for fast, selective, qualitative and quantitative nanoparticle characterization in natural waters.

This research was suported by UKF grant 62/10.

[3]University of Manitoba, Winnipeg, Manitoba, Canada (chakhmou@cc.umanitoba.ca)

Bayan Obo Fe-Nb-REE super large deposit in Inner Mongolia is the main source of REE in the world and makes China the monopolist producer of these strategic elements. A typical feature of the Bayan Obo super large deposit is the presence of polymetalic Fe-Nb-REE mineralization in 3 different ores - disseminated, banded and massive. The principal REE bearing minerals are bastnaesite [(Ce,La,Nd)(CO_3)F] followed by monazite [(Ce,La,Nd)PO_4] in disseminated and banded ores. Magnetite and hematite are the dominant Fe-ore minerals in massive ores. Mining process in grassland and ore processing in Baotou bring several environmental hazards. Actual risk assessment is contaminated dust by Th and heavy metals, and it´s transporting by sand storms to X00 km in main direction to SE (Peking capital). Leaching of old-mined ore is responsible for contamination of soil and ground water collectors by heavy metals and radioactive thorium (bastnaesite and monazite ores contain up to 0,5% ThO_2). The harm to environment of the past is mainly ore processing causing dominantly water contamination. Presently the ore processing is ecologically and economically well-developed under supervision of Baotou Institute of rare earth elements.

Structural aspects and surface reactivity of aluminous ferrihydrite precipitates

A.C. CISMASU [1]* F.M. MICHEL[1,2] J.F. STEBBINS[1], C.M. LEVARD[1] AND G.E. BROWN JR[1,2].

Ferrihydrite (Fh), a hydrated, nanoparticulate, high surface area, reactive Fe-oxide, impacts the mobility of inorganic and organic pollutants through sorption reactions in a variety of natural environments. Aluminous Fh is common in nature primarily because of the natural abundance of Al. However, few studies have dealt with Al-Fh, and thorough structural analyses of this phase are lacking. The mode of association of Al with Fh may vary from true chemical substitution, to surface precipitation, to formation of a mixture of two (or more) individual nanoscale phases. This may have a considerable effect on the composition and/or structure of Fh nanoparticle surfaces, and thus on their surface reactivity and their interaction with pollutant species.

Here we used a variety of laboratory (TEM, NMR), and synchrotron-based techniques (X-ray total scattering and PDF analysis, scanning transmission x-ray microscopy) to characterize two Al-Fh series synthesized at variable precipitation rates in the presence of 5 to 40 mol % Al. We find that roughly 25 mol % Al is incorporated in Fh, regardless of the synthesis method we used. Phase separation (formation of Al-hydroxides, e.g., gibbsite) was most significant at Al concentrations above 30 mol % Al. However, Al-hydroxide phases were also detected in samples of lower Al content (as low as 15 mol % Al), particularly in the slowly precipitated series; this finding may be a result of the kinetics of co-precipitation. Furthermore, it appears that the amount of Al incorporated in Fh is not affected by the synthesis method and is more likely controlled by the accumulated strain caused by Al in the Fh lattice. Finally, the surface reactivity of selected Al-Fh samples was investigated by Zn-adsoprtion experiments, which indicate a slight decrease in overall Zn adsorption in comparison to pure Fh. Our results provide an in-depth look at the structure and surface of Al-Fh, as well as insights about the interaction between Al and Fe during co-precipitation.

Re-partitioning of Fe and Cu during the oxidation and acidification of acid sulfate soil materials

S.R. CLAFF[1,2]*, E.D. BURTON[1], L.A. SULLIVAN[1] AND R.T. BUSH[1]

[1]Southern Cross GeoScience, Southern Cross University, Lismore, NSW, Australia (*correspondence salirian.claff@scu.edu.au)

[2]CRC CARE, University of South Australia, Mawson Lakes, SA 5095, Australia

Drainage and excavation of coastal lowlands for agricultural and urban development often results in the oxidation of underlying Fe-rich sulfidic sediments. Exposure and subsequent dissolution of these sulfide minerals creates acidity in the form of sulfuric acid and ferrous Fe [1]. The coupled processes of oxidation and acidification result in the release and re-partitioning of Fe and associated trace metals from stable, reduced mineral phases to more mobile, oxidised forms. Elevated metal concentrations are commonly associated with the drainage waters of these landscapes [2]

We followed the partitioning changes to Fe and Cu during the short-term oxidation and acidification of two acid sulfate soil materials. The “labile”, “acid-soluble”, “organic”, “crystalline oxide”, pyritic” and “residual” metal pools were measured sequentially [3].

Initially Fe and Cu were stored in the “pyritic”, “acid-soluble” and “residual” metal fractions. The “residual” fraction measured changed little during the 90-day oxidation experiment, indicating that it was not a major source for Fe and Cu to more mobile fractions during short-term oxidation events. The “pyritic” fraction, however, is dominated by minerals which undergo oxidative dissolution when exposed to atmospheric oxygen. Major re-partitioning of Fe and Cu was expected and observed - metals initially associated with the “pyritic” fraction were re-distributed to more environmentally available fractions i.e. the “acid-soluble” and “labile” fractions. The “acid-soluble” fraction was a major source of metals both initially and as oxidation progressed. The shift to “labile” and thus leachable metal pools did not occur until conditions of extreme acidification (i.e. pH <4) were reached.

As the “labile” fraction poses the most immediate environmental hazard, managing soil acidity will be the most effective means for reducing Fe and Cu mobility in acid sulfate soils.

[4]Nuclear Fuel Services, Erwin, Tennessee 37650 (csmorie@nuclearfuelservices.com)

Stabilization of aqueous-phase uranium can be achieved through injection of degradable organic carbon to create anaerobic conditions. Uranium is soluble under aerobic conditions, exhibiting complex geochemistry and persistence in these environments. Under anaerobic conditions, uranium reductively precipitates to the insoluble uraninite mineral phase. Under these conditions, oxidized iron minerals are transformed to reduced iron minerals such as iron sulfide. Under aerobic conditions, the reduced iron minerals provide stability to the uraninite by acting as a redox buffer and physical encapsulant. Formation of these reduced iron sulfide minerals can be engineered through the injection of soluble iron and sulfate along with degradable organic carbon. At Nuclear Fuel Services in Erwin, TN, localized areas of the facility with low concentrations of uranium in groundwater are being treated with in-situ reductive precipitation of uranium and engineered precipitation of reduced iron sulfide minerals.

In order to non-invasively characterize the treatment zone, time-domain induced polarization (IP), a surface geophysical technique capable of locating iron and sulfide minerals based on their chargeability was used to guide a drilling program. Based on the IP imaging, soil cores were obtained. The cores were analyzed using advanced mineralogical characterization methods including scanning electron microscopy, energy dispersive x-ray spectroscopy, microprobe x-ray fluorescence, and x-ray absorption spectroscopy to evaluate the elemental association and valence state of uranium, sulfur, and iron. The results of this comprehensive characterization indicates that targeted phases are forming in the soil as a result of treatment. This presentation will discuss the soil characterization, coupled with non-invasive geophysical characterization and strategy for the in-situ engineered precipitation of soluble uranium through creation of reactive mineral phases.

Combustion aerosol over marine stratus: Long range transport, subsidence and aerosol-cloud interactions over the South East Pacific

A. CLARKE[1]*, S. FREITAG[1], J. SNIDER[2], J. KAZIL[3,4], G. FEINGOLD[4], T. CAMPOS[5] AND V. BREKHOVSKIKH[1]

[1]University of Hawaii, Honolulu, HI, USA (*correspondence: tclarke@soest.hawaii.edu)
[2]University of Wyoming, Laramie, WY, USA
[3]CIRES, University of Colorado, Boulder, CO, USA

[5]NCAR, Boulder, CO, USA

The worlds largest stratus deck over the South East Pacific (SEP) was a study target for the VOCALS (http://www.eol.ucar.edu/projects/vocals/) experiment in October 2008. Aerosol-cloud interactions were one major goal of several ship and aircraft studies including results from 14 flights of the NCAR C-130 aircraft reported here. Each flight covered about a 1000 km range with multiple profiles and legs below, in and above the Sc deck.

Strong aerosol sources along the coast of Chile were expected and found to influence cloud condensation nuclei (CCN) in coastal clouds. However; “rivers” of elevated CO, black carbon (BC) associated with combustion aerosol effective as CCN at <0.3%S were also common in subsiding FT air overlying the extensive Sc deck for over 1000km offshore. This subsidence, linked to the Hadley circulation, brought in aerosol from sources over the western Pacific as well as South America. Observed entrainment of this aerosol was linked to cloud related turbulence. When present, this combustion aerosol increased available CCN and decreased effective radius compared to clouds in “clean” MBL air advected from the South Pacific. We hypothesize that this entrainment can help buffer MBL clouds over the SEP against depletion of CCN by drizzle. This may delay transition of closed cell to open cell convection, potentially leading to increased lifetimes of Sc clouds that entrain such aerosol.

Characterisation of Outer Membrane Cytochromes.

Extracellular mineral respiration is dependent on the correct expressionof an outer membrane porin-cytochrome complex, where a large transmembrane porin mediates direct electron transfer between a small decaheme periplasmic cytochrome and an extracellular decaheme cytochromeon the cell surface. [1] Over 30 % of the *Shewanella oneidensis* surface is covered with these outer membrane cytochromes and it has been shown that there are multiple members of the outer membrane cytochrome family are capable of interacting with a broad range of mineral oxides [2,3].

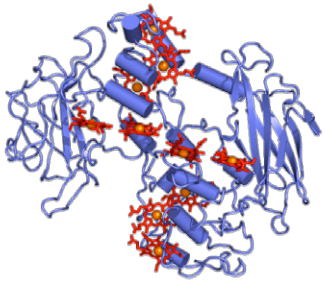

Figure 1: Structure of MtrF, a decaheme outer membrane cytochrome involved in mediating electron transport between *S. oneidensis* and extracellular mineral.

We have resolved the crystal struture of one of these outer membrane cytochrome, shown in figure 1, and this has revealed that these proteins comprise a c-type cytochrome core flanked by two β-barrel domains [4]. This structure provides a base for understanding how these systems interact with both the outer membrane and the extracellular enviroment.

Plate- versus plume-driven processes – South Atlantic DUPAL revisited

C. CLASS[1]* AND A. P. LE ROEX[2]

[1]Lamont-Doerty Earth Observatory, Palisades, NY10964, USA (*correspondence: class@ldeo.columbia.edu)
[2]University of Cape Town, Rondebosch, 7701, South Africa

The DUPAL anomaly in the South Atlantic is present in intra-plate volcanism associated with the Tristan-Gough, Discovery and Shona plumes, and along adjacent sections of the southern Mid-Atlantic Ridge. Its origin has been variably attributed to either plate-driven processes introducing continental material into the shallow mantle, or plume-driven processes sampling sources in the lower mantle, which cannot be distinguished based on geochemical arguments alone. Here we present an integration of geochemical arguments and dynamic considerations and test the following hypotheses:

(1) South American origin – Previous geochemical evidence suggests that the DUPAL originates from the South American sub-continental lithospheric mantle (SCLM), possibly thermally eroded by the Tristan plume head. However, our mass balance calculation shows that an unrealistic volume of SCLM would be needed for the contamination of thousands of cubic km of upper mantle in a direction unsupported by any obvious mantle flow regime.

(2) South African origin - A mantle flow field induced by the African Superplume has been inferred previously from seismic anisostropy, suggesting mantle flow from beneath Africa and possible contamination of the S Atlantic upper mantle with African plate material. However: (i) off-craton SCLM and lower crustal samples provide no evidence in support of thermally eroded or tectonically detached African plate material being the origin of the S Atlantic DUPAL anomaly [1]. (ii) Erosion of the base of the Kaapvaal craton by the Superplume-related mantle flow is not supported by available constraints on the composition of the Kaapvaal SCLM [1]. In addition, volcanism from upper mantle melting anomalies at Vema and 7 degree Seamount do not support an overall contamination of the S Atlantic shallow mantle [1].

(3) Deep origin – A deep, plume-related origin of the S Atlantic DUPAL is supported by the spatial extent of the anomaly in S Atlantic MORB adjacent to DUPAL plumes. Mixing systematics are consistent with the different plumes showing plume-ridge interaction as a function of distance to the ridge. Extreme isotopic heterogeneity of the S Atlantic DUPAL source is indicated from plume trail samples of the DUPAL plumes. Similarities and differences to Indian and Pacific Ocean DUPAL anomalies are explored.

[5]IGME, Avenida Miguel de Cervantes, 45, 30009 Murcia, Spain, (j.arostegui@igme.es)

Since 15 years numerous works have shown the influence of submarine groundwater discharge (SGD) on the water budget of lagoons, bays or open coastal areas [1]. In particular the high concentrations in nutrients of discharging groundwater may result in very productive ecosystems [2]. A radon-radium study was coupled with nutrients in semi-arid South-Eastern Spain. Mar Menor lagoon (135 km^2) is bordered by a Quaternary sedimentary aquifer extending over 1200 km^2. ^{222}Rn and ^{224}Ra activities in groundwaters along the coast range between 2200 to 17500 and 16 to 120 Bq/m^3 respectively. In the lagoon, ^{222}Rn and ^{224}Ra activities varied from 10 to 100 and 4 to 8 Bq/m^3 respectively. The increase of both nuclides is localized and synchronous with a peak in NO_3^- and chlorophyll, revealing groundwater input. In the same area, changes observed in coastal vegetation could be related. Further measurements will refine the SGD flux to Mar Menor and its ecological impact.

[3]Laboratoire d'Hydrologie et de Géochimie de Strasbourg EOST, 1 rue Blessig , 67084 Strasbourg cedex, (fchabaux@unistra.fr)

Spheroidal weathering (also named corestone-shell systems hereafter called CSS) is a common form of chemical weathering affecting many types of rocks [1]. The spheroidal structures are good models for studying weathering budget because the volume of shell rocks during weathering is conservative [2]. The CSS constitute therefore an open system for mobile elements such the major cations and silica that are leached out of the units. Conversely, they also can be seen as a closed system relative to poorly mobile elements such as Ti, Al or Fe which are only displaced from the core to the outer shell. During chemical weathering processes, natural radionuclides from the uranium series are either mobile or refractory and this differentiated behavior disturbs the status of radioactive secular equilibrium characterizing geological formations. Consequent radioactive ^{234}U-^{238}U-^{230}Th disequilibria can be used as a tool to estimate rate of soil formation on a time scale of circa 1 Ma. Here we combine mineralogical observations, geochemistry of major and trace elements to Sr isotopes and U-series as an attempt to constraint the rate of spheroidal weathering of a basaltic flow dated at 292 ±10 ka from la Reunion Island. U-transport model shows a remobilization process occurring on a time-scale of ca 250 ka. $^{87}Sr/^{86}Sr$ variations are small (0.7042 - 0.7050). Highly mobile Sr is leached out in 1500 yrs only. Sr fluxes are 1 order of magnitude higher than steady state conditions [3] suggesting that weathering rates could be higher during the first stages of alteration.

Evolving isotopic fluxes to Asian marginal seas controlled by Monsoon strength since the Last Glacial Maximum

PETER D. CLIFT, DENGKE HU AND DAVID LIMMER

School of Geosciences, University of Aberdeen, Aberdeen, AB24 3UE, UK

The intensity of the Asian monsoon is expected to have a major impact on the strength of erosion and chemical weathering in continental river basins. Because these processes are linked to solar insolation there should be major variations in the chemical flux to the ocean on millennial timescales. To test this hypothesis we have examined the erosional response of rivers in different parts of Asia to monsoonal changes since 14 ka. ODP Site 1144 in the South China Sea shows little provenance variation, but a major changes in Sr isotope composition, clay mineralogy, clastic mass accumulation rates and Ti/Ca values. We interpret this to reflect erosion of Pleistocene fluvial terraces in Taiwan and from the exposed Taiwan Strait during early Holocene monsoon intensification. The isotope and chemical proxy pulse lasts from 11 to 8 ka, considerably shorter than the period of strong summer monsoon derived from speleothem records. Assuming these latter to be robust rainfall proxies we suggest that the fall in weathering intensity after 10 ka reflects decline in the erosion of the terraces onshore as the valleys are emptied and the Taiwan Strait was drowned by rising sealevel. In the Pearl River estuary itself we see a clear but different signal. Here $^{87}Sr/^{86}Sr$ values rise after 9 ka and only begin to fall again after 6 ka, reaching minimum values at 3.5 to 1.0 ka. If Sr isotopes are controlled by weathering then the response appears to lag monsoon intensity by ~2 k.y. A major increase in $^{87}Sr/^{86}Sr$ after 1.0 ka and the large mis-match between modern river sediments and the Holocene delta suggests major changes in erosion patterns, probably caused by the expansion of farming. Further west in the Indus delta Nd and Sr isotopes change quickly during from 14 to 9 ka as the monsoon intensifies, likely driven by changing patterns of erosion as the location of heaviest rains migrates. In the offshore shallow delta rising $^{87}Sr/^{86}Sr$ values during the early Holocene also suggest stronger chemical weathering. The effect is strongest in the early Holocene, but does not reduce after the weakening of the monsoon after ~5 ka. We suggest that reworking of older more weathered material from the flood plain at that time buffers the flux to the ocean. Although a wetter monsoon might be expected to drive more chemical weathering we find that on millennial timescales reworking of material formed during drier glacial times is often the source of the most weathered materials.

H isotopes in lavas from Loihi and Pitcairn: Primitive or recycled water?

M. CLOG*, C. AUBAUD AND P. CARTIGNY

Laboratoire de Géochimie des Isotopes Stables, IPGP, UMR7154, 1 rue Jussieu, 75005 Paris, France (*corresponding author, clog@ipgp.fr)

Hotspots sample mantle domains distinct from mid-ocean ridge systems. The source of hotspot lavas has been shown to contain recycled, subducted materials but also primitive material as seen from noble gases isotopic compositions. Water contents are higher in OIBs than in MORB but due to divergent H_2O/Ce and δD measured on different hotspots, there is presently no consensus on either the origin of water in hotspot lavas or even if there still is juvenile water in their sources. Lavas from Loihi seamount and Pitcairn both contain EM-1-type material and have primitive neon isotopic compositions, pointing at a mixing between recycled and primitive components in the mantle, and making the comparison of H systematics between the two hotspots key to shed light on the potential existence of primitive water. 7 samples from Loihi and 17 from the active zone of the Pitcairn hotspot were analysed in this study. Water concentrations measured by manometry range from 0.4 to 0.9% for Loihi and 0.5 to 1.2% for Pitcairn, while δD range respectively from -72 to -65‰ and -53 to -36‰. All but one sample from Loihi are unaffected by degassing, and the H_2O content variations are mainly due to variations of partial melting and crystal fractionnation. The δD of the 6 other samples are very homogenenous (-67.9±1.5‰). For the Pitcairn samples, initial water concentrations and isotopic compositions are calculated using the concentrations and δD of water in the vesicles, assuming closed-system degassing for water.

In Pitcairn samples, the results are compatible with a two-components mixing, one D- (δD>-40‰) and water-rich (H_2O/Ce>150), and the other D- (δD<-45‰) and water-poor (H_2O/Ce<125). The water-rich samples are also those richest in incompatible trace elements. Previous studies [1,2] have shown that in samples from Pitcairn, the ones most affected by the EM-1 component have primitive neon isotopic composition and are also richer in incompatible elements. The contrasted δD between the two hot-spots suggests that the component bearing primitive Ne is water-poor, and, thus, that water in Pitcairn comes from recycling processes.

Zn mobility during oceanic crust alteration inferred by its isotopic composition

C. CLOQUET[1]*, J. CARIGNAN[1,2] AND C. FRANCE-LANORD[1]

[1]CRPG/CNRS, BP 20, 54501, Vandoeuvre-lès-Nancy, France (*correspondance: cloquet@crpg.cnrs-nancy.fr)
[2]Takuvik, CNRS-ULaval, Québec, G1V 0A6, Canada

In the last 10 years, with the multiplication of MC-ICP-MS, our knowledge of the transition metal isotope geochemistry has been expanded. Among the studied elements, Zn became a useful tracer in biological systems and to trace anthropogenic activities [1,2]. However, Zn geochemical behaviour still suffers from lack of information and remains not well characterised.

In this work, we studied volcaniclastic sediment and basalts from ODP Leg 129, Sites 800 & 802A, located in the northern Pigafetta Basin near the HIMU Seamount and in the center of the East Mariana Basin. The two sites were drilled for about 500 m through sediment sequence largely constituted of volcaniclastic sediments. Calcium and Sr contents and Sr isotopes already demonstrated the role of diagenetic reactions in these cores. The aim of the study was to investigate the mobility of Zn during various reactions occurring in these cores like alteration, diffusion and diagenetic processes in real samples.

After Zn isolation from the matrix, the isotopic composition was measured by MC-ICP-MS. All the results are expressed relative to IRMM 3702 which presents a δ^{66}Zn of +0.3‰ compared to JMC_{lyon}. The δ^{66}Zn total range is from 0.1 to 0.6‰ for the two cores, the highest value being found at the top of the core. Both cores present a similar behaviour with a mean value around 0.3‰ reflecting their relative homogeneity in the volcaniclastic sediments. The value obtained for the basalt is also around 0.3‰ which is higher than values reported so far for fresh basalts (0‰). Zn isotopes do not fully follow Sr isotopes behaviour. However, a trend of the Zn isotopic composition to the light value from the top to the bottom of the core is observed. Such a variation can be interpreted in term of interaction between the sea water and the sediments from one part and between hydrothermal fluids and sediments from an other part.

Calcium isotope fractionation during plant growth under limiting and non-limiting nutrient supply

F. COBERT[1], A.-D. SCHMITT[2], P. BOURGEADE[2], F. LABOLLE[3], P.-M. BADOT[2], F. CHABAUX[1] AND P. STILLE[1]

[1]Laboratoire d'Hydrologie et de Géochimie de Strasbourg; Université de Strasbourg/EOST, CNRS; 67000 Strasbourg, France.
[2]Université de Franche-Comté et CNRS-UMR 6249, Chrono-environnement, 25030 Besançon Cedex, France.
[3]Université de Strasbourg, Institut de Zoologie et de Biologie générale, 67000 Strasbourg, France.

Hydroponic experiments have been performed to identify the co-occurring geochemical and biological processes affecting Ca isotopic compositions within plants. Four experiments have been conducted combining two Ca concentrations (5 and 60 ppm) and two pHs (4 and 6). Another experiment was performed with limiting Ca nutrient supply at 5 ppm Ca and pH=6. All the experiments have been achieved on bean plants in order to have access to a complete growth cycle in a short duration. Several organs (root, stem, leaf, reproductive) were sampled at two different growth stages (10 days and 6 weeks of culture).

Our results show, in agreement with previously published field studies [1, 2, 3,4], that all the bean organs are enriched in the light ^{40}Ca isotope compared to the nutritive solution. Moreover, Ca concentrations and pH influence Ca isotopic composition within plant organs. We identified three fractionation levels. The first one occurs during the uptake of the nutrient elements by the lateral roots. The second one takes place during the long distance transport of Ca, from roots to shoots. The third one takes place during formation of reproductive organs. The experiment with limited Ca supply shows a ^{44}Ca enrichment in solution through time; the plants seem to establish an isotopic equilibrium with the nutrient solution.

The data confirm the potential of the Ca isotopic system for tracing biological fractionations in ecosystems.

Gold scavenging by liquid bismuth melts

A. B. COCKERTON* AND A. G. TOMKINS

School of Geosciences, Monash University, PO Box 28E, Victoria 3800, Australia
(*correspondence: amy.cockerton@monash.edu)

Bismuth is associated with gold in several different types of ore deposits. It has a melting temperature of only 271°C and therefore, when bismuth becomes saturated in a hydrothermal fluid at temperatures above this, it will precipitate from the fluid, not as a solid, but as a liquid. This liquid bismuth can subsequently continue to interact with and be transported by the hydrothermal fluid. Numeric modelling has shown that gold concentrations become several orders of magnitude higher in a bismuth melt versus the corresponding Bi-absent hydrothermal fluid, supporting the theory that a bismuth melt can scavenge and concentrate gold and other metallic ions from the hydrothermal fluid [1]. This theory is known as the Liquid Bismuth Collector Model (LBCM) [2].

We have investigated the bismuth-rich Stormont gold prospect in north-western Tasmania, to test the LBCM. Conditions at Stormont have been found to be favourable for bismuth to have precipitated as liquid with mineralisation temperatures between 400-500°C. In situ evidence for gold-scavenging by liquid bismuth is observed in the close textural relationship between native gold and bismuth. Zoned andradite crystals suggest hydrothermal fluid composition fluctuations, which may have contributed to zone refinement within the prospect. Liquid bismuth can sequester gold from undersaturated fluids [1]. Therefore, a zone refining process can potentially operate in a system where repeatedly infiltrating undersaturated fluids, controlled by favourable structures, can dissolve gold not attached to bismuth and then re-precipitate it where bismuth is concentrated. This leads to enhanced correlation between the two elements.

Revealing the hidden signature of biomacromolecules in ancient organic fossils

G.D. CODY[1], R.M. HAZEN[1], S.N. GUPTA[2] AND A.L.D. KILKOYNE[3]

[1]Geophysical Laboratory, Carnegie Institution of Washington, Washington DC 20015 USA (gcody@ciw.edu)
[2]Indian Institute of Science Education and Research, India
[3]Advanced Light Source, Lawrence Berkeley Laboratory, Berkely, CA, USA

The organic fossil record of eukaryotic organisms reaches back to the dawn of the Paleozoic. In the case of the arthropod fossil record, the preserved organic residue is derived from arthropod's exterior cuticle, the rigid exoskeleton characteristic of all members of the Arthropod phylum. In modern arthorpods, the exocuticle is composed of a nanocomposite of chitin and structural protein with very exterior region also containing fatty acids. The conventional geochemical view holds that the biopolymer chitin and structural protein is not preserved in ancient fossils as they are readily degradable through microbial chitinolysis and proteolysis and otherwise susceptible to destruction during diagenesis. Recently, however, we showed that a clear molecular signature of relict chitin-protein complex is preserved in a Middle Pennsylvanian (310 Ma) scorpion cuticle and a Silurian (417 Ma) eurypterid cuticle via analysis with carbon, nitrogen and oxygen X-ray Absorption Near Edge Structure (C-, N-, and O-XANES) spectro-microscopy [1]. The application of high-resolution X-ray microscopy employing functional group derived absorption contrast reveals the complex laminar variation in major biomolecule concentration across modern scorpion cuticle; XANES spectra highlight the presence of the characteristic functional groups of the chitin-protein complex. Modification of this complex is evident via changes in organic functional groups. Both fossil cuticles contain considerable aliphatic carbon relative to modern cuticle. In both cases, however, the concentration of vestige chitin-protein complex is high, 59 and 53 % in the fossil scorpion and eurypterid, respectively. We have recently used the Scanning Transmission X-ray Microscope (STXM) at beam line 5.3.2 at the Advanced Light Source to analyze the preserved organic cuticle of a Cambrian (507 Ma) trilobite from the Wheeler Shale. The thin section was prepared using a focused ion-beam mill. We detect very high N/C and O/C consistent with preservation of abundant, albeit altered, remnants of chitin/protein complex.

Large weakening in monsoonal rainfalls over western India during the Younger Dryas

ANTOINE COGEZ[1]*, LAURE MEYNADIER[1], CLAUDE ALLÈGRE[1] AND FRANCK BASSINOT[2]

[1]Equipe de Géochimie et Cosmochimie, Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Univ Paris Diderot, UMR 7154 CNRS, F-75005 Paris, France (*correspondence: cogez@ipgp.fr)

[2]Laboratoire des Sciences du Climat et de l'Environnement, CEA, CNRS, Gif sur Yvette, France

We studied the monsoonal rainfalls evolution since 30 kyrs over western India, using neodymium isotopes (εNd) in sediment cores. Since neodymium isotopes are not fractionated by physico-chemical processes, they are an excellent tracer of mixing in seawater between different continental sources weathered by rainfalls. Using this technique Gourlan *et al*. (2010) already found that Ganges and Brahmaputra discharge was 3 times stronger during interglacial than during glacial times. To test such a result for the Western Gaths in India where the precipitations are among the strongest in this area, we measured εNd since 30 kyrs in 5 oceanic cores, one in the middle of the Arabian Sea, two along the Western Indian Coast and two south of India, on the Maldives Plateau. The carbonate phase and Mn coatings around foraminiferae were leached using acetic acid; we also measured εNd in the detrital fraction of the sediment because it carries the signature of the sources. Dating was performed using $\delta^{18}O$ in planktonic foraminiferae from the same cores and three or four radiocarbon dates per cores.

Both signals from the cores located along the Western Gaths display a large positive peak synchronous with the Younger Dryas (YD) event, 12 kyrs ago. Using a first order mixing model we estimate that local precipitations could have been up to 5 times weaker during this period. Moreover the recovery to Holocene rain level could have been much more longer than the onset. To our knowledge this is the first time that εNd records display a dependency of monsoon rain on YD event. This clearly show that monsoon regime was controlled by Northern Hemisphere climate regime. Large amplitude differences are seen when comparing εNd to $\delta^{18}O$ in planktonic foraminiferae.

The three other cores display a pattern characteristic of the deglaciation (decreasing εNd since the Last Glacial Maximum) without the trace of YD and rather correlated with the $\delta^{18}O$ records. We surmise that those patterns are imprinted by Himalaya where ice covering has a large influence on the precipitations and sediments discharge.

Early Ordovician volcanism in Eucísia and Mateus areas, Central Iberian Zone, northern Portugal

C.J.M. COKE[1], R.J.S. TEIXEIRA[1], M.E.P. GOMES[1], F. CORFU[2] AND A. RUBIO ORDÓÑEZ[3]

[1]Department of Geology, UTAD, Apartado 1013, 5001-801 Vila Real, Portugal (ccoke@utad.pt, rteixeir@utad.pt, mgomes@utad.pt)

[2]Dep. of Geosciences, Univ. of Oslo, PO Box 1047 Blindern, N-0316 Oslo, Norway (fernando.corfu@geo.uio.no)

[3]Dep. of Geology, Univ. of Oviedo, C/ Jesús Arias de Velasco, 33005 Oviedo, Spain (arubio@geol.uniovi.es)

The Eucísia (Alfândega da Fé) and Mateus (Vila Real) areas are located in the Central Iberian Zone, a segment of the northern Gondwana margin which underwent a long Variscan geodynamic evolution. Lithostratigraphically both areas are characterized by a predominance of Precambrian to Cambrian metasedimentary rocks and by the transgressive nature of the Ordovician formations. Continental rifting on the platform of northern Gondwana began around the Middle Cambrian, and opening of the Rheic ocean took place near the Ordovician-Cambrian boundary. In the Eucísia and Mateus areas there is evidence of extensional volcanism related to these events, contemporaneous with a transient inversion, known as the Sardic phase. At Eucísia the Ordovician Armorican Quartzite Formation hosts a < 40 cm thick ash-fall tuff bed, which is mainly composed by muscovite and small amounts of quartz. At Mateus, a subvolcanic porphyritic rock occurs in a 3 m thick vein cutting Precambrian-Cambrian schists. The phenocrysts consist of euhedral/ovoidal plagioclase and microcline and rounded bluish quartz. The groundmass is dark, fine grained and contains quartz, feldspars, muscovite, rare biotite and graphite (identified by XRD). The mineralogical and textural features of this vein resemble those of the augen gneisses from the Ollo de Sapo Formation in Sanabria (Spain), except for a lower degree of deformation/recrystallization. The tuff and the porphyry are both alkali-calcic, peraluminous (ASI ≈ 1.75 – 2.91) and classified as rhyolites in the R_1-R_2 diagram. They show moderate REE contents ($\Sigma \approx 78.3 – 182.6$), $(La/Lu)_N$ values between 11.78 and 12.06, weak negative Eu anomalies ($Eu/Eu^* \approx 0.45 – 0.52$) and REE patterns typical of peraluminous granites. Both rocks have a high content of zircon xenocrysts, but also some magmatic zircon prisms which were dated by U-Pb (ID-TIMS) yielding concordia ages that indicate crystallization in the Early Ordovician: the ash-fall tuff from Eucísia at 482.1 ± 1.5 Ma and the rhyolite porphyry from Mateus at 478.0 ± 1.7 Ma.

The engineering of novel materials is a key development in the challenge of remediating toxic metals and radionuclides in the subsurface. Our work focuses on utilising nano-scale magnetite, synthesised through the bioreduction of ferrihydrite by *Geobacter sulfurreducens* at ambient temperatures. In order to increase the activity and longevity of this substrate in key reactions, including chromium(VI) and toxic organics reduction, the surface of the nano-magnetite is functionalised by a precious metal catalyst, nano-palladium, in a simple, one-step process, aided by the organic residue on the iron mineral surface derived from the bacterial culture [1].

Pd-functionalised nanomagnetite has been tested in the remediation of Cr(IV) in batch and continous-flow column experiments and in hollow-fibre membrane units. Conditions in the column studies were varied to take into account key environmental parameters including oxic, anoxic, and a nitrate co-contamination. An electron donor, sodium formate, was supplied in the influent leading to a substantial increase in the removal capacity of the Pd-magnetite. In addition, the columns containing both Pd-biomagnetite and formate were found to maintain an 80 % removal beyond 300 hours, whereas without formate complete breakthrough occurred at 60 hours. We hypothesise that oxidation of formate in these experiments is coupled to recharge of the nanocatalyst surface by the Pd, maintaining the reductive power of the system.

Cr(III) formed was associated strongly with the biomagnetite, and XMCD studies suggest that the Cr(III) replaces Fe in the magnetite lattice, effectively 'locking-up' the Cr, as seen previously [2]. This novel system could provide effective and sustained immobilisation of contaminants, far outreaching the reductive capacity of non-functionalised magnetite.

PGE contents and spinel compositions of different podiform chromitites in the Eastern Anatolia complex, Turkey

A.R. ÇOLAKOGLU[1]*, K. GÜNAY[1] AND H.M. PRICHARD[2]

[1]Yüzüncü Yıl University, Department of Geological Engineering, Zeve Campus, TR-65080 Van, Turkey (*correspondence:arc.geologist@yyu.edu.tr, kurtulusgunay@yyu.edu.tr)
[2]School of Earth and Ocean Sciences, Cardiff University, Main College, Cardiff, CF10 3AT, United Kingdom (hazelprichard@googlemail.com)

This study presents mineralogy, PGE contents and spinel compositions of four different podiform chromitite localities in the east of Turkey. The ophiolitic rocks are observed as relatively large tectonic units in the Eastern Anatolian Accretionary Complex [1]. Chromite texture are observed as massive, nodular and dissemine-banded type. The highest value (390 ppb) of ΣPGE are obtained from milonitic shear zone chromitites with an average ~290 ppb. Os, Ir and Ru show relatively enrichment, compare to Pt, Pd and Rh elements. This enrichment are consistent with other chromitite deposits in Turkey. Chromite grains contain inclusion of mafic silicates (olivine, amphibole and clinopyroxene), sulphides (etc. millerite, heazlewoodite, awaruite, chalcopyrite, godlevskite, orcelite) and euhedral Laurites. The chromite compositions of different localities ore exhibit characteristic of different tectonic setting. The high Cr# and low TiO_2 content of spinel from the eastern Anatolia chromitites possibly has genetic linkage with a boninite melt generated by high degrees of partial melting and the others are formed in island arc setting towards to back arc basin [2, 3].

Aerosol spatial scales in observations and models: Implications for the aerosol direct effect

PETER R. COLARCO*

Atmospheric Chemistry and Dynamics Branch, NASA GSFC, Greenbelt, MD 20771, USA
(*correspondence: Peter.R.Colarco@nasa.gov)

Consideration of variability in aerosol spatial and temporal distributions are prime concerns in developing sampling strategies for future satellite missions. Previous studies suggest homogeneity in tropospheric aerosol spatial distributions at scales of about 200 km. These studies, however, did not have access to the extensive global data sets of aerosols from the past decade of EOS observations, and so their conclusions on aerosol spatial scales must be viewed as tentative. In the first part of this study we evaluate what the global distribution of aerosol optical depth looks for different spatial sampling strategies. We sample MODIS observations at their native swath width, along a satellite-subpoint track like what the APS would have observed, and at an intermediate swath width similar to what MISR observes. We investigate the convergence of the aerosol optical depth statistics for all cases. In the second part of this study we employ these sampling strategies on the results of the NASA GEOS-5 global aerosol model to investigate the implications for computed aerosol direct radiative forcing.

Missed connection: Ignimbrite seeking plutonic relationship

DREW S. COLEMAN*, RYAN D. MILLS AND MICHAEL J. TAPPA

Department of Geological Sciences, University of North Carolina, Chapel Hill, NC 27599-3315
(*correspondence dcoleman@unc.edu)

New U-Pb zircon geochronologic data for rocks from the Southern Rocky Mountain volcanic field demonstrate a distinct disconnect between the timing of ignimbrite eruption and plutonism. In both the Questa and Aetna calderas, only discontinous dikes yield the same ages as ignimbrites. The dominant volume of exposed plutonic rocks was assembled either before or after the ignimbrite events.

Geochronology for rocks in the Questa and Aetna calderas demonstrate that the largest exposed plutons (the Rio Hondo and Mt. Princeton, respectively) were assembled incrementally. Data for the Rio Hondo pluton indicate a magma accumulation rate of 0.0003 km^3yr^{-1} for the exposed portion of the pluton. Data for the Mt. Princeton pluton indicate an accumulation rate of 0.0009 km^3yr^{-1}. Both rates are comparable to rates published for other plutons, and orders of magnitude too slow to accumulate large eruptible magma volumes. Extrapolation of the accumulation rate for the Rio Hondo pluton over the 8.5 m.y. history of the volcanic field yields an estimated volume of plutonic rocks comparable to the volume under the field indicated by geophysical studies. We propose that the bulk of the plutonic rocks beneath the volcanic center accumulated during periods of low volcanic effusivity (the waxing and waning stages of caldera formation), and that most of the magma generated during caldera formation erupted. Furthermore, because the oldest portion of the Rio Hondo pluton is the granitic cap exposed beneath a gently dipping roof contact, the roof granite cannot be a silicic liquid fractionated from the deeper (younger) portions of the pluton. Instead, the data suggest that the variation in composition of the pluton is inherited from the lower crustal source. We suggest that if magma flux is high enough, zoned ignimbrites can be formed by evolution of the melt compositions being generated at the source. Thus eliminating the “need” for large shallow magma chambers and plutons in support of ignimbrite evolution.

If the intrusive equivalents to the ignimbrites are limited to dikes, and the plutonic rocks crystallized over the history of the fields, then the plutonic record of the ignimbrite stage of caldera formation is sparse. This predicts that the plutonic record will be dominated by waxing and waning stage magmatism, and the volcanic record will be dominated by ignimbrite stage magmatism.

[5]Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA

Sulfur has a complex biogeochemical cycle in peatlands due to its chemical reactivity, wide range of oxidation states, and importance to bacterial metabolism [1]. In sulfur-limited systems sulfate plays a synergistic role in the production of monomethylmercury (MeHg), the bioaccumulative form of mercury [2]. Therefore an understanding of how sulfate is incorporated into and released from peat soils may improve prediction of MeHg production within, and export from, peatlands. Climatic variability can cause large changes in oxidation- reduction potentials within peatlands by influencing the position of the water table. Wetlands are often considered to be sinks in the landscape for sulfate because sulfate inputs to saturated systems are readily consumed by sulfate-reducing bacteria. However, following droughts wetlands have been found to be significant sources of sulfate to downstream aquatic ecosystems [3].

This research compared sulfur speciation in peat from a boreal peatland during and after an historic drought in northern Minnesota. Greater than 95% of sulfur in each peat sample was in an organic form making traditional, wet-chemical sulfur fractionation methods uninformative about a large portion of the total sulfur pool. As an alternative, sulfur speciation in peat was measured at the micron scale by X-ray fluorescence mapping at six incident energies spanning the sulfur 1s absorption edge. Composite maps were fit with reference spectra. X-ray absorption spectroscopy is being used to verify sulfur speciation maps. At naturally occurring sulfur levels, we are able to obtain high quality data. Our goal is to develop a data analysis protocol providing quantitative, spatially resolved sulfur speciation.

Magma degassing timescales from vesicle size distribution and bubble composition heterogeneity in MORB glasses

A. COLIN, P. BURNARD AND B. MARTY

CRPG-CNRS, 15 rue Notre Dame des Pauvres, 54500 Vandoeuvre-lès-Nancy, France

Vesicle size distributions (VSD), the number of bubbles of a given size plotted against the size interval are classically used to model the growth rate of vesicles by assuming continuous vesicle nucleation and growth (as for crystal size distributions [1]). However, VSD data in MORB samples are sparse, due to the difficulty in making representative measurements in low vesicle density samples. Here, we use direct 3D images in order to calculate vesicle sizes and their distributions.

The images were obtained by X-ray microtomography (resolution of 5μm or less) of small pieces (some mm^3) of glassy pillow lava rims sampled along the mid-Atlantic ridge and the East Pacific Rise. The observed trends allow us to discuss several key issues such as the duration of the vesicle-magma segregation and the link between magma initial volatile content and the vesicle growth rate. Atlantic MORBs and Icleandic glass samples show VSDs that have a distinct kink in the VSD at 100 – 200 μm micron vesicles, showing that there are (at least) two different episodes of vesicle generation: smaller vesicles result from decompression during the final stages of eruption while larger bubbles likely represent magma chamber processes. Vesicle-poor samples such as those from the East Pacific Rise tend to only have a single episode of vesicle generation.

In order to constrain these degassing processes, the trapped glass vesicles were subsequently opened by laser ablation and their volatile contents (He, Ar, CO_2) analysed vesicle by vesicle. The different vesicles preserved in the final glass nucleated at different stages in the magma history, and thus preserve more or less degassed stages of the magmatic volatile evolution. In some samples, the analysed vesicles have homogeneous compositions, while other samples show systematic inter bubble variations consistent with a solubility-controlled Rayleigh distillation. There is no evidence for kinetic fractionation of volatiles in the majority of our samples. These key observations allow the degassing mechanisms to be modeled, as well as the timescales involved in the preservation of such millimetric heterogeneities.

A New Paradigm

P/D isotope ratios of enriched mantle (EM) and high-μ (HIMU) reservoirs sampled by OIBs, CFBs, kimberlites and carbonatites are produced by CO_2-fluxed lower mantle (LM) melting [1]. Our model resolves the long-standing conjecture regarding the formation of HIMU and EM.

Modelling and Implications

Using measured or inferred partition coefficients, we show that U/Pb, Rb/Sr, Sm/Nd, Lu/Hf, and Re/Os ratios of EM are associated with C-rich melts while residues evolve to HIMU [1]. LM melting occurs in thermochemical upwellings by carbonate suppression of the liquidus. End-members originate in domains isolated from whole mantle convection. Melts with > 1% CO_2 and residues are variably buoyant allowing spatial separation of EM and HIMU. HIMU is a refractory residue with long LM residence time and thus it evolves to extreme isotopic compositions. EM is a melt that reacts with ambient mantle and does not produce such extreme isotope ratios. Entrainment in plumes transports EM and HIMU domains at different ascent rates to magmagenetic zones at the top of the LM and in the transition zone.

HIMU does not involve hydrothermally altered oceanic crust, and EM does not require entrainment of continent-derived sediment. Generating EM and HIMU by a single melting process from pristine mantle explains the presence of primitive rare gas end-member isotope ratios in mantle plume magmas as well as constraints of the Pb isotope paradoxes. Carbon in the deep mantle clearly plays an important role in Earth's geochemical evolution. Kimberlites, carbonatites and OIBs all preserve an isotopic record of their LM pedigree.

Ferric iron geometry and coordination during hydrolysis and ferrihydrite precipitation

[4]X-ray Absorption Spectroscopy Beamline, Australian Synchrotron Company Ltd, 800 Blackburn Rd, Clayton, VIC 3168, Australia.

Definitive structural characterisation of ferrihydrite has challenged scientists primarily due to its nanosized particles and inherent long-range structural disorder which challenges analytical methodology (and modelling) typically employed to determine the structure of minerals. Here we report on the application of a synchrotron quick-scanning X-ray absorption spectroscopy (XAS) approach, which allows the collection of Extended X-ray Absorption Fine Structure (EXAFS) spectral data to k = 15 $Å^{-1}$ in < 1 minute, to obtain unparalleled iron K-edge data on the hydrolysis of $Fe^{III}(H_2O)_6$ and ferrihydrite precipitation.

Modelling of the pre-edge and EXAFS data: 1) supports theoretical studies which have suggested the existence of a monomeric penta-coordinated Fe^{III} hydrolysis species and; 2) corroborates recently proposed structural models of ferrihydrite that contain tetrahedral Fe^{III}. Modelling results indicate that ferrihydrite consists of 15 to 25 % tetrahedral Fe^{III} and suggest that this geometry must be included in any comprehensive structural model of ferrihydrite and, furthermore, should be considered when evaluating the reactivity, stability and other structure-property relationships of this mineral.

Microbial uptake and methylation of dissolved elemental mercury

MATTHEW COLOMBO*, TAMAR BARKAY, JOHN R. REINFELDER AND NATHAN YEE

School of Environmental and Biological Sciences, Rutgers University, New Brunswick, NJ, USA (*correspondence: mcolombo@eden.rutgers.edu)

Introduction

Mercury [Hg] bioaccumulation in fish is critically dependent on the conversion of inorganic Hg to methylmercury [MeHg]. In aquatic ecosystems, Hg is primarily methlyated by anaerobic sulfate- and iron-reducing bacteria. These microbes are known to methylate mercuric Hg [Hg^{2+}] to form MeHg. The formation of dissolved elemental mercury [$Hg^0_{(aq)}$] is thought to limit the concentration of Hg available for methylation. However, the uptake and transformation of Hg^0 by anaerobic bacteria has never been tested. Here, we conducted experiments to determine if the sulfate-reducing bacterium *Desulfovibrio desulfuricans* ND132 and the iron-reducing bacterium *Geobacter sulfurreducens* PCA can produce MeHg when provided with $Hg^0_{(aq)}$ as their sole mercury source.

Materials and Methods

Strains PCA and ND132 were grown to exponential phase and subsequently exposed to a constant source of $Hg^0_{(aq)}$ under strict anaerobic conditions. Heat-killed cells (80°C for 30 min), bacterial exudates (growing culture passed through a 0.2 µm filter), and sterile medium were incubated under identical conditions. Samples were acidified and frozen for MeHg analysis and purged with N_2 gas at ~800 mL/min to remove all volatile $Hg^0_{(aq)}$ prior to total Hg analysis.

Results and Discussion

After ~24 h of exposure to $Hg^0_{(aq)}$, strains PCA and ND132 converted $Hg^0_{(aq)}$ to non-purgeable total Hg at rates of ~30 µg/L/d and ~1500 µg/L/d, respectively. Control experiments conducted with heat-killed cells, bacterial exudates, or sterile medium could not account for the Hg retention, suggesting an active role by the microorganisms. When provided with $Hg^0_{(aq)}$ as the sole mercury source, strains PCA and ND132 produced MeHg at rates of ~0.2 µg/L/d and ~0.3 µg/L/d, respectively. These experimental results indicate that iron-reducing and sulfate-reducing bacteria are able to uptake and methylate elemental Hg. The implications of this process in the terrestrial mercury biogeochemical cycle will be discussed.

An integrated approach to estimate the U and Th content of the Central Apennines continental crust

M. COLTORTI[1], R. BORASO[1], F. MANTOVANI[1,2], M. MORSILLI[1], G. FIORENTINI[1,2] AND G. RUSCIADELLI[3]

[1]Earth Sciences Department, University of Ferrara
[2]Physics Department, University of Ferrara
[3]INFN, Ferrara Section
[4]Earth Sciences Department, University of Chieti

A study for estimating the Th and U content of Central Italy continental crust was undertaken for evaluating the geo-neutrino flux, which is currently measured through Borexino experiment at LNGS (Laboratori Nazionale Gran Sasso). Three main layers were identified: Sedimentary Cover, Upper Crust and Lower Crust, only the first one outcropping in the Gran Sasso area. Sampling of the other two layers was performed in the Valsugana area and in the Ivrea-Verbano zone, assuming rock abundances and composition of the south Alpine basement fairly homogeneous.

U and Th abundances of the main lithotypes belonging to the Mesozoic and Cenozoic were grouped into four main "Reservoirs" based on similar paleogeographic conditions and mineralogy. Irrespective of magmatic or metamorphic origin Upper and Lower Crust lithotypes were also subdivided into a mafic and an acid reservoir, with comparable U and Th abundances. Based on geological and geophysical properties, relative abundances of the various reservoirs were calculated and used to obtain the weighted U and Th abundances for each of the three geological layers. Using the available seismic profile as well as the stratigraphic records from a number of exploration wells, a 3D modelling was developed over an area of 2°x2° centered at LNGS. This allows to determine the volume of the various geological layers and eventually integrate the Th and U contents of the whole crust beneath LNGS.

On this base the local contribution to the geo-neutrino flux was calculated and added to the contribution given by the rest of the world. This new calculation predicts a geoneutrino signal at Borexino detector about 4 TNU lower than that previously obtained based on general, worldwide assumptions. The considerable thickness of the sedimentary rocks, mainly represented by U- and Th-poor carbonate, is responsible for the difference. These results suggest that worldwide average of continental crust cannot be extrapolated to young terrains without taking into account composition and thickness of lithotypes within the Sedimentary Cover.

U-Pb perovskite ages of kimberlites from the Rosário do Sul cluster: Southern Brazil

R.V. CONCEIÇÃO[1], C. LENZ[2], C.A.S. PROVENZANO[3], A. SANDER[3] AND F.V. SILVEIRA[3]

[1]UFRGS-Brazil; (rommulo.conceicao@ufrgs.br)
[2]UFS-Brazil, (crislenz@yahoo.com.br)
[3]CPRM-Brazil, (carlos.provenzano@cprm.gov.br; andrea.sander@cprm.gov.br; fvsilveira@gmail.com)

The age of the Rosário do Sul kimberlitic magma is first presented here. The Rosário do Sul kimberlitic cluster is located in the southwestern part of the Rio Grande do Sul state (Southernmost Brazil). This cluster is composed of many pipes, dikes and sills intruding the Paraná Basin sedimentary rocks. The Rosário do Sul kimberlites are composed of macrocrystals and fenocrystals of olivine in a fine grained matrix which consist of serpentine, phlogopite, carbonate, spinel, perovskite, apatite and zircon. Xenoliths of peridotitic rocks of variable sizes were found (1 mm to 5 cm) immersed in the matrix. The dating of the kimberlite has been conducted using perovskite, which is found in the matrix and do not show any inheritance records, which relates it to a primary magmatic origin. *In situ* LA-ICP-MS analyses were performed at the Isotopic Laboratory at UFRGS in a Neptune equipment. Zircon standard GJ-01 was used, due to the absence of perovskite standart in the LGI. The laser was set up to produce a 30 μ diameter spots with a ~0.5 mJ/pulse output energy. The data reduction was performed using an Excel spreadsheet program from the University of Brasília, Brazil. The ages were plotted in a Concordia Diagram, which yield lower intercept U-Pb ages of 128 ± 5 Ma (MSWD of 3.4). This age is very close to that of the Parana Flood Basalts, which is assumed as ~130 Ma. Such new data suggest a very complex and heterogeneous mantle and the occurrence of a great geothermal variation underneath South America, on the region of Parana Flood Basalts.

Contrasting roles of continental and oceanic arcs in the growth of continents

K.C. CONDIE[1]* AND A. KROENER[2]

[1]Dept of Earth & Environmental Science, New Mexico Tech, Socorro, NM 87801 USA (*correspondence: kcondie@nmt.edu)
[2]Institut für Geowissenschaften, Universität Mainz, 55099 Mainz, Germany (kroener@uni-mainz.de)

Oceanic arcs (OAs) are commonly cited as the primary building blocks of continents, yet there are many lines of evidence that continental arcs (CAs) are more important in this regard. Modern OAs are mostly subducted and lithosphere buoyancy considerations show that OAs with crust <20 km thick should completely subduct. Analysis of terranes indicates that <10% of post-Archean accretionary orogens comprise accreted OAs, whereas CAs comprise 40-80%.

OA felsic igneous rocks are depleted in incompatible elements compared to upper continental crust (UC) and have lower La/Yb and Sr/Y ratios, whereas those produced in CAs are similar in composition to UC. Nd and Hf isotopic ratios suggest that accretionary orogens comprise 40-65% juvenile crustal components and that >50% of these components are produced in CAs.

These observations present a paradox: older continental crust is necessary for the production of new continental crust. As indicated by Th/Yb, Nb/Yb, and Nb/Yin greenstone volcanics, CAs did not become widespread until after the late Archean. Prior to 2.5 Ga, OAs may have been more difficult to subduct due to a hotter mantle, and together with oceanic plateaus, they may have contributed to the construction of Archean continents. After this time, however, the production site of continental crust shifted to CAs, and most OAs were subducted.

Synthetic 'age solutions' reference materials for U-Th geochronology

DANIEL J. CONDON[1], GIDEON HENDERSON[2], DAVID A. RICHARDS[3] AND JON WOODHEAD[4],

[1]NERC Isotope Geoscience Laboratory, British Geological Survey, UK
[2]Department of Earth Science, Oxford University, UK
[3]School of Geographical Sciences, University of Bristol, UK
[4]School of Earth Sciences, University of Melbourne, Australia

Over the past 15 years there has been considerable improvement in our ability to measure U and Th isotope ratios and concentrations resulting in a reduction of U-Th age uncertainties by an order of magnitude (age uncertainties are now as low as 0.1%). The accuracy of these dates is dominated by (1) the U/Th tracer calibration; (2) mass spectrometry, (3) various corrections applied, and (4) 'constants' used in the age calculation (secular equlibrium and decay constants, the $^{235}U/^{238}U$ value of natural U etc.). Some of these parameters can be considered as 'systematic' (i.e., decay constant uncertainties) and others either contain a random component or are systematic but 'laboratory' specific (such as tracer calibration).

At present inter-laboratory agreement and intra-laboratory long-term external reproducibility of U-Th Isotope Dilution Isotope Ratio Mass Spectrometry data is assessed through analyses of natural cabonate 'standards'. Though powdered carbonates standard zircons are ideal for assessing the total system (dissolution, purification via anion echange chemistry and mass-spectrometry), these are limited in supply and not widley avaibalbe limiting their use for asessing inter-laboratory agreement. Here we outline a proposal and the initial steps taken for the development the development and calibration of a series of synthetic U-Th 'age solutions' prepared by mixing different amounts of high-purity mono-isotopic solutions (^{234}U, ^{230}Th etc.) in proportions that mimic commonly analysed materials (e.g., a last-interglacial speleothem) so that their analyses closely replicates the analytical protocols employed on normal samples. We believe these solutions will augment natural carbonate standards as a means of interlaboratory comparsion and assessment of long-term external reproducibility, and as such are intended for community use and will be made available. The intercalibration project is part of a broader community effort that has developed out of the PALSEA and EARTHTIME initiatives.

Measuring the isotopic composition of small (<5 ng) U samples by MC-ICP-MS

J.N. CONNELLY AND M. BIZZARRO

Centre for Star and Planet Formation, State Natural History Museum of Denmark, Øster Voldade 5-7, 1350 Copenhagn K, Denmark.

Pb-Pb ages have been based on Pb isotopic measurements while assuming that the $^{238}U/^{235}U$ ratio is constant at 137.88. Using a second-generation multi-collector inductively coupled plasma mass spectrometer (MC-ICP-MS), [1] has documented 3400 ppm variability in the $^{238}U/^{235}U$ ratios of calcium-aluminum-rich inclusions (CAI) in chondrites [1], corresponding to a 5 Myr deviation in calculated Pb-Pb ages. This makes clear the need to measure the U isotopic composition of all meteorites and their components when determining their Pb-Pb ages. The challenge lay in developing analytical protocols to measure the isotopic composition of typically small samples of U (<5 ng) sufficiently precisely to be useful in constraining events that occurred in the first 10 million years of the solar system. With 100 ppm uncertainty corresponding to 0.15 Myr, we must achieve less then 200 ppm uncertainty on $^{238}U/^{235}U$ ratios. We have developed a three stage chemistry starting with Eichrom's UTEVA resin followed by two progressively smaller anion columns that effectively isolates U from the sample matrix elements. U is measured using an Aridus II desolvating nebulizer on a ThermoFisher Neptune with the Jet Cone Interface, a configuration that delivers ~2500 V of signal per 1 ppm concentration of U. Running with an uptake rate of 0.15 ml/min, we analyze 5 ng for a total acquisition time of 15 min with a ^{235}U intensity of ~40 mV. Fractionation correction for the measured $^{238}U/^{235}U$ ratio is controlled by the simultaneous measurement of the synthetic equal-atom ^{233}U-^{236}U tracer IRMM 3636 that was added to samples before dissolution. Blank correction is determined by bracketing runs (of equal time as unknown runs) of the 2% HNO_3 used to dissolve samples. CRM 112a spiked with IRMM 3636 is run as a bracketing standard to monitor within run stability. Using these methods, we are able to routinely determine the isotopic composition of small (<5 ng) amounts of U separated from terrestrial rock standards and doped meteoritic matrices to better than 200 ppm precision and external reproducibility. Analyzing meteorites and their components, we have investigated the $^{238}U/^{235}U$ variability of the inner solar system.

Isotopic evidence for microbial oxidation of dissolved methane in the Gulf of Mexico oil spill deep plume

M.E. CONRAD*, M. BILL, W.T. STRINGFELLOW, S.E. BORGLIN, O.U. MASON, E.A. DUBINSKY, Y.M. PICENO, J.L. FORTNEY, L.M. TOM, K.L. CHAVARRIA, R. LAMENDELLA, D.C. JOYNER, K. WETMORE, J. KUEHL, R. MACKELPRANG, C. WU, J. LIM, F. REID AND T.C. HAZEN

Earth Sciences Division, E.O. Lawrence Berkeley National Laboratory, Berkeley, CA 94720
(*correspondence: MSConrad@lbl.gov)

The blowout of BP's Macondo well and subsequent sinking of the Deepwater Horizon drilling platform on April 20, 2010 led to one of the largest oil spills in history. By the time the well was capped on July 12, 2010, ~4.9 million barrels of oil are estimated to have leaked into the Gulf of Mexico. Accompanying this spill was the development of a deep plume of dispersed oil and dissolved gases at a depth of 1100-1200 mbsl that was detected at distances of up to 35 km from the wellhead. The $\delta^{13}C$ values of dissolved hydrocarbon gases (C1-C5) and BTEX compounds in 77 samples collected from in and around the deep plume between May 28, 2010 and August 24, 2010 were analyzed to track the fate and potential biodegradation of those compounds. C2 to C5 gases and BTEX compounds were only high enough for $\delta^{13}C$ analyses in samples collected before mid-June. The $\delta^{13}C$ values of these compounds remained within ±2‰ of $\delta^{13}C$ values of samples from the Macondo well. CH_4 concentrations in early plume samples (collected before mid-June) were as high as 300 μM, but dropped off significantly in later samples. The $\delta^{13}C$ of CH_4 in the early samples were between -57‰ and -59‰ compared to an average $\delta^{13}C$ value of -58‰ for samples from the Macondo reservoir. After mid-June, CH_4 from some of the samples had higher $\delta^{13}C$ values. The last two CH_4 samples with measurable $\delta^{13}C$ values were collected during early August, 3 weeks after the well was capped and had $\delta^{13}C$ values of -44‰ and -23‰. For a fractionation factor of 0.984 for microbial oxidation of CH_4, those values indicate 60% and 90% oxidation of the methane, respectively. These samples coincided with drops in the dissolved oxygen concentrations in the water column of ~1.5 mM also suggesting increased aerobic microbial activity. In addition, the $\delta^{13}C$ values of bacterial phospholipids extracted from a single sample were lower than normal background biomass, suggesting that the bacteria were consuming CH_4 and other hydrocarbons with lower $\delta^{13}C$ values than the background organic matter.

Dynamics of the Pliocene East Antarctic Ice Sheet revealed by isotopes in marine sediments

C. COOK[1]*, T. VAN DE FLIERDT[1], T. WILLIAMS[2], S. HEMMING[2] AND E.L. PIERCE[2]

[1]Imperial College London, London, UK, SW7 2AZ (*correspondance: c.cook09@imperial.ac.uk)
[2]LDEO, Palisades, NY 10964-1000 USA

Our understanding of the dynamics of the East Antarctic Ice Sheet (EAIS) during the climatically warm early Pliocene, and the transition to the cooler, but more variable late Pliocene, is limited. Integrated isotope analyses of detrital marine sediments from ODP Site 1165 (64°22-77S, 67°13-14E), Prydz Bay, East Antarctica, offer novel insights into the evolution of the East Antarctic Ice Sheet, and reveal the controls on sediment composition in a glacial environment. Here we investigate the $^{40}Ar/^{39}Ar$ ages of hornblende grains from ice-rafted detritus (IRD) (>150μm) and neodymium and strontium isotope fingerprints of detrital marine sediments (<63μm).

Early Pliocene sediments, deposited between 5.0 and 3.5 Ma, are dominated by hornblende IRD grains typical of the local Prydz Bay region ($^{40}Ar/^{39}Ar$ ages of ~500 Ma). However, fine-grained (<63 μm) material exhibits εNd values of -14, untypical of modern marine sediments in this area (εNd: -17 to -19). The source of these higher εNd values could be either the nearby Mawson coast (εNd: ~-15- to -14) or the distal Wilkes Land margin (-12.3 to -14.8), with sediments carried by bottom currents. Strontium isotopes, however, are more radiogenic than expected, an observation that could either be due to sedimentary sorting, continental weathering, or subtle shifts in provenance affecting Rb/Sr rations. Conversely, Late Pliocene sediments with depositional ages of 3.3 to 2.8 Ma display an increase in distally sourced Wilkes Land IRD ($^{40}Ar/^{39}Ar$ ages of 1100-1300 Ma). The IRD provenance signal is positively correlated to detrital $^{87}Sr/^{86}Sr$ and εNd signatures in the fine fraction of the same samples, indicating an increasing amount of material derived from the distal Wilkes Land margin (εNd: -12.3 to -14.8; $^{87}Sr/^{86}Sr$: 0.730-0.735). Our results imply that ice rafting played an important control on sediment composition in the late Pliocene, possibly related to the growth of the EAIS in a cooler Late Pliocene climate.

Overall, the radiogenic isotope composition of Pliocene detrital sediments in the Southern Ocean reflects changing environmental conditions as well as sedimentary processes. Interpretation of such data can provide a valuable framework for the interpretation of ice sheet instability events along the Antarctic continental margin.

Systematic tapping of independent magma chambers during the 1 Ma Kidnappers supereruption

G.F. COOPER*, C.J.N. WILSON AND J.A. BAKER

SGEES, Victoria University, PO Box 600, Wellington, NZ
(*correspondence: george.cooper@vuw.ac.nz)

The 1.0 Ma Kidnappers eruption (~1200 km^3 bulk volume) from Mangakino volcanic centre produced the largest phreatomagmatic fall deposit in New Zealand, followed by the most widespread ignimbrite on Earth [1]. Samples collected through a proximal 4.0 m section of the Kidnappers fall deposit, representing the first 60-70 % of erupted material, reveal multiple, independent magma chambers of comparable size were tapped during the eruption. Evidence for this includes the following: (i) Major and trace element chemistries of individual matrix glass shards define three glass populations (types A, B and C), which display a systematic change through the fall deposit. (ii) Plagioclase, hornblende and Fe-Ti oxide compositions show bimodal distributions, corresponding to type A and B glass compositions, with a minor tail corresponding to C. (iii) Type B glass shards and biotite first appear at the same level in the fall deposit suggesting the later tapping of a biotite-bearing magma. (iv) Compositional gaps between glass types A and B imply that no mixing between these magmas occurred.

Parallel covariant trends in glass trace element chemistry indicate at least two independent magmas (A, B) underwent a parallel evolution with respect to crystallizing plagioclase and zircon. Temperature and pressure estimates from hornblende and Fe-Ti oxide equilibria from each magma type show that the two magma chambers were similar and therefore adjacent, not vertically stacked, in the crust. Hornblende temperature and pressure estimates from magmas A and B range from 770 to 860°C and 90 to 220 MPa corresponding to magma chamber depths of *ca*. 4 to 8 km. Hornblende pressure estimates coupled with *in situ* trace element fingerprinting imply that a horizontal stratification was also present in both of the A and B magma chambers. Pumice glass analyses from the subsequent ignimbrite display a broader compositional range than the fall deposits indicating the discharge of magma(s) that are not represented earlier in the eruption. This work has implications for understanding the dynamics of large (‘super‘) volcanic events and how such large volumes of silicic magmas are generated, stored and erupted.

Distinguishing between open and closed system magma differentiation at arc volcanoes by combining U-series and elemental systematics

L.B. COOPER[12]*, O. REUBI[1], M. DUNGAN[2], B. BOURDON[3] AND C.H. LANGMUIR[4]

[1]Inst. of Geochemistry and Petrology., ETH Zurich, Switzerland
(correspondence: lauren.cooper@erdw.ethz.ch)
[2]Sect. of Earth Sciences, Univ. of Geneva, Switzerland
[3]Ecole Normale Supérieure de Lyon and CNRS, France
[4]Dept. of Earth and Planetary Sciences, Harvard Univ., USA

Constraining crustal assimilation in volcanic arcs is important because crustal components can be added during both mantle melting and magma ascent. Reubi *et al*. [1] present evidence for up to 10-15% assimilation of crust at Volcán Llaima (38.7°S), Chilean Southern Volcanic Zone, resulting in a diminution of U-series excesses from mantle signatures towards U-rich plutonic endmembers on the equiline. These trends strongly correlate with trace element indices of contamination over 51-57 wt% SiO_2. Llaima is now a very well-characterized volcano with respect to U-series activity ratios (U-Th-Ra-Pa), with 28 historic samples selected from >180 on the basis of major and trace elements. These data will be used to model differences in magma evolution in seven historic eruptive episodes (1640-2009).

In order to evaluate along-arc variations in crustal contributions, we have analyzed five selected samples from nearby Volcán Lonquimay (30 km NE of Llaima, 38.4°). Major and trace element variations over 52-63 wt% SiO_2 provide much less evidence for open-system processes than that recorded by the more contaminated Llaima samples (Rb/Zr=0.12-0.31 at Llaima versus 0.14-0.17 at Lonq.). U-series activity ratios for Lonquimay are constant and overlap with the least contaminated Llaima samples. And, simple equilibrium phenocryst assemblages in the Lonquimay lavas suggest that magma evolution is controlled almost exclusively by closed-system crystal fractionation. The cause of the Llaima/Lonquimay contrast remains unclear. Llaima is larger and more active than Lonquimay, perhaps leading to a higher efficiency of assimilation.

With the further constraints provided by U-series, greater quantitiative understanding of the extent and causes of crustal contamination will become possible. Much of the earlier data from southern Chile may need to be re-evaluated. More U-series studies are currently underway at Nevados de Chillán (36.8°), Antuco (37.3°), Villarrica (39.5°), and Osorno (41°).

U-Pb geochronology of the Southern Scandinavian Caledonides: The Mesoproterozoic Espedalen anorthosite-gabbro-norite massif and associated rocks

F. CORFU[1] AND M. HEIM[2]

[1]University of Oslo, Dept. Geosciences PB 1047 Blindern, N-0316 Oslo, fernando.corfu@geo.uio.no
[2]The Norwegian University of Life Sciences (UMB), PB 5003, N-1432 Aas, (michael.heim@umb.no)

Exactly 100 years ago V.M. Goldschmidt completed his PhD thesis on contact metamorphism in the Oslo Graben, and shifted attention to the Caledonian mountains and their problems concerning tectonics, metamorphism and magmatism. Based on these studies, in 1916 he provided a detailed description of the two main plutonic suites that occur in the nappes, the anorthosite-charnockite series and the contrasting opdalite-trondhjemite series. He outlined the main features of the rocks and discussed many of the fundamental question concerning these suites, their relationships, ages, origin and processes controlling their formation. Interestingly, and in spite of the enormous progress in many fields, many of the problems discussed in his paper remain relevant and unsolved today, a century later. In our present study we deal with an anorthosite massif and associated rocks in the eastern-most part of the Jotunheimen mountains investigated by Goldschmidt. One basic question concerns the relationship between these rocks and the major other anorthositic domains in the Jotunheimen and Bergen regions, and the relationships between the various members of the suite including the out of order sequence of crystallization of anorthosite and other mafic to intermediate rocks. Zircon found in coarse grained noritic anorthosite in Espedalen indicates an age of about 1520 Ma, similar to, or slightly younger than those for tonalite and granite in the supposed metamorphous sub-volcanic complex at the interface with tectonically underlying psammitic rocks. Zircons from a lamprophyre dyke yields an age of 1514 Ma. The U-Pb data also record partial disturbances during the Sveconorwegian orogeny, a feature typical of most rocks of the Jotun Nappe Complex. The age of 1520 Ma for the Espedalen massif shows that this intrusion is clearly distinct from the Sveconorwegian anorthosite (ca. 965 - 970 Ma) in the Jotun and Lindås nappes. The 1500 Ma event correlates instead with the very intense activity that build much of the south-Norwegian crust, thus supporting a provenance of the nappe from southern Baltica.

Nuclear imaging of ^{99m}Tc transport and immobilisation through porous media

CLAIRE L. CORKHILL[1]*, JONATHAN W. BRIDGE[1], PHILIP HILLEL[2], CLAIRE UTTON[3], NEIL C.HYATT[3], STEVEN A. BANWART[1] AND MARIA ROMERO-GONZALEZ[1]

[1]Kroto Research Institute, Department of Civil and Structural Engineering, University of Sheffield, S3 7HQ, UK. (*corresponding author: c.corkhill@sheffield.ac.uk)

[3]Department of Materials Science and Engineering, University of Sheffield, S1 3JD, UK

^{99}Tc is a β-emitting radioactive fission product of ^{235}U, formed in nuclear reactors. Its long half life ($2.1x10^5$ years) and high environmental mobility in oxic conditions as the pertechnetate anion ($Tc(VII)O_4$) presents a major challenge to nuclear waste disposal strategies.

We demonstrate non-invasive quantitative imaging of the transport of ^{99m}Tc, a γ-emitting metastable isomer of ^{99}Tc commonly used in medical imaging. Transport of this radionuclide was measured during co-advection through quartz sand and various cementitious materials commonly used in nuclear waste strategies, including crushed ordinary portland cement (OPC), OPC combined with blast furnace slag (BFS) or pulversised fly ash (PFA), and Nirex Reference Vault Backfill material. Pulse-input experiments of approximately 25MBq ^{99m}Tc were conducted under saturated conditions and at a constant flow of 0.33ml/min. Dynamic gamma imaging was conducted every 30s for 2 hours.

Relative changes in mass distribution of ^{99m}Tc over time were quantified by spatial moments analysis of the resulting plume. ^{99m}Tc advected through quartz sand and crushed OPC demonstrated typical conservative behaviour, while transport through BFS- and PFA-containing cements produced a significant reduction in colloid centre of mass transport velocity over time. We propose that this is likely due to reduction of ^{99m}Tc by active reducing agents such as Fe and S in the cementitious material. Concurrent batch experiments using ^{99}Tc demonstrated the relatively irreversible sorption of Tc to these materials.

Gamma camera imaging has proven an effective tool for helping to understand the factors which control the migration of radionuclides for surface, near-surface and deep geological disposal of nuclear waste.

Pedogenesis and stabilization of soil organic carbon in a charcoal production plot

JEAN-THOMAS CORNELIS*, BRIEUC HARDY, BRUNO DELVAUX AND JOSEPH DUFEY

Earth and Life Institute – Environmental Sciences, Université catholique de Louvain, Louvain-la-Neuve, Belgium (*correspondence: jean-thomas.cornelis@uclouvain.be)

Charcoal addition to soil has the potential to improve physical, chemical and biological functions of soil [1], while being used as a potential long-term sink for atmospheric CO_2 due to the intrinsic recalcitrance of aromatic components [2]. Our hypothesis is that production process and addition of charcoal in soil can influence the pedogenic processes governing the soil capacity to stabilize organic carbon (OC).

The experimental site is located in an oak forest in the loessic silt belt of Belgium. The well-drained and acidic (pH 3.8-4.3) soil is classified as a Luvisol with an argic horizon occurring at 30 cm depth. We carried out the mineralogical and physico-chemical analysis (i) in an ancient charcoal production plot (1750-1870), and (ii) in the reference forest soil. Moreover, we analyzed the content of labile and stable (mineral-protected and recalcitrant) OC in charcoal-enriched, organo-mineral (Ah), eluvial (E) and argic (Bt) horizons.

The soil-pH increases by 0.6-0.8 units and the base saturation is until eight fold higher after the addition of charcoal. In the eluvial E horizon just below the charcoal accumulation, we observe a slight decrease of the content of amorphous and crystalline iron oxides, which provide reactive hydroxylated surfaces for OC associations. The mass of stable OC per unit area in the soil below the ancient charcoal production plot is significantly higher (13.9 $kg.m^{-2}$) than in the reference Luvisol (5.8 $kg.m^{-2}$). Charcoal, as residues of slow pyrolysis, strongly increases the sequestration of C in soil through (i) intrinsic recalcitrance and (ii) charcoal-organo-mineral interactions. Indeed, the part of humified, dissolved or colloidal OC released from charcoal and stabilized upon silicates and oxy-hydroxydes is not negligible (5.6 $kg.m^{-2}$). Finally, the pedological modifications induced by the charcoal production process do not significantly influence the stable OC stock. Therefore, the addition of charcoal will lead to higher C sequestration in topsoil without affecting the subsoil capacity to stabilize OC.

Spectral Gamma-ray applications to marine organic-rich sediments of the Lower Jurassic of Portugal

G.G. CORREIA[1]*, L.V. DUARTE[1], A.C. PEREIRA[1], R.L. SILVA[1] AND J.G. MENDONÇA FILHO[2]

[1]Universidade de Coimbra, Departamento de Ciências da Terra and IMAR-CMA, 3000-272 Coimbra, Portugal (*correspondence: gil.correia@gmail.com)

[2]IGEO and LAFO, Universidade Federal do Rio Janeiro, 21949-900 Rio de Janeiro, Brazil

This study is based on a high-resolution gamma ray analysis, performed on the hemipelagic Lower Jurassic organic-rich unis of the Lusitanian Basin (Portugal). This time interval, namely the Late SinemurianPliensbachian, is recognized as one of the most important potential oil source rock in Portugal [1].

Supported by more than 1000 gamma-ray measurements from outcrop and laboratory, the obtained data (total GR, Th, U and K) were correlated with several mineralogical (by X-Ray diffraction) and geochemical parameters, such as total organic carbon (TOC), insoluble residue (IR) and sulfur. From our results, and similarly to other case studies [2], we emphasize the relation between U and TOC, whose maximum value reaches 20%. A fair to good correlation is generally observed between these two variables (Fig. 1), however other lithological and geochemical (e.g. IR) parameters of the organic-rich facies may determine some variations.

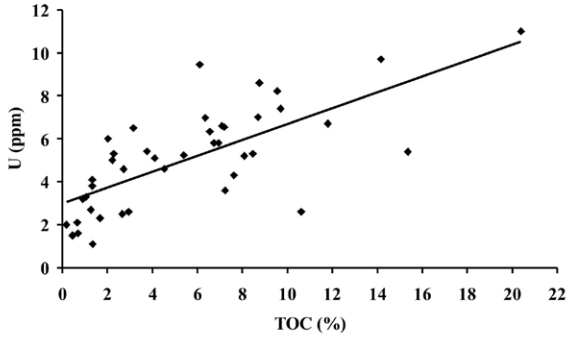

Figure 1: U/TOC correlation of the studied Lower Jurassic samples, with the U values obtained in laboratory.

This work has been financially supported by project PTDC/CTE-GIX/098968/2008 (FCT - Portugal).

Deglaciation pattern during the Late-Glacial / Holocene transition in the Southern French Alps. Chronological data from the Clarée Valley (Durance catchment, S. France)

ETIENNE COSSART[1], DIDIER BOURLES[2], REGIS BRAUCHER[2], MONIQUE FORT[3], ROMAIN PERRIER[3] AND LIONEL SIAME[2]

[1]Université Paris 1 Panthéon-Sorbonne, UMR Prodig 8586 – CNRS, 2 rue Valette, F-75005 Paris, etienne.cossart@univ-paris1.fr
[2]UMR CEREGE 6635 – CNRS, Plateau de l'Arbois, F-13100 Aix en Provence
[3]Université Paris Diderot (Paris 7), UMR Prodig 8586 – CNRS, 2 rue Valette, F-75005 Paris

The Southern French Alps, characterized by many climatic influences, remain a scientific problem for palaeo-environmental studies. Indeed, the lack of chronological benchmarks hitherto hampered the definition of sequences of glacier variations since the Last Glacial Maximum (LGM), even if a scenario was established in the Ubaye valley. This scenario was then considered as a regional model by many geomorphologists, but this valley is not necessarily representative of the entire region. We focus here on the upper part of the Durance watershed because it corresponds to the accumulation zone of the main glacier of the Southern French Alps during the LGM. Thanks to extensive fieldwork and geomorphic mapping of remnants of past glaciations, and thanks to new chronological data (about 35 cosmic ray exposure –CRE– ages) we propose the first absolute scenario established in the very upper part of the catchment. To assess CRE ages, we sampled glacially-polished surfaces, in order to assess both the retreat of the front and the thinning rate of the glacial tongue. We also paid attention to morainic ridges and glacio-fluvial remnants. The results show that cirque glaciation began only at the beginning of the Holocene, and that thick valley glaciers still occupied the upper valleys during the Late-Glacial period, until the Younger Dryas stadial. The disappearance of the tongue occurred rapidly, between Younger Dryas and Preboreal sequences due to both ELA rise and a topographic threshold effect. Finally, this scenario appears to be well in accordance with new data obtained in other parts of the Alps.

The composition of the Earth's outer core from first principles

ALEXANDER S. CÔTÉ[1,2], JOHN P. BRODHOLT[1] AND JAMES BADRO[2]

[1]Dept. of Earth Sciences, University College London, U.K.
[2]Institut de Physique du Globe de Paris, France.

The exact composition of the Earth's core remains an unanswered question. Published models for the outer core allow a mixture of several coexisting light elements (Si, S, O, C), and many arguments have been put forward over the years for and against each of those elements.

In this study we performed *ab initio* molecular dynamics calculations on liquid Fe and liquid Fe-(Si,S,C,O) mixtures at different P and T conditions of the Earth's outer core in order to attempt to constrain the light-element concentration based on densities and bulk sound velocities. By fitting equations of state to our P-V data, we were able to obtain density and velocity vs. concentration profiles for each iron-light-element liquid alloy; this allowed us to estimate the density for different outer core compositions found in the literature and compare them with seismic models such as PREM and AK135. We find that the density of liquid Fe containing 4% of Ni (no light elements) is approximately 7% denser than the core. Incorporating light element increases the bulk sound velocity while decreasing density. We also find that many of the published compositional models for the outer core result in densities lower than the seismological models. This indicates that the light element concentrations predicted in those models are slightly overestimated. Our data agree with an O-rich outer core (up to 6.3wt. %), and we find that large amounts (more than 3 wt. %) of Si cannot be incorporated in the outer core.

Zn isotope fractionation in the soil-plant system (a pot experiment)

E. COUDER[1]*, T. DROUET[2], B. DELVAUX[1], C. MAERSCHALK[3], C. MEEUS[3] AND N. MATTIELLI[3]

[1]Earth and Life Institute – Environmental Sciences – Science Soil, Université catholique de Louvain, Croix du Sud, 2/10, 1348 Louvain-la-Neuve, Belgium (*correspondence: Eleonore.Couder@uclouvain.be)
[2]Laboratoire d'Ecologie végétale et Biogéochimie, Université Libre de Bruxelles, 1050 Brussels, Belgium
[3]Département des Sciences de la Terre et de l'Environnement, Université Libre de Bruxelles, 1050 Brussels, Belgium

Zinc isotopes constitute a precious tool to trace metal sources and better understand the cycling of this micronutriment in the environment. The aim of the present study is to investigate the Zn isotope fractionation for evaluating the interaction between plant species and soil types, in order to better characterize Zn migration through the soil-plant system.

Three contrasted soils, originating from a zone with intense metallurgical activites in Belgium, have been used for the culture experiment conducted in controlled conditions: a calcareous soil ($\delta^{66}Zn_{bulk\ soil}$ = +0.06‰) and an acid shale-derived soil ($\delta^{66}Zn_{bulk\ soil}$ = +0.08‰) both essentially feeded by aerial fallouts, and a slag heap-derived soil ($\delta^{66}Zn_{bulk\ soil}$ = +0.37‰). Two plant species have been chosen: a dicot species (rape) and a monocot species (ryegrass). The Zn isotopic compositions have been measured in roots ($\delta^{66}Zn$ = +0.01 to +0.43‰) and in shoots ($\delta^{66}Zn$ = -0.23 to +0.28‰).

The results show that (a) the Zn isotopic compositions of all materials reflect the Zn isotopic signatures of the main Zn inputs (aerial fallouts *vs* smelter-slag residues); (b) light Zn isotopes are preferentially accumulated in shoots; (c) the magnitude of Zn fractionation during Zn transport from roots to shoots appears to be related to the cation exchange capacity of roots (CECR) and the water use efficiency (WUE). The plant species affects the Zn signature in plant parts through the density of negative charges in the roots, *i.e*. CECR being larger for the dicot species implies a larger Zn isotope fractionation between shoots et roots. In addition, the WUE might regulate a form of isotopic selection by controlling the efficiency of Zn adsorption on cell walls.

In the soil-plant system, enrichment in light Zn isotopes is favoured into the plants. As Zn is subsequently recycled to the soils through dead plant material return, the plant cover plays a key role on Zn fractionation in soils.

Early fossilization process of cyanobacteria in modern microbialites

ESTELLE COURADEAU[1,2], KARIM BENZERARA[1], EMMANUELLE GERARD[2], IMENE ESTEVE[1], DAVID MOREIRA[3] AND PURIFICACION LOPEZ-GARCIA[3]

[3]Ecologie, Systématique et Evolution, UMR 8079 CNRS & Université Paris-Sud, France (puri.lopez@u-psud.fr)

Most extant life diversity is microbial. Despite so, microbes are rarely described in the rock record. Part of the problem comes from the difficulty to identify microfossils unambiguously, since they can be morphologically confused with abiotic biomorphs [1]. Therefore, identifying traces that can be diagnostic of microbial fossils is crucial. To contribute to this aim, we studied the ongoing fossilization of cyanobacterial cells in modern microbialites from Alchichica Lake (Mexico). Alchichica Lake is a Mg-rich hyperalkaline crater lake (pH 8.9) containing living stromatolites composed of aragonite [$CaCO_3$] and hydromagnesite [$Mg_5(CO_3)4(OH)_2 \bullet 4(H_2O)$] [2]. Cyanobacteria comprise most of the microbialite biomass. Scanning electron microscopy coupled with confocal laser scanning microscopy were used to co-localize cyanobacterial cells and associated minerals. These observations showed that cells from the order Pleurocapsale become specifically encrusted within aragonite with an apparent preservation of cell ultrastructures. Early fossilization gradients from living to totally encrusted cells span distances of a few hundred micrometers. Cells with increasing levels of encrustation where observed down to the nm-scale by transmission electron microscopy performed on Focused Ion Beam (FIB) ultrathin (<100 nm) foils. Two types of aragonite crystals differing by their morphology were seen within and outside cells. Synchrotron-based scanning transmission x-ray microscopy (STXM) analyses at the C and N K-edges [3] were performed on the same FIB foils. They provide information on the evolution of carbon and nitrogen speciation along this early fossilization gradient. We propose a model of the early fossilization process of these cyanobacteria and their associated organic molecules.

Solid speciation of As, Pb and Sb-rich anthropogenic residues

A. COURTIN-NOMADE[1]*, O. RAKOTOARISOA[1], H. BRIL[1], M. KUNZ[2] AND N. TAMURA[2]

[1]University of Limoges, GRESE Laboratory, FST, 123, avenue A. Thomas, 87060 Limoges Cedex, France (*alexandra.courtin@unilim.fr)

[2]Advanced Light Source, Lawrence Berkeley National Lab, 1 Cyclotron Rd, Berkeley, CA 94720, USA

We studied As, Pb and Sb solid speciation to better understand the geochemical pathways and mobility of these potentially toxic elements, which are released upon weathering of mining and industrial waste products. Such studies are indispensible to understand soil and water contaminations and to propose remediation solutions. Studied samples are mining residues (mill tailings and slags) from the French Massif Central, generated by former activities over a century (1830 to 1970). They were collected at two different mining districts: Pontgibaud, which was one of the largest production site for Ag and Pb (c.a. 50'000 t Pb) and Brioude-Massiac, which produced around 40'000 t of Sb (second largest nationwide production). Samples were also studied to compare the evolution of industrial processes and to test the variations in Pb or Sb retention.

Mining residues from the two locations show elevated concentrations in As, Pb and Sb, up to 0.16%, 6.6% and 1.1% respectively. However spatially concentrated accumulations of As (up to 11 wt.%), Pb (up to 70 wt%) and Sb (up to 28 wt.%) are also observed. The mineralogical characterization of the products with such contents is essential for the modeling of the geochemical processes controlling the toxicity of these elements. Arsenic, Pb and Sb have only been detected in secondary products resulting from oxidation of Pb or Sb-rich sulfides (galena, stibnite and berthierite) but only few relics of primary sulfides have been observed. Synchrotron X-ray microdiffraction (beamline 12.3.2, Advanced Light Source, USA) and micro-Raman investigations indicate that Sb forms complex mixing phases with goethite and/or lepidocrocite. Antimony is also trapped by jarosite suggesting a substitution of $Fe^{3+}$by Sb^{5+} (up to 3% Sb). Antimony is present as oxides, stibiconite $SbSb_2O_6(OH)$ and associated with Fe, and possibly Mn (oxy-)hydroxides within solid phases of highly heterogenous compositions. Arsenic is also typically associated to iron (oxy-)hydroxides presenting various cristallinity. Main Pb host phases are sulfates (e.g., anglesite $Pb(SO_4)$, beudantite $Pb(Fe_{2.54}A_{1.46})(As_{1.07}O_4)(S_{0.93}O_4)(OH)_6$) but Pb is also associated to complex mixing of silicates and Fe oxides.

S isotopes distinguish two S pulses at terrestrial Cretaceous-Paleogene boundary sections

M.L. COUSINEAU[1]*, F. THERRIEN[2], T. MARUOKA[3], B.A. WING[4] AND D. FORTIN[1]

[1]Earth Sciences, University of Ottawa, Ottawa, Ontario, Canada (*correspondence: mlcousineau@uottawa.ca)

[2]Royal Tyrell Museum of Palaeontology, Drumheller, Alberta, Canada (francois.therrien@ab.gov.ca)

[4]Earth and Planetary Sciences, McGill University, Montréal, Québec, Canada (boswell.wing@mcgill.ca)

The Cretaceous-Palaeogene (K-Pg) boundary marks a major biotic turnover in Earth's history that may have resulted, at least in part, from a massive bolide impact.

Two of the northernmost occurrences of the K-Pg boundary in terrestrial sediments have been positively identified on the Knudsen's *T. rex* Ranch in the Scollard Formation of south-central Alberta, Canada. We conducted a high-resolution (2-cm intervals) study of bulk sulfur isotopes and sulfur content across a ~50-cm stratigraphic interval spanning the K-Pg boundary, representing a time interval of ~500 Ka.

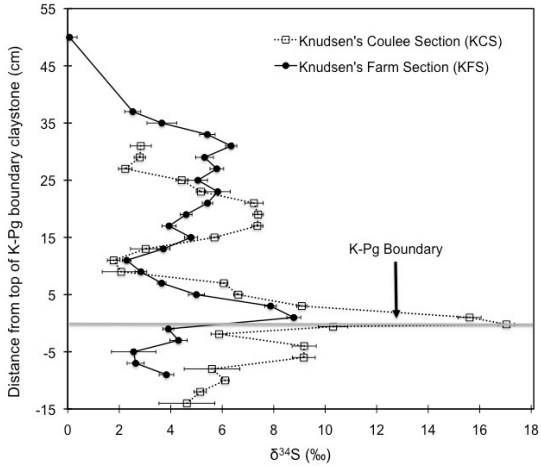

Figure 1: $\delta^{34}S$ profiles at the Knudsen's *T. rex* Ranch

Positive $\delta^{34}S$ excursions at both sites reveal a pulse of ^{34}S-enriched sulfur at the boundary, likely originating as oceanic sulfate and evaporite target rocks. Post-boundary $\delta^{34}S$ excursions may reflect injection of volcanically-derived sulfate aerosols; at least one peak (KFS) is contemporaneous with a major phase of Deccan trap volcanism. Analyses of minor S isotopes (^{33}S, ^{36}S) offer the possibility to validate our interpretation of the origins of the boundary and post-boundary S injections into the freshwater environment.

Copper and zinc isotope fractionation during their interaction with phototrophic biofilm

A. COUTAUD[1,2]*, O.S. POKROVKSY[1], J.L. ROLS[2], J. VIERS[1] AND L. TEN-HAGE[2]

[1]GET, CNRS/UPS, 14 av Edouard Belin, 31400 Toulouse, France (*correspondence: aude.coutaud@get.obs-mip.fr)
[2]EcoLab, CNRS/UPS, 118 rte de Narbonne, 31062 Toulouse cedex 9, France

In geochemistry, the study of the interactions between trace metals (TM) and aquatic microorganisms is limited essentially by the characterisation of surface's interactions for short exposure time and for uptake experiments for selected monospecific groups of algae and bacteria. The originality of our work is to combine the study of Cu and Zn isotope fractionation with biological characterisation of phototrophic biofilms during long incubation times in order to allow for the integration of an ecological dimension.

Towards this goal, batch and open flux experiments including trace metals (TM) sorption, incorporation and extracellular release were performed on mature biofilm having a cyanobacterial dominance. Moreover, the impact of temporary drying on metal release from biofilm was studied. Anothers experiments were performed in Taylor Couette reactor to study the relation between a biofilm growth cycle and the degree of stable isotope fractionation during metal uptake.

Results show that in batch reactor, the pattern of metal isotope fractionation is dramatically different between Zn and Cu. There is an accumulation of heavy Zn isotope in the biofilm during the first 96 hours with an average isostopic shift close to 0,3 ± 0,1 ‰. In contrast, the copper interacting with biofilm during 48 hrs is enriched in light isotopes (approx 0,16 ± 0,07 ‰) but later this trend is reversed bringing to enrichment the biomass in heavy isotope. The observed difference may be linked to (i) the different toxicity of metal with Cu being more toxic than Zn and (ii) the difference of physicochemical properties of metal interaction reactions: internalization of copper is faster than that of Zn and only Cu could undergo redox reaction within the biofilm matrix and inside the cells.

Our results provide firm basis for establishing the link between metal complexes structure and toxicity and the degree of stable isotope fractionation that can be used for tracing biological processes in natural waters.

Montalto Formation: A Middle Cambrian to basal Ordovician sequence in Dúrico-Beirã area (Northern Portugal)

H. COUTO

Universidade do Porto, Faculdade de Ciências, DGAOT, Centro de Geologia, Rua do Campo Alegre 687, 4169-007 Porto, Portugal (hcouto@fc.up.pt)

Montalto Formation [1] occur in Dúrico-Beirã area (northern Portugal) in Central-Iberian Zone. It's formed by three lithologic associations. The Lower lithologic association is mainly composed of grey and violet slates with intercalations of altered volcanic acid rocks and exhalites. The Intermediate lithologic association is composed by alternating sequences of slate, quartzite, and subordinate wacke. The Upper lithologic association is mainly composed of conglomerates usually clasto-suported with minor pelite, siltite, quartz arenite and wacke intercalations. Some conglomerates are well calibrated dominantly bearing quartz clasts usually elongated and orientated. Other conglomerates occurring to the top of the sequence are polygenic, poorly calibrated with clasts of varied nature (quartz, schist, black quartzite) intersperse with pelitic or quarztic layers evidencing a more superficial facies, probably continental. Dykes of diabase are particularly frequent in this lithologic association. This formation overlies the Terramonte Formation [1], a thick flyschoïd sequence, showing some turbiditic characters being equivalent to Desejosa Formation defined in Douro Group (Lower Cambrian to Middle Cambrian) [2]. Montalto Formation underlies a lithologic association mainly composed of conglomerates, quartz-arenites, minor pelites and wakes interbeded with volcanic rocks exhibiting bimodal composition (volcanoclastic rocks of rhyolitic affinities and basic volcanic rocks) that evidence a continental rifting [3] of probably Tremadocian age. To the top the Armorican quartzites occur (Floian). So, an age between Middle Cambrian and basal Ordovician (Tremadoc) is proposed to Montalto Formation. This contrast to a Floian age proposed by some authors [4] when correlating Montalto Formation to Vale de Bojas Formation and Eucísia Formation (Trás-os-Montes). These last formations can be correlated to the volcano-sedimentary sequence of probable Tremadocian age [3].

Late Ordovician to Lower Silurian transition in Valongo Anticline (Northern Portugal): Evidences of an erosional unconformity previous to the Silurian sea level rise

H. COUTO AND A. LOURENÇO[1,2]

[1]Universidade do Porto, Faculdade de Ciências, DGAOT, Centro de Geologia, Rua do Campo Alegre 687, 4169-007 Porto, Portugal. (hcouto@fc.up.pt)

[2]Universidade do Porto, Reitoria, Centro de Geologia, Praça Gomes Teixeira, 4099-002 Porto, Portugal. (aafonso@reit.up.pt)

This work discusses the transition of Ordovician to Silurian in Valongo Anticline. This structure is an antiform related with the Variscan orogeny, located in the Centro Iberian Zone (Northern Portugal). The Sobrido Formation representing the Hirnantian glacial deposits was recently revised [1] evidencing the presence of ice-contact deposits.

The transition between Upper Ordovician and Lower Silurian strata is variable. Transitional sections locally record a ferruginous level and black basal quartzites. These quartzites seems equivalent to Vale da Ursa Formation [2] of Central Portugal (Dornes). They are followed by black-shales or dark grey schist turning to light grey and purple with pyrophillite and bearing Middle to Upper Llandovery graptolites [3] with intercalations of centimetric cherty or quartzitic layers. The presence of a ferruginous level and the fact that sometimes quartzites are lenticular or absent evidences a minimum glacio-eustatic sea-level. The quartzites are interpreted to record scour, a lag, and the development of an erosional unconformity before the Silurian sea level rise. This is in agreement with what has been advocated by other authors [4] that consider the sea levels reached a minimum during the glaciation near the Ordovician-Silurian boundary before a further significant rise took place during the Llandovery. Black shales were controlled by the early Silurian palaeorelief as suggested for the Lower Silurian "hot shales" in North Africa and Arabia [5]. This model can explain why often in Valongo Anticline, the Lower Silurian black-shales or dark grey schist occur in the middle of Hirnantian diamictites.

Psychrophilic methanogens: A possible solution to more cost-effective anaerobic wastewater treatment

JILLIAN M. COUTO, GAVIN COLLINS AND WILLIAM T. SLOAN

School of Engineering, University of Glasgow, Glasgow UK, G12 8QQ

Wastewater treatment facilities are a rich source of methane gas, an effective renewable energy source. Methane is produced anaerobically by mesophilic or thermophilic microbial communities and thus currently requires a net input of energy to heat waste treatment facilities, reducing the cost-effectiveness of this process. Our aim is to investigate the potential of psychrophilic microbes to produce methane, hence reducing the need for this net input of energy. To do this we have designed a functional screen of metagenomes harvested from cold temperature environments, specifically arctic soils and cold-adapted agricultural waste sludge, which will be scanned for novel functional candidate genes. This screen entails scanning thousands of genes for their ability to be activated in an anaerobic and cold environment when exposed to intermediary metabolites produced during methanogenesis. Similar to a previous design (Uchiyama *et al*, 2005) [1], genes within our metagenomic library, housed in e-coli, will produce a fluorescence signal when activated by these metabolites. This is detected in a high throughput manner using fluorescence activated cell sorting technology. Once isolated, these candidates will then be further characterized and tested for use within a bioreactor system, with the ultimate goal of producing methane at cold temperatures.

Geochemical behavior of (thio)arsenates with Fe-minerals

R.M. COUTURE[1,*], D. WALLSCHLÄGER[2], K. MITCHELL[1] AND P. VAN CAPPELLEN[1]

[1]Earth and Environmental Sciences, University of Waterloo, Waterloo, Canada (*correspondence: r.couture@uwaterloo.ca)
[2]Environmental and Resources Studies, Trent University, Peterborough, Canada

Under microbially-mediated sulfate (SO_4) reducing conditions, the mobility of arsenic (As) in iron (Fe) rich sediments is influenced by the transformations of Fe minerals and changes in aqueous As speciation. Hence, to predict As mobility in complex biogeochemical systems, the sorption of aqueous As species to various Fe mineral phases should be fully understood. However, despite the accumulating evidence that thioarsenates dominate As speciation under a variety of environmental conditions, their sorption behaviour in sediments is poorly known. We used batch experiments to measure sorption of six individual As species in suspensions of 2-lines ferrihydrite (2L-Fh), hematite, goethite, mackinawite ($FeS_{m(s)}$) and pyrite. The table below shows the results for $FeS_{m(s)}$ and 2L-Fh. As can be seen, there are marked differences in the partition coefficients of the different soluble As species.

	$FeS_{m(s)}$	2L-Fh
Arsenate	5	1600
Arsenite	3	50
Mono-thioarsenate	0.1	12
Di-thioarsenate	310	70
Tri-thioarsenate	0.2	150
Tetra-thioarsenate	1.5	120

Table: Partition coefficients (K_d; L g^{-1}) for As sorption to selected Fe-minerals at pH 7 and ionic strength = 0.05M.

We also used flow-through reactors (FTRs) to look at the formation and sequestration of thioarsenates in Fe-rich and Fe-poor lake sediments run under SO_4 reducing conditions. The FTRs where supplied with either soluble arsenate or soluble arsenite. We monitored SO_4, total sulfide, zero-valent sulfur, Fe as well as pH and E_h in the outflow of the FTRs. The results indicate that arsenate is first reduced to arsenite, which is then sulfidized to thioarsenates. Thioarsenates only dominated As speciation in the FTR outflow of the Fe-rich sediments. In addition, As was released as mono-thioarsenate, in line with the observation that mono-thioarsenate is the least strongly bound to Fe-minerals (see Table). These preliminary observations are currently being used to improve existing reactive-transport models for the fate of As under sulfate reducing conditions.

Metatranscriptomics of the green sulfur bacteria in a meromictic Swiss lake (Lago di Cadagno)

R.P. COX[1,2*], K. HABICHT[1,3], M. MILLER[2], N. STORELLI[4,5], M. TONOLLA[4,5] AND N.-U. FRIGAARD[6]

[1]NordCEE, [2]Dept. Biochem. Mol. Biol., [3]Inst. Biol., Univ. of Southern Denmark, 5230 Odense M, Denmark (*correspondance: r.p.cox@bmb.sdu.dk)
[4] Dept. Plant Biol., Univ. Geneva, Switzerland
[5] Inst. Microbiol., Canton Ticino, Bellinzona, Switzerland
[6] Dept. Biol. Univ. Copenhagen, 3000 Helsingør, Denmark

Lake Cadagno in the Swiss Alps is a potential modern analog of the early ocean. The lake is permanently stratified with anoxic water containing sulfate (1.5 - 2.0 mM) and sulfide below the chemocline. The sulfidic water column contains high concentrations of phototrophic sulfur bacteria (peak concentrations more than 250 μg/L BChl *e*). We have previously shown that the bacterial community in this layer is dominated by the green sulfur bacterium *Chlorobium clathratiforme* (up to 70% of recovered bacterial 16S rRNA gene sequences in a clone library [1]. Several lines of molecular sequence evidence suggest that this population is clonal and has replaced the previously dominant purple sulfur bacteria over the last decade [1]. This feature makes the lake a highly suitable site for metatranscriptomic studies of natural populations.

Samples were collected at the top of the chemocline during the day (1) and at night (2) and at a depth where light intensity precludes active photosynthesis (3). The mRNA was converted to cDNA and subjected to high-throughput sequencing. As expected from previous results [1,2] a high proportion of the sequences could be matched to the genome of *Chlorobium clathratiforme* BU-1 which was isolated from a lake in Southern Germany. There were relatively small differences in the normalised transcript levels between the 3 samples. The highest transcript levels were observed for the major protein of the light-harvesting chlorosomes, *csmA*, and the gas vesicle protein *gvpA*.

Molecular modelling of carbon dioxide adsorption in zeolites

J.C. CRABTREE*[1], S.C. PARKER[2] AND J.A. PURTON[3]

[1]Doctoral Training Centre in Sustainable Chemical Technologies, University of Bath, BA2 7AY (*correspondence: j.c.crabtree@bath.ac.uk)
[2]Department of Chemistry, University of Bath, BA2 7AY
[3]Daresbury Laboratory, Daresbury, Warrington, WA4 4AD

There is growing concern about the dangers of climate change. The majority opinion is that a major cause is the emission of greenhouse gases such as carbon dioxide (CO_2). Adsorption and separation of CO_2 is therefore a key area of research. Silicate materials are a promising class of material for the adsorption of CO_2 [1][2]. Natural and synthetic zeolites have been chosen as the initial focus of this computational study. They present a good model system as they are microporous and there is experimental data for comparison with simulations.

The computational methods use interatomic potentials to describe the interactions between atoms. Energy minimisation is used to find the most stable configurations of the zeolites. Molecular dynamics is used to study the diffusion of CO_2 in the zeolites while Grand Canonical Monte Carlo (GCMC) simulations are used to generate adsorption isotherms. Zeolites have been modelled in the siliceous form and as aluminosilicates with counter-ions. The main counter-ion that has been considered is Na^+, but the models are being extended to cope with others including K^+, Li^+ and Ca^+.

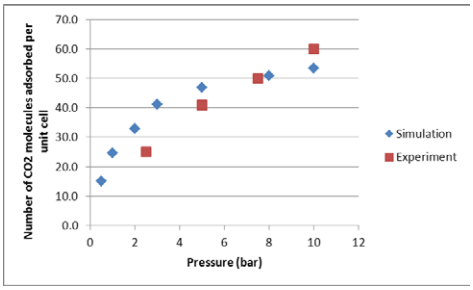

Figure 1: adsorption isotherm of CO_2 in siliceous faujasite, comparing simulations to experimental data [3]

The results gained in this work so far correlate well with experimental data and the work is currently being extended to cover a wide range of other structures and materials to find a good selective adsorbent for CO_2.

Fe and C isotopes in BIF carbonates: Evidence for authigenic formation and microbial Fe respiration

P.R. CRADDOCK AND N. DAUPHAS

Origins Laboratory, Dept of the Geophysical Sciences, The University of Chicago (craddock@uchicago.edu)

We report here iron ($\delta^{56}Fe$, vs. IRMM-014 [1]) and carbon isotopic ($\delta^{13}C$, vs. V-PDB) compositions of Fe-rich and Fe-poor carbonates in two Banded Iron-Formatios (BIF): the ~2.5 Ga Hamersley Basin, Australia and ~3.8 Ga Isua Supracrustal Belt (ISB), Greenland [2]. In the Hamersley Basin, Fe-rich carbonates (in the iron-formation) have $\delta^{56}Fe$ ranging widely from -1.0 to +1.2 ‰ (mean ~ 0 ‰), different from that of Fe-poor carbonates (platform dolomites) that have $\delta^{56}Fe$ lighter than -0.5 ‰. The $\delta^{13}C$ of the same Fe-rich carbonates (-8 to -16 ‰) are also distinct to those of Fe-poor carbonates (~ 0 ‰) [3]. The Fe and C isotope compositions are inconsistent with formation of Fe-rich carbonate in the iron-formation in isotope equilibrium with seawater, and instead reflect an authigenic origin via oxidation of organic carbon coupled to near-complete reduction of ferric precursors (e.g., ferrihydrite) in marine sediments [2,4]:

$$2Fe_2O_3{\cdot}3H_2O + CH_2O + 7H^+ \rightarrow 4Fe^{2+} + HCO_3^- + 10H_2O.$$

Organic carbon oxidation and ferric Fe reduction likely occurred rapidly following primary deposition at the seafloor, but the Fe and C isotope compositions of Fe-rich carbonates indicate that chemical exchange between pore waters and seawater was far from complete. Most likely, the reaction was mediated by heterotrophic microbes via dissimilatory Fe reduction; thus the Fe and C isotope data record evidence for evolution of microbial Fe respitation by ~2.5 Ga. Further, the authigenic formation of Fe-rich carbonate in the iron-formation implies no constraint on the pCO_2 of the overlying Archean ocean and atmosphere as suggested by [5; also see 6]. Coupled Fe and C isotopic signatures of Fe-rich meta-carbonates from the ISB are similar to those of known chemical sedimentary origin from Hamersley Basin [2,7,8]. By analogy, Fe-rich metacarbonates appear to have formed as chemical sediments and preserve isotope evidence that is consistent with the evolution of Fe catabolims by 3.8 Ga.

Electrolyte adsorption to goethite-water interfaces

LOUISE J. CRISCENTI AND DAVID HART

Sandia National Laboratories, Albuquerque, NM 87185, USA (*correspondence: ljcrisc@sandia.gov)

Adsorption onto goethite surfaces is a critical process influencing trace metal migration in the environment. This study investigates interfacial water structure and the adsorption of electrolyte anions and cations on different goethite surfaces to develop a better appreciation of the local environments that favour trace metal adsorption. The impact of different electrolytes (e.g., NaCl, Na_2SO_4, Na_2SeO_3) over a range of concentrations on water structure and surface loading will be presented.

Two goethite surfaces, the (100) and (101) surfaces as defined in the Pnma space group are under investigation. The (100) surface has three types of surface sites (5-fold Fe, Fe_2O_IH, Fe_3O_{II}) and the (101) surface has four types of sites ($Fe_1O_{II}H$, $Fe_2O_{II}H$, Fe_3O_{II}, and Fe_3O_IH). To date, molecular dynamics (MD) simulations have been performed to investigate the impact of 1M – 5M NaCl concentrations on interfacial water structure and surface loading. Each surface slab contains 192 Fe atoms and is protonated to create a neutral slab. The density of the bulk solution is maintaned at 1.0 g/L regardless of salt concentration. A Leonard-Jones wall is imposed at both the top and bottom of the simulation cell. A natural surface of water is allowed to form at the top of the cell through an NPT simulation. Then, a vacuum gap three times the cell height is added to prevent interactions between periodic cells in the Z direction. Production runs were performed using the NVT ensemble at 298K for10 ns.

Water layers at the (100) surface exhibit more structure and more hydrogen bonding with surface hydroxyl groups than at the (101) surface. Na^+ adsorbs as inner-sphere complex to both surfaces; Cl^- adsorbs as an outer-sphere complex. From atomic density profiles, the introduction of 5M NaCl does not change the overall interfacial water structure, reinforcing previous MD studies that also suggest that the electric double layer is dominantly formed by interfacial water structure rather than ions at the surface.

This research is supported by the U.S. Department of Energy, Office of Basic Energy Sciences, Division of Chemical Sciences, Geosciences, and Biosciences. Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockheed Martin Company, for the United States Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

Deglacial NW Atlantic ventilation from paired deep-water coral radiocarbon and Nd isotopes

KIRSTY C. CROCKET[1]*, TINA VAN DE FLIERDT[1], LAURA F. ROBINSON[2] AND JESS F. ADKINS[3]

[1]Earth Science and Engineering, Imperial College London, London SW7 2AZ, UK. (*k.crocket@imperial.ac.uk).

[3]GPS, Californian Institute of Technology, 1200 E. California Blvd., Pasadena, CA 91125, USA

Sequestration of carbon in the deep ocean during glacials and its subsequent release during deglaciation undoubtedly play a role in glacial/interglacial variation of atmospheric CO_2, although concrete evidence of the ocean's role has yet to be established. One route of investigation is to determine ocean ventilation rates. To do so requires combining dynamic tracer data, such as radiocarbon, with a conservative tracer to identify the water masses involved and their mixing ratios.

We describe the use of deep sea corals as an archive material providing same-sample U/Th ages, radiocarbon data and conservative water mass tracer data in the form of Nd isotope compositions. The majority of corals in this study are deglacial in age and span a water depth of 1000 to 2600 m in the NW Atlantic, where changes in the water column structure were pronounced across the last glacial/interglacial cycle [1]. Additional coral samples are located in the NE Atlantic and the northernmost parts of the North Atlantic to provide a broader picture of change.

This study builds on existing coral work, which has identified radiocarbon age reversals within single specimens [2] and rapid changes in radiocarbon content of the NW Atlantic water column [1]. By pairing the Nd isotope data to the radiocarbon data, we are able to identify the water masses present in the NW Atlantic during the deglaciation, the extent of mixing between these, and ultimately to translate the radiocarbon data into ocean ventilation rates.

Sinking Titanic (Ti^{IV}) – Insights into the speciation and distribution of Titanium in the Atlantic Ocean

P. CROOT[1], A. DAMMSHÄUSER[2] AND M. HELLER[3]

[1] Plymouth Marine Laboratory, Plymouth, United Kingdom (pecr@pml.ac.uk)
[2] IFM-Geomar, Kiel, Germany (adammshaeuser@ifm-geomar.de)
[3] IFM-Geomar, Kiel, Germany (mheller@ifm-geomar.de)

Titanium is a major component of the continental crust but is found in very low concentrations (< 300 pM) in seawater due to the strong hydrolysis of titanic (Ti^{IV}) and/or titanyl (TiO^{2+}) ions resulting in the formation of the poorly soluble TiO_2 (or $TiO(OH)_2$). The reduced form of Ti, titanous (Ti^{III}), is a strong reducing agent and is subsquently rapidly reoxidized to Ti^{IV} under all but the strongest reducing conditions.

There is no known biological enzyme that utilizes titanium and no organism has been found to require it for growth. However in recent years, research has been focused on Ti-complexes as potential anti-cancer drugs and in the utilization of Ti^{IV} to form nano-structures by the same enzymes that diatoms use to construct their silicate shells. Other recent developments include the common useage of Ti as a bio-inert substrate in the body and the increasing use of nanoparticle TiO_2 in a range of products. This increased exposure to Ti in our daily lives has new investigations into the biochemistry of Ti and revealed the potential for Ti competition for strong Fe(III) binding sites in organisms (e.g. transferrin).

To investigate the biogeochemistry of Ti in the ocean we recently developed a new sea-going voltammetric technique capable of rapidly measuring pM dissolved Ti, and we have applied this to work on a number of cruises in the Atlantic, including the preliminary German GEOTRACES cruise of 2005 and the IPY GEOTRACES Zero-Drake cruise in the Atlantic sector of the Southern Ocean. In this presentation we will outline our new findings on the speciation of dissolved Ti in the ocean, focusing on the evidence, or lack of it, for the existence of titanium-organic complexes in seawater. Finally we will show the distribution of dissolved Ti throughout the water column in the Atlantic ocean and comment on its potential for use as a tracer of dust input similar to Al and Fe.

Gas Phase Low Volatility Organic Compounds (LVOCs): Measurements from chambers, planes and automobiles

E.S. CROSS[1]*, K.E. DAUMIT[1], J.F. HUNTER[1], A.J. CARRASQUILLO[1], A.G. SAPPOK[1], V. WONG[1] S. HERNDON[2], J.T. JAYNE[2], D.R. WORSNOP[2] AND J.H. KROLL[1]

[1]Massachusetts Institute of Technology, Cambridge, MA 02139 USA
[2]Aerodyne Research Inc., Billerica, MA 01822 USA

Gas phase low volatilty organic compounds (LVOCs) comprise an atmospherically important, largely *unmeasured* class of organic species in the atmosphere. LVOCs consist of intermediate volatility organic compounds (IVOCs; *i.e.* C_{13}-C_{20} *n*-alkanes) and semivolatile organic compunds (SVOCs; *i.e.* C_{21}-C_{32} *n*-alkanes). Atmospheric oxidation of gas phase LVOCs results in the formation of secondary organic aerosol (SOA) which in turn has direct implications for climate and human health. The rates and the chemical properties of LVOC emissions and oxidation products (in the gas phase and particle phase) are poorly characterized and not accurately parameterized in atmospheric chemistry models.

This paper will provide an overview of experimental results obtained with a novel technique called the Total Gas Phase Organics (TGO) instrument that provides a volatility-resolved, quantitative measure of gas phase LVOCs (and LVOC oxidation products) in the atmosphere. Experimental results from instrument characterization studies, chamber oxidation studies, and LVOC emissions characterization studies (including a medium duty diesel engine and the NASA DC-8 aircraft engine) will be presented. The capability of the TGO instrument for tracking total gas phase carbon during a chamber oxidation experiment will be discussed.

New juvenile glass chemistry from Colli Albani, Italy and its use in understanding petrogenesis

JO CROSS[1]*, VICTORIA SMITH[2], GUIDO GIORDANO[3], JULIE ROBERGE[4], EMMA TOMLINSON[1] AND MARTIN MENZIES[1]

[4]Departamento de Geoquímica, Instituto de Geología, Universidad Nacional Autónoma de México, Ciudad Universitaria, Coyoacán D.F. 04510, Mexico

Colli Albani is a quiescent caldera complex located within the Roman Comagmatic Province, Italy. The recent Via dei Laghi phreatomagmatic eruptions led to the formation of nested maars. The largest is Lago Albano (ca 70-20ka) which has erupted at least seven times. The highly explosive nature of the eruptions from Colli Albani and contrasting alkali-rich, silica under-saturated magma compositions has resulted in several contrasting petrogenetic models [1].

Results are presented from a petrological and geochemical study of the Lago Albano deposits. Juvenile clasts in the deposits display evidence for mingling of different melt fractions. The juvenile (magmatic) fragments from explosive (base surge and fall deposits) and effusive (lava flows) episodes provide an opportunity to constrain the temporal magmatic and volatile history of the system. New WDS-EPMA and LA-ICPMS data for interstitial glass in magmatic cumulates (pre-eruptive), and melt within juvenile clasts (syn-eruptive) reveal extreme sub-volcanic fractionation generating distinct magma compositions (K-rich foidites).

Cr isotopes hold great promise for use as a paleoredox proxy, but the processes that induce Cr isotope fractionation remain speculative. The reduction of Cr(VI) favours the light Cr isotope, causing residual Cr(VI) to become progressively heavier [1], but we do not know if fractionation accompanies the oxidation of Cr(III) to Cr(VI). We present Cr isotope ratio measurements of a lateritic soil profile from Indonesia. Our measurements reveal that the Cr isotopic composition of the soil becomes progressively lighter with increased weathering up the profile. The uppermost unit, the topsoil, possesses the lightest composition, $\delta^{53}Cr = -1.19 \pm 0.25$ ‰ ($\delta^{53}Cr = 1000 \times [(^{53}Cr/^{52}Cr)_{sample}/(^{53}Cr/^{52}Cr)_{SRM979})-1]$), whereas the unaltered peridotite bedrock has Cr isotope ratios consistent with mantle-derived igneous rocks [2]. Our measurements demonstrate the preferential retention of light Cr in the soil and the release of heavy Cr(VI) to runoff, supporting the hypothesis that the marine Cr isotope record tracks the oxygenation of the atmosphere through geological time [3].

Magmatic processes leading to explosive mafic eruptions of Volcán de Colima, Mexico

JULIA CRUMMY[1]*, IVAN SAVOV[1], DAN MORGAN[1], CARLOS NAVARRO[2], MARJORIE WILSON[1] AND SUE LOUGHLIN[3]

[1]University of Leeds, Leeds, LS2 9JT, UK (*correspondence: j.crummy@see.leeds.ac.uk, I.Savov@leeds.ac.uk, D.J.Morgan@leeds.ac.uk, B.M.Wilson@leeds.ac.uk)

[2]Colima Volcano Observatory, University of Colima, Colima, Mexico (naoc@ucol.mx)

[3] British Geological Survey, Murchison House, Edinburgh, EH3 3LA, UK (sclou@bgs.ac.uk)

We present new geochemical and petrological data for the Holocene tephra deposits of Volcán de Colima. Historically, the volcano is characterised by mostly effusive andesitic lava flows and frequent Vulcanian-style explosions (up to 11 times per day in 2010), producing steam and ash clouds reaching heights of several km. Explosive basaltic-andesitic Plinian eruptions at Colima have occurred throughout the Holocene. The last such event was the 1913 eruption which produced an ash column 23km in height, and pyroclastic flows which travelled 15km from the vent. Ash was reported in the town of Saltillo 725km away. The 1913 eruption lava and ash samples contain magmatic water contents of up to 6.3 wt.%.

Deposits representing highly-explosive activity at Volcán de Colima reveal a tantalising story of magma evolution over a 30,000 year period [1]. We report results concerning the 4,400 and 4,700 yrs B.P. eruptions, which represent the felsic and mafic end-member magma, and show that Plinian-style explosions can occur at Colima over a range of compositions from basaltic-andesite to high-silica andesite, all with a common, high H_2O content of over 4.3 wt.% H_2O.

SEM, EPMA and CSD analyses support the bulk rock dataset and reveal a complex crystallisation history of the 4,400 and 4,700 yrs B.P. magmas. However, Sr isotope analyses indicate a well-established feeder system with little change in $^{87/86}Sr$ ratios (0.703459 - 0.703735, n=61) over >12,000 years.

At Volcán de Colima, high-MgO magmas (5.61 wt.%) are H_2O rich, implying little mixing and/or very fast ascent rates from source to surface.

U and Sr isotopic variations at a deep underground laboratory, Homestake Mine, SD

M.F. CRUZ[1]*, K. MAHER[1], N. OLSEN[1], T. JONES[2], M. CONRAD[3] AND E. SONNENTHAL[3]

[1]GES Dept., Stanford University, Stanford, CA 94305, USA (*correspondence: mfcruz@stanford.edu, kmaher@stanford.edu)

[2]South Dakota School of Mines, Rapid City, SD 57701, USA (tessaj@gmail.com)

[3]Lawrence Berkeley National Lab, Berkeley, CA 94720, USA (msconrad@lbl.gov, elsonnenthal@lbl.gov)

The U and Sr isotopic composition of groundwater in fracture-dominated flow systems can potentially provide a useful means of quantifying fluid flow, reaction rates and/or the extent of exchange with the bulk matrix. The Deep Underground Science & Engineering Laboratory (DUSEL) at the former Homestake gold mine in South Dakota provides a unique opportunity to assess the behavior of U and Sr isotopes in a fracture-dominated environment. The folded and fractured metapelites are low-permeability with flow localized in fractures and shear zones. Samples from depths up to 5000 ft below the surface were analyzed for major and trace elements, $\delta^{18}O$, δD, $^{87}Sr/^{86}Sr$ and ($^{234}U/^{238}U$),.

The ($^{234}U/^{238}U$) values of waters at the site is 2.99 at the surface, then increases to 3.24 at 800 ft depth, then decreases gradually to 1.94 at 4,850 ft depth. We interpret the initial increase to alpha-recoil enrichment of ^{234}U, while the subsequent decrease suggests that as temperature increases with depth, mineral dissolution dominates. This is consistent with $^{87}Sr/^{86}Sr$ values, which increase with depth from 0.71 to 0.77, approaching the bulk-rock value of 0.76 to 0.8, again suggesting increased reactivity. By coupling Sr and U isotopes with field and geochemical data investigations at DUSEL can provide further insights as to the isotopic exchange processes during fracture-dominated water-rock interactions.

[2]Creminer/LA-ISR, Geosciences Dep., Univ. Évora, Portugal
[3]Centre for Geobiology, Department of Earth Science, University of Bergen, Norway

Loki's Castle is the northernmost hydrothermal vent field known to date in the Arctic Ocean [1]. It is located in the junction between the Monhs and Knipovich Ridge, an ultra-slow spreading center at a rate of 17mm/year [2]. ROV-collected samples of chimney fragments and their surrounding deposits revealed to be mostly composed of sphalerite, chalcopyrite, pyrite and anhydrite, their maximum metal contents for Fe 31wt%, for Zn 5.4wt% and for Cu >1wt%. The surrounding sediments contain a significant hydrothermal component, denounced by high metal contents that average 4.6 wt% Fe, 100 ppm Zn and 33 ppm Cu. Sediments from the same area collected at depth by gravity cores show equally high average metal contents; although the Cu and Zn enrichment may be more prominent in particular layers reaching 446 ppm Zn and 128 ppm Cu. The REE sediment patterns mimic those of the North American Shale Composite [3]. Major and trace element geochemistry of the less altered volcanic rock fragments collected near the vent field allows their classification as tholeiitic basalts.

Metamorphic reaction rates from diffusion of Nb in rutile

ALICIA M. CRUZ-URIBE[1], MAUREEN D. FEINEMAN[1] AND THOMAS ZACK[2]

[1]The Pennsylvania State University, State College, PA 16802, USA (amc472@psu.edu, mdf12@psu.edu)
[2]Institut für Geowissenschaften, Universität Mainz, Becher Weg 21, 55128 Mainz, Germany (zack@uni-mainz.de)

Determining the timescales over which metamorphic reactions occur has long been an important and difficult question to answer. Here we examine rutile replacement by titanite in a migmatized garnet amphibolite from Catalina Island, CA, and compare the data to results from an amphibolitized eclogite from Tromsø, Norway. We estimate the timescales and rates of the rutile-to-titanite reaction by fitting models of Nb back-diffusion during titanite replacement to measured Nb profiles in rutile.

Trace element concentrations in rutile and titanite were determined by LA-ICP-MS for grains from Catalina. Niobium profiles across two rutile grains show clear evidence for Nb back-diffusion into rutile during titanite growth at the grain boundary (from 2280 to 3050 ppm over 350 μm). The same feature was reported and modeled by Lucassen *et al*. [1] for Nb and Zr in a 7 mm rutile from Tromsø. Zr-in-titanite thermometry suggests 740-770°C for Catalina and 650-730°C for Tromsø. New experimentally-determined diffusion coefficients for Nb in rutile (R. Dohmen, pers. comm.) were used to model Nb diffusion in the Catalina rutile, and to revisit the Tromsø sample in light of the new diffusion data.

A simple 1-D moving interface diffusion model yields reaction front velocities, which were converted to rates using the distance the boundary had moved relative to the pre-reaction rutile surface. Reaction rates of 0.2–2.0 x 10^{-6} a^{-1} were determined for Catalina, and 0.03–4.99 x 10^{-8} a^{-1} for Tromsø. Reaction rates were then normalized to the surface area of the rate-limiting mineral per unit of rock (Rnet, g/cm^2/a). Normalized reaction rates for Catalina are 0.18–1.42 x 10^{-5} g/cm^2/a and for Tromsø are 0.04–5.82 x 10^{-7} g/cm^2/a, which suggests 2-3 orders of magnitude difference in Rnet over ~120°C change in temperature for the rutile-titanite reaction. Reaction rates for the Tromso sample are consistent with those previously determined for regional metamorphism, whereas the Catalina reaction rates fall between those reported for regional and contact metamorphic settings [2]. This observation is consistent with the presence of free fluid or melt during subduction-related metamorphism.

Geological characteristics and genesis discovery of native copper in East Tian Mountain, Xinjiang, P.R. China

CUI BIN, HE ZHIJUN AND ZHAO LEI

China University of Geosciences , Beijing, 100083
(cuibin76@163.com, zhaolie51yh@yahoo.com.cn)

The Dongtianshan copper is a type of mineralization belt newly found by work in recent years. The copper from Shilipo, Dongtianshan is found in maroon basaltic tuff. Through analysis of the geochemical characteristics show the formation of Dongtianshan copper relates to the mineralization of the mantle plumes.

The main elements of two mineral occurrences are of the similar content characteristics. The K_2O and Na_2O content in Shilipo is apparently lower than that of Heilongfeng, but is similar to that of Bingdao volcanic rocks. Compared the copper-bearing basalt with Bingdao basalt, the MgO content of Dongtianshan basalt is relatively low, in the range of 3.06%-3.61% while the MgO content of Bingdao basalt is 7.53%-12.24%. To the alkali content, the Bingdao basalt has high Na_2O, but no high K_2O

The copper-bearing basalt from Dongttanshan shows the LR/ HR of 11.29×10^{-6} and 11.58×10^{-6},a little higher than the values of Bingdao basalt. However, the content values of the MREE and HREE have not much difference between Dongtianshan basalt and Bingdao basalt and show the relatively strong comparability. The Emeishan basalt with the LR/HR of 41.21×10^{-6}. In the curve ofn, Emeishan basalt presents the right-inclined shape of LREE slight concentration. The REE partition pattern of Cu-bearing basalt from Dongtianshan has the fairly strong comparability with the REE partition curve of the Bingdao basalt related to mantle plumes, reflecting the characteristics of the mantle magma.

It is considered that the copper-bearing basalt of Dongtianshan is from mantle sources and possesses the similar characteristics to the mantle plumes.

Water pollution treatment of chinese highway tunnel construction

CUI GUANGYAO[1]*, WANG MINGNIAN[1], LU JUNFU[2] , ZHANG WEIQING[1] AND WANG WEIJIA[1]

[1]School of Civil Engineering, Southwest Jiaotong University, Chengdu, 610031, China
(*correspondence: cyao456@163.com)
[2]State Key Laboratory of Geohazard Prevention and Geoenvironment Protection, Chengdu University of Technology, Chengdu, 610059, China

The damage to water environment in highway tunnel construction is mainly manifested in two aspects: the destruction of groundwater system in the tunnel area and wastewater pollution generated in the process of highway tunnel construction. The steady-state of groundwater system in the tunnel area must be destroyed in the process of highway tunnel construction, and the highway tunnel will become the natural channel discharging underground water. The waste water generated in the process of highway tunnel construction will also pollute groundwater system in the tunnel area and damage surrounding environment.

Water pollution treatment mainly focus on the six aspects: (1) construction and domestic garbage must be stacked centrally; (2) the domestic sewage can be discharged only after it is disposed; (3) the settling ponds should be build in the tunnel area; (4) the storehouse storing grease must be make anti-seepage treatment; (5) mechanic waste oil should be recycle or carefully dispose; (6) the management of chemical grout must be strengthen.

Taking the route that can develop continuously is the inevitable choice of 21 centuries China. To the sustainable development, the water environmental protection is of critical importance. The highway tunnel construction and water environmental protection go hand in hand only if we must consider the characteristic of the highway tunnel to perfect construction technology and take corresponding water environmental protection countermeasure.

Re-Os geochronology of lacustrine organic-rich sedimentary rocks: Systematics and implications

V.M. CUMMING[1]*, D. SELBY[1] AND P. LILLIS[2]

[1]Earth Sciences Department, Durham University, DH1 3LE, UK (*correspondence: v.m.cumming@durham.ac.uk)
[2]U.S. Geological Survey. Box 25046, MS977, Denver Federal Center, Denver, Colorado 80225, USA

The Re-Os geochronometer is widely utilised to determine precise depositional ages of marine organic-rich sedimentary rocks (ORS). However, Re-Os systematics have not been fully evaluated in lacustrine ORS. Lacustrine sedimentary rocks provide an invaluable archive of continental geological processes responding to tectonic, climatic and magmatic influences. The lack of marine biostratigraphic constraints in lacustrine sedimentary rocks means that correlation to global geological phenomena requires accurate and precise geochronological frameworks.

Here we apply the Re-Os geochronometer to the Eocene Green River Formation (GRF), the world's largest succession of lacustrine ORS representing a classic model of lacustrine deposition. We present two precise Re-Os ages of 48.5 ± 0.6 Ma and 49.2 ± 1.0 Ma from the Uinta basin that are in excellent agreement with Ar/Ar and U/Pb dates of interbedded tuffs within the GRF. An additional Re-Os age of 47.8 ± 9.9 Ma has a higher uncertainty attributed to a smaller spread in $^{187}Re/^{188}Os$ ratios. This third age is from a section suggested to have been deposited in the deepest lake setting. It possesses higher TOC that exhibits more significant correlation with Re, Os and trace elements than the sections which yield precise ages. The redox sensitive trace elements are used to assess Re-Os systematics in lacustrine ORS and suggest deposition from an oxic-dysoxic water column.

In addition to geochronology, the initial $^{187}Os/^{188}Os$ (Os_i) of the GRF (~1.4-1.5) has implications for the understanding of global ocean Os fluctuations. The Os_i is similar to continental runoff today (~1.54), suggesting that the $^{187}Os/^{188}Os$ of continental runoff into the ocean has not changed since the Eocene. Global ocean $^{187}Os/^{188}Os$ has evolved from ~0.56 during the Eocene to a modern day value of 1.06. This study suggests that global ocean Os evolution has been driven by a decrease of unradiogenic Os flux rather than an increase in radiogenic Os from continental runoff.

Geochemical and isotopic insights into the development of a large caldera-forming eruption, Atitlan Caldera, Guatemala

HEATHER S. CUNNINGHAM*

Department of Geoscience, University of Wisconsin at Madison, 1215 W Dayton St, Madison, WI 53706 USA, (*correspondence: hcunningham@geology.wisc.edu)

How do large volumes of rhyolitic magma accumulate prior to the eruption of large caldera-forming eruptions? Rhyolitic magmas are proposed to originate either from rhyolitic pods that are the result of rapid differentiation, through assimilation of crustal melts, or a combination of the two. High magma flux rates are required to sustain an eruptable crystal-melt reservoir. These issues are evaluated at Atitlan Caldera, Guatemala where eruption of the ~300 km^3 Los Chocoyos rhyolitic ignimbrite and air fall occurred at 84 ka. Eruption of a compositionally zoned ignimbrite recorded the presence of rhyodacite and high silica rhyolite in the proportions of 1:4. The rhyodacite displays trace element ratios similar to the basaltic andesite enclaves found in early Los Chocoyos fall deposits, as well as, stratocone lavas erupted around the caldera boundary before and after the Los Chocoyos. In particular, the rhyodacite displays higher Sr/Y, La/Yb and Ce/Y than the high silica rhyolites. Generation of rhyolitic magmas by exclusive melting of old granitic crust is inconsistent with trace element models and Sr isotopic data. Sr isotopes for the rhyodacite and high silica rhyolite are slightly elevated from the mafic enclave and unlike the Sr isotope ratios for the more evolved granite. The rhyodacite can be modeled to form via batch partial melting of the mafic enclave, assumed to reflect the least differentiated end member, with garnet in the residuum. The high silica rhyolite can be modeled from 70% fractional crystallization of the basaltic andesite and 15% assimilation of 15.2 Ma granitic pluton exposed along the caldera boundary. Thus, partial melting and differentiation of basaltic andesite stalled in the crustal plumbing system with minor addition of granitic crustal melts can account for the formation of rhyolitic magmas at Atitlan Caldera. Thermal models project that a flux rate of 10^{-2} km^3/yr is required to provide enough heat to form large volume rhyolitic eruptions. Stratocone eruption rates of basaltic andesite at Atitlan Caldera since the Los Chocoyos are 4 x 10^{-3} km^3/yr. Assuming a 3:1 intrusive:extrusive ratio, current magma flux rates at Atitlan Caldera are at least 1.2 x 10^{-2} km/yr and able to sustain the formation of large volume rhyolitic magmas.

Understanding biological control and environmental influence – unlocking the secrets of biomineralisation

MAGGIE CUSACK

School of Geographical & Earth Sciences, University of Glasgow, G12 8QQ, UK

In the natural world of biominerals elegant, functional structures are produced from the most basic of resources. Vertebrates have skeletons made from calcium phosphate (apatite) while invertebrates tend to assemble mineral structures from silica or calcium carbonate. Although the ingredients are simple, the control of how these fundamental building blocks are put together is very much under the control of biological processes. Understanding this biological control and its rôle in the formation of biominerals has implications in a number of diverse areas. Understanding the biomineralisation process will provide a much more accurate interpretation of the climate information stored within marine biominerals, e.g. brachiopods and corals. An exploration of the biological control exerted in biomineral formation in several phyla provides the context for the consideration of the recording of environmental information.

C, O and H isotope compositions of the Wilmott and Yungul 'carbonatites' and the associated fluorites in the Speewah Dome, Kimberley Region, Australia

GY. CZUPPON[1]*, L.G. GWALANI[2], A. DEMÉNY[1], R. RAMSAY[2], K. ROGERS[2], A. EVES[2] AND CS. SZABÓ[3]

[1] Inst. for Geochemical Research, Hung. Acad. Sci., Budaorsi ut 45, Budapest, 1112, Hungary (*correspondence: czuppon@geochem.hu, demeny@geochem.hu)

[2] Speewah Metals, 22/77 Allendale Square, St Georges Terrace, Perth, WA6000, Australia (lgwlani@gmail.com, ramsay@iinet.net.au, karogers@bigpoint.net.at, fridgelizard@gmail.com)

[3] LRG, Dept. of Petrology and Geochemistry, Inst. of Geog. and Earth Sci., Eötvös University, Pázmány 1/C, Budapest 1117, Hungary (cszabo@elte.hu)

The Yungul and newly discovered Wilmott 'carbonatites' (carbonate-cemented breccias and carbonate veins), as well as the associated fluorite veins are located on the eastern margin of the Kimberley Block (NW Australia). The C and O isotope compositions of Wilmott carbonatites show a distinct negative trend different from that observed for Yungul 'carbonatites', in which the $\delta^{13}C$ and $\delta^{18}O$ values form a positive trend and has been explained by high-temperature rock-fluid interaction and H_2O degassing. However, the observed $\delta^{13}C$ shift in Wilmott 'carbonatites' requires additional processes such as CO_2 and H_2O degassing. Inclusion-hosted H_2O contents (determined by vacuum crushing) range from 250 to 1300 ppm for Yungul, whereas the Wilmott 'carbonatites' yielded H_2O contents between 250 and 510 ppm. The H isotope compositions determined for inclusion-hosted H_2O show a large range for Yungul 'carbonatites' (from -83‰ to -24‰) with the Wilmott rocks at the lower end (from -85‰ to -60‰). δD-H_2O variations in both 'carbonatites' indicate an open system in which the H_2O degassing took place at relatively high temperature (>400°C). The associated fluorite veins are characterized by high H_2O contents (600-2300ppm) with relatively high δD values (between -30‰ and -17‰) forming a positive linear trend related to close system evolution. The fluorite and 'carbonatite' trends converge to the same isotopic composition, thus, although the fluid regimes were likely different for fluorites and 'carbonatites' (i.e. open – closed systems), the ultimate origin of the fluids could be the same.

Microbial life associated with low temperature alteration of ultramafic rocks in the Leka ophiolite complex

FRIDA LISE DAAE[2], INGUNN THORSETH[1], HÅKON DAHLE[2], STEFFEN LETH JØRGENSEN[2] AND ROLF B. PEDERSEN[1]

[1]Centre for Geobiology/Department of Earth Science, Allegaten 41, 5007 Bergen, Norway (*correspondance: frida.daae@bio.uib.no, Ingunn.Thorseth@geo.uib.no)

[2]Centre for Geobiology/Department of Biology, Allegaten 41, 5007 Bergen, Norway

The Leka Ophiolite Complex (Mid-Norway) is a unique location for sampling oceanic crust and mantle lithologies. To examine peridotite-hosted subsurface microbial communities we have drill-sampled a dunite unit that is located close to ancient crust-mantle boundary. Samples were taken of mineralised fractures as well as of ground water produced by a 50 m deep borehole. Microbial community analyses were done by 16S rRNA gene sequence amplification clone library constructions. The morphological diversity was examined by electron microscopy. Enumeration of *Archaea* and *Bacteria* were done with fluorescent microscopy and real time polymerase chain reaction.

Different microbial communities were observed in the groundwater, the fracture fillings and the surface water. The groundwater, having a pH of 9.1, was dominated by close relatives of putative hydrogen oxidizing beta Proteobacteria suggesting that microbial communities at Leka are largely driven by hydrogen possibly produced by low temperature water-rock reactions. The microbial communities in the mineralised fractures are dominated by close relatives of heterotrophic hydrocarbon-degraders, but close relatives of hydrogen-, manganese-, and iron-oxidizers were also present.

Metal-silicate mixing during impact-driven planet accretion – Implications for the age of the Moon

T.W. DAHL[1] AND D.J. STEVENSON[2]

[1]NordCEE and Univ. of Southern Denmark, 5230 Odense, Denmark

[2]Division of Geological and Planetary Science, Caltech, Pasadena, CA 91125, USA,

The final accretion of planet Earth involved giant collisions between protoplanets (>1000km radius) with the Moon forming as a result of one of these impacts. At this stage both bodies had differentiated into a metallic core surrounded by a silicate mantle. During the Moon-forming impact nearly all metal sank into the Earth's core. We have investigated to which extent large self-gravitating iron cores can mix with surrounding silicate as they sink through the Earth's mantle. This allows us to evaluate how incomplete metal-silicate equilibration during core formation influences the short-lived chronometer, Hf-W, used to infer the age of the Moon.

We have established fluid dynamical models of turbulent mixing in fully liquid systems to constrain the degree of iron-silicate mixing. Erosion of sinking cores driven by Rayleigh-Taylor instability does lead to mixing, but only 1-20% of Earth's core would emulsify and equilibrate with the silicate mantle during Earth's entire accretion process. The initial speed and obliquity of impact is of little importance, but the size and shape of the sinking core matters. We evaluate the mixing potential for shear instabilities where silicate entrainment across vertical walls leads to mixing. The turbulent structure indicates that vortices remain at the largest scale and do not cascade down to centimeter length scales where diffusion operates and isotopes can equilibrate.

Because most of the impacting metal plunge directly through the silicate mantle, and the fraction of impacting metal that mix within diffusion distance from silicate is small, giant impacts have limited effect on siderophile depletion during core formation. On a global scale residual ^{182}W from early core formation processes is left behind in the mantle and this source of ^{182}W generates a higher ε_W excess compared to what is expected in early models for ^{182}W evolution in the silicate Earth. Hence, the Moon forming impact must have occurred >30 Myrs after CAI formation. Furthermore, we find that a single giant impact has limited ability to reset the Hf-W system and that ε_W is more sensitive to early core formation processes than to radiogenic ingrowth after the giant impact [1].

Effects of mining on groundwater quality in Gaft Chromite Mine, Iran

B. DAHRAZMA[1]*, M. KHARGHANI[2] AND M. AKHIANI[2]

[1]Shahrood University of Technology, Shahrood 3619995161, Iran
(*correspondence: behnaz_dahrazma@shahroodut.ac.ir)
[2]Islamic Azad University – Shahrood Branch, Shahrood, Iran.

Effluent from chromite mines due to extraction activities into aquatic systems is an environmental issue [1, 2]. To investigate the effects of chromite extraction on the groundwater quality in Gaft Chromite Mine, water samples were taken from the mine area.

Due to basic condition of the tunnel effluent (pH=9.74), solubility of most ions decreased [3, 4] and thus EC, total hardness, and concentration of ions in tunnel effluent were similar to the upstream groundwater as well as groundwater in the mine site [Fig.1]. In other words, mining activities had no adverse effect on the water quality of the region although it slightly increased the concentration of Cr (VI) in the groundwater in the mine site. The concentrations of Cr (IV) in water samples were 0.04, 0.04, 0.06 and 0.02 (all in mg/L) in upstream and downstream groundwater, groundwater in the mine site, and tunnel effluent respectively. Because of the geochemical condition downstream of the mine [5], the reduction in the pH of downstream groundwater (pH=8.13), the concentration of bicarbonate, chloride, calcium, magnesium, and sodium ions as well as the total hardness and EC in downstream groundwater (4 Km far) were increased.

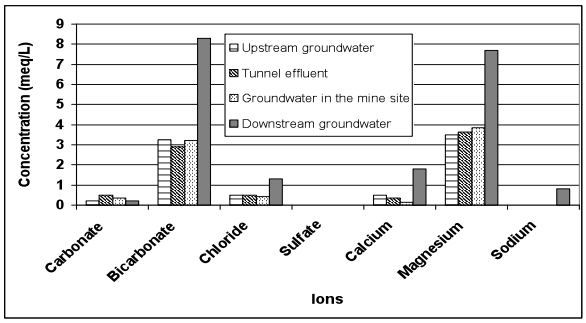

Figure 1: Concentration of ions in water samples.

Zircon Hf-O isotope evidence for crust-mantle interaction during continental deep subduction

LI-QUN DAI, ZI-FU ZHAO AND YONG-FEI ZHENG

School of Earth and Space Sciences, Univisity of Science and Technology of China, Hefei 230026, China (lqdai@mail.ustc.edu.cn)

In situ SIMS zircon U-Pb dating and O isotope analysis as well as LA-(MC)-ICPMS zircon U-Pb dating and Lu-Hf isotope analysis were carried out for postcollisional mafic-ultramafic rocks in the Dabie orogen, China. The zircon U-Pb dating gives consistent ages of 126±1 to 131±1 Ma for magma crystallization. Survival of residual zircon cores is identified by CL imaging and U-Pb dating, yielding ages of 697±10 and 770±11 Ma that agree with protolith ages of UHP metaigneous rocks in the orogen. Zircon Hf-O isotope compositions show systematic variations that can be categorized into three groups. Group I has the lowest $\delta^{18}O$ values of 2.0 to 2.9‰ but the highest $\varepsilon_{Hf}(t)$ values of -6.3 to 1.1 with the youngest Hf model ages of 1.1 to 1.6 Ga. Group II displays intermediate $\delta^{18}O$ values of 4.0 to 5.1‰ and $\varepsilon_{Hf}(t)$ values of -29.0 to -9.9 with Hf model ages of 1.8 to 3.0 Ga. Group III exhibits the highest $\delta^{18}O$ values of 5.2 to 7.3‰ but the lowest $\varepsilon_{Hf}(t)$ values of -33.7 to -18.2 with the oldest Hf model ages of 2.3 to 3.3 Ga. The three groups of Hf-O isotope compositions correspond to a three-layer Hf-O isotope structure in the subducted continental crust, suggesting its involvement in the mantle source. Along with existing data for whole-rock Sr-Nd isotopes and trace elements, it appears that the mantle source for the postcollisional mafic-ultramafic rocks is characterized by fertile lithochemistry, the continental crust-like signature of trace elements, the heterogeneous enrichment of radiogenic isotopes, the differential incorporation of supracrustal materials, and the variable concentrations of water. Clearly, such a source is neither the asthenospheric mantle nor the refractory subcontinental lithospheric mantle (SCLM). It is a kind of orogenic SCLM that would be generated by reaction of the overlying SCLM peridotite with hydrous silicate melts derived from the different layers of subducted continental crust. Therefore, the postcollisional mafic-ultramafic rocks provide a petrological record of crust-mantle interation during the continental deep subduction. Melt-peridotite reaction is hypothesized to take place in the Triassic to generate the mantle source of pyroxenite and hornblendite, which underwent partial melting in the Early Cretaceous to cause the mafic-ultramafic magmatism.

[3]Eng. Res. Center of Groundwater Pollu. Control and Remed., ME, Beijing, China
[4]Key Lab. Rare Earth Chem. and Phys., Changchun Institute of Appl. Chem., CAS, Changchun, China

Many Ionic Liquids have significant solubility in water, which can result in the potential problems with degradation or persistence in environment. Biodegradation is the microbial breakdown of chemical compounds, such as Ionic Liquids. Compared to chemical or physical methods, it seems to be more environmentally friendly. This study focuses on the biodegradation efficiency and the pathways of [omim][PF_6] under anoxic conditions. Biodegradation efficiency of [omim][PF_6] under anoxic conditions was studied by acclimatizing the activated sludge with the UASB reactor. The proposal of possible metabolic pathways of $[omim]^+$ in anoxic conditions was analyzed by identification of the breakdown products using GC-MS. The biodegradation experiments were also performed under aerobic conditions. It suggests faster flow enhanced the contact frequency of [omim][PF_6] and microbe, but was not conducive to the removal rate with the increase of run-time. The results showed that the [omim][PF_6] removal efficiency reached the highest as the flow velocity of UASB was 0.75 $mL{\cdot}min^{-1}$ in this study. The molecular weights of the main degradation products were 83, 155, 102, 170 and 109, respectively. It is predicted that there were 3 main pathways for anoxic biodegradation of $[omim]^+$, which were different from the aerobic process because of the different electron acceptor. Similar to the aerobic process, N—C bond ruptured first, but the metabolism of $[omim]^+$ did not appear to undergo oxidation reactions but reduction reactions in anoxic conditions. The toxicity of the breakdown products was reduced under anoxic conditions according to their polarities and EC_{50} in references.

Controls on and effects of surface ocean oxygenation prior to the Great Oxidation

STUART DAINES*, JAMES CLARK AND TIM LENTON

School of Environmental Sciences, University of East Anglia, UK (*correspondence: s.daines@uea.ac.uk)

Multiple lines of evidence suggest that organisms that produced free oxygen had evolved by ~2.7Ga, while geochemical evidence shows pervasive oxygenation of ocean margins prior to the Great Oxidation Event (GOE) at 2.4Ga [1]. However, given the likely heterogeneous spatial distribution of environments supporting oxygen-producing ecosystems, it is unclear whether oxygen production would have resulted in a significant flux to the atmosphere, or remained a local phenomenom restricted to “oxygen oases” in the surface ocean or mat-based environments. Here we use a combination of ocean GCM and box-model coupled atmosphere-ocean-ecosystem studies, in combination with constraints from proxy data, to investigate: (i) factors controlling the prevalence of surface ocean oxygenation prior to the GOE, (ii) the (local) geochemical signature of early oxygenic photosynthesis in different environments (i.e., restricted to shelf seas, or widespread in the surface ocean), and (iii) the likely impacts on atmospheric oxygen, including constraints on the relative timing of the evolution of oxygen photosynthesis relative to the GOE.

As an initial geochemical diagnostic for spatial structure we focus on factors controlling the production of isotopically light organic carbon via methane recycling. We show that oxygenation of the surface ocean could have been widespread in upwelling regions, that consumption of oxygen in the surface ocean increases stability of a low atmospheric pO_2 state, and that aerobic methanotrophy in open environments produces only relatively small changes in $\delta^{13}C$ insufficient to explain the excursions seen at ~2.7Ga [2] which would then require a different mechanism and most likely restricted environments.

Chemical and isotopic composition of Lower Vindhyan organic rich sediments: Role of chemical alteration and grain size distribution

TARUN K. DALAI

Department of Earth Sciences, Indian Institute of Science Education and Research-Kolkata, Mohanpur, West Bengal 741252, INDIA (dalai@iiserkol.ac.in)

Several grey and black shales samples from the Lower Vindhyan section in the Central India have been collected. The samples have been chosen to represent various degrees of chemical alteration; those collected from the surface are extensively weathered whereas those collected from deeper in the mine cuts are relatively fresh. These samples have been analyzed for major ion composition, C_{org} and $\delta^{13}C$ of bulk organic matter.

The major ion compositions indicate influence of both chemical alteration and grain size distributions driven by mineralogical sorting. Abundances of bulk organic content (C_{org}) show significant positive correlation with Na/Al and an inverse correlation with K/Na. In contrast, C_{org} exhibits a weak positive correlation with Si/Al. Together, these observations indicate that organic carbon content in these samples are controlled by various degrees of chemical alteration and that the influence of grain size distributions and mineraological sorting may be rather weak. It is unclear to what extent the original relationship between the grain size and C_{org} has been lost by chemical alteration.

Carbon isotpic composition ($\delta^{13}C$) of bulk organic matter shows a significant positive correlation with ($1/C_{org}$). A first order interpreation of this trend is that relatively fresh organic matter is characterized by more negative $\delta^{13}C$ values whereas less negative $\delta^{13}C$ values represent organic matter that are altered by exchanging carbon with the weathering solution. Our results are in contrast to those observed by Van Os *et al*. [1]. Abundances of specific organic compounds, a suite of trace elements and grain size distributions would be measured to better understand the role of chemical alteration, grain size distributions and specific organic compounds in influencing the abundances of metals, organic carbon and carbon isotope composition of organic mater of these organic rich sediments.

XPS heating with mass spectrometry: Tackling chalk, coccolith and calcite surfaces

K.N. DALBY*, N. BOVET AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*kdalby@nano.ku.dk)

Chalk hosts significant quantities of the North Sea oil and biogenic calcite ($CaCO_3$) is a major component of the chalk. The biogenic calcite is in the form of coccoliths, precipitated by some species of single-celled marine algae. To understand the complex recrystallisation behavior of natural chalk, abiogenic calcite is often used as a model system. Abiogenic calcite is also used as a proxy for chalk during surface reactivity studies[1].

In this study to examine similarirties and differences between the biogenic and abiogenic calcite surfaces, we used X-ray photoelectron spectoscopy (XPS), coupled with an *in situ* residual gas analyzer (RGA), to examine natural chalk, cultured coccoliths and natural abiogenic calcite (Iceland Spar). We characterised, compared and contrasted the surface of the natural and model systems before, during and after heating to 500 ºC. The samples were heated to mimic reservoir conditions and to investigate the kinetics of the decarbonation reaction.

High resolution carbon 1s (C 1s) XPS spectra of the samples show differences in the surface composition. All samples display C-C bonds at 285.0 and CO_3 bonds at 290.1 eV. In addition, the chalk and coccoliths show evidence of C-OH (287.0 eV) and COOH (289.0 eV) compounds coating the surfaces. The ratio of all four C contributions is variable between the various samples of chalk and coccoliths. These coatings could prevent recrystallisation and dissolution of ancient coccoliths in chalk.

During heating to 500 ºC, both H_2O and CO_2 are released by all samples. The abiogenic calcite contains water-rich inclusions and these 'explode' during heating, producing spikes in the mass spectrometer data. No evidence of inclusions exist in the chalk or coccolith samples, which release H_2O and CO_2 at a more constant rate. During the heating experiments, the C-OH and COOH coatings are removed from the surfaces of the coccoliths and chalk, and the surface composition becomes more similar to the abiogenic calcite. Ongoing work will examine sample reactivity, including dissolution rates of chalk and coccolith surfaces before and after heating.

A Late Triassic major negative $\delta^{13}C$ spike linked to Wrangellia LIP: The Carnian Pluvial Event revealed

J. DAL CORSO[1]*, P. MIETTO[1], R.J. NEWTON[2], R.D. PANCOST[3], N. PRETO[1], G. ROGHI[4] AND P.B. WIGNALL[2]

During the Carnian (Late Triassic) a major climatic and biotic change is known, namely the Carnian Pluvial Event (CPE) [1]. This event is characterized by more humid conditions testified by hygrophytic palynological assemblages and palaeosols typical of humid climates; the crisis of rimmed carbonate platforms, a rise of the CCD and the increase of siliciclastic input across the western Tethyan realm; high extinction rates among ammonoids, crinoids, bryozoans and conodonts [2] and the first occurrences of dinosaurs and calcareous nannoplankton [3]. The CPE is similar in age to the eruption of Wrangellia large igneous province (LIP) [3], an oceanic plateau outcropping in western North America. Here we report an abrupt negative $\delta^{13}C$ shift at the onset of the CPE: high and low molecular weight n-alkanes, isoprenoid lipids and total organic carbon (TOC) show a sharp 2‰ - 4‰ negative carbon isotope excursion (CIE) that testify for a rapid injection of ^{12}C into the atmosphere-ocean system. This CIE occurs at the end of a ~3‰ long term Ladinian-Carnian positive CIE previously explained with organic carbon sequestration by coal swamps after the end-Permian mass extinction [4]. We propose that this CIE was caused by an injection of light C by the Wrangellia volcanism into the reservoirs of the exogenic C-cycle with strong consequences for climate and biota.

[4]PSSRI, Open University, Milton Keynes, UK

The abundance and relative proportion of highly siderophile elements (HSEs) in Earth's mantle deviate from those predicted by low-pressure equilibrium partitioning between metal and silicate during formation of the core. For many elements, high-pressure equilibration in a deep molten silicate layer (or 'magma ocean') may account for this discrepancy [1], but some highly siderophile element abundances demand the late addition, a 'late veneer', of extraterrestrial material (i.e. heterogeneous accretion) after core formation was complete [2]. Siderophile elements in smaller asteroidal bodies will not be affected by high-pressure metal-silicate equilibration and so, with highly efficient core formation [3] and if a 'late veneer' is absent, significant differences in the proportions of HSEs can be anticipated.

Here we present new HSE abundance and $^{187}Os/^{188}Os$ isotope data for basaltic meteorites, the HEDs (howardites, eucrites and diogenites thought to sample the asteroid 4 Vesta), anomalous eucrites (considered to be from distinct Vesta-like parent bodies) angrites and aubrites (from unidentified parent bodies) and SNCs (thought to be from Mars). Our data, taken with those for lunar rocks [4], demonstrate that these igneous meteorites all formed from mantle sources that possessed chondritic (i.e. primitive solar system) elemental and isotope compositions, indicating that late accretion is not unique to Earth, but is a common feature of differentiated planets and asteroidal bodies. Variations in the total HSE abundance suggest that the proportion of 'late veneer' added is a simple consequence of the size of each body (cross-section and/or gravitational-attraction), and may account for the volatile element budget, and the oxidation-state of Earth, Mars, the Moon and Vesta.

Transport of endocrine disruptive compounds in Hawaiian soils

MATTEO D'ALESSIO[1,2], JOSEPH LICHWA[2], MICHAL SNEHOTA[3] AND CHITTARANJAN RAY[1,2]*

[1]Department of Civil Environmental Enegineering, University of Hawaii at Manoa, Honolulu, HI, 96822, USA (*correspondence: cray@hawaii.edu)
[2]Water Resources Research Center, Hawaii
[3]Czech Technical University in Prague, Czech Republic

The release of endocrine distruptive compounds (EDCs) into the environment is of increasing concern due to their impact on freshwater organisms, ecosystem sustainability and human health. Several studies have emphasized that extended exposure to low concentration of some hormones can alter the endocrine and reproductive systems of aquatic animals. This study was conducted to investigate the transport behavior of two natural EDCs (17 beta estradiol, E2 and estrone, E1) in several Hawaiian soils under different experimental conditions. Soils collected in Hawaii showed higher cotent of mineral oxides, such as iron and manganese oxides compared to most soils in the continental US. Batch sorption and column leaching experiments were used to better understand the fate of both chemicals.

During batch experiments, equilibrium conditions were reached within 12 hours. In all soils having E2 only, its loss occurred due to sorption and degradation. Microbial degradation was inhibited using sodium azide. 100 mg/L azide alone did not completely stop degradation of E2. It was unclear whether this loss was due to microbes or partially due to abiotic mechanisms.

Column experiments showed that with E2 only, E1 was constantly present, showing the degradation of E2 to E1 despite the addition of a sodium azide. For different soils (5 total), breakthrough curves (BTC) of E1 and E2 appeared after the BTC of bromide, suggesting the presence of sorption process during the transport of estrogens through the soil matrix. Facilitated transport was mostly observed in presence of volcanic ash soil. The presence of recycled water enhanced the transport of estrogens in all the different soils. Early appearance of peaks, long tails and complete recovery (mass balance) of both estrogens was more pronounced in transport studies involving the recycled water. Non-equilibrium conditions were observed during the study, especially in presence of undisturbed soil when flow interruption occurred. These conditions were mostly related to the presence of macropores in the soil. Macropores were able to reduce the contact time between soils and estrogens, facilitating their transport.

The oxygen isotopic composition of xenoliths from Tallante (Southern Spain): Evidence for crust recycling into the mantle

L. DALLAI[1] * AND G. BIANCHINI[1,2]

[1]CNR - Istituto di Geoscienze e Georisorse, Pisa, Italy (*correspondence: dallai@igg.cnr.it)
[2]Dipartimento di Scienze della Terra, Università di Ferrara, Ferrara, Italy

Mantle xenoliths from Tallante (Betic Cordillera, Spain) include samples recording a peculiar distinct style of metasomatism that induced orthopyroxene, plagioclase, phlogopite and amphibole crystallization and generated "hydrous" opx-rich mantle domains. The latter are locally crosscut by felsic veinlets containing plagioclase and orthopyroxene ± quartz ± phlogopite ± amphibole. The observed parageneses and available Sr-Nd-Hf isotopic data suggest that metasomatic agents were related to recycling of crust components within the mantle, plausibly in connection with subduction processes occurred during the Cenozoic Betic orogenic cycle.

In this study we investigated representative samples of composite xenoliths consisting of peridotite crosscut by felsic veins (varying in size from centimetric to millimetric) and unveined peridotites, measuring the $^{18}O/^{16}O$ ratios of the constituent minerals by laser fluorination. Results show that the narrow O-isotope compositional "typical" of mantle rocks, and the limited oxygen isotope fractionation at mantle temperatures, make oxygen isotopes a powerful tool for identifying recycled crustal material in the mantle. Orthopyroxene and plagioclase of the centimetric vein show $\delta^{18}O$ values of +9.8 and +10.6‰, respectively, whereas clinopyroxene of the surrounding peridotite country rock has $\delta^{18}O$= +6.2‰. Plagioclase of two distinct millimetric felsic veins show $\delta^{18}O$ of 7.6 and 7.3‰. The $\delta^{18}O$ values significantly higher than typical mantle ones provide insights to the genesis of the Cenozoic subduction-related magmas of the Betic region that include silica-oversaturated calcalkaline (s.l.) and lamproite products, possibly resolving source vs. shallow level crustal contamination of the magmatic rocks. Moreover, the different O-isotope composition recorded in veinlets characterized by different thickness could provide insights into diffusion-assisted O-isotope requilibration of mantle rocks, thus constraining the time for "crust digestion" into the mantle.

How do plant emissions affect atmospheric nanoparticle formation?

MIIKKA DAL MASO[1,2], THOMAS F.MENTEL[2], ASTRID KIENDLER-SCHARR[2], EINHARDT KLEIST[2], RALF TILLMANN[2], MIKKO SIPILÄ[1], TUUKKA PETÄJÄ[1], JANI HAKALA[1], LI LIAO[1], KATRIANNE LEHTIPALO[1], MARKKU KULMALA[1] AND DOUGLAS WORSNOP[1]

[1]Department of Physics, University of Helsinki, PO Box 48, 00014, Helsinki, Finland, miikka.dal@helsinki.fi
[2] Institut für Chemie und Dynamik der Geosphäre (ICG), Forschungszentrum Jülich, 52425 Jülich, Germany

Non- and semivolatile compounds, produced by the oxidation of atmospheric trace gases that are emitted by human and biological activity, can undergo a phase transition and enter the atmospheric aerosol phase, either onto existing particles or forming new nanosized condensation nuclei. The most likely candidates of precursors of aerosol number-producing vapors are sulphur dioxide and plant-originated volatile organic compounds.

Currently, the controlling mechanism of tropospheric nanopartile formation is still an open question. Field and laboratory measurements have clearly indicated a strong correlation between observed sulphuric acid – a product of SO_2 oxidation – and nanoparticle concentrations and formation rates (eg. [1]). On the other hand, observed seasonality and comparisons with plant VOC emission strengths show that aerosol formation is also correlated with biogenic organic oxidation. Laboratory studies with real plant emissions have shown a clear dependence of aerosol formation on the VOC emission strength and also the chemical mixture ([2, 3]), thereby ruling out the possibility that nanoparticle formation by nucleation would be completely independent of organic compounds.

We investigated the formation of nanosized condensation nuclei (nano-CN) from sulphuric acid and plant emissions in the Jülich Plant Chamber setup. We performed a series of experiments using boreal forest tree emissions at levels commonly found in the boreal boundary layer.

We found that while the variation of the VOC concentration had a strong inpact on the gas phase chemistry and also the hydroxyl radical and sulphuric acid levels, the changes in particle formation rates were not explainable by sulphuric acid concentration variations alone, but the particle formation process is directly influenced by the plant emissions.

Estimating mantle temperature from a global comparison of seismic models and the petrology of mid-ocean-ridge basalts

COLLEEN A. DALTON*[1], ALLISON GALE[2] AND CHARLES H. LANGMUIR[2]

[1]Earth Sciences, Boston University, 675 Commonweath Ave., Boston, MA 02215 USA (*correspondence: dalton@bu.edu)
[2]Earth and Planetary Sciences, Harvard University, 20 Oxford St., Cambridge, MA, 02138 USA; (agale@fas.harvard.edu; langmuir@eps.harvard.edu)

Inferring mantle temperature and composition is one of the primary applications of seismic tomography. Mantle temperature and composition also strongly influence the petrology of mid-ocean-ridge basalts (MORBs) erupted on the seafloor. It is therefore reasonable to hypothesize that a relationship exists between seismological and petrological data. We have investigated whether such a relationship does exist using global seismic models and a new and expanded global compilation of MORB major-element chemistry. Petrological data obtained from PetDB form the core of our geochemical database, which is augmented by unpublished analyses and Iceland samples from GEOROC. We correct all measured values to 8% MgO and determine the mean composition for 231 individual ridge segments. We compare the petrological data (ridge depth, Na8, Fe8, etc.) with global mantle models of shear-wave speed, attenuation, and transition-zone topography. Ridge depth and wave speeds at 200-400 km depth are correlated globally, suggesting that the same factors that control ridge depth and crustal thickness also influence seismic velocity. For several ridges, anti-correlation between ridge depth and depth to the 410-km discontinuity is seen, in particular the Southwest Indian Ridge and the Mid-Atlantic Ridge. The comparisons also reveal correlation between Na8 and shear-wave speed at 200-300 km globally. Comparison of the petrological data and mantle seismic models provides an opportunity to understand the connection between temperature and composition at depth and the processes occurring at the surface.

Xenoliths reveal lower crustal deformation and metamorphism with no obvious surface expression

J.S. DALY[1]*, R. VAN DEN BERG[2], M.J. WHITEHOUSE[3], AND H. O'ROURKE[1]

[1]UCD School of Geological Sciences, University College Dublin, Belfield, Dublin 4, Ireland (*correspondence: stephen.daly@ucd.ie)
[2] Barberton Mines (Pan African Resources), Consort Section, Mpumalanga, South Africa
[3]Swedish Museum of Natural History, Stockholm, Sweden

Lower crustal xenoliths afford an opportunity to investigate the crustal architecture in 3D and to test whether deformational and metamorphic events in the lower crust are coupled to those known from outcrop studies.

Within the Iapetus Suture Zone (ISZ) in Ireland, where Laurentia and Avalonia collided obliquely during the c. 420 Ma Caledonian Orogeny, Carboniferous magmatism has transported granulite-facies lower crustal xenoliths at several localities. The xenoliths are predominantly metasedimentary and on seismic and geochemical grounds provide a near-perfect match with present-day lower crust [1, 2]. Thermobarometry indicates original depths of c. 22-33 km, and temperatures in the range 700 - 900 °C [1]. Ion microprobe U-Pb zircon dating of syn-tectonic granitic leucosomes in metasedimentary xenoliths indicates at least three discrete high-grade metamorphic events (382 ± 2 Ma, 373 ± 3 Ma and 360 ± 3 Ma), all younger than Caledonian. The oldest corresponds to an episode of Middle Devonian volcanism and may be related to syn-sedimentary extension. However, the younger events have no deformational or thermal effects known at outcrop. They demonstrate that ductile deformation and melting took place c. 25 km below the surface without significant surface expression suggesting significant mechanical and thermal decoupling of the lower and upper crust.

Pt-bearing metabasites from the East Sayan (Russia): Composition and origin

B.B. DAMDINOV

Geological Institute SB RAS, Ulan-Ude, Russia (damdinov@gin.bscnet.ru)

Glaucophane-bearing metabasites in the East Sayan are known as Okinsky blueschist belt. In one of the small massifs PGE mineralization was established. This massif is presented by latitudinal strike body, which contained by greenschist strata. Basic and ultrabasic rocks are altered to amphibolites, epidote-actinolite-amphibolic rocks and serpentinites, which most fractured and rich by asbestos veinlets. Further small pyroxenite bodies, gabbro and lherzolite relics are detected. Amphiboles are presented by three varieties. At first has a dark-green to light-brown color diagnosed as ferrichermakite, at second has light-blue color – vinchite, ferribarruasite, at third presenting as violet-color margin is a magnoriebeckite. From the center to outside direction Na-content increases whereas Ca and Al contents are decrease. PGE is concentrated by extensive zones of pyrite-magnetite mineralized amphibolites and sulfidized garnet-diopside-chloritic rodingites. Ore minerals are presented by magnetite with rare ilmenite relics, hematite, rutile, cassiterite and sulfides which form single areas and presented by pyrite, chalcopyrite, zigenite, arsenopyrite, sphalerite, galena. Noble metal minerals are native gold, mercurian gold, Cu-bearing gold. Platinum-Group element (PGE) minerals are presented by sperrylite. Concentrations of noble metals in ores attain to Au – up to 1.47 ppm, Pt – up to 5.2 ppm, Pd – up to 0.55 ppm. Obtained P-T conditions of metabasite formation correspond to P>8 kbar, T – 250 - 300°C are indicate it's formation in the subduction zone or accretion wedge. Island-arc complexes are characterized by mercury and tin deposit presence, where ore-forming elements are entered from mantle fluids. These fluids also contain noble metal, incoming by the mantle ultrabasic rocks partial melting.

The pecularities of Khasurta massif rocks formation on the melt inclusion study (Angaro-Vitim batholith, Western Transbaikalia)

L.B. DAMDINOVA AND B.TS. TSYRENOV

Geological Institute SB RAS, Ulan-Ude, Russia
(ludamdinova@mail.ru, tsyrenov@mail.ru)

The Khasurta pluton (about 900 km^2) presents early phase of the Angara-Vitim batholith formation. On the south this pluton is overlapped by Mesozoic and Cenozoic deposits of the Udinskaya intermontane trough, on the north it is limited by a regional break, and on the east and west it intrudes Proterozoic - Early Cambrian volcano-terrigenous and terrigene-carbonaceous sediments. As a whole the pluton is in discordant contact with surrounding rocks.

The pluton's interior is not homogenous and consists of monzonitic and granosyenitic rocks. As a rule surrounding carbonaceous rocks are substituted by scarns in contact with the pluton.

Zircon grains were selected from monzonites. Zircon grain sizes of - up to 1 mm in length, they often form intergrowths. Small crystals (200 - 600 microns) have a zircon habit, and a light pink color.

Melt inclusions in zircon grains from monzonites were studied. A composition of ungomogenized melt inclusions was analysed using the electron microscope (LEO 1430 VP), have been identified: quartz, K feldspar, plagioclase, apatite, muscovite.

Six experiments each with a duration of about 1-3 hours at different temperatures (800-1000°C) were carried out (inclusions size – 4-10 μm). Using an electron microscope the composition of the three homogenized inclusions has been studied. Its composition is more acidic as compared with monzonite and has increased Na, K content.

Thus, based on these results we conclude that Khgasurta massif rock crystallisation temperature was more than 920°C. Monzonites are represent acid ("sienitic") magmas cumulates. High Na and K content permit to suggest monzonite affiliation to the shoshonitic series.

Study was supported by Lavrentievsky grant SB RAS.

Radiochemical analysis of environmental radioactivity for surveillance and characterization

HAIJUN DANG*, HAITAO ZHANG AND XIAOWEI YI

Northwest Institute of Nuclear Technology, Xi'an, China
(*correspondence: harryhjdang@163.com)

Great changes have been achieved in the world politics and economics with the development of nuclear science and technology. However, many problems in the sustainable developing of society and potential risks to the ecology have been also aroused by radioactive pollution. To assess the risk of radionuclides in environment, not only the total amount but also the biogeochemical behavior, the origin and the diffusion (migration) path of these radioactive pollutants in environment need to know. For this purpose, radiochemical analytical methods are keys to characterization of radioactivity.

Since 1990s, inductively coupled plasma mass spectrometry (ICP-MS) has been widely used for monitoring trace radionuclide and identifying the source terms for different environment samples, including soil, underground water, plants and air [1]. In our laboratory, different analytical methods based on ICP-MS measurement and radiochemical separation have been developed to monitor and characterize radionuclides in environment. This work aims to summarize the newly developed analytical methods using UTEVA extraction chromatography combined with ICP-MS for monitoring transuranium nuclides in soil [2] and a direct aerosol measurement attempt with ICP-MS for determining the radionuclide concentration in air [3]. Meanwhile, the result of an environmental radioactivity investigation will be presented to show the bioavailability of radionuclides of different origin [4], as well as the radioactivity transfer from soil to plant. In addition, the developed methods to identify nuclear materials by isotopic signature and age determination have also been well shown with satisfactory result [5]. However, tackle for very low level contamination and for deliberately mixed material is still a challenge to work on.

High-pressure microbiology in the synchrotron light

I. DANIEL[1], A. PICARD[2,3], D. TESTEMALE[4] AND J.-L. HAZEMANN[3]

[1]Université Lyon 1, ENS de Lyon, CNRS, UMR 5276, Laboratoire de Géologie de Lyon, France (isabelle.daniel@univ-lyon1.fr)
[2]Max Planck Insitute for Marine Microbiology, Biogeochemistry Department, Bremen, Germany
[3]MARUM, Center for Marine Environmental Sciences, Bremen, Germany
[4]Institut Néel, Département MCMF, Grenoble, France

The Earth's subsurface is characterized by hostile conditions for life in terms of temperature, pressure and nutrient availability. Although our current view of the biosphere extension is restricted to shallow geological depths, deep life may enconter pressures of hundreds MPa. As an important microbial energetic process, dissimilatory metal reduction needed to be investigated as a function of pressure.

We measured the effects of pressure on the reduction of Se(IV) and Fe(III) to Se(0) and Fe(II), respectively by the bacterial model Shewanella oneidensis MR-1. This strain is a mesophilic and piezosensitive counterpart of psychrophilic and piezophilic Shewanella representatives that have been frequently isolated from deep-sea environments. Kinetics and yields of Se(IV) and Fe(III) reduction were monitored *in situ* by X-ray Absorption Spectroscopy (XAS) in an autoclave optimized for *in situ* XAS measurements [1]. Most measurements were performed at the BM30B beamline of the European Synchrotron Radiation Facility (ESRF, Grenoble, France). Early measurements on the reduction of Se(IV) were also performed in diamond anvil cell at the ID22 beamline of the ESRF.

Metal reduction occurs in cultures of MR-1 at pressures in excess of 100 MPa. This shows that the metabolic activity of a microbe, despite being piezosensitive, extends far beyond its pressure limits for growth here at 50 MPa. Consequently, considering only the ability to grow in the conditions of the deep subsurface as a proof of metabolic activity may lead to an underestimation of the impact of the biosphere in deep environments. Although the exact experimental conditions do not mimic complex subsurface environments, we show here that the metabolic activity of a surface microbe potentially brought to the deep subsurface can affect significantly biogeochemical cycles as those of selenium, but more importantly those of iron and carbon.

Subduction factory unroofed: Modern submarine magmatism in the North Fiji Basin, Southwest Pacifc

LEONID DANYUSHEVSKY AND TREVOR FALLOON

CODES CeO and School of Earth Sciences, University of Tasmania, PB 79, Hoibart, TAS 7001, Australia (*correspondence l.dan@utas.edu.au, Trevor.Falloon@utas.edu.au)

An extensional setting at the southern termination of the North Fiji Backarc Basin (southwest Pacific), which occurs in response to westward roll-back of the Vanuatu trench and eastward roll-back of the Tonga trench, allows subduction-related magmas to reach the surface (seafloor) with only a minimal extent of both fractionation and crustal contamination, thus providing a unique insight into magma generation processes with the subduction factory.

Volcanic rocks collected within this are during the SS10/2004, SS08/2006 and SS03/2009 voyages of the R/V "Southern Surveyor" reveal a large spectrum of subduction-related magma compositions from backarc basin basalts to boninites, calc-alkaline basalts and high-Mg adakites. All magma series have very primitive, high MgO endmembers, which contain abundant high-magnesian olivine phenocrysts (Fo 92-94) formed during the earliest stages of melt evolution.

The data reveal that melts produced due to adiabatic decompression of the mantle wedge play an important role in magma genesis. Within the studied area, a number of such melts can be identified which differ in both the extent of the contribution of the subduction-derived components, and the extent of depletion of the mantle source. Also abundant are melts produced by melting of the basaltic component of the subducted oceanic crust, which extensively re-equilibrate with the surrounding mantle during their accent to the surface. These melts are also characterised by a range of compositions, range from low-Si, high-Mg to high-Si, high-Mg adakites.

There is clear petrographic and geochemical evidence for extensive mixing between high-Mg adakitic and backarc basin magmas in this area, which results in formation of primitive magmas with typical calc-alkaline and boninitic affinities. Our results suggest that in less extensional settings, where unfractionated magmas rarely reach the surface, the role of this mixing in the genesis of typical calc-alkaline magmas may be more difficult to identify, however it may play an important role in subduction-related magma genesis in general.

Application of the correspondence analysis to determine anomalous elements and samples

F. DARABI GHOLESTAN[1]*, R. GHAVAMI- RIABI[1] AND H. ASADI-HARONI[2]

[1] Mining, Petrolum and Geophysics Faculty, Shahrood Univ. of Tech, 7 Tir square, Danshgh Bolv. (*Corresponding author: farshad_darabi@yahoo.com)

[2]Mining Engineering Dept., Isfahan Univ. of Tech., Khomani shahr Bolv.

Determination of the anomaly elements and samples

Based on the soil lithogeochemistry samples were taken from a probable porphyritic Cu-Au mineralized area, the mineralized elements and anomalous samples were identified [1,2,3]. For this propose, a correspondence analysis was done on a matrix of 29 elements (columns) and 149 samples (rows) from the study area. According to the correspondence analysis, a final matrix of 28 factors or variables (columns) and 29+149 labels (rows), which includes of elements and sample numbers, was calculated. The cross plots of two variables (Fig. 1 A and B) from the final matrix were confirmed Au and Cu as anomaly elements and numbers 40, 74, 22 and 84 as anomalous samples.

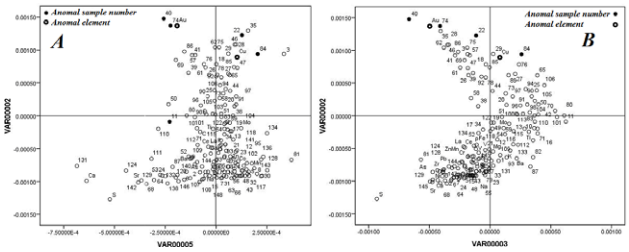

Figure 1: Correspondence analysis for identification of the anomalous element and samples

Conclusion

Identiification of the anomaly sample numbers and anomaly elements could be possible by using the correspondence analysis. The combination of this method and anomaly separation method could separate the high potential eara for follow up exploration program.

Large-area input, inventories, and transport of ^{129}I and ^{127}I in Germany

A. DARAOUI, M. SCHWINGER AND B. RIEBE

Inst. f. Radioökologie u. Strahlenschutz, Leibniz Universität Hannover, Germany (riebe@irs.uni-hannover.de)

The environmental abundance of ^{129}I has been changed substantially, mainly as a consequence of the ^{129}I releases from European reprocessing plants. The stable ^{127}I and the long-lived ^{129}I exhibit massive disequilibria in all biotic and abiotic compartments of the environment in Western Europe. Measurements of ^{127}I and ^{129}I in some German soils revealed ^{129}I/^{127}I ratios of 10^{-7} to 10^{-10} [1, 2], whereas the ^{129}I/^{127}I ratio in a pre-nuclear Russian soil was found to be 5.7 x 10^{-12} [3]. Iodine from wet and dry precipitation is accumulated in soils, transported by surface waters, infiltrates groundwater, and makes its way through the biosphere. Many of the ecological pathways of iodine are still unknown.

The goal of this project is to investigate the continuous atmospheric input via dry and wet deposition, the inventories in the pedosphere and the output by river waters of ^{129}I and ^{127}I in entire Germany.

To this end, aerosol filter samples from 4 locations will be analysed, as well as precipitation samples from 10 locations, and surface water samples from 15 locations along the major rivers in Germany. Sampling is supported by DWD (German Meteorological Service), BfG (Federal Institute for Hydrology), PTB (Federal Metrology Institute), and BfS (Federal Office for Radiation Protection). Additionally, sampling of different soil types at various locations in Germany, down to a depth of 50 cm, is in progress.

Deposition rates, deposition densities and transport rates will be calculated using inductivity coupled plasma mass spectrometry (ICP-MS) and accelator mass spectrometry (AMS) as analytical tools. First results from the two-year sampling, which startet in March 2011, will be shown. A sufficiently dense grid of sampling points will allow a nation-wide mapping of the atmospheric input, the accumulation in soils, and the transport with surface waters back to the sea. Based on these data, a model will be established describing the different pathways of iodine isotopes in the environment.

Formation of Platinum-Group Minerals from an evolving sulfide liquid at Sudbury, Canada

S.A.S. DARE[1]*, S.-J. BARNES[1], H.M. PRICHARD[2] AND P.C. FISHER[2]

[1]L'Université du Québec à Chicoutimi, Québec, Canada, G7H 2B1 (*correspondence : sasdare@hotmail.com)
[2]Cardiff University, Wales, U.K., CF10 3AT

Chalcophile and platinum-group elements (PGE) are collected by a magmatic sulfide liquid and form PGE (± Ni-Cu) deposits. Early-crystallizing monosulfide solid solution (MSS) concentrates Os, Ir, Ru and Rh (IPGE) and the residual liquid concentrates Cu, Pt, Pd, Ag, As, Bi, Te, and Sn. It is important to determine the host phases of the PGE, which are sulfide minerals and/or platinum-group minerals (PGM), in order to understand the petrogenesis of the deposit and to improve PGE extraction. Previous work shows that PGM form by:
1) exsolution from base metal sulfides, 2) crystallization from the residual Cu-rich liquid and/or a late-stage immiscible melt and 3) remobilization during metamorphism or by hydrothermal fluids.

We have investigated the origin of PGM from Sudbury Ni-Cu-PGE deposits by combining a PGM study with whole-rock data and laser ablation-ICP-MS analysis of the sulfides. We found that a large proportion of the PGE are hosted in As-, Bi-, Te- and Sn-rich PGM, which formed over a wide range of temperatures during the evolution of the sulfide deposit. The amount of As in the initial sulfide melt, which varied according to the As content of the assimilated country rocks, was critical in determining whether As-PGM (IrAsS, RhAsS ± $PtAs_2$) crystallized early (1200-900°C) from the sulfide liquid togther with MSS. An As-rich sulfide melt crystallizes sulfarsenides so that the co-existing MSS is depleted in Ir and Rh whereas an As-poor sulfide melt does not crystallize sulfarsenides and the IPGE remain in MSS. The amount of Bi, Te and Sn increases during sulfide fractionation so that the following Pt-Pd-minerals crystallized from the residual liquid. Solitary grains of Pd_2Sn and PtSn crystallized early (1300-800°C) from the Cu-rich sulfide liquid whereas an un-named Pt(Sn,Bi)Te phase together with numerous Pt-Pd-Bi-Te-Ag minerals crystallized as composite grains from micro-droplets of an immiscible late-stage melt (1000-600°C). The small amount of Pt, Pd, Bi and Te, which partitioned into MSS, later exsolved (< 600°C) as laths of $(PtPd)(BiTe)^2$ and PdBiTe and were remobilized during greenschist metamorphism.

Probable Mars atmospheric changes by the proposed terraforming process with silicon utilizing organisms

SATADAL DAS

Peerless Hospital & B. K. Roy Research Centre, Kolkata, India. (drsatdas@hotmail.com)

The silicon utilizing organisms particularly diatoms are well known to tolerate different stress as evidenced in studies on past mass extinctions on Earth and also in artificial laboratory conditions. Thus these organisms may be utilized in terraforming suitable solar system objects and such proposals have already been given for Mars and the Moon [1] and further proposals are likely to be placed for Venus, Callisto, Europa, Ganymede, Enceladus and Titan in near future. In Mars, after initiation of such a terraforming process, by application of these organisms on the surface among basalts, clays, ice etc, a target oxygen level of 150 m bar in the atmosphere may reach within 500 years, with expected significant increase in nitrogen to 300 m bar and decline of carbon dioxide to as low as 10 m bar. As most solar radiations usually reach the surface of Mars, these organisms are expected to grow even at a low temperature in a surface pressure of 6-7 m bar. High carbon dioxide levels will affect the growth, fluorescence, pigmentation and carbonic anhydrase activity of these organisms with involvement of chlorophyll a, chlorophyll c and fucoxanthin. Presence of diverse genes is essential for proper terraforming process with organisms, mainly for efficient management of C and N. Thus a set of such organisms may be chosen for initial terraforming process according to gene library matching. Iron present on Mars surface has also a pivotal role in controlling carbon uptake by these organisms and regulating atmospheric partial pressure of carbon dioxide. Finally atmospheric erosion and escape processes particularly solar wind ion or proton and magnetospheric-plasma-driven sweeping may alter the expected values to some extent.

Silicate melting in the Earth's deep upper mantle caused by C-O-H volatiles

R. DASGUPTA[1]*, K. TSUNO[1], A. C. WITHERS[2] AND A. MALLIK[1]

[1]Dept. of Earth Science, Rice University, Houston, TX (*correspondence: Rajdeep.Dasgupta@rice.edu)
[2]Dept. of Geology & Geophysics, University of Minnesota, Minneapolis, MN

The onset of silicate melting in the Earth's upper mantle influences the thermal evolution of the planet, geochemical differentiation of the interior, flux of key volatiles to the exosphere, and geophysical properties of the mantle. Although the first initiation of melting beneath mid oceanic ridges likely produces dry carbonatite melt as deep as ~350 km, owing to vanishingly small volume (~0.03%), its effect on geochemical and geophysical properties of the mantle is unclear. Geophysical data, however, suggest possible presence of partial melts to depths exceeding 200 km. Silicate melts have better prospects in this respect owing to higher viscosities and densities; however, they are not thought to be generated at depths approaching or in excess of 200 km. Here we present experiments in natural peridotite+CO_2 systems over 2 to 5 GPa and constrain the location and the slope of the onset of silicate melting (melts with ≤25 wt.% CO_2) in a carbonated mantle. We show that the P-T slope of transition from carbonate to silicate melt is steeper than the solidus of volatile-free peridotite owing to diminishing non-ideality of mixing between carbonate and silicate melt components as a function of pressure. This causes carbonated silicate melting of dry peridotite beneath ridges to commence as deep as ~230 km. Taking into account 50-200 ppm water in the nominally anhydrous mantle and its effect on freezing point depression, the onset of silicate melting for a sub-ridge mantle with ~100 ppm CO_2 becomes as deep as ~260-300 km. Deep carbonated silicate melting can deplete the mantle from its water storage capacity, to match the depleted mantle water content beneath ridges. Deep onset of silicate melting also restricts the stability of carbonatite in the Earth's deep upper mantle and the inventory of carbon and other highly incompatible elements at ridges becomes almost entirely controlled by flux of deep, wet carbonated silicate melts.

Finally, deeper transition from carbonatite to carbonated silicate melts causes the melt CO_2 to be diluted at greater depths than previously modeled. This causes graphite to carbonated melt transition depth beneath continents to be deeper than recent estimates.

SHRIMP U-Pb geochronology of Neoproterozoic Rio Una sequence, NE Brazil, and the Rodinia break-up

*A.F. DA SILVA FILHO[1], I.P. GUIMARAES[1] AND R.A. ARMSTRONG[2]

[1]Universidade Federal de Pernambuco, Departamento de Geologia, Recife, Brazil, (*correspondence:afsf@ufpe.br)
[2]Australian National University, RSES, Canberra, Australia, (richard.armstrong@anu.edu)

The amalgamation of Gondwana resulted from the fragmentation of Rodinia and the reassembly of the cratonic blocks during the Neoproterozoic. The Borborema Province is the western part of a major Brasiliano belt that extends from Brazil through NW Africa in pre-drift reconstructions. This province results from the convergence and collision among the West African, Congo-São Francisco, and Amazonia land masses about 600 Ma. The Rio Una Sequence is located within the PEAL Domain of the Borborema Province. It is comprised by 3 units. We are presenting U-Pb dating of the unit 1.This unit comprises migmatized metapelites with peraluminous mesossome (andaluzite-, cordierite-, garnet-bearing biotite gneisses), with quartzites intercalations. The studied sample was collected near one of these intercalations. The analyzed sample shows zircon grains with length ranging from 80μm up to 200μm. They are elongate to rounded zircons, with aspect ratio ranging from 1:1 to 2:1. They usually show oscillatory zoning, and in some case a narrow metamorphic overgrowth. The $^{232}Th/^{238}U$ ratio of almost all analysed grains ranges from 0.20 to 2.16, suggesting that they come from an igneous protolith, or from a recycled igneous rock. The U-Pb data with less than 5% discordance cluster mostly in the intervals 850-1100 Ma and 1800-2100 Ma. The data points that the unit 1 show a maximum depositional age of 854Ma. The age of this sequence is coeval with the age attributed to the beginning of the Rodinia break-up.

Mechanisms of copper immobilization by bacteria during precipitation of iron oxides

C.J. DAUGHNEY[1]*, P. J. SWEDLUND[2] AND M. MOREAU-FOURNIER[1]

[1]GNS Science, Lower Hutt, New Zealand (*correspondance: c.daughney@gns.cri.nz)
[2]University of Auckland, Auckland, New Zealand

This project focuses on interactions between bacteria and iron oxides, and the effects of such interactions on the behaviour of dissolved copper ions. Laboratory experiments were performed to track the fate of dissolved copper and iron during the gradual, incremental oxidation of dissolved Fe(II) and precipitation of iron oxide in the presence of *Anoxybacillus flavithermus* cells. The experimental data reveal significant and complex controls on copper immobilization, related to progressive changes in 1) ratio of copper to dissolved Fe(II) concentration, inferred to result from competition for bacterial sorption sites; 2) ratio of precipitated iron oxide to bacteria, inferred to result from desorption of Fe(II) initally associated with the bacterial surface; and 3) reaction time, inferred to result from increasing quantities of biogenic dissolved organic matter. Surface complexation models are developed to describe the experimental data. This study demonstrates that the immobilization of metal cations in bacteria-bearing settings should not be examined independently of progressive oxidation, hydrolysis and precipitation of iron.

Mars as a planetary oligarch

NICOLAS DAUPHAS[1] AND ALI POURMAND[1,2]

[1]Origins Laboratory, Department of the Geophysical Sciences and Enrico Fermi Institute, The University of Chicago, Chicago IL 60637, USA (dauphas@uchicago.edu).
[2]RSMAS, Division of Marine Geology and Geophysics, University of Miami, Miami, FL 33149, USA.

There is considerable uncertainty as to how and when Mars formed [1,2]. In particular, its small mass compared to Earth and Venus is difficult to explain and some have suggested that Mars could be a stranded planetary embryo (also called an oligarch) that escaped collision and merging with other embryos [3]. A diagnostic parameter to assess this idea is its accretion time, which can be calculated using ^{182}Hf-^{182}W systematics of martian meteorites [2,4]. Unfortunately, the Hf/W ratio of the martian mantle is very uncertain, resulting in model age estimates that range between 0 to 15 My after solar system birth. To better constrain the Hf/W ratio of the martian mantle, we have measured the concentrations of Lu, Hf, U, Th by isotope dilution, as well as ^{176}Hf/^{177}Hf isotopic ratios of 43 chondrites from all major groups of chondrites [the methodology is described in ref. 5].

We estimate the Hf/W atomic ratio of the martian mantle to be 3.51±0.45 . Using this Hf/W ratio, the measured value of $\varepsilon^{182}W_{Mars\ mantle}$=+2.6 [2,4] can only be reproduced with an accretion timescale of ~2 Myr [6]. This is consistent with a stranded planetary embryo origin for Mars. Objects formed in the first few million years of the formation of the solar system would have incorporated enough ^{26}Al to melt. We thus demonstrate that a magma ocean powered by ^{26}Al-decay must have been present on early Mars. This changes our perspective on the formation of our planet as we have now identified a sample of the embryonic material that the Earth was made of. For example, Earth may have inherited its missing Xe problem [7] from a Mars-like precursor.

Linking solution composition and surface topography to the rate and mechanisms of diopside dissolution

D. DAVAL[1]*, G. D. SALDI[1], R. HELLMANN[2] AND K. G. KNAUSS[1]

[1]ESD, LBNL, Berkeley, CA 94720, USA (*correspondence: ddaval@lbl.gov)
[2]ISTerre, CNRS/UJF, 38041, Grenoble, France

Whereas the dissolution rate of silicate minerals has been extensively studied at far-from-equilibrium conditions, extrapolating such rates over a broad range of solution composition has proven challenging. Regarding diopside, recent studies [1, 2] suggested that below 125 °C, an unexpected drop of the rate occurred for Gibbs free energies of reaction (ΔG_r) as low as –76 kJ.mol^{-1}, with severe consequences on our ability to predict the rate of complex processes such as carbonation reactions [2].

The mechanism responsible for such a drop remains unclear and therefore needs to be deciphered. An examination of our previous data [2] led us to envisage that two different, non-exclusive aspects were worth investigating: (i) the possible passivating ability of interfacial, nm-thick Si-rich layers developed on weathered silicate surface, and (ii) the stop of etch pits formation on crystal surface, which were found to be responsible for drops of olivine [3] and albite [4] dissolution rates, respectively.

Our ongoing experiments aim at better constraining these two mechanisms, and determining in turn whether one of them could explain the above-mentioned drop of diopside dissolution rate. Classical flow-through experiments with controlled SiO_2(aq) concentrations are combined with both *ex situ* AFM measurements and *in situ* monitoring of the topography of the dissolving surface of diopside in a hydrothermal AFM flow-cell (e.g. [5]). By investigating the dissolution of several cleavages, we will show how these latter techniques represent a powerful tool for studying the anisotropy of diopside dissolution, and determining which face ultimately controls its dissolution rate. An attempt to link these observations to macroscopic determination of diopside dissolution rates as a function of fluid composition will be discussed.

Zone of Anomalous Mantle

A.W. DAVIES AND R. DAVIES

Talmora Diamond Inc. 6 Willowood Ct, Toronto M2J2M3 Canada (rayal.davies@sympatico.ca)

The most striking characteristic of both the Siberian and Slave diamond fields is their linear distribution. The concept of the "Corridor of Hope" was introduced [1] to refer to a northwest trend that appears to have controlled the emplacement of the most significantly diamondiferous kimberlites of the Slave craton. With displaced northern [2, 3] and southern extensions the corridor is 2300 km long.

The Siberian diamond fields have a linear distribution over 1000 km with one offset. The linear is described [4] as a "Zone of Anomalous Mantle" and mantle xenoliths and xenocrysts [5] show that Hartsburgite makes up a significant part of the lower mantle beneath 190-240 km thick lithospheric Archean terrane to the south but is missing beneath 125 km thick lithospheric Proterozoic terrane to the north.

Helmstaedt [6] proposed a model for the Slave craton in which Paleoproterozoic lithosphere has underplated Mesoarchean lithosphere beneath the corridor and the upper edge of the underplating Proterozoic is 270 km west of the corridor and controls the geometry of the corridor. Significantly Mirny is 250 km NW of the Akitkan Proterozoic fold belt and there is evidence [7] for a Proterozoic fold belt 250 km east of the Alakit/Daldyn/Muna diamond fields.

A modified 2.0-0.8 Ga reconstruction of the Proterozoic Supercontinent [8] has the Siberian "Zone of Anomalous Mantle" lined up with the N American corridor.

Conclusion

Proterozoic lithosphere underplated an Archean craton (Siberia & N America) on its Pacific ocean side that resulted in a single zone of anomalous mantle. Except where the zone was cut by the Aekit Proterozoic orogenic belt that separated, thinned and destroyed the base of the adjoining Siberian and N American (Alaska North Slope) cratons, it is extremely favourable for hosting diamondiferous kimberlites.

Dynamical constraints on mantle reservoirs through time

G. F. DAVIES

Research School of Earth Sciences, Australian National University, Canberra ACT 0200, Australia (Geoff.Davies@anu.edu.au)

It is now generally accepted that Earth formed hot, due particularly to a giant, moon-forming impact late in accretion. A resulting magma ocean probably cooled on a geologically short timescale, and may not have left a strongly differentiated mantle, due to vigorous internal mixing, except possibly in the D" region. Loss of excess initial mantle heat would have taken ~0.5 Gyr. Core cooling is controlled by mantle plumes and may always have been slow. Plume activity may have been 2-8 times stronger during the Hadean and early Archean.

The Earth's surface would have cooled early, soon after the last giant impact (~4.45 Ga?). An active mantle would be expected to produce mafic crust at a substantial rate, and this may have tended to founder episodically, possibly in large bodies. Conceivably some of these persist in D".

Gravitational settling of foundered or subducted mafic crust could have left the upper mantle strongly depleted, explaining isotopic evidence of stronger early depletion of incompatible elements. This upper mantle would produce only a thin mafic crust, which would facilitate an early start to plate tectonics and efficient cooling of the mantle.

A 'basalt barrier' may have formed within the transition zone, yielding a cool upper mantle and a hot lower mantle. Episodic breakdown and overturn of this stratified mantle during the first 1-2 Gyr could have volcanically resurfaced much of the planet.

An accumulation of denser mafic material in D" probably formed early. This persists strongly to the present, though it might not be able to form now. It could retain a record of major melting events from throughout Earth history.

No other mantle stratification is plausible at present. A putative thick layer in the lower mantle should produce mantle plumes several times stronger than what is observed, so it is unlikely.

Lithologic heterogeneity of the mantle probably formed early from foundering differentiated material. Much of the mantle complement of incompatible elements may be carried in hybrid pyroxenite, formed by reaction of melt from mafic inclusions with surrounding peridotite. Noble gases plausibly persist from the early Earth in this material, and the present mantle complement of incompatibles may be 2-3 times previous estimates, whose assumptions make them lower bounds.

Dynamical geochemistry

G.F. DAVIES

Research School of Earth Sciences, Australian National University, Canberra ACT 0200, Australia (Geoff.Davies@anu.edu.au)

Despite progress in reconciling important aspects of mantle chemistry with dynamics, mass balances of key elements and observations of noble gases have remained enigmatic. Resolution may follow from taking fuller account of the lithological heterogeneity of the mantle [1].

The Hofmann-White-Christensen reconciliation of refractory trace elements and their isotopes with the dynamical mantle has been strengthened by work over the past decade. The apparent age of lead isotopes and the broad refractory-element differences among and between ocean island basalts (OIBs) and mid-ocean ridge basalts (MORBs) can now be quantitatively accounted for with some assurance.

Noble gases may reside in a so-called *hybrid pyroxenite* assemblage that is the result of melt from fusible pods reacting with surrounding refractory peridotite and refreezing. Hybrid pyroxenite that rises off-axis may not remelt and erupt at MORs, so its volatile constituents would recirculate within the mantle. Hybrid pyroxenite is likely to be denser than average mantle, and thus some would tend to settle in the D" zone at the base of the mantle, along with some old subducted oceanic crust. Residence times in D" are longer, so the hybrid pyroxenite there would be less degassed. Plumes would sample both the degassed, enriched old oceanic crust and the gassy, moderately enriched hybrid pyroxenite and deliver them to OIBs. This model can account quantitatively for the main He, Ne and Ar isotopic observations, and for the poor correlation of unradiogenic gases with refractory-element enrichment in OIBs.

The difficulty with mass balances can be traced to the common inference that the MORB source is strongly depleted of incompatible elements. However conventional estimates focus on an ill-defined "depleted" mantle component while neglecting less common enriched components. Recent estimates have also been tied to the composition of peridotites, but these probably do not reflect the full complement of incompatible elements in the heterogeneous mantle. New estimates that account for enriched mantle components can satisfy mass balance requirements, although some additional uncertainties apply to argon. The result is that the MORB source is depleted by only about a factor of 2, relative to the primitive Earth.

Approaching the final frontier in lateral resolution for isotopic and chemical analysis with CHILI

A.M. DAVIS[1,2,3]*, T. STEPHAN[1,2], M.J. PELLIN[1,2,3,4], M.R. SAVINA[1,4], I.V. VERYOVKIN[1,4], R. YOKOCHI[1,2], R. TRAPPITSCH[1,2], N. LIU[1,2], A.J. KING[1,2]

[1]Chicago Center for Cosmochemistry
[2]Dept. of Geophysical Sciences, Univ. of Chicago, Chicago, IL 60637 (*correspondence: a-davis@uchicago.edu)
[3]Enrico Fermi Inst., Univ. of Chicago, Chicago, IL 60637
[4]Materials Science Div., Argonne National Laboratory, Argonne, IL 60439

There is a clear need for improvements in lateral resolution and sensitivity beyond what is available with current state-of-the-art secondary ion mass spectrometry (SIMS) instruments. SIMS lateral resolution has reached ~50 nm and useful yields are at most a few percent. We are completing construction of CHILI (the CHicago Instrument for Laser Ionization), a resonant ionization mass spectrometry (RIMS) nanobeam instrument designed for isotopic and chemical analysis at the few-nm scale with a useful yield of 35–50% [1]. CHILI is equipped with a COBRA-FIB high resolution liquid metal ion gun (LMIG) and an e⁻CLIPSE Plus field emission electron gun from Orsay Physics, each of which can be focused to <4 nm. The electron gun will be used for secondary electron imaging, as the built-in optical microscope is diffraction-limited to ~0.5 μm. A piezoelectric stage capable of reproducible nm-scale motions and equipped with a sample holder that will accept a wide variety of sample mounts is operational. The flight tube for the time-of-flight mass spectrometer mounted vertically above the sample chamber; this assembly is mounted in the center of an H-shaped laser table equipped with active vibration cancellation devices. The table has been demonstrated to have a vertical vibrational amplitude of less than 0.2 nm. Resonant ionization will be done with six Ti:sapphire tunable solid state lasers pumped with three 40W Nd:YLF lasers, which will allow two to three elements to be analyzed simultaneously. Ion detection in existing RIMS instruments [2,3] is done with a microchannel plate with a single anode. Isotope ratio precision is limited by counting statistics, as no more than one ion of the most abundant isotope of an element can be counted for each pulse. CHILI will initially be equipped with such a detector, but we are developing a multianode detector to significantly improve the count-rate capability.

Partitioning of first-row transition elements between peridotite and melt

FRED A. DAVIS[1]*, MUNIR HUMAYUN[2], MARC M. HIRSCHMANN[1] AND RUPERT S. COOPER[1]

[1]Dept. Of Earth Sciences, Univ. Of Minnesota, Minneapolis, MN 55455, USA (*correspondence: davis957@umn.edu)
[2]Dept. of Earth, Ocean, & Atmospheric Science, and National High Magnetic Field Laboratory, Florida State University, Tallahassee, FL 32310-4100, USA

To constrain possible lithologies in source regions of OIB [1-3], we experimentally determined partitioning of first-row transition elements (FRTE), Ga, and Ge between minerals in garnet peridotite and near-solidus partial melt at 3 GPa using LA-ICP-MS. K_D^{Mn-Fe} between peridotite and melt is ~1, so low-degree partial melts of peridotite inherit Fe/Mn of their source, similar to the results of previous studies [1]. K_D^{Zn-Fe} between peridotite and melt is 0.80, lower than previously determined from intermineral partitioning in natural peridotites (0.85-1) [3], primarily due to a lower measured K_D^{Zn-Fe} for opx (0.77 rather than 0.96). Most peridotite xenoliths have $(Zn/Fe)*10^4$ from 4-12 [4], thus partial melts of peridotite may have $(Zn/Fe)*10^4$ ratios as great as 15. Most primitive OIB have $(Zn/Fe)*10^4$ from 10-15 [4], so derivation from a peridotite source can only be ruled out for a very few OIB lavas based solely on Zn/Fe. A fertile peridotite with 0.2 wt.% TiO_2 can generate a near-solidus melt with ~3.3% TiO_2. OIB with >3.3% TiO_2 require a non-peridotite or metasomatized source.

D_{Sc}	D_{Ti}	D_V	D_{Cr}	D_{Mn}
0.86	0.062	0.65	4.1	0.81
D_{Fe}	D_{Co}	D_{Zn}	D_{Ga}	D_{Ge}

A coupled ion exchange, surface complexation, calcite dissolution, and mass transfer model to describe uranium(VI) desorption and reactive transport at the Rifle (USA) field site

J.A. DAVIS[1]*, M. HAY[2], P.M. FOX[1] AND K. WILLIAMS[1]

[1]Lawrence Berkeley National Laboratory, Berkeley, CA, 94720, USA (*correspondence: jadavis@lbl.gov)
[2]U. S. Geological Survey, Menlo Park, CA 94025, USA (mbhay@usgs.gov)

Predicting uranium mobility in the subsurface requires detailed knowledge of geochemical processes controlling the sorption dynamics of U(VI). This is a particular challenge in cases where aqueous solution conditions are highly variable. Desorption of U(VI) from mineral surfaces is strongly dependent on aqueous chemistry (e.g., pH, HCO_3 and Ca concentrations). Further, kinetic processes such as intragranular diffusion affecting U(VI) desorption equilibrium may become increasingly important under conditions where changing solution chemistry causes relatively steep U(VI) concentration gradients.

In this research we have quantified the effects of aquifer sediment properties on the transport dynamics of U(VI) under variable chemical conditions and developed a reactive transport model that can be applied to field settings. An ion exchange model was calibrated first in experiments conducted with the aquifer sediment <2 mm fraction with calcite removed. This was then applied in combination with a surface complexation model to describe U(VI) transport in laboratory columns. Chemical conditions within the columns were varied through the injection of influent solutions with differing pH, bicarbonate, and major ion concentrations. Initial conditions within the columns were impacted by slow calcite dissolution. Stopflow events during column elution demonstrated U(VI) desorption was not at local equilibrium, and U(VI) elution data were used to calibrate a distributed rate mass transfer model for U(VI) desorption, at flow rates and alkalinity concentrations relevant to the Rifle site. Oversaturation with respect to calcite was observed in this column experiment and in the Rifle aquifer. In a column experiment with high influent bicarbonate, calcite oversaturation exceeded one order of magnitude, suggesting calcite nucleation and precipitation and U(VI) co-precipitation within the column. The model was successfully applied to describe field injection experiments after correction for local surface sediment properties (surface area, ion exchange capacity, and initial adsorbed U(VI)).

Geochemistry of granites from magmatic-metamorphic complex of Boein-Miandasht, Sanandaj-Sirjan Zone, Iran

A.R. DAVOUDIAN[1]*, N. SHABANIAN[1] AND F. PANAHDAR[2]

[1]Faculty of Natural Resources and Earth Sciences, Shahrekord University, Shahrekord, Iran (*correspondence: alireza.davoudian@gmail.com)
[2]Islamic Azad University- Khorasgan Branch, Isfahan, Iran

Geological Setting and sample description

The granitic plutons crop out the north of the Boein – Miandasht city: they intruded into the metamorphic rocks. Various ages have been assigned to the metamorphic complex: Precambrian [1], Paleozoic and Mesozoic [2]. Metamorphic rocks in the study area comprise phyllite, mica schist, amphibolite, marble and meta-rhyolite with minor quartzite. Alkali granite is the major rock type in the plutons. It is composed of quartz, K- feldspar, plagioclase, biotite, amphibole, epidote, allanite, zircon, sphene, magnetite, tourmaline and apatite.

Discussion and Results

The granites have contents of SiO_2, ranging from 68.7 to 73.3%. They have high alkalis, with K_2O= 2.3 to 5.01% and Na_2O =3.75 to 5.0%, but low Fe_2O_3 (0.8 - 1.7%), FeO (1.1-1.9%), MnO (<0.1%), MgO (0.4-0.7%), CaO (0.9-1.8%), TiO_2 (0.3-0.5%) and P_2O_5 (0.1-0.2%). Al_2O_3 ranges from 13.8% to 14.9%.

Similarly the trace element compositions exhibit significant variations, particularly in the case of Rb (146.7–212.8 ppm), Y (32.1–40.2 ppm), Sr (65.3–153.0 ppm), Ba (400–633ppm), Ga (18.0-20.0 ppm) and high field-strength elements (HFSE) (Nb: 15.6–27.4 ppm; Ta: 1.5– 2.4ppm; Zr: 184.3–346.0 ppm; Hf: 5.2–10.1 ppm). The granites displays the characteristics of A-type grnitoids. According to a geochemical classification scheme for granitoids, proposed by Frost *et al*. [3], the granitic rocks belong to ferroan, alkali-calcic, mildly peraluminous granites. The plot of Zr + Nb + Ce + Y vs. 10000*Ga/Al suggest an A-type to fractionated granites character for the rocks. The granites show A2 field on ternary diagrams from Eby [4].

Molecular characterization of archaeal lipids across a hypersaline gradient

K.S. DAWSON*, K.H. FREEMAN AND J.L. MACALADY

Dept. of Geosciences, Pennsylvania State Univ., University Park, PA 16802, USA
(*correspondence: katsdawson@psu.edu)

Four halophilic archaeal strains, *H. utahensis, N. pharaonis, H. sulfurifontis* and *H. gomorrense*, were grown at a range of salinities (10-30% NaCl, (w/v)). These strains represent four archaeal genera and have a range of salinity optima. Molecular analysis of membrane lipids in each strain by GC-MS revealed structures consistent with saturated, unsaturated and polyunsaturated dialkyl glycerol diethers (DGDs) of both phytanyl (C_{20}) and sesterpanyl (C_{25}) isoprenoid chains. In addition, we observed three trends: (1) the percentage of unsaturated DGDs increased with increasing NaCl concentration in the growth medium; (2) strains with a higher optimal NaCl concentration had a higher percentage of unsaturated DGDs; and (3) $C_{25\text{-}20}$ DGDs occurred in the two strains with higher optimal NaCl concentrations, *N. pharaonsis* and *H. utahensis*. The strong linear correlation between optimal growth salinity and the amount of unsaturated DGDs (Fig. 1) suggests that the degree of membrane lipid unsaturation is an important adaptation to specific salinity niches in archaeal halophiles. In addition, in three of the four halophile strains we tested, the fraction of unsaturated DGDs increased above a salinity threshold or in response to increasing salinity in the growth medium. Thus, halophilic archaea may regulate membrane lipid unsaturation in response to environmental salinity changes regardless of their salinity optima.

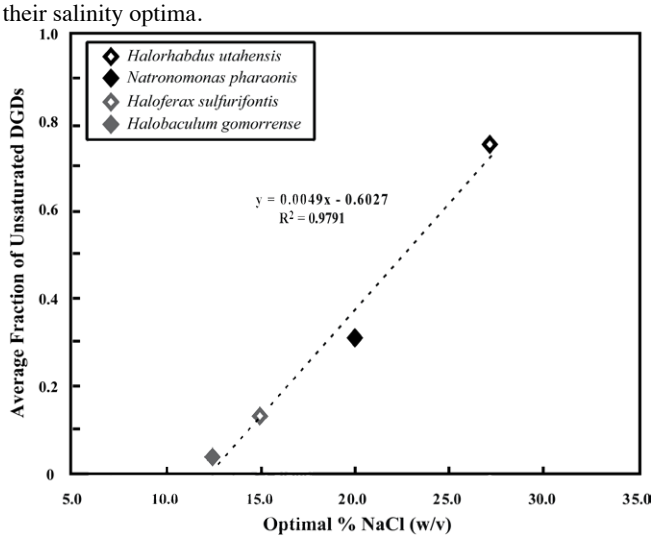

Figure 1: Average fraction of unsaturated DGDs versus optimal % NaCl (w/v) for four halophilic archaeal strains.

O and Ca isotopes in calcite grown under cave-analogue conditions

C.C. DAY[1]*, L.M. REYNARD[2], M.D. POINTING[1], C.L. BLÄTTLER[1] AND G.M. HENDERSON[1]

Speleothem oxygen isotopes and growth rates are valuable proxies for reconstructing climate history. However, oxygen isotopes and growth rate are controlled by diverse environmental variables (including the climatically important variables rainfall and temperature) and there is a paucity of laboratory experiments to quantify the influence of these variables on speleothem chemistry. Quantitative data from such studies would dramatically improve our ability to reconstruct palaeoclimate from stalagmites.

We have completed a new series of carbonate growth-experiments in karst-analogue conditions in the laboratory [1,4]. The setup closely mimics natural processes (e.g. precipitation driven by CO_2-degassing, low ionic strength solution, thin solution film) but with a tight control on growth conditions (temperature, pCO_2, drip rate, calcite saturation index and the composition of the initial solution).

We derive a relationship between growth mass, temperature and drip rate, whilst in a more qualitative sense we observe a wider diameter of calcite growth with increased drip rate. $\delta^{18}O$ results show that speleothem growth from fast dripping, cold settings are most favourable for palaeoclimate work. $\delta^{18}O$ and $\delta^{44/42}Ca$ provide important insight into the mechanisms of stable isotope fractionation in speleothems, which we discuss in the context of surface entrapment controlling Ca and O isotopic fractionation [2, 3].
Collectively, these experiments therefore provide a more robust understanding of the way that stalagmite carbonate responds to climatically important environmental variables.

^{186}Os-^{187}Os and highly siderophile element abundance systematics of Earth's upper mantle

J.M.D. DAY[1,2], J.M. WARREN[3] AND R.J. WALKER[2]

[1]Geosci. Res. Div., Scripps Institution of Oceanography, La Jolla, CA 92093-0244 (jmdday@ucsd.edu)
[2]Dept. Geol., Univ. Maryland, College Park, MD 20742
[3]Dept. Geol. Env. Sci., Stanford University, CA 94305

Osmium isotope and highly siderophile element (HSE) abundance systematics of abyssal peridotites may provide new constraints for interpreting isotopic and elemental signatures preserved in terrestrial lavas, as well as for deciphering melt depletion and recycling in the convecting mantle. Here we report new high-precision ^{186,187}Os/^{188}Os isotope and HSE abundance data for bulk samples of abyssal peridotites from the Arctic (Gakkel), Indian (central [CIR] and southwest [SWIR]), and Atlantic (Kane) ridges.

Peridotites from the global suite range from relatively fresh to serpentinized harzburgites and lherzolites, with no systematic variation observed for HSE abundances or ^{186,187}Os/^{188}Os with alteration. Average HSE abundances of different ridge segments are broadly similar (0.007±2 × CI-chondrite). The HSE are in approximately chondritic-relative abundances, although all ridges studied have supra-chondritic Ru/Ir (Kane = 1.4±0.2; Gakkel = 1.6±0.6; SWIR = 1.5±0.3; CIR = 1.4±0.1), similar to estimates for primitive upper mantle (PUM). Unlike PUM, there is no systematic supra-chondritic Pd/Os in SWIR, CIR, or the majority of Gakkel peridotites. There is greater HSE abundance variability in ultra-slow spreading Gakkel, versus Indian or Atlantic peridotites. Abyssal peridotites analyzed in this study have ^{187}Os/^{188}Os ratios ranging from 0.1217 to 0.1587. The ^{186}Os/^{188}Os of SWIR peridotites (0.1198385±4), which were affected by the Bouvet hotspot at ~20Ma, are, on average, higher than for CIR (0.1198360±5), Kane (0.1198353±7 [1]), and Gakkel peridotites (0.1198332±6). SWIR show a general positive correlation for ^{187}Os/^{188}Os-^{186}Os/^{188}Os, but no other correlations are observed between these ratios in the dataset. If CIR, Kane and Gakkel peridotites are representive of convecting upper mantle, then this reservoir has evolved with a long-term Pt/Os that is well within the range of chondrites. In contrast, SWIR peridotites derive from a mantle source with higher Pt/Os. If SWIR ^{186}Os/^{188}Os values relate to high time-integrated Pt/Os, how this signature is transferred from the hotspot to the peridotites is unclear. Lack of correlation between Pt/Os and ^{186}Os/^{188}Os for the suites suggests abyssal peridotites do not record absolute and relative abundances of the HSE in the convecting upper mantle with high fidelity.

Metasomatism beneath the Kerguelen Plateau associated with heterogeneous mantle plume

V. DEBAILLE[1]*, G. HUBLET[1], N. MATTIELLI[1] AND D. WEIS[2]

[1]DSTE, Université Libre de Bruxelles, Brussels, Belgium. (*correspondence: vinciane.debaille@ulb.ac.be)
[2]PCIGR, University of British Columbia, Vancouver, Canada

The Kerguelen Plateau, in the Southern part of the Indian Ocean, represents the second largest igneous province on Earth. Its main emerging feature is the Kerguelen Archipelago, located in the Northern part of the plateau (NKP). Basic and ultrabasic xenoliths are commonly found disseminated within alkaline lava series, especially in the Southern and South-East part of the archipelago. The xenoliths were formed in PT conditions generally comprised between 0.75 to 1.6 GPa and 880 to 1010°C, corresponding to lithospheric conditions [1]. The xenoliths thus provide a unique opportunity to understand the processes that occurred during the construction of the NKP.

While there is no evidence for contamination of the xenoliths from their host lavas during their ascent, the xenoliths are metasomatized, as showed by the presence of both silicate and carbonate melt inclusions [2], and enrichment in incompatible trace elements [1]. In light of the comparable isotopic signatures for the Kerguelen alkaline volcanism and the xenoliths, the origin of this metasomatism, both silicate and carbonatitic-silicate melts, seems related to the Kerguelen Mantle Plume itself [3]. Using various types of xenoliths, we show here that (i) the metasomatism event is ~40 million years old, corresponding to the onset of the interaction between the South-East Indian Ridge and the Kerguelen mantle plume [4], and (ii) the two metasomatic melts can be distinguished using both trace element and isotope ratios. As such, xenoliths metasomatized by carbonatitic-silicate melts have $(Sm/Yb)_N$ > 1, and ^{206}Pb/^{204}Pb < 18.200. Using Nd, Hf and Pb isotope ratios, xenoliths metasomatized by carbonatitic-silicate melts show a stronger affinity with the EM-I component, while the one metasomatized by silicate melts are closer of the EM-II component. This suggests that the carbonatitic-silicate and silicate melts do not initially originate from a homogeneous source that later separated due to immiscibility at shallow depths between silicate and carbonatitic melts, but instead reflect the heterogeneity of the Kerguelen mantle plume.

Borosilicate glass alteration driven by magnesium carbonates

M. DEBURE[1,2], P. FRUGIER[1], L. DE WINDT[2] AND S. GIN[1]

[1]CEA Marcoule, DTCD/SECM/LCLT, BP 17171, 30207 Bagnols-sur-Cèze Cedex, France (mathieu.debure@cea.fr; pierre.frugier@cea.fr)

Multi solid interactions: experiment and modeling

Geochemical modeling of glass and silicate mineral alteration is a major challenge for understanding natural processes in the earth sciences (e.g. chemical compositions of natural waters and oceans...). In confined media, solids reactivity quickly controls solution compositions. The alteration of a simplified synthetic glass, representative of the French reference nuclear glass in the presence of a simple Mg-bearing phase is a key step towards the understanding of the interactions between nuclear glass and nearfield materials in geological repository. Indeed, magnesium in solution is one of the elements known to potentially enhance glass alteration. In a first study, hydromagnesite was chosen as the simplest and as the most reactive Mg bearing carbonate.

Experiments were performed in closed system at 90°C and characterized by SEM, XRD and TofSIMS. They revealed that glass alteration is enhanced in presence of hydromagnesite at 90°C.

Geochemical modeling was performed using the GRAAL model [1] implemented within the CHESS/HYTEC reactive transport code. The model was efficient enough for quantifying the amount of present solids, the pH and the elements concentration with time whatever the glass/hydromagnesite ratio.

Future experimental and modeling work will concern more representative solids, like dolomite and smectites.

Carbonation of forsterite and serpentine: Modeling the optimum conditions in terms of pH and temperature

JULIEN DECLERCQ AND ERIC OELKERS

14 Av. Edouard Belin 31400 Toulouse, France; (declercq@get.obs-mip.fr, oelkers@get.obs-mip.fr)

Carbonation of forsterite into magnesite and quartz following the reaction:

$$Mg_2SiO_4 + 2CO_2 \rightarrow 2MgCO_3 + SiO_2$$

has been assumed in a plethora of studies. However the consumption of metals by the formation of secondary phases has been overlooked.

In this study we intent to shed some light and define the conditions of successful carbonation experiments and industrial CO_2 mineralization projects in terms of pH and temperature. In order to minimize the precipitation of secondary phases we have mapped out the thermodynamic stability of magnesite relative to mineral phases like antigorite and brucite from 25 to 200°C, a pH ranging from 4 to 8 and 10 bars of CO_2 and performed both closed system batch simulations and kinetic simulation of the carbonation of forsterite and serpentine using the kinetics expressions and data available in the literature.

The results illustrate several important constrains on the formation of magnesite or serpentine. A key role in the reaction process is played by the temperature, due to the lowering reaction rates below 100°C where both magnesite and quartz fail to precipitate;whereas at temperatures greater than 200°C the overall forsterite to magnesite reaction is thermodynamically unstable. Furthermore, the pH effect cannot be ignored, as at pH below 4 the magnesite is extremely soluble and will not precipitate whereas at pH above 9 brucite is becoming the dominant precipitating phase, thus it is unlikely that carbonation will occur.

SIMS U-Pb ages for heterogenite from Katanga (DRC): Implications for the genesis of Co-U deposits in Shinkolobwe

S. DECRÉE[1]*, É. DELOULE[2], T. DE PUTTER[1], S. DEWAELE[1], F. MEES[1] AND C. MARIGNAC[3]

[1]Royal Museum for Central Africa, B-3080 Tervuren, Belgium (*correspondence: sophie.decree@africamuseum.be)
[2]CRPG/CNRS, F-54501 Nancy, France
[3]UMR-G2R CREGU & Ecole des Mines de Nancy, Nancy, France

Heterogenite (CoOOH) deposits are the most abundant Co ore in the Katanga Copperbelt (DRCongo), which hosts world-class Co deposits accounting for ~50% of the world's reserves [1]. Most of the heterogenite deposits occur in the upper oxidized zone of the primary deposits, and were formed during a Mio-Pliocene major uplift and weathering episode [2]. However, U-rich heterogenite, present in deeper zones of several deposits, may have a different origin and age.

Assuming that U in this heterogenite is in the UO_2 form, we attempted to obtain *in situ* U-Pb ages for heterogenite samples from Shinkolobwe, using a Cameca IMS 1270 ion microprobe, with settings comparable to those used for standard U-Pb age measurements on uraninite. These analyses yield two distinct Neoproterozoic ages, recorded by the upper intercept of the concordia lines: 680.9 ± 7.4 Ma and 823.2 ± 2.2 Ma. In both cases, the lower intercepts provide imprecise near-zero ages indicating recent (or continuous) Pb loss from the heterogenite.

At the present stage of knowledge, the 823 Ma date cannot easily be related to a known oxidizing event in the area. It is, however, reasonably close to the 816 ± 62 Ma Re-Os age obtained for Zambian primary sulfides [3]. The 681 Ma date could correspond to the Nguba karstification/weathering event described for the area [4]. If our age is meaningful, heterogenite could have formed in a period of superficial weathering, during the formation of the Katanga basin. This supergene event would, however, be contemporaneous with significant precipitation/reconcentration of uraninite, since the oldest uraninite age obtained for the Shinkolobwe deposits (at 652.3 ± 7.3 Ma) overlaps with ages for heterogenite in $^{207}Pb/^{206}Pb$ age density diagrams.

At this stage, the present study does not allow a full understanding of the timing and conditions of Co and U mineralization in Katanga. The results, however, indicate the importance of acquiring additional ages for heterogenite-uraninite deposits in order to understand the genesis of these giant Co-Cu-U ore deposits.

Chemical limits of trace elements in pyrite

ARTUR P. DEDITIUS[1], STEPHEN E. KESLER[2], MARTIN REICH[3,4], SATOSHI UTSUNOMIYA[5] AND RODNEY C. EWING[2]

[1]Institute of Appplied Geosciences, Graz University of Technology, Rechbauerstrasse 12, 8010 Graz, Austria
[2]Department of Geological Sciences, University of Michigan, 1100 N. University Ave., Ann Arbor, MI, USA
[3]Department of Geology, Universidad de Chile, Santiago, Chile
[4]Andean Geothermal Center of Excellence, Universidad de Chile, Santiago, Chile
[5]Department of Chemistry, Kyushu University, Hakozaki 6-10-1, Fukuoka-Shi, 812-8581, Japan

Pyrite in magmatic-hydrothermal settings contains significant concentrations of trace elements of economic and environmental importance, including Ag, As, Au, Bi, Cd, Co, Cu, Hg, Ni, Pb, Sb, Se, Te, Tl and Zn, which reflect the availability (solubility) of these elements in their parent hudrothermal solution. A review of our own and published analyses (including EMPA, SIMS, LA-ICP-MS, PIXE and HRTEM) of pyrite from Carlin-type, epithermal, and orogenic gold deposits reveals positive correlations for Sb-Pb-Bi, Au-Ag-Te, and Cu-Ag-Sb in all samples. Element-element ratios for most analyzed pyrites are: Au/Ag – 0.8-1.1, Au/Te – 0.8 to 1.0, Au/Sb – 0.7 to 1.1, Te/Pb – <1.1, Sb/Pb – 0.9-1.1, Sb/Cu – <1.0, Ag/Pb – 0.8-1.1, Bi/Pb – 1.0-0.7, and Bi/Sb – 0.7-1.1 in all types of deposits. Silver is enriched with respect to Te in low-T deposits, which have relatively high Ag/Te ratios of 1.0-1.2. Previous work has shown that As facilitates the incorporation of Au into pyrite via structural distortion and charge imbalance and that the Au content of pyrite is related to its As content such that the maximum Au content is $C_{Au} = 0.02C_{As} + 4 \cdot 10^{-5}$. Pyrite with Au-As contents above this maximum contain nano-inclusions of Au. These relations apply to epithermal and Carlin-type deposits, which form at relatively low temperatures. Au-As relations in pyrites from orogenic gold and skarn deposits, which form at higher temperatures, show similar relations but with smaller amounts of Au for any specfic As content, suggesting that the solubility of Au in pyrite (as a function of As) decreases with increasing temperature. Arsenic also appears to facilitate incorporation of Ag, Te, Sb, Bi and Hg into the pyrite structure in the same mode as for gold, although analyses are not sufficient to establish specific solubility limits. Samples with contents of these elements that exceed the apparent solubility limits contain nanoparticulate sulfides and sulfosalts in distorted, polycrystalline areas of pyrite.

Boron isotope systematics during magma-carbonate interaction

F.M. DEEGAN[1], E.M. JOLIS[1], V.R. TROLL[1,2], C. FREDA[2] AND M.J. WHITEHOUSE[3]

[3]Swedish Museum of Natural History, Stockholm, Sweden

Carbonate assimilation is increasingly recognised as an important process affecting the compositional evolution of magma and its inherent ability to erupt explosively due to release of carbonate-derived CO_2 [e.g., 1, 2, 3]. In order to gain insights into this process, we performed short time-scale carbonate dissolution experiments in silicate melt using natural starting materials from Merapi and Vesuvius volcanoes at magmatic pressure and temperature [1, 4]. The experiments enable us to resolve in detail the timescales, textures and chemical features of carbonate assimilation. Three compositionally distinct glass domains have been defined: i) Ca-normal glass, similar in composition to the starting material; ii) Ca-rich, contaminated glass; and iii) a diffusional glass interface between the Ca-normal and Ca-rich glass. Here we present new boron isotope data for the experimental products obtained by SIMS. The glasses show distinct and systematic variation in their $\delta^{11}B$ values. The contaminated regions generally show extremely negative $\delta^{11}B$ values (down to -41 ‰) relative to fresh arc volcanics (-7 to +7 ‰ [5]). Considering that carbonates have $\delta^{11}B$ values of +9 to +26 [6], the data can not be explained by simple mixing processes between the end-members alone. This implies that the $\delta^{11}B$ of the original contaminant was drastically modified before being incorporated into the melt, which can be explained by B isotope fractionation during early degassing of the carbonate. Our preliminary results are the first of their kind and provide well constrained insights into the behaviour of boron upon degassing of carbonate. This in turn has implications for both late stage contamination in dangerous volcanic systems and deep subduction zone processes, where B is frequently employed as a tracer of crustal recycling.

Alteration of nitrogen isotopic signatures during phytoplankton degradation

A. DEEK[1]* , M. F. LEHMANN[1] AND C. J. SCHUBERT[2]

[1]University of Basel, Insitute of Environmental Geosciences, Bernoullilstr. 30, CH-4056 Basel, Switzerland (*correspondence: astrid.deek@unibas.ch)
[2] Eawag, SURF, CH-6047 Kastanienbaum, Switzerland

Stable nitrogen isotope ratios in sediments are widely used in paleoenvironmental studies to reconstruct past biogeochemical conditions and processes in the water column. Previous investigations have revealed that both the decay of sinking particulate organic matter in the water column and early diagenesis of deposited organic matter within sediments are associated with significant bulk N isotope effects that can mask primary isotope signals.

To study the mechanisms that underly the alteration of N isotope signals by bacterial degradation, we conducted a series of oxic and anoxic incubation experiments that mimic the decay of organic matter in nature. We used closed system experiments containing defined algae/sediment mixtures (*Chlorella vulgaris*), suspended in oxic or anoxic water from Lake Lugano, and inoculated with a natural consortia of bacteria. In order to assess N isotope partitioning during simulated organic matter decay, we monitored the N-isotope changes in specific organic (amino acids, amino sugars) and inorganic compounds (NH_4^+, NO_3^-) in both the particulate and dissolved fractions.

We will present initial data in the light of organic compound selectivity, kinetic isotope fractionation associated with degradation of specific organic components, and the effect of bacterial biosynthesis on bulk N isotope composition during early diagenesis.

The Malayer plutonic rocks (48° 35'-48° 54' E and 34° 03'-34° 20' N) are located in Sanandaj-Sirjan zone. The plutonic rocks in this region were attributed to active continental margin, and subduction of Neotethys under Iraninan micro-continet. Based on field observations and petrographic studies, this region can be divided into three major parts: Granitic, Granodioritic and Gabrodioritic. The isotopic studies have been shown that initial Sr ratios range from 0.70797 to 0.71087, $\varepsilon_{Nd(t)}$ from -2.3 to -4.9 and T_{DM} from 955 to 1.33 Ga. The $^{87}Sr/^{86}Sr_{(i)}$ and $\varepsilon_{Nd(t)}$ of the Malayer rocks are consistent with lower crust and oceanic sediments signatures. All felsic and intermediate samples regardless of their ages have a negative $\varepsilon_{Nd(t)}$ values and plot close together in $\varepsilon_{Nd(t)}$ vs $^{87}Sr/^{86}Sr(i)$ diagram and mid-Proterozoic depleted-mantle model ages, which shows a genetic link between them. These isotopic signatures, coupled with the presence of inherited zircon with Proterozoic and Paleozoic ages, suggest that these rocks are the products of crustal melting and crust-mantle interaction during arc magmatism along the active margin of Iranian micro-continet in the Middle-Jurassic. U-Pb dating for this rocks yielded data between 162 Ma and 187 Ma (Middle-Jurassic). With respect to similar state in adjacent regions of MPC in SSZ, has been suggested that in Middle Jurassic had been occurred extreme plutonism. Based on different geochemical evidences such as discordant variation pattern for some major and trace elements between felsic to intermediate rocks and mafic rocks to enclaves and from mafic to felsic rocks, high potassium calk-alkaline character of granitc rocks, enrichment of LILEs in comparison with HFSEs, constant variation of compatible elements such as V, Ni, and Cr in the differentiated phases, negative anomaly of Nb and Ta, and En negative anomaly, the main processes in formation of granitic are magmatic differentiation associated with crustal contamination and with respect to equivalent age of granite and diorite that indicate the contemporaneity of the granitic and basaltic magmas, magma mingling or mixing for diorites and magmatic enclaves. Negative anomaly of Eu, non-concordant REEs variations, low enrichment of LREEs in mafic rocks imply to plagioclase differentiation due to partial melting process. These may indicate partial melting of ultramafic source as responsible for generating of mafic rocks.

Origin and isotope composition of the radium content in highly saline fluids

D. DEGERING* AND M. KÖHLER

VKTA Kernverfahrenstechnik und Analytik Dresden, P.O. Box 510119, D-01314 Dresden, Germany (*correspondence: detlev.degering@vkta.de)

The occurrence of highly saline fluids is characteristic for several facilities in deep geothermal energy. These brines contain inter alia enhanced contents of the radium isotopes ^{226}Ra, ^{228}Ra and ^{224}Ra. Activity concentrations up to 50 Bq l^{-1} were observed for geothermal systems in Germany. Radium isotopes are accumulated in scales of the $Ba/SrSO_4$ type resulting in specific activities > 500 $Bq{\cdot}g^{-1}$ [1]. Such levels of natural radioactivity demand for the application of radiation protection meausures in the plant.

This phenomenon is not only limited to hydrothermal systems. Deep waters from rock aquifers can show salinities > 100 $g{\cdot}l^{-1}$, thus enhanced geothermal system (EGS) plants may also be faced with this problem.

Otherwise, the concentrations and the isotope ratios of these three radium isotopes with quite different half-lifes in the order of days until 10^3 years allow conclusions about origin and transport characteristics of the geothermal brines.

A detailed investigation of the radium release at the rock/fluid interface is necessary for the description of the source term of radium isotopes in hydrothermal brines. The α-recoil during the decay of the thorium precursors in the decay chains ($^{230}Th \rightarrow ^{226}Ra$, $^{232}Th \rightarrow ^{228}Ra$, $^{228}Th \rightarrow ^{224}Ra$) is considered as the dominating process in comparison to selective solution. Based on a range calculation for the recoil nuclei by the SRIM code [2], a model was developed that predicts the concentration of each radium isotope in the fluid. The crucial parameters according to this model are the U/Th-contents of the source material and its specific surface.

The model was tested on the well investigated aquifer system of the deep geothermal plant at Neustadt-Glewe, Germany. A good agreement between modelling and analytical results was obtained.

The radium concentration can be predicted for any aquifer type if its composition and structure are sufficiently known. Otherwise, the model may serve as a tool for clarifying the source of saline waters in hardrock systems.

Correlations between Hf, O and trace element concentrations in zircon from rhyolitic rocks (NE German Basin)

E. DEJA[1]*, A. PIETRANIK[1], J. KIERCZAK[1], R. MILKE[2] AND C. BREITKREUZ[3]

[1]University of Wrocław, Institute of Geological Sciences, Poland; (elka_deja@yahoo.com)
[2]Freie Universität Berlin; (milke@zedat.fu-berlin.de)
[3]TU Bergakademie Freiberg, Germany; (cbreit@geo.tu-freiberg.de)

Hundreds of deep hydrocarbon exploration wells exposed the Late Paleozoic volcanic province in NE Germany, which covers the area 500 by 800 km^2 and comprises rhyolites (ca. 70%), andesites and basalts (ca. 30%) [1]. SHRIMP zircon emplacement ages of volcanic rocks in NE Germany range from 303 to 290 Ma with the major peak of the volcanic activity being 299 - 295 Ma [2,3].

The range of εHf and $\delta^{18}O$ values in these magmatic zircons in the three sites investigated have been modelled by simple assimilation - fractional crystallization processes of mantle derived magma contaminated by sediments with model ages of ca. 2.1 Ga.

Trace element composition of zircons do not correlate with the isotopic composition, but zircons from the least contaminated sample have different chemical characteristic to that of zircons from more contaminated samples. For example distribution of Hf is bimodal in the least contaminated sample, whereas Hf has intermediate values in the more contaminated ones. The implication is that the least contaminated sample contains zircons from various sources recording different stages of fractional crystallization, whereas more contaminated samples contain one population of zircons, probably crystallized from the surrounding magma.

Melts in the deep mantle: Insights from first principles molecular dynamics

NICO DE KOKER[1], LARS STIXRUDE[2] AND BIJAYA KARKI[3]

[1]Bayerisches Geoinstitut, Bayreuth, Germany, (nico.dekoker@uni-bayreuth.de)
[2]University College London, UK
[3]Louisiana State University, Baton Rouge, USA

As the primary medium through which planetary differentiation occurs, silicate melts are a key entity in the study of the thermal and chemical evolution of Earth. Over the past few years we have used first-principles molecular dynamics simulations to investigate the liquid state physics of the magnesio-, calsio- and aluminosilicate melts at pressure and temperature conditions relevant to the entire mantle. First-principles methods characterize bonding directly in terms of the electronic charge density computed via density functional theory, and is equally robust at ambient and extreme pressure and temperature conditions. This allows accurate predictions of the physics of melts at extreme conditions to be made.

Liquid state diffusion and thermodynamics have been investigated in detail, with special attention to dependence on pressure, temperature and composition. Comparison to corresponding changes in liquid structure enables us to understand thermodynamic and diffusive behavior in a detailed atomistic context. Our results provide a rigorous test for a new fundamental thermodynamic relation for melts, which we derived to accurately describe liquid state thermodynamics. The relation is unique in that it accounts for electronic free energy contributions and displays the correct limiting behavior at extreme volume and temperature, capturing the thermodynamics of liquid-vapor coexistence.

Our work has allowed for deeper insight into the evolution of terrestrial planets, including the thermal state and mode of crystallization of magma oceans, the possible presence of melt in the deep earth, and their relative buoyancy. This insight in turn acts as a guide for questions to be addressed in the future, as first-principles simulations of systems of larger numbers of atoms and complex chemical compositions representative of natural systems become feasible.

Ab initio study on lattice thermal conductivity of minerals

HARUHIKO DEKURA[1]*, TAKU TSUCHIYA[2] AND JUN TSUCHIYA[1]

[1]Senior Research Fellow Center, Ehime University, 2-5 Bunkyo-cho, Matsuyama, Ehime 790-8577, Japan (*correspondence: dekura@sci.ehime-u.ac.jp)
[2]Geodynamics Research Center, Ehime University, 2-5 Bunkyo-cho, Matsuyama, Ehime 790-8577, Japan

Thermal transport property of materials under pressure and temperature is of importance for understanding the dynamics of the solid Earth and the thermal history. However, both experimental and theoretical determinations of the thermal conductivity still remain technically challenging particularly at the deep mantle condition.

Recent progress in *ab initio* computational method based on the density functional theory (DFT) is making it possible to examine the transport phenomena including the lattice thermal conduction. The intrinsic bulk thermal conduction of insulator is essentially caused by lattice anharmonicity owing to phonon-phonon interaction. Determination of the anharmonic coupling constant is therefore the key to predicting the thermal transport property. Earlier theoretical works calculated the lattice thermal conductivity of MgO with *ab initio* molecular dynamics (MD) simulation or direct evaluation of the anharmonic force constants [1,2]. However, in these approaches, the simulation cell size could often be insufficient for accurate description of the long wavelength phonon scattering. As an alternative approach, the anharmonic coupling strength between phonon modes can be more efficiently and more accurately evaluated within the density functional perturbation theory (DFPT). In this approach, the higher-order force tensors are calculated based on the perturbative scheme taking care only of the primitive cell. We developed a technique for calculation of the phonon linewidh to obtain the phonon lifetime. Then the lattice thermal conductivity is evaluated combining with additional harmonic-level properties. In this presentation, we show the decay process of phonons and the lattice thermal conductivity of MgO and some typical minerals as a test for the applicability of our technique.

Modelling of long-term diffusion-reaction in the Callovo-Oxfordian clay for radioactive waste confinement

M. DELALANDE[1], B. FRITZ[1], A. CLEMENT[1] AND N. MICHAU[2]

[1]LHYGES, Université de Strasbourg/EOST, CNRS, France (correspondence: delalande@unistra.fr)
[2]ANDRA, 1/7 rue Jean Monnet, F-92298 Châtenay-Malabry Cedex, France (nicolas.michau@andra.fr)

One of the French options for the final disposal of high-level radioactive waste is a deep geological repository into the Callovo-Oxfordian formation (COX, Haute-Marne, Meuse, France). In this concept, COX clay associated with compacted bentonite, or not, may constitute the barrier system. In such systems, the interactions between groundwater and clays, as well as between the corrosion products of steel overpacks and clays under the influence of temperature elevation, may modify the chemical and physical properties of the selected clay buffers. Clay material has a low permeability, and consequently molecular diffusion is the main mechanism of mass transport in a clay barrier. The system is modeled in reducing conditions using the KIRMAT code (KInetic Reactions and MAss Transport). The software has been developed [1] from the single-reaction path model KINDIS [2] generated from the purely thermodynamic code DISSOL [3, 4].

This study is focused on the possible feedback effects of geochemical reactions on the transport properties (porosity and diffusion) of COX clay. The results of modeling obtained after 10,000 years of simulated mass transport-reaction are compared to the previous studies on an engineer pure bentonite barrier [5, 6, 7, 8, 9]. The mineralogical modifications of clays in contact with the geological interacting fluid, and with Fe^{2+} and OH^- ions provided by the corrosion of the steel overpacks as well as the evolution of porosity and molecular diffusion will be discussed.

Mediterranean sapropel formation; Preservation and palaeoceanography

GERT J. DE LANGE[1], C. SLOMP[1], D. CRUDELI[2], C. CORSELLI[2], M. SPERANZA PRINCIPATO[3], ELISABETTA ERBA[3], J. THOMSON[4,] AND A. REITZ[5]

[1]Geosciences-Utrecht, NL; (gdelange@geo.uu.nl)
[2]University bicocca Milano, IT
[3]Universita degli Studi di Milano, IT

Precession-related deposition of eastern Mediterraneran sapropels are associated with humid climate conditions. The last of such 'humid periods' occurred from 10.4 to 5.7 kyr ^{14}C ago, simultaneous with the sustained wet period in the circum Mediterranean area. The end of this humid period coincides with a high peak of MnO_2. This peak in all 30 studied cores occurs in response to a relatively abrupt re-ventilation event at 5.7 kyr. Subsequently, oxygen continued to progressively move downward into the sapropel sediment thus removing organic C.and organic biomarkers. Such removal mechanism seriously affects the traditional interpretation based on palaeoproxies.

From a detailed study of the mechanisms of formation of sapropel S1 across the eastern Mediterranean basin as a function of time and water depth, we demonstrate that surface waters had a reduced salinity and concomitantly that the deep (> 1.8 km) eastern Mediterranean Sea was devoid of oxygen during 4,000 years of S1 formation. This has resulted in a differential basin-wide preservation of S1 determined by water depth, as a result of different ventilation/climate-related redox conditions above and below 1.8 km. Climate-induced stratification of the ocean may thus contribute to enhanced preservation of organic matter, ie to formation of sapropels (and potentially black shales)

Production flux of sea-spray aerosol

GERRIT DE LEEUW[1,2,3], EDGAR L ANDREAS[4], MAGDALENA D. ANGUELOVA[5], C. W. FAIRALL[6], ERNIE R. LEWIS[7], COLIN O'DOWD[8], MICHAEL SCHULZ[9] AND STEPHEN E. SCHWARTZ[7]

Knowledge of the size- and composition-dependent production flux of primary sea-spray aerosol (SSA) particles and its dependence on environmental variables is required for modeling cloud microphysical properties and aerosol radiative influences, interpreting measurements of particulate matter in coastal areas and its relation to air quality, and evaluating rates of uptake and reactions of gases in sea-spray drops. The current status of the knowledge on the primary SSA production flux, mainly for particles with r_{80} (equilibrium radius at 80% relative humidity) less than 1 μm, has recently been reviewed by de Leeuw et al. (2011). These authors discussed the production of sea-spray particles and its dependence on controlling factors which have been investigated in laboratory studies that have examined the dependences on water temperature, salinity, and the presence of organics, and in field measurements with micrometeorological techniques that use newly developed fast optical particle sizers. Extensive measurements show that water-insoluble organic matter contributes substantially to the composition of SSA particles with r_{80} < 0.25 μm and in locations with high biological activity can be the dominant constituent. Order-of-magnitude variation remains in estimates of the size-dependent production flux per white area, the quantity central to formulations of the production flux based on the whitecap method. This variation indicates that the production flux may depend on quantities, such as the volume flux of air bubbles to the surface, that are not accounted for in current models. Variation in estimates of the whitecap fraction as a function of wind speed contributes additional, comparable uncertainty to production flux estimates.

de Leeuw et al. (2011) conclude that despite the many gains in understanding in recent years, the uncertainty in the SSA production flux remains sufficiently great that present knowledge of this quantity cannot usefully constrain the representation of emissions of SSA in chemical transport models or climate models that include aerosols. As a consequence it is not yet possible to improve the modeling of these emissions much beyond the current state of affairs which shows nearly two orders of magnitude spread in current estimates of global annual SSA emissions.

On the morphology and chemistry of (micro)fossils: Matches, mismatches and kerogen formation

JAN W. DE LEEUW[1,2]

[1]NIOZ Royal Netherlands Institute for Sea Research, P.O. Box 59, 1790 AB Den Burg-Texel, The Netherlands. (jan.de.leeuw@nioz.nl)

[2]Utrecht University, Depts of Earth Sciences and Biology, Budapestlaan 4, 3584 CD Utrecht, The Netherlands.

The far greater part of organic matter on Earth is present in sediments and consists of high molecular weight, insoluble constituents collectively known as kerogen. To improve our understanding of the origin, chemistry and fate of this kerogen, morphologically well preserved organic (micro)fossils and their extant counterparts are studied assuming that the preservation of such fossils is a consequence of the resistance towards (bio)degradation of the organic constituents they are made of.

Many investigations of well-preserved (micro)fossils and laboratory experiments with their extant counterparts using pyrolytic, chemical and spectroscopic analytical approaches do indeed indicate that biopolymers such as algaenan in algae, cutan in plant cuticles and lignin in wood are resistent towards diagenesis and may thus be responsible for excellent fossil preservation.

However, this “match” of preserved biochemistry and morphology is not always encountered. In many well-preserved fossil algal cells and plant cuticles and their extant counterparts these resistant biomacromolecules, algaenan and cutan resp., are completely absent. Recent studies seem to indicate that the excellent preservation of such fossils is due to a gradual replacement of originally present labile bio(macro)molecules by newly formed highly resistant geomacromolecules without significant morphological changes, a “mismatch” between biochemistry and morphology. In particular studies of sporopollenin in extant and fossil macro- and microspores indicate that pre- or post depositional exposure of organic entities to oxygen triggers oxidative cross linking of “nearby” low molecular weight (poly)unsaturated membrane lipids resulting in resistant, mainly aliphatic geopolymers partly or completely replacing the original biopolymers.

This kind of (micro)fossil studies is crucial to unravel the molecular structure of kerogen and, consequently, to understand the molecular chemistry of fossil fuel genesis.

Origin of karstic dissolution voids in Jurassic shallow marine carbonates at SW of Ankara, (Turkey)

ARIF DELIKAN AND HÜKMÜ ORHAN

Selçuk Üniv. Müh. Mim. Fak. Jeoloji Müh. Bölümü Konya, Türkiye (adeli@selcuk.edu.tr, horhan@selcuk.edu.tr)

Jurassic rocks cropping out at the southwest of Ankara (Turkey) rest unconformably on the basement rocks commonly as microbial deposits but also as detrital sediments. Karstification occurs in shallow marine biomicrite bearing sponge spicules as well as in microbial carbonates. Most of the cavities in the carbonates developed when they were carried to subaerial conditions as a result of sea level changes and, also by tectonic activities. Karstic voids are irregular in shape and disconnected. Their fillings are initiated with more than one crystallization phase of low-magnesian calcite with different colors [1]. Following this coating crystallization phase, the remaining voids were filled by different type of sediments. These infilling sediments are generally laminated, pink, or in different color.

They are vadose silts in varying size, but in some cases, comprises grains derived from host rocks. Compared to others, some karstic cavities are large. They were interpreted as being formed following fracturings in relation with tectonic activities. These cavities commonly were filled by marine sediments. Being coated by calcite crystals implies that these cavities were inundated by marine water having adequate condition for calcite crystallization before filling by marine sediments. Lamination of fine filling sediments is commonly parallel to the parent rocks. But fillings of cavities in a 12 cm thick layer have laminated sets which are neither parallel to each other nor to the bedding of parent rocks. This shows that the basement of the basin was not stabile and, was tilted differently in time.

Potentiality and limits of applying DSC and TG to complex systems: Direct and indirect information

MARIA TERESA DELL'ABATE

CRA-RPS, Via della Navicella 2, 00184 Rome, Italy (mariateresa.dellabate@entecra.it)

The relationships between agriculture and environmental quality find a key issue in the study of the processes enhancing organic matter stability in soil, in order to increase C sink and mitigate the effects of global change. Various and different approaches are possible, due to the complexity and heterogeneity of the soil system where SOM chemical composition and its architecture are widely interdependent within the soil matrix. In recent years the application of thermal analysis to the study of soil organic matter has found a renewed interest, mainly due to the possibility to obtain quantitative estimation of organic matter within the soil mineral matrix, possibly without chemical extraction. In addition, the dynamic measure conditions obtained through the thermal scans give the theoretical possibility to deduce the kinetics of the thermally induced processes. Different patterns of thermal stability are shown by different biomasses, compost or soils. However, it could be misleading to assimilate the time based output of DSC and TG measures to the kinetics of the processes occurring in soil, thus the concepts of organic matter stability or lability or recalcitrance needs to be better defined according to appropriate definition of the reference context.

In the presentation, the comparison between information obtainable from compost or soil analysis will help us to highlight potentiality and limits in applying DSC and TG to complex systems in order to move from a qualitative approach to a better definition of thermal and biochemical stability indexes. Finally, an open question should be discussed: can we forecast or imagine to include information on thermal behaviour of SOM within an ecological approach to the soil system?

Sorption of metals on a novel synthesized Mn (oxy)hydroxide

L. DELLA PUPPA[1], M. KOMÁREK[2] AND F. BORDAS[1]

[1]Faculté des Sciences et Techniques, Université de Limoges, 123 Avenue Albert Thomas, 87060 Limoges Cedex, France (loic.della@etu.unilim.fr)

Novel synthetic manganese (oxy)hydroxide

A novel synthetic manganese (oxy)hydroxide is synthetized using the modified protocol of Ching *et al*. [1], wich is commonly used for the preparation of birnessite. This (oxy)hydroxide is studied as a possible chemical stabilizing agent for metals in contaminated soils. Its stability in deionized water and the sorption of Cu and Pb are studied.

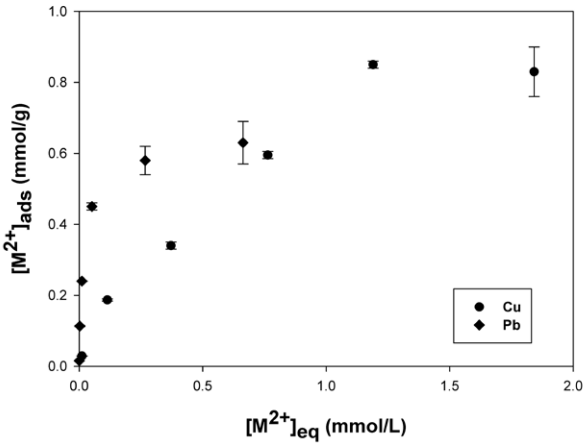

Figure 1: Adsorption isotherms of Cu and Pb on the Mn (oxy)hydroxide at pH 4

Results

The dissolution of the Mn (oxy)hydroxide in water reaches 12 and 1 mmol/g for solid/liquid ratios of 1/500 and 1/10, respectively and indicates that the phase could be fairly stable in soils. The Langmuir isotherm parameters calculated show that the maximum adsorbed quantity of Cu and Pb reach 1.3 and 0.6 mmol/g. The sorption parameters of the Mn (oxy)hydroxide were compared to those of birnessite at pH 4, which reached 1.1 and 1.4 mmol/g for Cu and Pb, respectively. Birnessite thus adsorb better Pb than the synthesized phase, but for praticial use as a chemical stabilizant, our Mn (oxy)hydroxide could be promising due to its easy synthetisation.

Impact of authigenic particles on phosphate and trace metal budgets of anoxic basins

O. DELLWIG[1], T. LEIPE[1], C. MÄRZ[2], M. GLOCKZIN[1], K. HÄUSLER[1], M. MOROS[1], F. POLLEHNE[1], B. SCHNETGER[3], M.E. BÖTTCHER[1] AND H.-J. BRUMSACK[3]

[1]Leibniz Institute for Baltic Sea Research, Rostock, Germany, (olaf.dellwig@io-warnemuende.de)
[2]Newcastle University, Newcastle upon Tyne, UK
[3]Institute for Chemistry and Biology of the Marine Environment, University of Oldenburg, Germany

Intense element cycling causes steep gradient of nutrients and redox-sensitive trace metals at pelagic redoxclines; the transition zone separating oxygenated surface waters from sulphidic bottom waters. Besides well-known Mn-oxides, SEM-EDX inspection of authigenic particles from the redoxcline of the Black and Baltic Seas evidence existence of postulated Fe-phosphates as well as mixed phases comprising Mn, Fe, and P as a new solid species (Mn-Fe-P shuttle). Throughout the redoxcline, these minerals show a general succession with maximum abundance of Mn-oxides above the redoxcline followed by mixed phases and almost pure Fe-phosphates within and below the redoxcline. Morphological similarities and molar Fe/P ratios suggest the formation of irregular Fe-oxyhydroxo coatings on sinking MnO_x particles followed by immediate adsorption of phosphate. Despite oxidation by O_2, batch-type experiments using biogenic Mn-oxides demonstrate the efficient potential of Fe^{2+} oxidation by sinking MnO_x particles. When entering sulfidic waters MnO_x is further reduced, thus causing an increasing relative abundance of Fe-phosphate.We suggest a conceptual model for the Mn-Fe-P shuttle at pelagic redoxclines, which affects phosphate transport throughout the water column and thus impacts primary production at least over longer time scales. This Mn-Fe-P-shuttle likely played an important role for the cycling of P in ancient ocean basins, e.g., during certain periods of Cretaceous black shale formation and should be considered in future modelling approaches dealing with stratified ecosystems. Furthermore, this shuttle influences the cycles of certain trace metals via scavenging. High-resolution determination of trace metals in sapropelic sediments from the Gotland Basin (Baltic Sea) will be compared with the elemental composition of authigenic particles from the water column in order to assess preferential enrichments in the sedimentary record.

Li content and isotopic distributions in granulite of Kerguelen plateau

E. DELOULE[1], J. INGRIN[2], Q.-K. XIA[3] AND M. GRÉGOIRE[4]

[1]CRPG-CNRS, BP20, 54500 Vandoeuvre les Nancy, France. (deloule@crpg.cnrs-nancy.fr)
[2] UMR CNRS 8207, Univ. Lille 1, 59655 Villeneuve d'Ascq, France. (jannick.ingrin@univ-lille1.fr)
[3]CAS Key Lab. of crust-mantle materials and environment, USTC, 230026, Hefei, China. (qkxia@ustc.edu.cn)
[4]GET, UMR CNRS 5563, OMP, Univ. Toulouse III, 31400, Toulouse, France. (gregoire@get.obs-mip.fr)

Kerguelen basalts contain abundant mantle xenoliths, including mantle peridotites and deep magmatic segregates equilibrated in the granulite facies [1]. Lithium chemical and isotopic distribution were measured in two-pyroxene granulites, in order to define their signature and describe the Li behavior during the lower crust formation processes. Li content and isotopic composition were measured in using the Cameca IMS 1270 Ion probe at CRPG, with reference Cpx and Opx with compositions close from those of the samples.

The studied xenoliths display close mineralogical compositions, bearing Mg81-92 Al-diopside, Mg-78-93 enstatite and labradorite or bytownite. Spinel and garnet are observed in 2 of them, and they all are type II xenoliths [1,2]. On the whole rock scale the Li contents range from 1,5 up to 9 ppm, with Li content decreasing from Cpx to Opx with a ratio Opx/Cpx of 0.8-0.9 and a ratio Plag/Cpx of 0.2-1. At the grain scale, Li displays a homogeneous distribution, at the exception of depleted or enriched Cpx rims. Only the more Li depleted sample display heterogeneous Li distribution in both Cpx and Opx.

The δ^7Li values measured on Cpx and Opx range between +4 and +14, with most of the values between +5 and +8. The cpx depleted or enriched rims display δ^7Li values associated to Li diffusion. Only the Li poor xenolith display δ^7Li values scattered on a large range, from -9 to +14. A general observation is that Cpx display rather slightly higher δ^7Li values than Opx, and those values are more scattered in Opx than in Cpx. The δ^7Li values for Plag are in progress and will be presented, but could not affect a lot the Li isotope budget, are most of Li is beard by Opx and Cpx.

The bulk value for these granulite samples is in agreement with a direct derivation from the mantle (5-8 ppm, δ^7Li≈+5). But their Li content is lower than expected for the lower continental crust [3], suggesting that Li in the lower continental crust is not mainly derived from the mantle.

[4]INRA, UR 135 Agropedoclimat Zone Caraibe Environm & Agro, Petit Bourg, Guadeloupe

The weathering of continental silicate rocks influences global climate by consuming atmospheric CO_2. Magnesium and Si stable isotopes are used as weathering proxies in soils and rivers, but the impact of the mineralogy of secondary phases on isotope fractionation remains unexplored so far. Here, we investigate variations in δ^{26}Mg vs. DSM-3 and δ^{30}Si vs. NBS28 in bulk soils and clay fractions relative to their parental andesite in two soil weathering sequences (Guadeloupe) that were formed in contrasting climatic conditions. The Western slope of La Soufrière volcano (dry conditions) presents a soil sequence Andosol - Cambisol - Vertisol with formation of smectite, whereas the Eastern slope (high rainfall) presents Andosol - Nitisol - Ferralsol with formation of kaolinite.

For Mg isotopes, clay fractions (δ^{26}Mg -0.41 to -0.10‰) were isotopically heavier than the andesite (δ^{26}Mg -0.47‰), supporting a preferential incorporation of heavy Mg isotopes in secondary Mg-bearing clay minerals. The clay fractions on the Eastern slope were progressively heavier with increasing weathering degree, -in contrast to the Western slope were clay fractions were progressively lighter with increasing weathering degree and with increasing exchangeable Mg associated with smectite. For Si isotopes, clay fractions were lighter than the parental material, and progressively lighter with increasing weathering degree. More importantly, larger Si isotope fractionation was associated with the formation of kaolinite (δ^{30}Si -1.95 to -1.32‰) than with the formation of smectite (δ^{30}Si -1.05 to -0.94‰) relative to the parental andesite (δ^{30}Si -0.37‰). Our results highlight that a similar parental andesite exposed to different climatic conditions can generate contrasting Mg and Si isotope fractionations in secondary phases, which offers great potential for paleo-reconstruction of soil environments.

Impact of reductants on the optical properties of Humic Substances (HS)

ROSSANA DEL VECCHIO*[,1,2] LYNNE HEIGHTON[1], KELLI GOLANOSKI[1] AND NEIL V. BLOUGH[1]

[1]Department of Chemistry and Biochemistry University of Maryland, College Park, MD United States
[2]Earth System Science Interdisciplinary Center, University of Maryland, College Park, MD United States (*correspondence:rossdv@umd.edu)

Our previous results have shown that the reduction with sodium borohydride of Suwannee River humic and fulvic acids, a commercial lignin, and a series of solid phase C18 extracts from fresh, estuarine, coastal and offshore waters of the middle Atlantic bight produces a preferential loss of long wavelength (visible) absorption and enhanced, blue-shifted emission [1]. These results are consistent with and interpreted within a previously proposed charge transfer model [2, 3]. Here we extend this work to other reducing agents (such as cyanoborohydride and sodium dithionite) and other humic substances (from aquatic and soil environments) to investigate the impact of other reductants on the optical properties of humic substances and attempt to assess the relative importance of quinones and ketones to the optical properties of these materials. Preliminary results indicate that a) borohydride reduces all HS examined independent of their source as determined by UV/Vis and fluorescence; b) cyanoborohydride did not reduce any of the HS examined to a significant extent; c) dithionite appears to reduce HS but to a much smaller extent that borohydride. Ongoing work aims to extend this work to more HS and model quinones/ketones and to quantify the loss of absorption with respect to dithionite consumed.

δ^{30}Si and Ge/Si changes in BIFs along the Archaean

C. DELVIGNE*[1,2], D. CARDINAL[2,3], A. HOFMANN[4] AND L. ANDRÉ[1,2]

[1]Department of Earth Sciences and Environment, Université Libre de Bruxelles, Brussels, Belgium (*correspondance: cdelvign@ulb.ac.be)
[2]Department of Geology and Mineralogy, Royal Museum of Central Africa, Tervuren, Belgium
[3]LOCEAN, University Pierre and Marie Curie, Paris, France
[4]Department of Geology, University of Johannesburg, South Africa

The Precambrian ocean underwent a long-term cooling as inferred by oxygen isotopes and recently corroborated by an increase in δ^{30}Si values [1]. However, this was questioned because both primary and secondary cherts were considered. To get new insights to the Archaean ocean evolution, we coupled δ^{30}Si and Ge/Si ratios in Banded Iron Formations (BIFs) spanning a large time scale (from 3.8 to 2.46Ga). Trends in Si-rich mesobands of BIFs confirm an increase of δ^{30}Si values from ~-2.1‰ (3.8Ga, [2]) to ~-1.1‰ (2.46Ga) with a simultaneous decrease in Ge/Si ratios from ~29.1μmol/mol (3.8Ga, [3]) to 2.7μmol/mol (2.46Ga). We suggest they both reflect a decrease of high-T hydrothermal inputs to oceans through time. As high-T hydrothermal fluids display high Ge/Si ratios, a decrease in hydrothermal inputs would lower the oceanic Ge/Si ratio as well as it would have contributed to cool the ocean. The maintenance of an Early Archaean high-T ocean would prevent significant direct silica precipitation from the ocean and its gradual cooling would have facilitated direct silica-rich precipitation that may have led the oceans towards heavier δ^{30}Si signatures.

A warming-cooling cycle between 3.8 and 3.2 ky BP: Correlations of speleothem and bivalve compositions with ice core records

A. DEMÉNY[1]*, G. SCHÖLL-BARNA[1], Z. SIKLÓSY[1], G. SERLEGI[2], P. SÜMEGI[3] AND M. BONDÁR[2]

[1]Institute for Geochemical Research, Hungarian Academy of Sciences, H-1112 Budaörsi út 45, Hungary (*correspondence: demeny@geochem.hu)
[2]Archaeological Institute, Hungarian Academy of Sciences, H-1014 Budapest, Úri str 49, Hungary
[3]Department of Geology and Paleontology, University of Szeged, H-6722 Szeged, Egyetem str 2, Hungary

Climate conditions during the Holocene were relatively stable compared to the entire Quaternary, so that only minor fluctuations are detectable – for example – in the stable isotope records of ice cores. On the other hand, climate fluctuation events have been detected in Europe by geological and geochemical records interpreted to reflect temperature and/or humidity changes, sometimes in contradiction with each other. In this study freshwater bivalve shells (*Unio* sp.) were collected from Bronze age archaeological excavations around Lake Balaton (Central-Western Hungary) spanning the period of about 3 to 4 ky BP and their stable C and O isotope compositions were measured in order to investigate lake evolution processes in this period of time. The data indicate warmer/dryer conditions around 3.7 ky BP, bracketed by relatively cooler and/or wetter environments. These observations seemed to be in contradiction with earlier results that lead us to compare the geochemical data from bivalve shells with speleothem records of the region as well as with the GISP2 ice core oxygen isotope data. H, C and O isotope compositions and trace element data (e.g., Mg/Sr ratios, P concentrations) in stalagmites can be correlated with the bivalve shell data, indicating warming around 3.8-3.6 ky BP associated with lower humidity during summer (elevated winter/summer precipitation ratio), followed by an ~300 year long cool phase with summer-dominated precipitation. Good agreements between different paleoclimate records indicate that the warming-cooling events affected a large region from the North Atlantic at least to Central Europe. Temperature and humidity variations inferred from the data suggest that the North Atlantic Oscillation was a major governing factor in climate changes during the Bronze Age.

Structure and relative stability of hydrous and anhydrous Ca-Mg carbonates from first-principle calculations

R. DEMICHELIS*, P. RAITERI AND J. D. GALE

Department of Chemistry, Faculty of Science and Engineering, Curtin University, GPO Box U1987, Perth, WA 6845, Australia
(*correspondence: raffaella@ivec.org)

Calcium and magnesium carbonates play an important role in the chemistry of the hydrosphere, lithosphere, atmosphere and biosphere. From a technological point of view, the precipitation of carbonates in industrial and domestic environments represents a problem in terms of process efficiency and maintenance costs.

The crystallisation and growth mechanisms of these compounds, as well as their structure and relative stability, are still a matter for investigation. In particular, relatively little data is available for the hydrated phases, due to limited natural occurrence and low stability. However, they may well play a role during the crystallisation and growth mechanism of the anhydrous phases (included Ca-Mg carbonate solid solutions) and in CO_2 sequestration, especially at low temperature [1-5]. Information regarding the formation of mixed calcium-magnesium carbonates is also pertinent to understanding the dolomite problem.

A comprehensive *ab initio* structural and thermodynamic study of calcium-magnesium carbonates and their hydrates will be presented. The good agreement between calculated and available experimental data attests to the validity of the applied computational approaches, namely Density Functional Theory in the present study.

Nucleation of amorphous calcium carbonate: A combined theoretical and experimental perspective

R. DEMICHELIS[1], P. RAITERI[1]*, J. D. GALE[1], D. GEBAUER[2] AND D. QUIGLEY[3]

[1]Nanochemistry Research Institute, Department of Chemistry, Curtin University, PO Box U1987, Perth, WA 6845, Australia. (*correspondence: p.raiteri@curtin.edu.au)

[3]Department of Physics and Centre for Scientific Computing, University of Warwick, Gibbet Hill Road, Coventry CV4 7AL, UK

The nature of the nucleation of amorphous calcium carbonate is examined in the light of both recent experimental [1,2] and theoretical [3] results. While experiment demonstrates the existence of stable pre-nucleation clusters, followed by a nucleation event, computer simulations suggest that the free energy of adding ion pairs to amorphous calcium carbonate is exothermic regardless of size, which may indicate the absence of a barrier. How these two different sets of observations can be reconciled will be examined in this work through the use of molecular dynamics simulations of pre-nucleation calcium carbonate solutions.

In this presentation we will explore the use of computer simulation methods to try to unravel the complexities of the nucleation and growth processes for calcium carbonate. Central to this is the development of a force field that is accurately calibrated against experimental free energies [3] since failure to do so can result in qualitative errors for interfacial properties. Based on this we have explored the stability of ACC versus crystalline nanoparticles while accounting for the variable water content in the amorphous structure [4]. In the light of this, and new experimental results, we propose a model to explain the non-classical aspects of the nucleation mechanisms of calcium carbonate, the origins for which can be traced back to the interfacial properties.

S in CAMP and Paranà-Etendeka CFBs

A. DE MIN[1], S. CALLEGARO[2], D. BAKER[3] AND A MARZOLI[2]*

[1]Università di Trieste, Italy (*correspondence: demin@univ.trieste.it)
[2]Università di Padova, Italy (sara.callegaro@unipd.it; andrea.marzoli@unipd.it)
[3]McGill University, Canada (don.baker@mcgill.ca)

Synchrony of continental flood basalts (CFB) and significant Phanerozoic mass extinction events may suggest a trigger effect of large scale basaltic eruptions on the global climate and environment, mainly due to intense emissions of volcanic gases such as SO_2 and CO_2 [1]. However, this interpretation is based on poorly constrained gas contents of the basalts and on even less well known gas emission rates. Here we investigate the S content of basalts of two of the largest CFB provinces: the Central Atlantic magmatic province (CAMP) and the Paranà-Etendeka (PE). Notably, while the CAMP is synchronous with and possibly triggered the end-Triassic extinction [2], PE basalts had a very minor effect on the early Cretaceous biosphere [3].

Melt inclusions in CAMP basalt olivines yield S contents (electron microprobe analyses) comparable to those found in Deccan basalts [1], whereas S in matrix glass is close to detection limit, suggesting that degassing during the eruption was almost complete.

As an alternative approach, we measure S (and Cl) contents (synchrotrone analyses) also in phenocrysts from CAMP and PE basalts and extrapolate the magmatic S content through newly established crystal/melt partition coefficients. These results illuminate the difference which seem to exist between the two CFB provinces and contribute to our understanding of their different environmental impacts.

Mineral chemistry and fluid inclusion characteristics of the Kabadüz Ore Veins (Ordu, NE-Turkey)

Y. DEMIR[1], M.B. SADıKLAR[2], I. UYSAL[2], A. CERIANI[3], AND N. HANILÇI[4]

[1]Gümüşhane Uni., Dep. of Geol., Gümüşhane, Turkey, (ydemir78@hotmail.com)
[2]KTU, Dep. of Geol., 61000 Trabzon, Turkey
[3]Pavia Uni., Dep. of Geol., Pavia, Italy
[4]Istanbul Uni., Dep. of Geol., Istanbul, Turkey

Hydrothermal vein type deposits of Kabadüz region (Ordu, NE-Turkey), are located in the Upper Cretaceous andesitic-basaltic rocks and formed in fault zones of the NW-SE directions. The primary mineral paragenesis of the ore veins are composed of pyrite, chalcopyrite, sphalerite, galena and tetrahedrite-tennantite with quartz and lesser amount calcite and barite as a gangue mineral. Petrographical studies suggest that ore veins in the region have similar mineral paragenesis, succession and textural properties.

Pyrite contains up to 0.95 wt% Zn, and 0.60 wt% As, chalcopyrite contains up to 0.86 wt% Zn and 0.14 wt% Au. Sphalerite is poor in Fe and contains up to 0.35 wt% Mn, 2.18 wt% Cu, and 0.89 wt% Cd. Tetrahedrite and tennantite are also poor in Fe content (up to 1.56 wt%). Different phases from the each different veins are found to be similar in composition. Lower Ni and Co content of the pyrites and Zn/Cd ratio of the sphalerites suggest that hydrothermal solutions related to the acidic type magmatic activity.

Homogenisation temperature (Th) and salinity data vary between 180-436.1 ºC and, 0.4-14.7 % NaCl, at the fluid inclusions of sphalerite and quartz. On the basis of first melting temperatures, $CaCl_2$, $MgCl_2$ and $FeCl_2$ were dominant at the higher Th, whereas NaCl and KCI at the lower Th conditions. Salinity content of the inclusions imply that hydrothermal solutions related to the magmatic sources. On the other hand well defined positive correlation between Th and salinity indicate that meteoric water involved in the hydrothermal solutions. In addition to petrographical studies, mineral chemistry analyses and fluid inclusion properties indicate that ore veins in the region have occured same or similar ore formation conditions.

Water weakening in dunite: Highlights from torsion experiments

S. DEMOUCHY[1]*, L.N. HANSEN[2], M.E. ZIMMERMAN[2], A. TOMMASI[1], F. BAROU[1], D.L. KOHLSTEDT[2]

[1]Geoscience Montpellier, Université Montpellier 2 & CNRS, Montpellier 34095, France (*correspondence: sdemouchy@um2.fr).

[2]Dept. Geology and Geophysics, University of Minnesota, Minneapolis, MN 55455, USA.

We have performed torsional deformation experiments on pre-hydrogenated fined-grain olivine aggregates using an innovative assembly to estimate water-weakening in mantle rocks at high shear strains. San Carlos olivine powder was cold-pressed, then 45 μL of water was added, and the sample was subsequently hot-pressed at 1523 K and 300 MPa for 3 h, producing aggregates with average grain sizes of 7 or 15 microns. Deformation experiments were performed in a high-resolution gas-medium apparatus equipped with a torsional actuator under a confining pressure of 300 MPa, a temperature of 1473 K, and constant shear strain rates of 1.4 x 10^{-4} to 8 x 10^{-5} s^{-1}.

Peak shear stresses ranged from 150 MPa to 195 MPa, values slightly weaker than determined in previous torsion experiments on dry fined-grain dunites with equivalent grain sizes, shear strain rates, and finite strains. Textures and microstructures of the starting material and deformed specimens were fully characterized by scanning electron microscopy and by electron backscatter diffraction. All deformed aggregates show a shape preferred orientation marking a foliation and lineation, grain size reduction, and a well-developed olivine crystal preferred orientation consistent with deformation by dislocation creep with dominant activation of the (010)[100] slip system. The hydrogen concentration in olivine aggregates was determined with unpolarized Fourier transform infrared spectroscopy. Analyses of the spectra indicate that the hydrogen concentration of the olivine might be limited and show a potential contamination by water-rich inclusion or intergranular material. These torsion experiments on hydrogenated fined-grain dunite provide new insights into the water weakening phenomenon observed in various nominally anhydrous minerals.

A missing process in the Eastern margin of Tibetan Plateau from multi-system thermochronology and its implication for late Cretaceous tectonic change from the Paleo-Tethyan to Neo-Tethyan regime

BIN DENG[1] AND SHUGEN LIU[2]

[1]State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation in Sichuan Province,China (dengbin3000@163.com)

[2]State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation in Sichuan Province (lsg@cdut.edu.cn)

Due to be lack of structural and sedimentary records to constrain the Jurassic-to-Cretaceous evolution, a missing process was here in Eastern margin of Tibetan Plateau. Given that all radioisotopic systems are subject to disturbance and resetting at different temperatures, we can restore the cooling process or emplacement of rock using different minerals or radioisotopic systems, which we call multi-system thermo-chronology. Based on the analysis of 125 thermochronology ages (e.g., U/Pb, Ar/Ar, Rb/Sr, FT, U-Th/He) of igneous rocks from the eastern margin of Tibet in the Yidun Arc, Yadjiang Deprssion and Songpan-Garze Fold Belt, we reconstruct the emplacement process of different granites using the multisystem thermochronology approach, to decipher the process.

At mid-to-late Indosinian, the initial emplacement age and depth of granites distinctly decrease from north to south, followed by a long slow cooling process in mid-to-upper crust during Yanshanian indicating a long period of thermal stability and tectonic quiescence. Those reflect the control of Paleotethyan tectonic setting. Whereas, between early and late Cretaceous, there was widespread granite emplacement and uplift-related cooling on the eastern margin of Tibetan again, with the declining tendency of magmatic activity and tectogenesis from south to north due to far-field effects of Lhasa-Qiangtang collision. In addition, the granites in north do not have an obvious emplacement process. Which reflect the control of Neotethyan tectonic setting. Correspondingly, as a sedimentary respose to the change of tectonic regime, there is an obvious change on depositional contact in adjoint basins from Late Cretaceous to Neogene. That is from a southward decreasing angularity of the unconformity in early to a northward decreasing angularity in later. Thus, the eastern margin of Tibet is thought to have experienced an important late Cretaceous (about 100Ma) tectonic change from the Paleo-Tethyan regime to Neo-Tethyan regime.

The applications of x-ray fluorescence analysis in the resource assessment of Dashui Gold deposit in Gansu, China

HUI DENG[1], JIANGSU ZHANG[2], XIUHONG PENG[3,4]*, HAI YANG[3] AND CHENGSHI QING[3]

[1]State Key Lab. of Geohazard Prevention and Geoenvironment Protection, Chengdu University of Technology
[2]Third Geology and Mineral Resources Exploration Academy of Gansu Province, China (*correspondence:pengxhh@cdut.edu.cn)
[3]Geochemistry Dep., Chengdu Univ. of Technology China
[4]Key Lab. of Nuclear Techniques in Geosciences, China

X-ray Fluorescence Analysis Technique is fast, nondestructive and portable for measuring in the field. It has been widely used in ore exploration and prospect such as searching and delineating mineralization anomalies, and looking for concealed ore, etc.

Dashui Gold Deposit in Maqu, Gansu, which was found in west Qinling mountain area, is a type of gold deposits with unique mineralization. The mineralization intensity was closely related to the silicification and hematitization. Recent years because of mining of the gold deposit, the ore-prospecting results are descending with mineral resource crisis. Therefore applying the X-ray Fluorescence Analysis in Dashui Gold Deposit will serve for locating mineralization, dividing ore bearing strata and delineating the prospecting target area promptly.

On the basis of geochemical exploration and actual situation of the deposit, the representative 3530m, 3605m and 3645m middle sections of exploration line 72 of Dashui Gold Deposit were selected for measuring. The measuring device is CIT-3000SMP. The design spacing is 3m, and the measuring time is 120 seconds per point. Five limestone and six diorite porphyrite samples with chemical analysis results had been used to fit standard curves respectively, do multi-element measurement, delineate the beneficial occurrence areas of gold and quickly access the location and distributional pattern of the geochemical halos of the gold mine. The results indicate that:

The measuring results of Au, As, Cu, Fe, Mn, Sr, Zr, Mo, Sb, Ag and Zn, etc. are good, they all reflect the fluorescence anomaly. The anomalies of Au, Cu, As, Fe and so on appear obviously in the known ore bodies. They concomitantly appear with a high anomaly coincide degree. One first-grade prospective area (the anomaly contrast is more than 2.5 times) with excellent potential has been delineated. The width is 10-24m, and the controlling length is 250m. It is like the lens with a wilder bottom than the top, and the long axis is parallel to the existed ore body Au2.The second-grade prospective area (the anomaly contrast is from 1.5-2.5 times) with good potential is also lenticular. Its controlling width is about 10m. The length is 80m.

Effect of Carbon, Sulfur and Silicon on Iron melting at high pressure: Implications for composition and evolution of the terrestrial planet cores

L. DENG[1,2]*, Y. FEI[1], X. LIU[2] AND A. SHAHAR[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington, 5251 Broad Branch Road, NW, Washington, DC 20015, USA (*correspondence: ldeng@ciw.edu)
[2]The Key Laboratory of Orogenic Belts and Crustal Evolution, Ministry of Education of China; School of Earth and Space Sciences, Peking University, Beijing 100871, China

High-pressure Fe-S-C and Fe-S-Si-C melting experiments, with a reasonable abundance of carbon, sulfur and silicon in the terrestrial planet cores, have been conducted to investigate how melting relations and crystallization sequences change with pressure and bulk composition. The results were used to understand the composition and evolution of the terrestrial planet cores.

For $Fe_{84.69}C_{4.35}S_{7.85}$, the first crystallized phase is Fe_3C at 5 GPa and Fe_7C_3 at 10-20 GPa. For $Fe_{84.87}C_{2.08}S_{11.41}$, Fe_3C is the stable carbide at subsolidus temperature at 5-15 GPa. For $Fe_{86.36}C_{0.96}S_{10.31}$ and $Fe_{85.71}C_{0.33}S_{11.86}$, the first crystallized phase is metallic Fe instead of iron carbide at 5-10 GPa. It is observed that the cotectic curve between Fe and Fe_3C moves toward the iron-rich direction with pressure increasing from 5 to 10 GPa in the Fe-C-S system. If this tendency persists to the Earth's present pressure condition, only a small amount of carbon is needed to form an iron carbide solid inner core.

Experiments on $Fe_{82.95}C_{0.66}S_{13.7}Si_{2.89}$ show even a small amount of C significantly lowers the closure pressure of the miscibility gap. Given an Earth's core containing a significant amount of S and moderate Si and with small amount of C, no compositional stratification is expected for Earth's Fe-S-C-Si core, although it may occur during early melting events. It is observed that S preferentially partitions into molten iron while significant amount of Si enters the solid phase with temperature decrease. Meanwhile, the C concentration in the liquid and solid iron metal changes little with temperature variations. If S, C and Si partitioning behaviour between molten iron and solid iron metal with temperature are expected to be the same under Earth's present core pressure condition, the solid inner core should be iron dominated with dissolved Si. On the other hand, the liquid outer core will be S rich and Si poor. Moderate carbon will be evenly present in both solid and liquid iron metallic core.

Based on our melting data in a multi-component system, no layered liquid core should exist in Venus and Mars, because of their high core pressures. On the other hand, Mercury, which has an estimated CMB pressure of ~7 GPa, may have a layered liquid outer core due to immiscible liquids (one is S rich and one is Si rich) and a solid Fe-Si inner core.

Confocal Raman spectroscopic characteristic of pseudoleucite in alkaline intrusive rocks: Central Anatolia, Turkey

K. DENIZ* AND Y.K. KADIOGLU

Ankara Univ., Dept., of Geol., Eng., & YEBIM Ankara, Turkey (*correspondence: kdeniz@eng.ankara.edu.tr)

Pseudoleucite is one of the main mineral of the silica undersaturated rocks of alkaline rocks of Central Anatolian Crystalline Complex. The pseudoleucite comprises aggregates of K-feldspar and nepheline preserving orginal crystal forms of leucite. Confocal Raman spectroscopic studies reveal that the leucite has been replaced by disordered K-feldspar with a structural state intermediate between orthoclase and nepheline form in spheluritic texture under the microscope (Figure 1). The pseudoleucites are inferred to have grown of crystallization of leucite at high temperature and pressure then transformed to orthoclase with less amount of nepheline through reaction with sodium-rich fluids and PH_2O at low pressure and temperature in proportion to previous original formation of the leucite in the same system.

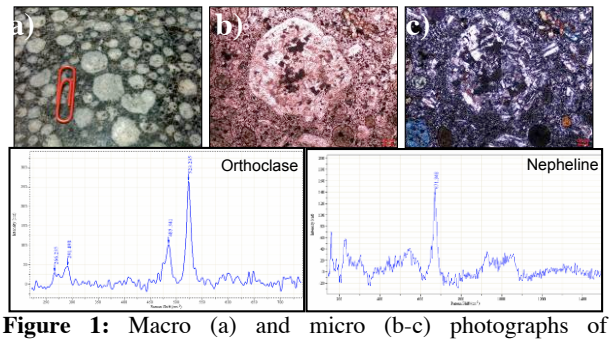

Figure 1: Macro (a) and micro (b-c) photographs of pseudoleucite and CR Spectrums of orthoclase and nepheline

Discussion and Results

Compositional zoning in primary and late-stage minerals indicates complex, multi-stage crystallization and replacement histories. Late stage fluids of alkaline magma, rich in F, Cl, CO_2 and H_2O, reacted with primary minerals to form complex intergrowths of minerals such as pseudoleucite, cancrinite, fluorite, V-bearing magnetite, F-bearing garnet and Na-augite. Early crystallization of apatite and titanite controlled the compatible behavior of P and Ti, respectively.

The formation of melanite and uvarovite garnet also affected the behavior of Ti, Cr as well as Zr, Hf and the heavy rare-earth elements in these rocks. The innovator crystalization of leucite, cause to intergrowths of K-feldspar and nepheline at the late stage of fractionation.

Global asssesments of linkages between air quality and climate

F. DENTENER

European Commission, Joint Research Center, Ispra, Italy. (frank.dentener@jrc.ec.europa.eu)

Aerosols are among the most important contributors to air quality problems, and are also active constituents of the climate system. Unfortunately, there are large scale differences between global climate models and urban-to-regional scale air quality models, which prevented consistent and extensive scientific analysis of air quality and climate impacts. In addition, since air pollution and greenhouse gas mitigation policies were often developed independently, a policy driver to the integrate these urban-to-global scales was missing. This situation is changing- global models are increasing resolution, and regional models are expanding model domains. Global model analysis are used for air quality analysis, and regional models are use for regional climate assessments. The co-benefits for air quality are increasingly important aspects of climate policies, while targetted air quality policies may help to prevent rapid climate change on the decadal time scales.

In this overview talk, I will present results from the international HTAP (Hemispheric Transport of Air Pollution) assessment, with a focus on the role of contintal transport versus 'local' emissions of aerosols and precursors, discuss re-analysis efforts to understand the interaction between changing climate and air quality in the past decades, and the describe the current understanding of the health and climate effects of these aerosols on the global scale. I further present the implications and insights derived from various air pollution/climate scenarios resulting from recent assessments (GEA, RCP, etc).

Influence of solute-solvent interactions on mass discrimination during chemical diffusion

D.J. DEPAOLO[1,2]*, J.M. WATKINS[2] AND F.J. RYERSON[3]

[1]Lawrence Berkeley National Lab, Berkeley, CA 94720, USA (*correspondence: depaolo@eps.berkeley.edu)
[2]University of California-Berkeley, Berkeley, CA 94720, USA
[3]Lawrence Livermore National Lab, Livermore, CA 94550, USA

Chemical diffusion in molten silicates and aqueous solutions leads to stable isotope variations in nature because chemical diffusivities are mass dependent. For diffusion in liquids, there is no general theory that relates cation diffusivity to mass, but mass discrimination during diffusion must be affected by the nature of cation-solvent interactions.

To investigate the relationship between liquid structure and cation diffusion, we measured Ca and Mg isotope diffusivities in silicate liquids using diffusion couples of natural and synthetic compositions. In all experiments, the initial isotopic composition is uniform and each isotope diffuses in the same direction down a substantial concentration gradient, enriching the Ca- or Mg-poor liquids in the lighter isotope by an amount dependent on: (1) the initial concentration contrast between liquids, (2) the relative chemical diffusivities of isotopes, and (3) the efficiency of isotopic exchange or self diffusion superimposed on chemical diffusion. Results from these experiments, in combination with results from natural volcanic liquids, show clearly that the efficiency of isotope separation (E) is systematically related to the solvent-normalized diffusivity - the ratio of the diffusivity of the cation (D_{cation}) to the diffusivity of silicon (D_{Si}).

We present an idealized quantitative model to explain the relationship between E and D_{cation}/D_{Si}. The model views cation diffusion as a combination of two (or possibly more) distinct mechanisms of transport: “free” cations that site-hop among aluminosilicate structures, and “bound” cations that translate or rotate with aluminosilicate structures in the melt. We assume that the rate of exchange between free and bound cations is infinitely fast to maintain local equilibrium. In this model, the observed or net diffusivity and its mass dependence are determined by the relative abundance (K) of free versus bound cations in the liquid. This conceptualization provides a framework for describing mass discrimination in complex liquid systems and for understanding the role of diffusion in contributing to stable isotope variations in minerals.

Bimodal volcanism of the Northern frames of the Eastern link of the Mongolian-Okhotsk orogenic belt (Russia)

INNA DERBEKO

Institute of Geology and Nature Management FEB RAS, Blagoveshchensk, Russia, (derbeko@mail.ru)

In the Southern frames of Eastern link of Mongol-Okhotsk orogenic belt (MOOB), in the end of early Cretaceous (119 - 97 Ma), a bimodal volcano-plutonic complex was formed. It correlated by a whole number of parameters with bimodal formations of the Western link of the belt [1]. The formations in the Northern frames of the Eastern link of MOOB, that are analogical by the age and petrochemical characteristics, are separated. There are insignificant differences in geochemical characteristics (Fig.1). There are also diversities by isotopic parameters $^{87}Sr/^{86}Sr$ =0.70592-0.70620, by $\varepsilon Nd_{(T)}$ = (-11.77) – (-12.20) and T_{Nd}(DM-2st)=1901-1937 Ma [2]. Along Southern and Northern borders of the Eastern flank of MOOB the bimodal volcano-plutonic complexes were formed during 119-97 Ma. Their geochemical characteristics show that they were formed in the situation of convergence borders of the platforms (collision of North-Asian and North-Chinese continents).

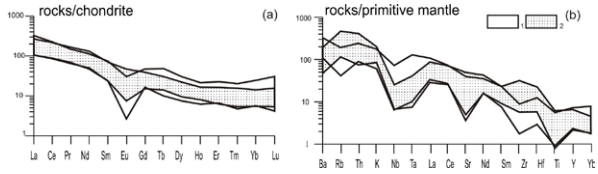

Figure 1: Geochemical characteristics of the rocks of the bimodal complexes framing MOOB: 1 – Northern, 2 – Southern. Concentrations of the rear elements in the Compositions of chondrite C1 and primitive mantel are brought according to the data (Sun, McDonough, 1989).

The insoluble organic matter in carbonaceous meteorites

S. DERENNE[1] AND F. ROBERT[2]

[1]BioEMCo, CNRS-UPMC, Paris, France (sylvie.derenne@upmc.fr)
[2]LEME, MNHN-CNRS, Paris, France (robert@mnhn.fr)

Carbonaceous meteorites are the most primitive objects of the solar system. They exhibit significant carbon contents mostly occuring as insoluble organic matter (IOM). IOM might be the first OM available on early Earth for life and should provide information on solar system history. It is therefore esential to decipher the chemical structure of IOM.

IOM was isolated from the Murchison meteorite using successive water and solvent extractions and acid treatments (HCl, HF). Its chemical structure was investigated through a combination of various spectroscopic methods (Fourier tranform infra-red, solid-state ^{13}C and ^{15}N NMR, electron paramagnetic resonance, X-ray absorption near-edge spectroscopy), chemical (RuO_4 oxidation) and thermal (pyrolysis) degradations and high resolution transmission electron microscopy. The use of these complementary analytical tools yielded key information on the IOM structure at a molecular level and led to 11 quantitative parameters. A statistical model was therefore proposed for this molecular structure, fitting with these 11 parameters.

Moreover, deuterium isotope abundance was determined in individual compounds released through RuO_4 oxidation and pyrolysis pointing to 3 types of H (aromatic, benzylic and aliphatic) with different D enrichment related to the C-H bond strength. This was further confirmed by laboratory experiments. We therefore propose that the IOM formed in a D-poor environment and was then transported and further enriched through exchange in a D-rich medium. EPR studies also revealed that free radicals were the hosts of extreme D enrichments revealed through nanoSIMS.

These results are difficult to reconcile with the usual interpretation according to which high D/H ratios represent survivals of interstellar grains. More likely, the deuterium-enrichment process took place after the formation of organic grains characterized by low D/H ratios, through an isotopic exchange-reaction with D-rich gaseous molecules, such as H_2D^+ or HD_2^+. This exchange reaction most likely took place in the diffuse outer regions of the protoplanetary disk around the young Sun.

Element transport and mineral replacement reactions during alkali contact metamorphism

I.T. DERREY*, M.A.W. MARKS AND G. MARKL

Eberhard Karls Universität Tübingen, Wilhelmstraße 56, 72072 Tübingen, Germany (*correspondence: insa-theresa.derrey@student.uni-tuebingen.de)

To study element transport in crustal rocks, high concentration gradients are favorable, as they are present along the margins of peralkaline rocks intruded into common crustal rocks. The 1.16 Ga peralkaline Ilímaussaq intrusion in SW-Greenland is characterized by its high alkali as well as high LILE, HFSE and volatile content. It intruded at the contact between the granitic Julianehåb batholith and a volcano-sedimentary succession [1].

We took 19 samples along a 1 km long profile from the contact of the Ilímaussaq intrusion into the adjacent granite. Accounting for the exponential character of diffusive processes, we chose a close spacing between samples near the contact with increasing distances further away from the intrusion.

Significant contact alteration, accompanied by growth of new minerals (aegirine, arfvedsonite) has been previously reported [2] and can be observed in the field up to a distance of 40 m away from the contact. This is confirmed by stable isotopic data of Li and B [3, 4], supporting diffusive alteration of the contact rocks.

Our whole rock analyses reveal an influence of the alkaline fluids released by the Ilímaussaq complex on the host granite up to ca. 200 m by elevated contents of e.g. Na, Ca and P as well as depletion in Si and K. In addition, batches of eutectic quartz-feldspar intergrowths in the granite up to ca. 10 m from the contact imply partial melting of the granite.

Among the mineral replacement reactions the growth of amphibole and pyroxene at the expense of biotite as well as the replacement of perthitic alkalifeldspar by almost pure albite are most obvious. To get a full insight on replacement reactions and changes in mineral chemistry along the profile, microprobe analyses will be carried out.

Reconciling multiple constraints on late Cenozoic erosion and weathering fluxes: Can we do it?

LOUIS A. DERRY

Dept. of Earth & Atmospheric Sciences, Cornell University, Ithaca NY USA 14853; (derry@cornell.edu)

Records of geochemical tracers in late Cenozoic marine sediments show large changes, the causes of which have been the subject of intense interest in the geoscience community. Intensive tracers include $^{87}Sr/^{86}Sr$, $^{187}Os/^{188}Os$, $\delta^{18}O$, $\delta^{13}C$, $^{44}Ca/^{42}Ca$, $^{26}Mg/^{24}Mg$ $\delta^{11}B$, Ge/Si, $\delta^{30}Si$ and $^{10}Be/^{9}Be$. Information from these tracers needs to be integrated with elemental mass balance constraints such as Mg/Ca in forams, sediment accumulation rates, changes in the CCD, and reconstructions of pCO_2. To date, a quantitative and self-consistent scenario that successfully integrates this diverse and increasingly detailed set of observations has been elusive. All of the isotopic tracers are subject to provenance effects, i..e. values can vary as a function of source, and the mix of sources changes in time. The stable isotope tracers are additionally subject to fractionation at the source via changes in weathering processes and/or biological cycling. They can be further impacted by fractionation during incorporation into sediment archives.

Studies at the small watershed scale suggest that several of the tracers ($^{87}Sr/^{86}Sr$, $^{26}Mg/^{24}Mg$, Ge/Si, $\delta^{30}Si$) can be used to identfy particular mineral weathering reactions and/or identify the effects of biocycling. Integrating this information over larger spatial and temporal scales is not straigtforward. Biocycling effects can be important over short time scales but their impact is reduced over time scales much longer than the residence time of the tracer in regolith-soil-plant system.

Recycling of the sedimentary mass is a major source of the erosional flux, and can be particularly significant for tracers significantly stored in carbonate rocks, as these are nearly quantitatively recycled during erosion. While the late Cenozoic shift in $\delta^{13}C$ has received relatively little attention comparted to some other tracers, a decrease in $\delta^{13}C_{sw}$ beginning in the mid–Miocene is consistent with both a proportional and absolute increase in the weathering flux of carbonates. A mid-Miocene acceleration in sediment recycling appears at least consistent with most of the available constraints from other tracers of weathering and erosion, and a model can be used to make testable predictions for other tracer systems. Since each system is individually underconstrained, a quantitative approach that attempts to satisfy multiple tracer records is necessary.

Spatial vegetation patterns, catastrophic shifts and desertification in arid ecosystems under land use and climate regimes

PETER C. DE RUITER[1] AND SONIA KEFI[2]

[1]Land Dynamics of Wageningen University (NL); (Peter.deRuiter@wur.nl)

[2]Institut des Sciences de l'Evolution, CNRS UMR 5554 Montpellier, France

Desertification currently affects the livelihood of more than 200 million people. A primary aim of the international community is to stop desertification to enhance agricultural productivity and combat hunger of many millions of people. Desertification, especially the shift of productive semi-deserts into non-productive full-deserts, can have a 'sudden' or 'catastrophic' character, indicating the existence of critical transitions over 'thresholds' or 'tipping points'

These catastrophic events result from the interplay between two different ecological interactions among the plants making up the vegetation in semi-desert ecosystems. The first is facilitation, where plants support each other in terms of collectively attracting water and nutrients and provide the soil with organic matter compounds. Facilitation acts at relatively small spatial scales. Second, there is competition between plants for the same resources (water, nutrients), but then on a relatively large spatial scale. The process of facilitation helps plants to survive, together, under harsh conditions. Such survival under harsh conditions requires though a critical vegetation biomass, below which the plants cannot adequately acquire the necessary resources. Similarly, when conditions becomes gradually harsher (e.g. less resources, higher grazing intensity), then at a critical point, the vegetation cannot attract enough resources anymore to survive and the ecosystem will collapse into a non-vegetation bare soil desert ecosystem.

We will present the outcome of a study in which spatial explicit models that simulate desertification is combined with field observations on semi-deserts under various land use and climate regimes. The results showed that particular non-random patterns in the spatial distribution of the vegetation are indicative the proximity of a critical threshold. The model results closely resembled the patterns that were observed in the field trials.

Bacterial cells can biosorb and accelerate the transport of heavy metals mixtures in soils

AURELIEN DESAUNAY AND JEAN M.F. MARTINS

LTHE-CNRS-Univ. Grenoble I (UMR 5564), Domaine Universitaire BP 53, 38041 Grenoble Cedex 9, France; (jean.martins@hmg.inpg.fr)

Recent field observations have demonstrated that supposedly poorly mobile metals can be detected at long distances from their source, highlighting the importance of poorly predicted transport processes. The fast mobilisation of metals by the colloidal and mobile fraction of soils and in particular biotic colloids (bacteria, algae, fungi, virus, etc.), is now identified as an important secondary transport process that can lead, under specifc conditions, to accelerated and potentially dominant pollutant transfer towards aquifers. In order to better understand the role of the bacterial compartment of soils to metal leaching, we conducted a coupled study under static and dynamic conditions. Firstly we evaluated Zn and Cd metal biosorption onto active or inactive Gram negative bacteria (*Escherichia coli* and *Cupriavidus metallidurans* CH34) by characterizing the sub-cellular distribution of the metals through a cell disruption approach. The quantification of Zn and Cd in extracellular, membrane and cytoplasm compartments of the cells permitted to show that metals are unequally distributed between the three cell compartments and also between the two bacteria. Surprizingly, metals internalization appeared to be the dominant accumulation process of metals (high cytoplasm contents). The physiological state of the cells was also shown to be important in metal management by the bacteria, since metal accumulation in active cells was reduced due to enhanced efflux and/or EPS production mechanisms. These results suggest bacteria can internalize important amounts of heavy metals and also that adsorption onto cell surface is only a first step in metal management by bacteria. The so-determined thermo-dynamic reactivity constants were used to fit metal breakthrough curves performed in natural sand columns. The transport experiments of bacterial cells, metals or mixtures of bacteria and/or metals performed in the second part of the study, demonstrated that bacteria are able to accelerate the *in situ* mobilization of Cd and Zn retained in natural sand columns. This transport process was shown to be dominant upon aqueous transport and was correctly fitted using a combined transfer and geochemical modeling approach. Altogether, these results showed that, under specific conditions, heavy metal transport by bacterial cells can dominate aqueous transport processes in soils.

Silicon stable isotope constraints on the global oceanic Si cycle

G. F. DE SOUZA[1]*, B. C. REYNOLDS[1] AND B. BOURDON[1,2]

[1]ETH Zurich, Institute of Geochemistry and Petrology, Zurich, Switzerland (*correspondence: desouza@erdw.ethz.ch)
[2]École Normale Supérieure de Lyon and CNRS, France

The global oceanic distribution of nutrients such as silicon (Si) governs the distribution and magnitude of primary productivity in the sea, and thus the strength of the ocean's biological carbon pump. These nutrient distributions are the combined result of biological and physical processes that interact over a range of temporal and spatial scales. Information on the stable isotope composition of dissolved nutrients can be employed to deconvolve the processes contributing to the observed oceanic tracer field, potentially allowing the identification of nutrient sources and/or the relevant biological–physical cycling processes.

We will present a dataset of the stable Si isotope composition of dissolved silicon (expressed as δ^{30}Si) from three major oceanic regions: the Atlantic, the Southern Ocean and the South Pacific, including samples collected as part of the GEOTRACES programme. This high-precision dataset has been produced by a single laboratory, allowing a more robust assessment of intra- and inter-basin gradients than has been previously possible.

The coherence of the δ^{30}Si distribution in the deep Atlantic is a testament to the strength of δ^{30}Si as a tracer of the modern oceanic Si cycle. Values of δ^{30}Si vary systematically with Si concentration, from +1.7‰ and higher in the Si-poor deep subpolar North Atlantic to values of +1.2‰ in the deep South Atlantic, associated with the mixing of water masses of Nordic and North Atlantic origin with Si-rich bottom waters from the Southern Ocean. The North Atlantic most likely owes its high-δ^{30}Si signature to the input of ^{30}Si-enriched silicic acid through the upper return path of the meridional overturning circulation (MOC), indicating that the basin-scale δ^{30}Si gradient in the deep Atlantic is dominantly controlled by the interaction of biological Si utilisation with subsurface watermass formation in the Southern Ocean, and subsequent Si transport by the MOC.

In our presentation, we will extend our analysis of oceanic δ^{30}Si in the MOC context to the global ocean, including the interpretation of our dataset in the framework of geochemical box models of the ocean.

Use of stable (HOCN) and radiogenic (Sr) isotopes to determine the geographic provenance and traceability of artisanal cheeses of Quebec, Canada

S. DESROCHERS*, R. K. STEVENSON, J-F. HÉLIE, AND A. POIRIER

GEOTOP et, Science de la Terre et de l'Atmosphère, Université du Québec à Montréal, P.O. Box 8888, Station Centre-Ville, Montreal, Qc, Canada, H3C 3P8 (*correspondence: desrochers.steph@gmail.com)

Introduction

Analysis of stable isotopes has often been used to determine the traceability of different food products [1] The light stable isotope ratios in dairy products such as cheese can provide information for tracing geographical origin.[4] The province of Quebec is Canada's largest cheese producer and artisanal cheeses are becoming a larger part of this market. In this context, we selected artisanal cheeses from six different regions of the province of Quebec to study the applicability of light stables isotopes and radiogenic isotope (Sr) ratios as descriminants to provide geographic traceability.

Sampling method and results

The cheese samples were analysed for light stable isotope ratios (HOCN) which are mainly influenced by altitude, distance from the sea, use of fertilizer, rainfall, food type, temperature, longitude and latitude [2,3,6]. The Sr isotope analyses are indicative of the geology of the type of substrate of the grazing areas [5]. Prelininary results yeild $^{87}Sr/^{86}Sr$ ratios that vary from 0.71084 to 0.71347. These values reflect soils composed largely of galcial tills derived from either the Canadian shield or Appalachain Orogen. Stable isotope δD values vary beteween -103.06‰ to -55.74‰, and $\delta^{18}O$ between -17.99‰ to -7.54‰. In addition, samples of the food, water, soil and raw milk will also be analysed to determine if enrichment or depletion of the different stable isotope ratios occurs during the manufacture of milk and during the conversion of milk to cheese.

Indian Ocean monsoon dynamics recorded in a speleothem from Socotra, Yemen

D. DE VLEESCHOUWER[1], M.VAN RAMPELBERGH[1], PH. CLAEYS[1], H.CHENG[2], S.VERHEYDEN[1] AND E. KEPPENS[1]*

[1]Earth System Science, Vrije Universiteit Brussel, Pleinlaan 2, B-1050 Brussels, Belgium (*correspondence: ekeppens@vub.ac.be),

[2]Geology and Geophysics, University of Minnesota, 100 Union St SE Minneapolis, MN 55455, USA

On the arid Indian Ocean Socotra Island (12º30'36" 53º55'12"), the Intertropical Convergence Zone (ITCZ) induces a bimodal distribution of the precipitations. Rain falls only as the northward migrating ITCZ passes in May-June and as it returns southward from September to December. The watershed effect of the 1540m-high SW/NE oriented Haggeher Mountains forces precipitations to concentrate on the windward side of the range [1]. Multi-proxy analyses ($\delta^{18}O$, $\delta^{13}C$ & greyscale) are carried out at high resolution (500μm = time-scale ~3 years) on two stalagmites collected in the eastern part of the island: STM1 from the Hoq Cave and STM5 from Casecas cave, 6 km away. Based on TIMS U/Th-dating they resp. cover the last 6000 years and the last 1000 years. Spectral analysis of the obtained records reveals an important ~205-years component in STM1. Comparing the ∂18O & ∂13C records with a reconstruction of solar activity [2] indicates that for most of the last 6000 years periods of lower precipitation and less vegetation are associated with periods of high solar activity. Periods of low solar activity induce more precipitations and higher vegetation abundance. In Oman, solar activity is positively related with the intensity of the rainy seasons because of changes in the latitudinal position of the ITCZ and the convective activity [3]. The Socotra results independently confirm this hypothesis and refine it by identifying the 205-years "De Vries / Suess" sunspot cycle as the dominant forcing cycle for the Indian Monsoon Dynamics on a centennial scale.

Evolution of crust in the Dharwar craton: The Nd isotopic evidence

SUKANTA DEY

Department of Applied Geology, Indian School of Mines, Dhanbad – 826004, India (geodeys@gmail.com)

The western and eastern Dharwar cratons (WDC and EDC) show appreciably different crustal evolution patterns as recorded by 333 whole-rock Nd isotopic data (including 34 unpublished data of the author). Both the cratons exhibit evidence of Palaeoarchaean crust (Fig. 1) whose rock record is either destroyed by later crustal reworking or awating to be discovered. In EDC 3-2.7 Ga is the most significant crust extraction period, whereas in WDC crust was extracted in two dominant episodes i.e. 3.5-3.2 and 3-2.9 Ga. Some komatiites and mafic volcanics of the older episode have considerably higher εNd values (>4.5) indicating that at least parts of the contemporary mantle was extremely depleted possibly due to extraction of crust during some earlier event(s). Younger mantle-derived rocks in the WDC (especially the 2.9 Ga mafic volcanics) do not show evidence of such extremely depleted mantle. This requires immediate refertilization of the mantle below WDC after the older episode of crust formation (~3.2 Ga). The Neoarchaean period in the WDC is characterized by some juvenile addition of crust and extensive crustal recycling during 2.7-2.6 Ga. For EDC contrasting source characteristics of contemporary mantle-derived Neoarchaean rocks (extremely depleted to chrondritic mantle) suggests juxtaposition of unrelated terranes by accretionary processes. The terminal Neoarchaean in EDC is characterized by granitoid formation from metasomatized mantle wedge as well as widespread crustal recycling.

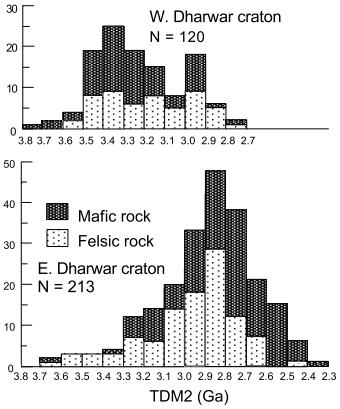

Figure 1: Distribution of depleted mantle model ages in the eastern and western Dharwar cratons.

Isothermal, kinetic and mechanism studies of uranium biosorption by *Aspergillus niger* from aqueous solutions

R. DHANKHAR* AND A. HOODA

Department of Environmental Sciences, M.D.U, Rohtak, INDIA (*correspondence: dhankhar.r@rediffmail.com)

Biosorption have emerged as an alternative technology for heavy metal and radionuclide removal from ground water contaminated due to mining sources [1, 2]. In light of this, present study has been carried out to investigate the biosorption potential of *Aspergillus niger* for removal of uranium form aqueous solution. Some concerned results are shown in Fig. 1.

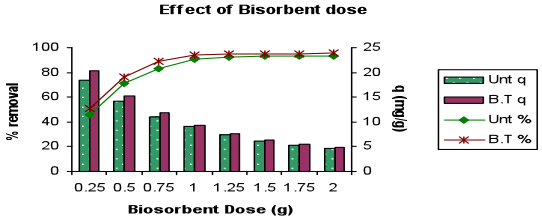

Figure 1: Effect of Biosorbent dose on biosorption of U (VI) on non-living *A. niger* biomass.

Discussion of Results

Uranium uptake at pH 5 and 100 μm particle size, Adsorbent dose of 10g/L and initial metal concentration of 100mg/L. Maximum uptake of 9.21 mg/g was observed after the Contact time of 75 minutes. Equilibrium data fitted well to Langmuir model and Uptake kinetic followed pseudo-second order model. Base treatment was found to enhance the metal removal ability of untreated biomass. The mechanism of process was gained by FTIR and SEM. IR spectra analysis revealed that Carbonyl and amino groups have played important role in U (VI) biosorption.The results are well in concordance with some earlier findings in that concern [3, 4].

Growth and reworking of Gondwana through time

B. DHUIME[1,2]*, C.J. HAWKESWORTH[1], P.A. CAWOOD[1], C.D. STOREY[3] AND K.N. SIRCOMBE[4]

[1]Department of Earth Sciences, University of St. Andrews, North Street, St. Andrews KY16 9AL, UK (*correspondence: b.dhuime@bristol.ac.uk)
[2]Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queens Road, Bristol BS8 1RJ, UK
[3]School of Earth and Environmental Sciences, University of Portsmouth, Portsmouth PO1 3QL, UK
[4]Minerals Division Geoscience Australia PO Box 278 Canberra, ACT 2601 Australia

The timing of continental crust generation is dependent on the nature of the rock record. Juvenile igneous rocks from various continental segments usually show marked age peaks suggesting episodic growth [e.g. 1]; and fine-grained sediments, which provide an average of their igneous source terranes, provide smooth curves of crust generation [e.g. 2], which are more consistent with the continuous nature of crust formation at the level of destructive plate margins. Thus there are long-standing questions over (i) whether the age peaks of juvenile rocks are representative, or merely artefacts of selective preservation [3], and (ii) the extent to which the processes and rates of crust generation and recycling have varied with time.

We present an integrated U-Pb, Hf and O isotopes study on zircons from sedimentary deposits along ~2000 km of the eastern Australian coastline. The data establish that continental growth of Gondwana is continuous, with a significant inflection point in the rate of generation at around 3 Ga. This point marks the transition between (i) very rapid generation of continental crust in the first ~1.5 Ga of Earth history and (ii) lower volumes of preserved crust towards the present day. Such a fundamental change in the way the continental crust was generated and preserved can be linked to the onset of 'modern' plate tectonics, which may have been active since at least 3.1 Ga [4]. This is also consistent with the formation of Hadean/Early Archean crust in a tectonic environment different from modern plate tectonics [5].

Soil closure ages from meteoric ^{10}Be, McMurdo Dry Valleys, Antarctica

W.W. DICKINSON[1]*, M. SCHILLER[2], B.G. DITCHBURN[3], I.J. GRAHAM[3] AND A. ZONDERVAN[3]

[1]Antarctic Research Ctr., Victoria University, Wellington, NZ (*correspondence: Warren.Dickinson@vuw.ac.nz)
[2]Centre for Star and Planet Formation, University of Copenhagen, Copenhagen, DK-1350, Denmark
[3]GNS Science, PO Box 30368, Lower Hutt, New Zealand

Understanding Neogene polar climate in the McMurdo Dry Valleys relies largely on evidence from landscape evolution, glacial modelling and stratigraphy. We provide new evidence from meteoric ^{10}Be for the onset of frozen, hyper-arid conditions in Dry Valley soils. A simple decay model for the co-occurrence of ^{10}Be and illuviated clay in two adjacent profiles indicates the clays were actively migrating down from the surface in a warmer climate until the system froze between 6 and 9 Ma. The model also suggests denudation rates of 0.02–0.06 m Myr^{-1} since closure. These data provide an independent test to glacial-stratigraphic evidence used to determine Antarctic paleoclimate.

Clays bound with meteoric ^{10}Be are prevalent in many Dry Valley soils to depths of over 4 m. These particles, which are now frozen in place, were illuviated by percolating water from the surface, during a previous 'wet period'. We use two adjacent profiles to take advantage of the ^{10}Be clock and determine when ^{10}Be was sealed or closed off from the surface. The two-profile method allows elimination of several variables and hence, calculation of how long ^{10}Be has been in the soil since freezing or closure. By sampling soils at a variety of altitudes and locations, we may build up a better picture of the transformation from sub-polar to polar conditions in the Dry Valleys.

Ocean oxygenation during the PETM: Mo isotope data from the Arctic and Tethyan Oceans

A.J. DICKSON[1]*, A.S. COHEN[1], A.L. COE[1], Y. GAVRILOV[2] AND E. SHCHERBININA[2]

[1]Department of earth and Environmental Sciences, The Open University, Milton Keynes, MK7 6AA, U.K. (*correspondance: a.dickson@open.ac.uk)

[2]Geological Institute of the Russian Academy of Sciences, Pyzhevsky 7, Moscow 119017, Russia.

Evidence for ocean deoxygenation during past intervals of global warming can help to set observations of expanding oxygen minimum zones in the moderns oceans into a longer term geological context. The molybdenum (Mo) isotope composition of the hydrogenous Mo in marine sediments that accumulated in euxinic settings can preserve the seawater Mo-isotope composition, which in turn reflects the balance between oxic, anoxic, and euxinic sinks in the global ocean. As such, it can be used to determine the extent of de-oxygenated waters in past oceans when the local depositional environment is well characterised. We present new Mo isotope data of samples from Arctic Ocean IODP Site 302 and from continental shelf sites on the northern Tethyan margin (Guru-Fatima and Kheu River) that accumulated during the Paleocene-Eocene Thermal Maximum (PETM) ~56 Ma ago. The PETM is characterised by a global C-isotope excursion (CIE) caused by the introduction of a large amount of isotopically depleted carbon into the earth-ocean-atmosphere system, which in turn caused global temperatures to rise by 5-8ºC.

Mo isotope data from IODP Site 302 broadly mirror the organic carbon isotope excursion recorded in the same sample suite, with near uniform values of 2.1 ‰ during the peak of the CIE and lower values during the late Paleocene and during the PETM recovery interval. Samples that accumulated during the peak of the CIE were deposited under locally euxinic conditions, demonstrated by trace element data measured in the same samples and also by comparision to published organic geochemical data. Their Mo-isotope values consequently record the seawater value at this time, which was only ~0.2 ‰ lower than modern seawater (~2.3 ‰). This finding suggests that (1) once euxinia in the Arctic Ocean is accounted for, global ocean anoxia was not widespread during the PETM and (2) the Arctic ocean was unrestricted during the PETM. In contrast, preliminary Mo isotope data from the northern Tethys Ocean suggest a slight expansion of ocean anoxia at the onset of the CIE, an interval that is missing within the Arctic core.

Hydrogen sorption by synthetic montmorillonites and clayrock at high temperature

MATHILDE DIDIER[1,2,3], FABRIZIO BARDELLI[2], ERIC GIFFAUT[1] AND LAURENT CHARLET[2]

[1]ANDRA, Châtenay-Malabry, France

[2]ISTerre, University Joseph Fourier, Grenoble, France

[3]CEA/LITEN/DTNM/LCSN, Grenoble, France

Hydrogen is more and more studied as a future energy carrier due to its availability and its energy capacity. The montmorillonite clay minerals are recognized as good hydrogen adsorbents [1] due to their large specific surface area and their wide range of porosity. In addition to this application, a clayrock has been considered as a host rock for French nuclear waste and particularly the Callovo-Oxfordian (COx), principally constituted by smectite and illite clays. Regarding nuclear waste repository, hydrogen gas is expected to develop from the anaerobic corrosion processes of the waste containers after the disposal closure. It is therefore of fundamental importance to study the fate of the hydrogen gas produced in the system, in terms of reactivity and integrity of the surrounding claystone layer.

This study aims at investigating hydrogen sorption on different types of synthetic montmorillonites and COx clayrock using gas chromatography and Sievert technology. Two-month long experiments were carried out at 90°C (the maximum temperature in the waste repository site) with dried or saturated clays. The hydrogen partial pressure varies from 0.1 to 0.45 bars.

Dried experiments show a sorption of hydrogen amount of 0.13 wt%. Experiments with saturated clays highlight a decrease of headspace hydrogen pressure (the figure below) as a function of time for a COx powder in NaCl aqueous solution taking into account the dissolved hydrogen. Sievert technology using high pressure of pure hydrogen gas (up to 80 bars) at 90°C shows a maximum sorption of 0.20 wt% for synthetic montmorillonite and 0.16 wt% for COx sample.

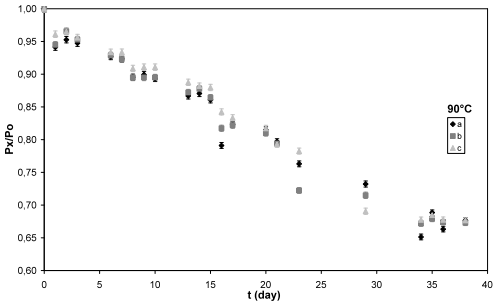

Figure 1: Evolution of hydrogen relative pressure with time for clay fraction of a COx sample at T = 90°C

The effect of size on nanoparticle dissolution rate

TAMARA DIEDRICH[1]*, JACQUES SCHOTT[1], ERIC OELKERS[1], AGNIESZKA DYBOWSKA[2] AND EUGENIA VALSAMI-JONES[2]

[1]GET-Université de Toulouse-CNRS-IRD-OMP, 14 Avenue Edouard Belin, 31400 Toulouse, France, (*correspondence: tdiedric@gmail.com)
[2]Department of Mineralogy, Natural History Museum, Cromwell Road, London, SW7 5BD, U.K.

The dissolution rate of nanoparticles affects both their persistence in the environment and the release rate of their metal content, and, hence, can control their toxicity. While previous studies concluded that nanoparticles dissolve faster than their bulk analogs, contradictory evidence suggests that nanoparticles dissolve more slowly. Furthermore, insufficient characterization of the nanoparticulate samples and the solution chemistry in past studies obscures the relationship between particle size, surface area, and dissolution rate. There is a critical need for additional studies, using well-characterized nanoparticles and reactive solutions, to develop a model of nanoparticle dissolution rate.

Dissolution rates are a function of both the distance from equilibrium (providing the driving force for dissolution) and a dissolution rate constant (reflecting the dissolution mechanism and the strength of bonds critical to maintain the structure). The current study takes the approach of studying dissolution rates at far-from-equilibrium conditions to quantify the effect of particle size on the dissolution rate constant, isolating any potential kinetic effect of particle size from the well-established effect of particle size on solubility.

Multiple samples of both nanotalc and amorphous silica nanospheres were synthesized, ranging in size from approximately 20 to 200 nm. Samples were characterized by XRD, SEM, TEM, dynamic light scattering, and gas adsorption. Flow-through experiments were performed at far-from equilibrium conditions with pH from 2-10. Batch experiments were performed at both far-from and approaching equilibrium.

Preliminary interpretation of these data suggests that any effect of size on dissolution kinetics is minor. Thus, as the dissolution rate constant appears to be size independent (within experimental error), the dissolution rate of nanoparticles as a function of size and departure from equilibrium can be modeled by using classical kinetic rate laws and taking account of the effect of size on solubility.

Marine redox conditions and sulfur cycling during the deposition of the 2.3 Ga Timeball Hill Formation

D. DIEKRUP[1]*, A.J. KAUFMAN[2], B. KENDALL[3] AND H. STRAUSS[1]

[1]WWU Münster, Institut für Geologie und Paläontologie, Corrensstr. 24, 48149 Münster, Germany (*correspondence: daviddiekrup@uni-muenster.de)
[2]Department of Geology and the Earth System Science Interdisciplinary Center, University of Maryland, College Park, MD 20742, USA
[3]School of Earth and Space Exploration, Arizona State University, Tempe, Arizona 85287, USA

Rhenium and Molybdenum concentrations in shales and sulfur isotopes in disulfides and organic matter provide new insights in the development of the ocean-atmosphere system during the deposition of the 2.3 Ga Timeball Hill Formation, South Africa. Relatively low enrichment factors (relative to average crustal abundances) of Mo between 0.1 and 2.4 and high Re enrichment factors between 1.1 and 25.0 can be distinguished. Marginal concentrations of Mo correlate with the highest enrichments of Re, and appear to be coupled to the most negative $\delta^{34}S$ values (down to -30 ‰ against V-CDT in disulfides) and highest concentrations of organic bound sulfur.

High Re concentrations over wide parts of the stratigraphy argue for a deposition under anoxic but, as indicated by low Mo concentrations, not for euxinic deepwater conditions. Pyrite from these stratigraphic levels show the lowest $\delta^{34}S$ values, thus high isotopic fractionation, which suggests the establishment of an oceanic sulfate pool. The absence of large Mo and Re enrichments in the middle parts of Lower and Upper Timeball Hill shales indicate potentially oxic oceanic conditions. These samples show high $\delta^{34}S$ values in disulfides which could indicate a low sulfate flux to the oceans.

These observations lead to the conclusion that the water column was constantly non-euxinic at 2.3 Ga. The intensity of continental weathering and the subsequent delivery of nutrients to the oceans was variable and a consequence of the fluctuations of the atmospheric oxygen content.

Structural incorporation of selenium in iron sulfides

A. DIENER* AND T. NEUMANN

Institut für Mineralogie und Geochemie, Karlsruher Institut für Technologie, Adenauerring 20b, 76131 Karlsruhe, Germany (*correspondence: alexander.diener@kit.edu)

One of the key issues regarding the disposal of high-level nuclear waste in deep geological formations is related to the long term safety of a waste repository. Different performance assessment calculations for such repositories show a domination of ^{79}Se radionuclide with regard to the total exposure to the biosphere in the period of 10^4-10^6 years after disposal. Selenium is often associated with sulfides such as pyrite, a frequent minor constituent of host rocks and bentonite backfills considered for radioactive waste disposal. In this study, we investigated the incorporation of Se(-II) and Se(+IV) into pyrite.

The syntheses occurred via direct precipitation in batch and as coatings on natural pyrite in mixed flow reactor (MFR) experiments under anoxic conditions for Se-concentrations in the solutions up to 10^{-3} molL^{-1}. Furthermore, a high temperature synthesis by chemical vapor transport enabled the synthesis of Se-doted pyrite for single-crystals with a size up to 1 cm.

The mineralogical analyses by SEM and XRD reveal the syntheses of pure phases. Neither achavalite (FeSe), nor ferroselite ($FeSe_2$) were detected. The average of Se-uptake in 34 samples in batch experiments has been 98% and in MFR syntheses 99.5%, indicating a high potential for the retention of selenium by pyrite.

XAFS investigations have been performed at synchrotron light facility ANKA, Karlsruhe. These analyses and additional XPS measurements point out a reduced valence state of Se by initially dissolved Se(-II) and Se(IV) coprecipitated in pyrite and mackinawite. Curve progression and k-edge values [1,2] for selenide doted mackinawite (E_0: 12655.3 eV) in batch experiments imply a valence state of Se(-II) and for selenide doted pyrite (E_0: 12656.9 eV ± 0.3) in batch experiments a valence state of Se(-I), while the k-edge value of Se(0) as reference is higher (E_0: 12658.0 eV).

XAFS analysis on the coatings from MFR-syntheses, performed under slightly supersaturated conditions, indicate a coprecipitation of Se(-II) and Se(IV) predominantly as Se(0). With regard to batch experiments, these results indicate a substitution of sulfur with selenide just for high supersaturated solutions. In selenide doted mackinawite via direct precipitation in batch experiments occured a substitution of S with Se in an achavalite-type compound. As well, S is substituted by Se in selenide doted pyrite, ending in a FeSSe compound which could be best described by a slightly distorted pyrite structure.

Geochemical expression of buried iron-oxide Copper Gold mineralisation within physical and chemical interfaces of the deep cover at the Hillside Prospect, South Australia

B.J. DIETMAN AND S.M. HILL

Deep Exploration Technologies Cooperative Research Centre, School of Earth & Environmental Sciences, University of Adelaide, SA 5005 Australia

Iron-Oxide Copper Gold (IOCG) mineralisation is an economically important mineral system in Australia, and includes the enormous Olympic Dam resource. Relative to its economic significance, however, little is known about the regolith geochemical expression of IOCG mineralisation, and therefore geochemistry has been under-utilised within the exploration for further deeply (10s-100s metres) buried deposits. This study shows that the weathered and transported cover overlying buried mineralisation can host systematic geochemical expressions of buried IOCG mineralisation.

The Hillside Prospect is 100 km northwest of Adelaide within the southern end of the IOCG prospective, eastern Gawler Craton. Mineralisation here is associated with N-S trending structures of the Pine Point Fault Zone.

Surface (soil) geochemistry results have shown locally elevated Cu-Au concentrations overlying buried mineralisation. The processes and associations with the underlying mineralisation and parts of the 10s-100s m deep cover in between the mineralisation and the soil are poorly constrained. Coastal cliffs in the area expose buried mineralisation at 10s of metres depth and the overlying saprolite, palaeodrainage, marine and aeolian sediments. Multi-element geochemical characterisation of these profiles shows variations in the chemical parametres associated with physical interfaces (e.g. unconformities and sediment lithologies) and chemical interfaces (e.g. palaeo- and contemporary redox boundaries, watertables) that provide strong expression and contrast within the cover for settings laterally proximal or distill to mineralisation. Many of the chemical interfaces are associated with supergene halos that are organised into locally enriched and differentiated U, Au and Cu zones flanking mineralisation. Whilst redox conditions and secondary iron oxide hosts provide important constraints on this geochemical expression, the secondary carbonate minerals and deep-rooted plant biogeochemical processes are also important.

Os isotopes in detrital Os alloys from the Rhine and evidence for a 1.2-1.3 Ga global? mantle melting event

ARJAN H. DIJKSTRA[1,*], CHRIS W. DALE[2], DMITRY S. SERGEEV[3], ZELIMIR GABELICA[4] AND ALAIN DEVILLIERS

[1]Centre for Research in Earth Sciences, University of Plymouth, UK (*arjan.dijkstra@plymouth.ac.uk)
[2]Department of Earth Sciences, Durham University, UK
[3]Institute of Mineralogy and Geochemistry, University of Lausanne, Switzerland
[4]ENSCMu, Université de Haute-Alsace, Mulhouse, France

Osmium isotope 'dating' of large populations of mantle-derived osmium-bearing alloys provides a key test for the idea of episodic crustal growth linked to global mantle melting events in Earth history [1]. Os alloys are formed within the mantle during high-degree melting, and their $^{187}Os/^{188}Os$ isotopic ratio can be used to date their formation.

Over 200 detrital Os alloys from placer gold occurrences in the Rhine between Basel and Frankfurt were obtained by gold washing techniques and hand-picking from gold separates. These 20-300 μm detrital Os alloys are derived from outcrops of ultramafic rocks in the Alps, which include blocks of mantle rocks with Tethyan affinity such as the Totalp Massif, and ultramafic lenses of unknown (Precambrian?) age in the Gotthard and Aar Massifs. Another source may be the Molasse of the Alpine foreland basin. $^{187}Os/^{188}Os$ isotope ratios were measured by LA-MC-ICPMS, to determine Re-depletion ages that should constrain the ages of melting in the mantle source rocks. The data show distinct age peaks at 0.5 and 1.2-1.3 Ga.

The 1.2-1.3 Mesoproterozoic age peak recorded by the Rhine Os alloy population does also occur in Os alloy age distributions of other ophiolites worldwide, generally as a subsidiary peak [1]. We show that the Mesoproterozoic age is also prevalent in Re-depletion age distributions of whole rock samples of refractory mantle xenoliths from ocean islands, and whole-rock samples of anomalously depleted abyssal peridotites from modern oceans, *e.g.,* from the 15-20 Fracture Zone (MAR) and Macquarie Island [2]. Therefore, analysis of Re-depletion ages from mantle rocks worldwide collectively point to a Mesoproterozoic, 1.2-1.3 Ga high-degree mantle melting event of global significance. This event may be related to a slab-avalanche or whole-mantle overturn event in Mesoproterozoic times.

Adsorption of a textile dye (Acid Red 88) by montmorillonitic clay: Estimation of equilibrium, kinetic and thermodynamic parameters

S. DIKMEN[1*], B. ERSOY[2] AND A. GUNAY[3]

[1]Dept. of Physics, Anadolu Univ., Eskisehir, 26470, Turkey (*correspondence: sdikmen@anadolu.edu.tr)
[2]Dept. of Chem. and Materials Eng., King Abdulaziz Univ., Jeddah, 21589, Saudi Arabia. (bersoy@aku.edu.tr)
[3]Istanbul Metropolitan Municipality, Waste Management Directorate, Sisli, Istanbul (ahmetgunay2@gmail.com)

Introduction

Textile dyes are one group of the pollutants and the presence of dyes in the aquatic environment has been of great concern because of their potential health hazards associated with the carcinogenic, mutagenic, allergenic and toxic natures as well as negatively effects on the photosynthetic activity in aquatic life [1].

Method

The adsorption of AR88 onto montmorillonite was studied with variation in the parameters of pH, contact time, adsorbent and dye concentrations, and temperature to estimate the equilibrium, kinetic parameters and thermodynamic [2].

Kinetic models including pseudo-second-order, pseudo-nth-order, Bangham and double-exponential models were selected to follow the adsorption process. Kinetic parameters such as the rate constants, the equilibrium adsorption capacities and the related correlation coefficients, for each kinetic model were calculated and discussed. Thermodynamic parameters such as activation energy (Ea), Gibbs free energy (ΔG^o), enthalpy (ΔH^o) and entropy (ΔS^o) were also evaluated.

Discussion of Results

The dynamic data were fitted well the pseudo-nth-order kinetic model and also followed double-exponential function, the pseudo-second-order and Bangham Model, respectively.

The adsorption data obtained were well described by the Langmuir isotherm model. The maximum adsorption capacity was found to be 588 mgg^{-1} from the Langmuir isotherm model at 20 ºC. The negative value of change in Gibbs free energy indicates that the adsorption is spontaneous. The results show that montmorillonitic clay could be employed as low-cost material for the removal of acid dyes from textile effluents.

Geochemical and tectonic fingerprinting of ophiolites

Y. DILEK[1]* AND H. FURNES[2]

[1]Department of Geology, Miami University, Oxford, OH 45056, USA (*correspondence: dileky@muohio.edu)
[2]Department of Earth Science & Centre for Geobiology, University of Bergen, Bergen 5007, Norway

We present a new classification of ophiolites, incorporating the diversity in their structural architecture and geochemical signatures that result from the variations in petrological, geochemical and tectonic processes during formation in different geodynamic settings. We define ophiolites as suites of temporally & spatially associated ultramafic to felsic rocks related to separate melting episodes & processes of magmatic differentiation in particular tectonic environments. Their geochemical characteristics, internal structure and thickness vary with spreading rate, proximity to plumes or trenches, mantle temperature, mantle fertility, and the availability of fluids. Subduction-related ophiolites include *suprasubduction zone* and *volcanic arc* types, whose evolution is governed by slab dehydration and accompanying metasomatism of the mantle, melting of the subducting sediments and repeated episodes of partial melting of metasomatized peridotites. Subduction-unrelated ophiolites include *continental-margin*, *mid-ocean ridge* (*plume-proximal, plume-distal and trench-distal*), and *plume-type* (*plume-proximal ridge* and *oceanic plateau*) ophiolites that generally have MORB compositions. Subduction-related ophiolites develop during the closure of ocean basins, whereas subduction-unrelated types evolve during rift-drift and sea-floor spreading. Geochemical and tectonic fingerprinting of Phanerozoic ophiolites within the framework of this new ophiolite classification is an effective tool for identification of the geodynamic settings of oceanic crust formation in Earth history that in turn helps us deduce the processes by which these oceanic rocks were incorporated into continental margins. We apply this new ophiolite classification to Precambrian greenstone belts as a conceptual framework to examine potential vestiges of Proterozoic and Archean oceanic lithosphere.

Protection of organic matter by clay minerals in source rocks revealed by biomarker analysis

DING FEI* AND CAI JINGONG

State key laboratory of marine geology, Shanghai, 200092, China (*correspondence: dingf2007@163.com)

Several mechanisms have been proposed in description the accumulation and preservation of organic matter(OM) in sediments, and the adsorption of clay minerals is concerned as an important way. It is significant that these different occurrences of OM studies with the biomarker information obtained from an source rock. The 10 source rock samples, an depth interval from 1294 to 3357 m from Shayejie formation in Dongying depression of China, were collected. The clay size fraction (<2μm) were isolated by sedimentary approach after the dispersion of the source rock by ultrasonic and deionized water. Both the clay size fraction and bulk source rocks were extracted by dichloromethane, and GC/MS was applied.

The normalized amount of the extractable organic matter (EOM) is higher in clay size fraction than it in the whole rock, 0.56mg/g and 0.37mg/g respectively, although the composition are similar between them. This suggestes that EOM mainly occurred as combined with clay size fraction in source rocks. The biomarker data show that there is no notable difference on characteristics of OM associated with clay fraction and in the whole rock. However, the differences between clay size fraction and whole rock show that the weak degradation of OM combined with clay fraction occur no matter caused by micro-organisms or thermalism, which could be demonstrated by the relative abundance of alkanes and isopreiods (Pr/nC_{17} and Ph/nC_{18} ratios are 1.44 and 1.54 in mean for the whole rock while 1.33 and 1.2 in mean for clay size fraction) and the ratios of maturity parameters(such as C_{31}22S/S+R ratios are 0.46 and 0.41 in average respectivelly, C_{29} ααα 20S/20(S+R) ratios are 0.18 and 0.14 in average respectively, for the whole rock and clay size fraction). In addition, the information acquired from biomarker of the whole rock may be obscured for the variety occurrences of OM in the whole rock, which should be caution.

This research was supported by the National Natural Science Foundation of China(Grants 40872089 and 41072089) and the State Key Lab. of Marine Geology Fund, Tongji University (MG200902).

Application of the field seismic data in superficial structure study for Wenshui Area

L. DING, S.G. HE AND E.G. GAO*

Institute of Disaster Prevention Science & Technology, Yanjiao, 101601, Beijing, China
(*correspondence: grg@ustc.edu.cn)

The Wenshui area is located in middle-west of Shanxi Province in north China, where plenty of coal resources are mined. In recent years, a large amount of seismic exploration work with the aim at coal recources has been done in the area successively. Based on the foundation of seismic exploration data, this study focuses on the superficial structure of sedimentary basin in the Wenshui area.

A 3D seismic data acquisition had been done in the Wenshui area. Seismic exploration lines are little longer than the field survey profile to cover all the possible coal resources area. In order to obtain the superficial structure of the area, seismic data processing had been done. And it can be summarized concisely into the following steps [1]: (1) carefully checked the positions of field shot-receiver pairs to obtain accurate localities; (2) calculated the static corrections in details; (3) eliminated bad shots, bad courses and abnormal amplitudes; (4) selected appropriate deconvolution parameters; (5) made accurate velocity analysis and got residual static corrections through stacking; (6) carried out the post stack processing and precise migration.

The result shows that there is a large syncline structure in the centre of the region, suggesting long-term tectonic push influenced Wenshui area since Triassic. This crustal deformation was accompanied with rock cracking in both coal sills and their wall rocks, which could lead to potential danger to the deep exploitation for coal mines.

This study is supported by Teacher Foundation of China Earthquake Administration (No: 20090112)

Silicon isotope composition of chert in carbonate rocks, as an indicator of paleo-environmental variation in ocean

TIPING DING [1,2], JIANFEI GAO [1,2] AND SHIHONG TIAN [1,2]

[1]Institute of Mineral Resources, CAGS, Beijing, China
[2]Key Laboratory of Isotope Geology, CAGS, Beijing, China

An investigation on the silicon isotope variation of chert bands and nodules in carbonate sedimentary formation from early Proterozoic to Mesozoic is undertaken in this study to study the temporal variation of the environmental conditions of the ocean.

The cherts in carbonate formation of Proterozoic period show large variation on their silicon isotope compositions. The δ^{30}Si values of chert from early Proterozoic Futuo Group vary from 0.1‰ to 1.3‰, with an average of 0.76‰, whilst those from middle Proterozoic Changcheng Group vary from 1.1‰ to 3.4‰, with an average of 2.09‰. The chert from late Proterozoic strata has lowest δ^{30}Si values, varying from 0.0‰ to 0.9‰ and with an average of 0.36‰.

The cherts in carbonate formation of Palaeozoic and Mesozoic periods show smaller δ^{30}Si variation than for Proterozoic. The chert of early Palaeozoic shows δ^{30}Si values from -0.6‰ to 1.7‰, averaging 0.70‰. Similarly, the chert of late Palaeozoic shows δ^{30}Si values from -0.4‰ to 1.7‰, averaging 0.61‰. Furthermore, the chert of Mesozoic shows δ^{30}Si between -0.3‰ and 1.1‰, averaging 0.55‰.

The positive δ^{30}Si values observed in all cherts in the carbonate formation from Proterozoic to Mesozoic indicate that the ocean has positive δ^{30}Si value since early Proterozoic period. This may be caused by the increase of biological activities, which generate silicon isotope fractionation while reduce the silicon content in the ocean water. The higher and more variable silicon isotope compositions of Proterozoic chert may reflect the significant change of environment conditions (temperature and Si content) in ocean from Archean to Proterozoic.

Volatiles and viscosity

D.B. DINGWELL

Earth and Environment, LMU – University of Munich, Theresienstr. 41/III, 80333 Muenchen, Germany

The physical properties of magmatic melts are notably influenced by the presence of dissolved volatiles. The influence of volatiles on the PVT-equation-of-state of silicate melts is slowly being mapped out in terms of the molar volume and its temperature- and pressure derivatives. The influence on transport properties is , to date, better constrained, and indeed the effects are even more dramatic for some volatiles. In both cases a wide range of complementary experimental techniques are being applied and it is often the case that proxy methods for property determinations yield results where direct determination is experimentally hindered.

Perhaps the most exhaustively investigated example of the influence of volatiles on properties is the case of the influence of water on viscosity. Its extensive investigation in the past 20 years contains many examples of experimental foresight and advance, as well as a number of pitfalls. Using this example, together with the allied determinations of transport properties in melts, a sketch of the state-of-the-art will be attempted.

An example of fluid immiscibility during the subvolcanic emplacement of a boron-rich acidic melt: The Capo Bianco aplite (Elba Island, Italy)

ANDREA DINI

Istituto di Geoscienze e Georisorse - CNR, Pisa, Italy

Very unusual melts rich in boron and other volatile and rare elements are produced during partial melting of continental crust as well as by differentiation of granitoid plutons. Commonly these melts crystallize at plutonic depths producing typical coarse-grained rocks (pegmatites) that are industrial sources for rare elements (e.g. Ta, Li). Sometimes, such melts produce intrusive bodies showing a fine grained microgranite-aplite texture. In both cases the final equigranular isotropic texture reached by these rocks masks the original structure of magma (e.g. presence of early phenocrysts) and the eventual dynamic patterns experienced during transfer and emplacement of magma.

The Capo Bianco aplite sill (Elba Island, Italy) was emplaced at shallow depth (≈ 2.6 km) in the Late Miocene, recording very peculiar petrographic (layered and oriented texture) and geochemical features that recall a fluid immiscibility process between silica-rich and boron-rich melts. The rapid crystallization of the peraluminous, boron-rich Capo Bianco aplite allowed the preservation of the original structure of the acidic magma with a small percentage of early, millimetric phenocrysts (quartz, K-feldspar, oligoclase, muscovite) into a very fine-grained quartz-feldspatic groundmass. The groundmass also hosts a large number of spherical-ellipsoidal tourmaline orbicules ranging in size between few mm up to 15 cm. The tourmaline orbicules are made up by fibrous-radiating schorl-elbaite needles and quartz. Their textural relationships with the host, internal textural and chemical-isotopic features suggest that they represent an early character of the magma and excludes their formation by late- to post-magmatic processes. This observation coupled with geochemical composition of the rock and available experimental data on silicatic melts/glasses indicate that tourmaline orbicules can represent the product of rapid crystallization of boron-rich silicate melt bubbles earlier separated from the acidic magma before the final emplacement. Capo Bianco aplite can thus be regarded as a serendipitous occurrence of a boron-rich magma that escaped the source region and stopped/crystallized in a subvolcanic setting, just at the right depth for maintaining a snapshot of the silicate-liquids immiscibility processes and the emplacement dynamic.

The vast number of high molecular substances in soil and their specific degradation pathways all end up in a reasonable small number of low molecular substances (LMWOS). Thus, the transformation and fate of LMWOS is one of the most important processes in biogeochemical cycles. These transformations are mainly controlled by microbial utilization and thus coupling the fate of LMWOS with their use by microbes is one of the tasks in the elucidation of C transformations and cycles.

Therefore we performed field experiments including application of dual-labeled and uniformly or position-specifically labeled amino acids. The microbial utilization was measured by means of ^{13}C- and ^{15}N-analysis of microbial biomass with the chloroform-fumigation-extraction method. A more specific look on the utilization of individual amino acids or C positions by distinct microbial groups was gained by the ^{13}C-PLFA approach.

Comparison of ^{13}C- and ^{15}N-incorporation revealed, that for a well N-supplied microbial community (C:N~6) of a grassland ecosystem appr. 50% of the amino acid N is mineralized by the microbes, whereas the remaining amino acids were incorporated into the microbial biomass. Incorporation of amino acid C into microbial biomass was highest for osmotrophic, prokaryotic groups. Position-specific labeling showed that highly oxidized groups are preferentially degraded, whereas more reduced C positions showed higher incorporation into the microbial biomass.

Our results show, that the combination of labelling with compound specific isotope analysis of microbial biomarkers opens a new way to investigate the microbial transformations of LMWOS in soil. Especially investigating the utilization of individual C atoms by microbial groups allows conclusions about the mechanisms and kinetics of microbial substrate utilization and the interactions between these groups. This will improve our understanding of soil carbon fluxes.

Control of biomineral formation during microbial Fe(III) reduction by local Fe^{2+} gradients – A multiscale approach

U. DIPPON*, C. SCHMIDT, M. OBST, A. PIEPENBROCK AND A. KAPPLER*

Geomicrobiology, University of Tuebingen, 72076 Tuebingen, Germany (*correspondence: urs.dippon@uni-tuebingen.de, *correspondence: andreas.kappler@uni-tuebingen.de)

The identity of minerals formed as a consequence of microbial iron(III) reduction is a function of geochemical conditions and microbial metabolic activity. While geochemical conditions set a thermodynamic framework for biomineralization, the microbial cells can influence the mineralization product by providing templates for mineral nucleation, localization of mineral precipitation, production of electron shuttles and changing the rate of Fe(III) reduction. Local Fe(II):Fe(III) ratios are known to be a key parameter for the transformation of Fe(III) minerals such as ferrihydrite to either dissolved Fe^{2+}, Fe(II) minerals (siderite), Fe(II)/Fe(III) minerals (green rust or magnetite) or other Fe(III) minerals (goethite).

We showed that under identical total concentrations of Fe(III) minerals, the geometry of the experimental setup significantly affected the local geochemistry, iron reduction rates and mineralogy of the reduction products in experiments with the iron-reducing strain *Shewanella oneidensis* MR-1. In these setups, the bacteria reduced 2.5 to 15 mM ferrihydrite with lactate as electron donor in glass tubes that were stored either horizontally or vertically.

In all setups with >7.5 mM ferrihydrite, magnetite formation was observed probably due to a high Fe(III):Fe(II) ratio present during ferrihydrite reduction. At lower concentrations of ferrihydrite, no magnetite but rather dissolved Fe^{2+} and/or siderite were formed in horizontally incubated tubes. However, in vertically incubated tubes magnetite was formed even at ferrihydrite concentrations as low as 2.5 mM. Probably ferrihydrite accumulation at the bottom of vertically incubated culture tubes also led to high Fe(III):Fe(II) ratios allowing magnetite to form. A multiscale approach combining bulk analysis with high resolution geochemical measurements and confocal laser scanning microscopy allowed us to characterize the microenvironments, localize cells at the mineral-solution interface and correlate geochemical data to mineral identification by XRD and Mössbauer spectroscopy.

Molecular microstratigraphy via laser-desorption ionization Fourier-transform ion cyclotron resonance mass spectrometry (LDI-FT-ICR-MS)

THORSTEN DITTMAR[1]*, SAMUEL ABIVEN[2], JUTTA NIGGEMANN[1] AND JENS FUCHSER[3]

[1]Max Planck Research Group for Marine Geochemistry, University of Oldenburg, Germany, (*correspondence: tdittmar@mpi-bremen.de; jniggema@mpi-bremen.de)

[2]University of Zurich, Soil Science and Biogeography, Switzerland (samuel.abiven@geo.uzh.ch)

[3]Bruker Daltonics, Bremen, Germany (Jens.Fuchser@bdal.de)

Ultrahigh-resolution mass spectrometry via the Fourier-transform ion cyclotron resonance technique (FT-ICR-MS) offers fundamentally new insights into the molecular world of natural waters. Oceans and freshwater systems are among the most complex molecular mixtures on Earth, containing ten-thousands if not millions of different compounds, collectively known as dissolved organic matter (DOM). With help of FT-ICR-MS, DOM can now be appreciated in its full molecular complexity, and a holistic geo-metabolomic approach is in sight that will allow a mechanistic understanding of element cycles in the ocean. In sediments and soils similar progress has been hampered by limited capabilities for the ionization of organic matter from solid samples for FT-ICR-MS analysis. In the life sciences, different laser-desorption ionization techniques (LDI) coupled to FT-ICR-MS are established tools for the molecular characterization of metabolites in organic tissues. Recently, this technique was extended for two-dimensional imaging of organic tissues allowing the identification of specific metabolites on a micrometer spatial scale. Objective of our study was to apply LDI-FT-ICR-MS for the molecular imaging of sediments. We obtained detailed molecular fingerprints of finely layered marine sediments, spatially resolved on a 50 micrometer scale. These first molecular images of marine sediments illustrate the enormous potential of LDI-FT-ICR-MS for the geosciences. Instead of targeting a small number of specific biomarkers, molecular formulae of hundreds to thousands of individual compounds are simultaneously obtained. Micrometer-scale stratification can be resolved on an extremely small amount of sample which is otherwise not accessible to molecular analysis.

Origin of iron layer in sediment of Lake Superior: Abiotic vs. biotic

M. DITTRICH[1], J. GORDON[1], B. RAOOF[1], A. CHESNYUK[1], S. QUAZI[1], R. SHEN[1], J. BOLLMANN[2], S. KATSEV[3] AND R. FULTHORPE[1]

[3]Large Lakes Observatory 2205 East 5th Street, Duluth, MN 55812, (skatsev@d.umn.edu)

In spite of being the largest by surface and one of the most oligotrophic fresh water bodies in the world, Lake Superior is rather a blank spot on the map of modern Geochemistry and Geomicrobiology. Although the limnological puzzles of Lake Superior are increasingly attracting scientists [1], very little is known about the sediments and their associated microflora. In this study we investigated geochemical and microbiological processes that may lead to the formation of a two cm thick iron layer about 10 cm below the sediment surface. Sediment cores from two stations (EM, 230m water depth and ED, 310m water depth) in East Basin were used. We monitored oxygen and pH depth profiles with microsensors, porewater and sediment solid matter were analyzed for nutrient and metal contents. The total cell count was determined using DAPI. DNA was extracted from the sediment samples and 16S ribosonal RNA amplicons were analyzed with denaturing gradient gel electrophoresis (DGGE).

The cluster analysis performed on the DGGE fingerprint revealed that there is no distinct microbial community in the iron layer, infact the bacterial community of the iron layer was 97% similar to that of adjacent layers. The scanning electron microscope (SEM) images from the iron layer 10-12cm show filament like structures that was encrusted with spheres ca. 20 nm in diameter (Figure 1A,B).

A B

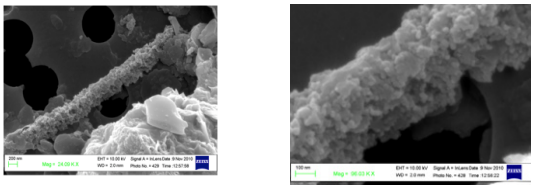

Figure 1. SEM images of filament like structure in the iron layer (A). Filament or tube covered was with spheres (B).

Gallium in bauxite deposits

TH. DITTRICH*, TH. SEIFERT AND J. GUTZMER

Department of Mineralogy, TU Bergakademie Freiberg, Brennhausgasse 14, D-09596, Freiberg, Germany (*correspondence: Thomas.Dittrich@mineral.tu-freiberg.de Thomas.Seifert@mineral.tu-freiberg.de, Jens.Gutzmer@mineral.tu-freiberg.de)

Gallium is consumed in rapidly increasing amounts by high technology applications. The annual primary production of Ga in 2009 of 111t is set to increase twentyfold by 2030 [1,5]. However, Ga is the sixteenth most common element in the Earth's crust (16ppm) and thus is much more common than metals like Cu, Zn, Ag or Cu. Despite of its relative abundance, Ga minerals are very rare and no distinct ore deposits from which gallium could be exploited as major product are known. This is attributed to the close geochemical affinity of Ga to Al resulting in Ga to substitute easily in rock-forming Al silicates (e.g., feldspar, nepheline).

Currently, almost all Ga is extracted as byproduct during beneficiation of bauxite. Ga occurs in bauxite in concentrations of <10-160ppm (Ø50ppm) [4, 5]. Based on the data of bauxite reserves and resources given by the USGS (2010) [5] and Bogatyrev & Zhukov (2009) [2] and under the assumption of an average Ga content of 50ppm, the geologically available Ga quantities in bauxites are estimated as 1.355Mt and between 2.75—3.75Mt Ga, respectively. The majority of bauxite deposits form by intensive chemical weathering of Al-rich lithologies During this process Ga behaves immobile much like Al, and is incorporated into Al-bearing minerals (e.g. gibbsite, kaolinite).

Crustal growth in the North China Craton at ~2.5 Ga: Evidence from *in situ* zircon U-Pb dating, Hf isotopes and whole-rock geochemistry of the Dengfeng complex

CHUNRONG DIWU[1]*, YONG SUN[1], ANLIN GUO[1], HONGLIANG WANG[2] AND XIAOMING LIU[1]

[1]State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi'an, 710069, China (*correspondence: diwuchunrong@163.com)

[2]Xi'an Institute of Geology and Mineral Resource, Xi'an 710054, China

The Dengfeng complex situated on the southern margin of the North China Craton (NCC) belongs to the southern portion of the Trans-North China Orogen. This late Neoarchean (~2.5 Ga) terrane is important to understand the formation and evolution of NCC during this period. The Dengfeng complex is well exposed in the Junzhao region and comprises two distinct lithologic units: supracrustal assemblage and plutonic rocks. LA-ICPMS magmatic zircon U–Pb dating shows that the complex formed within the range of 2547~2504 Ma. The available Hf isotope data indicate that the majority of ca. 2.5 Ga zircons from the Dengfeng complex give high $\varepsilon_{Hf}(t)$ values close to the initial Hf isotope ratios of the contemporaneous depleted mantle. These indicate that the rocks in the Dengfeng represent juvenile crust. The TTG gneisses in the Dengfeng complex display low Mg# (41-48), MgO (<2 wt%), Cr (6-14 ppm), Ni (9-22 ppm) contents and low Nb/Ta ratio (6-12), which are interpreted to have been produced by the partial melting of a flatly subducted slab. The metadiorites of the Dengfeng complex are typically characterized by high $Mg^{\#}$ (59-69), MgO (3.5-6.6 wt %), Ni (82-130 ppm) and Cr (148-237 ppm) abundances, elevated Sr (1759-1927 ppm) and Ba (1742-2289 ppm) concentrations, and high LREE (La_N=38-487). Such geochemical features are similar to Archean sanukitoids. A two-stage model is applied here to explain the genesis of metadiorites of Dengfeng complex: (1) firstly, the mantle is metasomatized either by melts or by aqueous fluids from a subducted slab; (2) then, sanukitoid magmas were produced by partial melting of the hybridized mantle. Furthermore, the amphibolites of supracrustal rocks have a mixture of MORB- and arc-like geochemical affinities, suggesting the development of a back-arc in the southern part of the NCC at ca. 2.5 Ga. The contemporary late Neoarchean TTGs, sanukitoids and MORB-back arc association may represent a late Neoarchean tectonic mélange, implying for a Neoarchean subduction-accretion process and the modern-style plate tectonics processes probably initiated in the southern NCC by 2.5 Ga.

Molecular iodine emission rates from *Laminaria digitata* as a function of algal part, irradiance and temperature

S. DIXNEUF[1,2], A.A. RUTH[1,2], U. NITSCHKE[3] AND D.B. STENGEL[3]

[2]Environmental Research Institute, University College Cork, Ireland
[3]Botany and Plant Science, School of Natural Sciences, Ryan Institute for Environmental, Marine and Energy Research, National University of Ireland Galway, Galway, Ireland

Sea-to-air biogenic iodine fluxes play a key role in the global and local environmental iodine cycles, particularly in coastal areas where kelp beds are exposed to air during spring tides. The general knowledge of the marine sources and mechanisms of (elemental) iodine emission, either as molecular I_2 or volatile iodo-carbons, is still very limited.

Here time-resolved flux measurements of I_2 emitted by the brown macroalga *Laminaria digitata*, probably the strongest iodine accumulator amongst living organisms, were achieved by applying incoherent-broadband cavity-enhanced absorption spectroscopy (IBBCEAS) [1,2]. I_2 emission rates of three different (air-exposed) thallus parts of *L. digitata*, i.e. the distal blade, the meristematic area, and the stipe, were investigated under low-light and dark conditions [3]. Furthermore, impacts of light intensity and temperature on the I_2 emission rates were investigated for blades. Overall I_2 emissions were highly variable, but the release from stipes was ten times higher than that from meristematic areas and distal blades. Increased irradiances and temperatures resulted in higher I_2 emissions, indicating the importance of I_2 in algal stress responses. The results suggest that I_2 emission may be considered an indicator of the physiological status of the alga, and that iodine might have a multifunctional role in *L. digitata*.

Advances in theory, algorithms, software, and computer architectures, have made it possible to begin to calculate reliably the thermodynamics for geochemical processes in solution. There is a need to develop a fundamental understanding of actinide-aggregate formation under conditions that promote hydrolysis. We are developing the scientific basis for a molecular-level understanding of nanoaggregate species in terms of their structures, stabilities, formation reactions, and surface reactivities, particularly the formation of colloidal particles containing heavy elements. In addition, this research will help us to meet the need to develop new separations strategies for next generation nuclear fuels that are better able to remove stable metal aggregates without the need for extreme solution conditions. Our focus is on the initial aqueous reactions including olation and oxolation as well as the acidity of metal ions in solution. For the +2 metal aquo ions, it is possible to predict the size of the first solvation shell by predicting the correct pK_a in terms of experiment. Positive ions with a charge > +2 require more solvent shells in order to predict the pK_a reliably. We have studied a wide range of oxolaton and olation reactions of +2 cations and the type of reaction that dominates in terms of the thermodynamics is dependent on the cation size, the size of the first solvation shell, and the electronic structure of the ion. The structures of $(ThO_2)_n$ nanoclusters have been studied and compared to the analogous transition metal nanoclusters. Calcuations of the hydrolysis reactions of the nanoclusters provide for the first time an estimate of the physisorption and dissociative chemisortion energies of H_2O on the ThO_2 surface. The electronic structure of nanoparticles containing a Th_6O_8 core will be discussed including predicitions of particle acidity and proton location. These particles are of interst as they contain a Th_6O_8 core embedded in an anion shell. There is good agrement between theory and experiment for the structures of the clusters.

Speed limits to soil weathering and CO_2 withdrawal

JEAN L. DIXON AND FRIEDHELM VON BLANCKENBURG

GFZ German Research Centre for Geosciences, Potsdam, Germany (jeannie@gfz-potsdam.de, fvb@gfz-potsdam.de)

Weathering fluxes in soil-mantled landscapes are capped by a global maximum that has important implications for Earth's long term climate. We identify the empirical, statistical and theoretical limits to climate, weathering and uplift feedbacks using a new global compilation of long term, soil-based denudation and weathering rates from cosmogenic nuclides and short term, river-based sediment and dissolved loads. Weathering accelerates by the increased exposure of minerals to erosion, and recently it was suggested that 50% of the global CO_2 withdrawal occurs in the worlds active mountain belts [1]. The observation that chemical weathering rates and physical erosion rates are tightly correlated has vindicated this hypothesis. But this relationship is predominantly valid for soil-mantled landscapes, and not rapidly uplifting mountain belts. We show that the rate of soil production obeys a global 'speed limit' of 270 t km^{-2} y^{-1}, and the associated soil weathering flux a limit of 135 t km^{-2} y^{-1}, corresponding to denudation and weathering rates of 100 and 50 mm ky^{-1}, respectively. Erosion rates may far exceed the soil speed limit, and are typically associated with landscapes of high relief and hillslope gradients [2]. There, erosion is governed by mass wasting processes typical of non-soil-covered landscapes in active mountains [3]. Yet chemical weathering rates from dissolved loads of rapidly eroding mountain rivers suggest that these landscapes also obey or fall below the limit of weathering observed for soils. Considering that such mountain belts are a small component of the continental land surface, we quantify that even if weathering fluxes in such areas were higher than today, they would represent a minor contribution to global CO_2 withdrawal. Therefore, Earth's long term climate sees little drawdown and more drawbacks from uplifting areas where denudation drives above the soil speed limit.

Why do earthworms synthesize ACC?

P. DIZ[1] , C.L. GIL[1], J. MENDEZ[3], M.J.I. BRIONES[2] AND L.G. DUPORT[1]

[1]Dept. Geociencias Marinas. Universidad de Vigo, 36310 Vigo, Spain

[2]Dept. Ecología y Biología Animal. Universidad de Vigo, 36310 Vigo, Spain

[3]CACTI. Universidad de Vigo, 36310 Vigo, Spain

From the early work by Darwin [1] several hypotheses have been proposed to answer this question, namely pH buffering of the blood and the ingested plant material, respiratory functions, egg formation or simply spurious mineralization.

In this study we investigated the microstructural transformations which take place during the carbonate formation inside the calciferous gland of the earthworm species *Lumbricus friendi* Cognetti. We firstly identified the presence of ACC [2] by FTIR and then we followed the different evolution stages of calcium carbonate in the precursor fluid previous to the formation of to the solid phases by performing *in situ* XRD experiments.

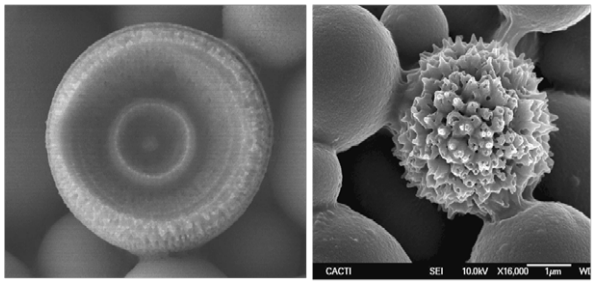

Figure 1. Two transformation stages from ACC to crystalline phases in earthworm's spherulites.

The results presented here shown that the formation of crystalline polymorphs of calcium carbonate in earthworms is preceded by the precipitation of ACC in a process that seems to follow a truly biomineralization mechanism, controlled by the organism. The high solubility is beneficial for temporal storage of calcium carbonate ions which could then get dissolved and used elsewhere according to the organism's requirements. Stabilisation of ACC seems to be achieved thanks to the presence of macromolecular constituents in the organic matrix, which also could be selectively used to promote the elimination of carbonate excess by nuclei induction of the crystalline phases and thus providing an efficient mechanism for Ca^{+2} control in the intracellular fluids.

Toxicity of silver nanoparticles to environmental microbial consortia

JAN DOBIAS[1], ALESSANDRA COSTANZA[2], ELENA I. SUVOROVA[1], MASSIMO TROTTA[3] AND RIZLAN BERNIER-LATMANI[1]*

[1]Environmental Microbiology Laboratory, EPFL – Ecole Polytechnique Fédérale de Lausanne, 1015 Lausanne, Switzerland. (*correspondence: rizlan.bernier-latmani@epfl.ch)
[2]Università degli Studi di Bari Aldo Moro, 70121 Bari, Italy.
[3]Department of Chemistry, University of Bari, 70126 Bari, Italy.

Nanomaterials, particularly silver nanoparticles (AgNPs), are present in a large number of consumer goods due to their strong antimicrobial properties. Their extensive use raises concerns as to their release to the environment and their potential toxicity to aquatic microbiota.

The mechanism of AgNPs toxicity remains elusive and may include direct inhibition by the nanoparticulate form and/or indirect toxicity via soluble silver released from AgNPs. Additionally, numerous studies have attempted to unravel the role of AgNP size and coating in bacterial toxicity response but there remains a large gap in our understanding of the impact of basic AgNP characteristics on their toxicity.

Here we report on a systematic study of AgNP toxicity towards two pure cultures -*Escherichia coli* and *Bacillus subtilis*- and a microbial community from lake Geneva. We studied the effect of size (5nm, 10nm, 20nm, 50nm and 100nm) and that of surface coating (polyvinylpyrrolidone, tannic acid, citric acid and carbonate) on toxicity.

The AgNPs were obtained commercially and extensively characterized by electron microscopy (EM), dynamic light sacttering, zeta potential and the release of silver ions quantified by inductively coupled plasma mass spectrometry. The impact of AgNPs (0 to 1mg/L) on growth was monitored by optical density at 600nm, by colony formation for pure cultures and by measuring protein concentration and monitoring the microbial diversity of the community for the consortia. Additionally, the spatial relationship of AgNPs and cells was assayed by EM imaging of resin-embedded cells. The environmental relevance of the experimental conditions was ensured by growing cultures in artificial lake water.

Results to date show little toxicity to laboratory strains with *E. coli* being more sensitive than *B. subtilis* and size being a less important factor than surface coating. The systematic approach of this study –where AgNP size distribution is narrow and the geochemical conditions and microorganisms environmentally relevant- may be helpful to policy makers aiming at regulating the use of AgNPs in consumer goods.

VESPERS XRF and Laue Diffraction mapping of Carlin-type auriferous arsenian pyrite

A. DOBOSZ[1]*, G.R. OLIVO[1] AND A.R. PRATT[2]

[1]Department of Geological Sciences, Queen's University, Kingston, Ontario, K7L 3N6, Canada (*correspondence: 6ad2@queensu.ca)
[2]CANMET Mining and Mineral Sciences Laboratories, Natural Resources Canada, 555 Booth St, Ottawa, Ontario, K1A 0G1, Canada (Allen.Pratt@NRCan-RNCan.gc.ca)

Carlin-type gold deposits produce 8% of the world gold, and the main ore is auriferous pyrite commonly associated with various trace elements (Ag, As, Au, Cu, Hg, Ni, S, Sb, Se, Te, Tl and Zn). Their compositions have been investigated using electron-microprobe (EMP) and dynamic Secondary Ion Mass Spectrometry (SIMS), which indicates that gold and related trace elements occur in complex, micrometer-size irregular zones or overgrowths within single grains. The development of VESPERS (Very powerful Elemental and Structural Probe Employing Radiation from a Synchrotron) allows for non-destructive elemental mapping and crystal structure determination through XRF and Laue diffraction (LD). This methodology was applied in selected auriferous pyrite grains that were previously investigated using EMP and SIMS to advance our understanding of the relationship between the abundance of trace-elements and crystal structure.

The VESPERS elemental mapping results are consistent with those obtained by SIMS and EMP; however it offers the advantage of mapping a wide range of elements and the collection of LD patterns simultaneously and non-destructively. The elements that have adequate peak resolutions are Au (L series) and As, S, Fe, Ni, Cu (K series). Elements with peak overlap that have not yet been resolved include Ag, Sb, Te, Tl and Zn. Synchrotron LD data was collected along selected domains and the crystal structures are being interpreted.

Fluids nature at peak of ultrahigh-pressure metamorphism in deep subduction zones – Evidence from diamonds

L. Dobrzhinetskaya[1]*, R. Wirth[2], H.W. Green[1] and H. Sumino[3]

[1]University of California, Riverside, CA 92521, USA (*correspondence: larissa@ucr.edu)
[2]GeoForschungsZentrum, D-14473, Potsdam, Germany
[3]The University of Tokyo, Tokyo, Japan

Role of fluid circulating in deep subduction channels was/is a subject of many outstanding geochemical and numerical modelling studies. One of the intriguing processes is a fluid-rock interaction during subduction of the continental slab because the latter is characterized by contrast chemistry in comparison with the surrounding mantle and its fluids. Diamond due to its chemical inertness is the only mineral which contains "unchanged" fluids that was trapped during its crystallization at the peak of UHP metamorphism. We have demonstrated earlier with FIB-TEM studies that many diamonds from the UHPM terranes of Kazakhstan and Germany preserved intact C-O-H fluid inclusions [1]. This fluid responsible for diamond crystallization contains traces of both crustal and mantle components: Al, K, Ca, Mg, Fe, Si, Ti, V, Zn, Co, Fe F, Cl, S [1]. We have recently found more evidence to support crust-mantle origin of the fluids penetrating continental slabs in the deep subduction channels. This derives from a new finding of the polycrystalline diamonds included in zircons from Erzgebirge quartz-feldspathic gneisses containing remnants of fluid available for their compositional evaluation with EDAX spectrometry. The diamonds consist of 5-15 crystals of 0.3-5 micron size with a typical "zig-zag" grain boundaries and triangle voids filled with a C-O-H fluid with traces of Al, Co, F, V, Zn, Si, Cl, S, Ca, Mg, Fe, K in different combination. Such observations emphasize that diamonds from UHPM terranes have a similar nature of crystallization – from a fluid originated from a mixed crust-mantle geochemical reservoir. Moreover, the Kokchetav diamonds $^3He/^4He$ ratios are similar to those known for OIB setting [2]. Sumino *et al*. have suggested an interaction of the subducted continental slab with the deep mantle plume at the depth of the diamond stability filed. Therefore, the fluids penetrated continental slabs in deep subduction channels at peak of UHPM might originate from crust – mantle – deep mantle plume reservoirs.

Kinetics of the reaction perovskite + ferropericlase = ringwoodite

David Dobson[1], James Badro[2], Anders Meibom[3] and Elisabetta Mariani[4]

[1]UCL, UK, (d.dobson@ucl.ac.uk)
[2]IPGP Paris, France.
[3]MNHN, Paris, France
[4]University of Liverpool, UK

The kinetics of solid-state disproportionation reactions can be strongly assymetric due to the different diffusive length scales of disproportionation versus recombination. Transport of material from the lower mantle into the transition zone requires the reaction of perovskite (pv) plus ferropericlase (fp) to produce ringwoodite (rw); this reaction is diffusive on the grain-length scale and hence might allow a significantly wide region where metastable phases exist. We present experiments to investigate the kinetics of this reaction. We have assumed that the transformation from pv to majorite (mj) is fast (being diffusive at the unit-cell length scale) and hence performed coupled reaction experiments of MgO with $(Mg,Al)(Al,Si)O_3$ mj at a pressure of 20 GPa (in the rw and mj stability fields) at temperatures of 1773 to 2123 K. The reaction is, as expected, mediated by diffusion of chemical components through the growing rw layer, with growth rate of the layer being linear with t^2. Rw grows with strong topotactic relations to the MgO which would, on completion of the reaction, result in single (or twinned) crystals of rw replacing the MgO grains. However, the kinetics of the reaction is further complicated by the incompatibility of aluminium in rw. As the rw layer grows, a double-diffusive instability develops with the rw-mj interface becoming fingered to maximise the surface area from which to diffuse aluminium into the garnet. The mean grain-size of regions with this texture is ~2 micrometres, which shows little coarsening due to zenner pinning. Reaction continues until all of the MgO is replaced leaving fine-grained reaction rims between these rw regions and the remaining excess $(Mg,Al)(Al,Si)O_3$ garnet. Two ways to estimate the grain size of the lower mantle might arise from this:

1. Seismological estimates of the thickness of the 670-km discontinuity are consistent with the equilibrium reaction. This means that the width of the region where the metastable mj + fp = rw reaction occurs is below seismological resolution.

2. The reaction texture might (occasionally) survive in porphyroclastic mantle xenoliths.

Both these estimates are consistent with a maximum lower-mantle grain size of about 1 cm.

Mid and heavy REE in carbonatites at Lofdal, Namibia

V.N. DO CABO[1], F. WALL[2], M.A. SITNIKOVA[3], R. ELLMIES[1,3], F. HENJES-KUNST[3], A. GERDES[4] AND H. DOWNES[5]

[1]Geological Survey of Namibia, Ministry of Mines and Energy, Windhoek, Namibia

[3]BGR, Federal Institute for Geosciences and Natural Resources, Hannover, Germany
[4]Goethe-University Frankfurt, Frankfurt, Germany
[5]Birkbeck University of London, London, UK

Carbonatites provide most of the World's rare earth elements (REE) but are characteristically enriched in the light REE with low contents of the more highly sought after mid and heavy REE. The Lofdal carbonatite complex, 35 km NW of Khorixas, Namibia, is an exception in that it contains hundreds of carbonatite dykes, some of which are mid and heavy REE-enriched, containing up to 3% xenotime-(Y) in dolomite-ankerite and ferruginous calcite carbonatite. Gd and Dy are the most abundant lanthanides in the xenotime-(Y). ThO_2 content is the main environmental problem with REE deposits and at Lofdal, there is up to 1 wt% ThO_2 in magmatic xenotime-(Y) and usually lower, about 0.3 wt%ThO_2, in hydrothermal xenotime-(Y). However, many rocks contain Th silicate. The hydrothermal xenotime-(Y) occurs in shear zones and associated calcite has a high $^{87}Sr/^{86}Sr$ ratio of 0.70804, $\delta^{13}C$ (‰V-PDB) of -3.66 and $\delta^{18}O$ (‰V-SMOW) =18. The xenotime-(Y) at Lofdal is the same age as the main carbonatite (765 ±16 Ma) and thus later metamorphic alteration can be ruled out. However, together with the presence of xenotime-(Y) in albitised country rocks and carbonatite-free shear zones, there is good evidence that most of the xenotime-(Y) formed from a carbonatite-related hydrothermal system circulating around the dykes.

Magmatic processes during the formation of Monte dei Porri Volcano, Island of Salina, Aeolian Islands, Italy

A. DOHERTY[123], B. DE VIVO[3], R. BODNAR[1], H. BELKIN[4] AND A. MESSINA[2].

[1]Fluids Research Laboratory, Virginia Tech (VT), Blacksburg, USA (angdoh@vt.edu)

[3]Dipartimento di Scienza della Terra, Università di Napoli Federico II), Italy
[4]United States Geological Survey, Reston, VA, USA

The island of Salina is the second largest of the Aeolian Islands, the subaerial expression of the Aeolian Magmatic Arc, located in the Tyrrhenian Sea, southern Italy. Salina lies in the centre of the arc and exhibits the widest variation in geochemical composition across all the Aeolian Islands, ranging from high-alumina basaltic to dacitic lava flows to rhyolitic pumiceous tephras erupted from 6 volcanic centres.

The Monte dei Porri volcanic eruptions were the last cone building events on the island occurring between 67ka and 13ka and occurred after 60ka of repose. The units consist of basaltic-andesite to dacite lavas, interlayered with unconsolidated tephras consisting of juvenile scoria fragments, entrained lithics and rhyolitic pumices. Phenocryst assembleges consist of calcic plagioclase (often with oscillatory zoning), clinopyroxene (augite), olivine and titanium-iron oxides ± orthopyroxene (often zoned), K-feldspar and quartz. Melt inclusions are a ubiquitous feature of all units and appear to be recrystallized in the lavas and occur as both recrystallized and glassy inclusions with and without vapour bubbles in the tephras. Rare primary fluid inclusion assemblages are also present in the tephras.

Raman spectroscopy of the glassy melt inclusions of the tephras reveals the presence of volatiles in the melt inclusion glass in the form of H_2O. CO_2 was not found in the glass or the vapour bubbles. Geothermometry based on plagioclase-liquid and clinopyroxene-liquid models indicates crystallisation temperatures of ~1200°C for feldspars and ~1050°C for clinopyroxene phenocrysts.

Petrographic analysis suggests the mixing of one or more magmas with different compositions played an important role in the evolution of the magmatic system.

A predictive thermodynamic model for element partitioning between plagioclase and melt

RALF DOHMEN[1] AND JON BLUNDY[2]

[1]Ruhr-University Bochum, Germany (ralf.dohmen@rub.de)
[2]University of Bristol, UK (jon.blundy@bristol.ac.uk)

There are various attempts in the literature to infer from the chemical zoning in plagioclase phenocrysts the magma evolution [1] and to determine magma residence times of plagioclases from diffusion modelling [2]. Both methods rely on accurate knowledge of partitioning coefficients between plagioclase and melt, D_i, and their dependencies on thermodynamic parameters and chemical composition. Based on a regular mixing model and numerical fitting of numerous experimental data [3] derived an equation for Sr and Ba of the form, $RT \ln D_i = A_i{*}X_{An} + B_i$. In a more recent work [4] the same relation was also used for various other elements to fit experimental pl-melt partitioning data. However, there is no a priori justification to use this relation also for other elements than Ba and Sr.

Here we present a new predictive model for the element partitioning between the metal site in plagioclase and melt. We have used the Brice model [5] to fit simultaneously the experimental data of 115 partitioning experiments, including those of [4] and unpublished data (partially published in [5]). The dependency of D_i on X_{An} is dominated by lattice strain effects and is related to the linear dependence of the optimum ionic radius r_0 on the anorthite content. Once the relevant parameters of the Brice model, r_0 and the Young's modulus of the site, are calibrated, the partitioning data can be corrected to isolate their T dependence. The inferred T dependence of the divalent cations and monovalent cations is perfectly consistent with available data for the free energy of fusion for anorthite and albite, respectively. The effect of the melt chemistry cannot be ignored in general but is minor compared to the lattice strain effects in most cases.

The major implication of this new model is that D_i becomes less sensitive to X_{An} and more sensitive to T than predicted by the relations of, e.g., [3] and [4]. This can be explained by the implicit relationship of X_{An} and T in most partitioning experiments.

Sr-Nd-Hf-Pb isotope systematics of the Oyu Tolgoi Cu-Au deposit (Mongolia)

A. DOLGOPOLOVA[1]*, R. SELTMANN[1], R. ARMSTRONG[1], E. BELOUSOVA[2] AND R. PANKHURST[3]

[1]NHM, Department of Mineralogy, CERCAMS, London SW7 5BD, UK (*correspondence: allad@nhm.ac.uk)
[2]GEMOC, Macquarie University, NSW, 2109 AUSTRALIA (elena.belousova@mq.edu.au)
[3]BGS, Keyworth, Nottingham NG12 5GG, UK (rjpankhurst@gmail.com)

New Sr-Nd, Hf and Pb isotope data are presented for a representative suite of 21 samples of plutonic and volcanic rocks (D_3 to C_1) from the giant Oyu Tolgoi porphyry Cu-Au district in the South Gobi, Mongolia.

Sr-Nd isotopes (whole-rock) show a restricted range of initial compositions, with εNd varying from +2.1 to +7.4 and ($^{87}Sr/^{86}Sr$)t predominantly between 0.7035 and 0.7045 reflecting formation from a relatively uniform juvenile lithophile-depleted source.

Hf isotopes (zircon) exhibit a range of -4.5 to +13.6 (**Fig. 1**). Felsic rocks show predominantly (apart from one sample) a juvenile mantle-derived signature whereas volcanic rocks exhibit some mixing with evolved crustal sources.

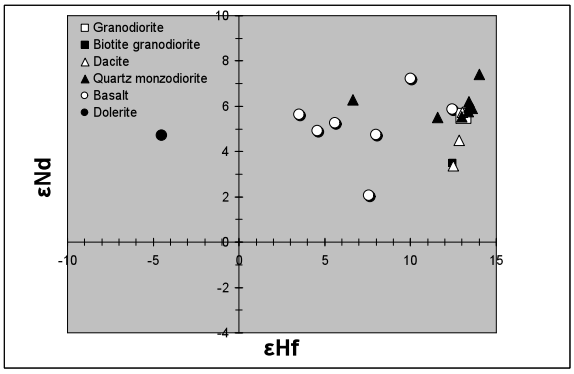

Figure 1: Hf and Nd isotopes for the Oyu Tolgoi deposit.

Pb isotopes (whole-rock) indicate a rather preserved array of isotopic compositions such as $^{206}Pb/^{204}Pb$ 17.773-19.058, $^{207}Pb/^{204}Pb$ 15.445-15.544 and $^{208}Pb/^{204}Pb$ 37.456-38.489. These are in full agreement with Sr-Nd-Hf isotopes indicating presence of a mantle component. Several samples show contributions from a MORB-related source.

All four isotopic systems hint that magmas from which the large Oyu Tolgoi porphyry system was generated, originated predominantly from juvenile material within the subduction-related setting of the Gurvan-Saikhan terrane.

Biogeochemical sustainability of semi-natural ecosystem

V.V. DOLIN

Institute for Environmental Geochemistry, 34-a, Palladin av., 03680 Kyiv, Ukraine (vdolin@i.com.ua)

The research is based on the novelty balance approach to the migration of artificial matter between biotic levels of an ecosystem and inanimate matter. *The Geochemical transition factor (GTF)* that represents the quantity of substance accumulated by plants from the area unit has been utilized for balance calculations. The temporal dinamics of GTF, permiting to asses the intensity of *biogeochemical flux,* suggested as volume of substance transferring during the time unit through the area unit of conditioned interface between abiotic and biotic levels.

In meadow ecosystem the only 10^{-5}–10^{-3} part of artificial contaminants is involved to biogeochemical cycling. The conciderably greater part accumulates in living matter of forest ecosystem: up to 50% of ^{14}C (Fig. 1), 10% of ^{3}H, 20% of ^{90}Sr, 13% of ^{137}Cs, 3% of ^{241}Am, 6% of Zn, 1% of Al and Ni, and less than 1% of Fe, Mn, and Cu. Artificial radionuclides and heavy metals are strongly accumulated in bottom deposits of aqueous ecosystem: anomalies of contamiation are closely localized to the pollution source. Accumulation of ^{14}C by micelium from irradiateted graphite is 50-100 times less than from sucrose solution in check experiment.

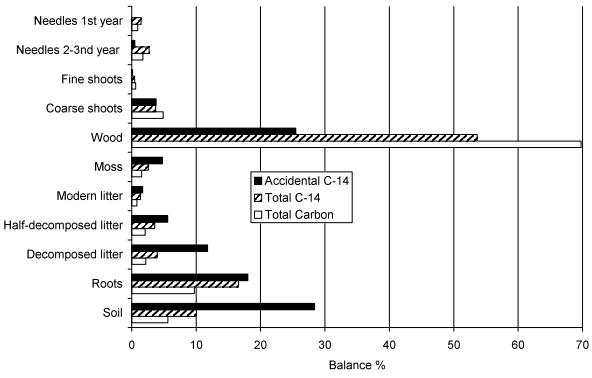

Figure 1. Distrubution of Carbon isotopes in pine ecosystem

The insignificant part of artificial matter involved to biogeochemical cycling determines the environmental capacity to contamination. Experience of geoecological investigations gives rise to conclusion about comparative sustainability of ecosystems in spite of the catastrophic increase of artificial loading.

Compact representation of complex organic aerosol processes

M.M. DONAHUE

Center for Atmospheric Particle Studies, Carnegie Mellon University, Pittsburgh, PA 15213, USA

Myriad organic compounds constitute organic aerosol (OA), tightly interconnecting multiphase chemistry, phase partitioning equilibria, and mass-transfer dynamics. Representations range from bare-minimum simplicity (e.g. emitting 12.5% of all terpenes as non-volatile, non-reactive, water-soluble organic aerosol) to maximal complexity (explicitly representing the multiphase chemistry and phase partitioning of millions of compounds). We favor a middle ground, grouping organic compounds in a property-based space that is directly tied to both vial physical properties as well as observable characteristics of ambient and lab-generated organic particles. This is the volatility basis set.

The first incarnation followed a single property – volatility – expressed in terms of a saturation mass concentration and typically lumping compounds into bins separated by factors of 10 in a logarithmic space. The 1D-VBS can precisely describe ideal phase partitioning over as many orders of magnitue as the number of bins. It can thus span the complete range of volatility relevant to atmospheric organics with 9 or so model compounds. It can also be used to fit chamber and dilution data to empirically constrain the volatility distribution of complex processes. It fosters insight into chemical evolution by forcing a mass balance. However, the single dimension suffers when confronted with non-ideal solutions as well as complex chemistry.

We have now added a second dimension, representing the oxidation of organics, to form a 2D-VBS. Oxidation state of bulk aerosol can be directly measured with advanced mass spectroscopy, and of course individual molecules can be located in this space as well. Oxidation in the atmosphere is irreversible, while volatility goes through a minimum as oxidation progresses. These fundamental behaviors are readily captured in the 2D-VBS.

As an illustration and test of OA evolution, a large team conducted the Multiple Chamber Aerosol Chemical Aging Study (MUCHACHAS) in 2008-2010 to observe the effects of OH radical "aging" on biogenic secondary organic aerosol (SOA). The effects were dramatic. They varied in different chambers, but a 2D-VBS model of the chemistry and chamber characteristics captures this variation using a predictive, previously published description of OA aging chemistry, showing that OA mass can double with aging. This aging chemistry must be included in transport models.

[3]Institute of Earth Environment CAS, Xi'an, China
[4]IIT-Kanpur, 208016 (UP), India

Copper (Cu) and zinc (Zn) play key roles in aquatic ecosystems. Zinc is an essential trace element limiting the biological productivity in the open ocean and Cu is potentially toxic to phytoplankton. Work to date suggests that the stable isotope systems of these metals can improve our understanding of their aqueous chemistry and behaviour in the marine environment. Significant spatial variability in isotopic ratios was found between and within ocean basins.

At present, one of the major gaps in knowledge is the characteristics of the isotopic composition of Zn and Cu of terrestrial sources into the marine ecosystem, in particular atmospheric deposition, which is the major source of trace elements to the remote open ocean.

Here we present the first characteristics of the Cu and Zn isotope compositions of the major dust sources in China and India, and discuss the findings with respect to (i) the dominant controls (mineralogy size fractions and Enrichment Factor), and (ii) their implication for the application to marine studies, focussing on the North East Pacific Ocean (NEPO).

a) We observe significant Cu and Zn isotopic variations between bulk samples from Chinese dust, Chinese Loess, and Indian dust (error in 2SD), i.e., Chinese deserts (Taklamakan, Badain Jaran, and Tengger): $\delta^{65}Cu_{NIST976}$= 0.06±0.11‰ (n=10), $\delta^{66}Zn_{Lyon}$= 0.19±0.19‰ (n=10); Chinese loess: $\delta^{65}Cu_{NIST976}$= 0.27±0.19‰ (n=12), $\delta^{66}Zn_{Lyon}$= 0.41±0.17‰ (n=15); Thar Desert (India): $\delta^{65}Cu_{NIST976}$= 0.48±0.12‰ (n=4), $\delta^{66}Zn_{Lyon}$= 0.49±0.22‰ (n=5). b) Cu isotope values seem to be negatively correlated with the abundance of the clay mineral illite at 95% CI R^2 = 0.74, (n=10). c) The $\delta^{65}Cu_{NIST976}$ and $\delta^{66}Zn_{Lyon}$ values differ among the various size fractions of Chinese deserts by up to 0.97 ‰ (Tengger Desert) and 0.35 ‰ (Taklamakan Desert), respectively. This implies that bulk isotopic signatures might be misleading for the characterization of dust. d) Enrichment factors (EF) of the dust range between 0.48 (Thar Desert) and 1.86 (Taklamakan Desert) for Cu and between 0.40 (Chinese loess) and 0.70 (Tengger Desert) for Zn, suggesting that the lower EF values, the heavier the isotope signature of the dust. e) The isotope signature of long range transport Chinese dust (≤5 μm) input to the NEPO area has values of $\delta^{65}Cu_{NIST976}$ = 0.16±0.19‰ and $\delta^{66}Zn_{Lyon}$ = 0.29±0.24‰, which are lower for Cu and similar of Zn relative to the isotope signatures of dust input estimated in pervious studied of NEPO surface waters.

Multiple magma inputs and sulfur sources in the development of the BIC intrusion, Northern Michigan, Midcontinent Rift system

KELLIE DONOGHUE* AND EDWARD RIPLEY

Indiana University, Bloomington, IN 47408 (*correspondence: Kdonoghu@indiana.edu, Ripley@indiana.edu)

The BIC intrusion is located in the Marquette-Baraga dike swarm in the Upper Peninsula of Michigan, and is associated with magmatism related to the development of the ~1.1Ga Midcontinent Rift System. The intrusion is currently being evaluated for the presence of economically viable sulfide-rich Ni- Cu-(PGE) mineralization. Rio Tinto's Eagle deposit is located 43 km to the west within the same dike system; the geometric form of the BIC intrusion, however, is distinctly different from those of the intrusions found in the vicinity of the Eagle deposit. The BIC intrusion is funnel-shaped with basal peridotite overlain by clinopyroxenite and gabbro. Sulfide minerals (pyrrhotite, chalcopyrite, pentlandite) are found in all of the units units but massive sulfide mineralization is restricted to the base of the peridotite unit. Country rocks are composed of siltstones and shales that are sulfide-bearing themselves. A smaller satellite intrusion is referred to as Little BIC, which is composed of peridotites with both massive and semi-massive (net-textured) mineralization.

Sulfide distribution in the BIC intrusion is variable, suggesting that multiple pulses of sulfide-saturated magma were involved in its genesis. $\delta^{34}S$ values of sulfide minerals throughout the intrusion fall within a narrow range of -2 to +2‰. $\delta^{34}S$ values of the sedimentary country rocks show a much wider range of -6 to +20‰. The massive sulphides in Little BIC have the same narrow range of $\delta^{34}S$ values as in BIC, but semi-massive sulphides are considerably higher (~+6‰) and clearly signify a large component of crustally derived sulfur. The BIC system conforms to a growing body of evidence for the importance of multiple sulfur sources in conduit-related Ni-Cu-(PGE) occurrences. We are currently evaluating the possibility that different processes for the attainment of sulfide saturation (e.g. fractional crystallization versus sulfur assimilation) are responsible for the sharp difference in $\delta^{34}S$ values between semi-massive sulfides at Little BIC and other sulfide occurrences in the system.

Do fluid inclusions preserve their initial composition? Experimental studies of H_2O diffusion through quartz

G. DOPPLER*, M. BAUMGARTNER AND R.J. BAKKER

University of Leoben, 8700 Leoben, Austria
(*correspondence: gerald.doppler@unileoben.ac.at)

The main focus of our diffusion studies lies on experimental works on synthetic and natural fluid inclusions (FI) in well selected quartz crystals. A major point of our investigations is to perform re-equilibration experiments with synthetic FI which are composed of water-related species, such as H_2O, D_2O and $H_2{}^{18}O$, at known P-T conditions and specific molar volumes of the liquid phase. Due to the possibility of post-entrapment compositional and density changes of FI, the analyses of fluid properties have to be performed with particular attention. To comply with this requirement we work on molecules with different properties, e.g. different melting points of H_2O and D_2O (melting points: 0 °C H_2O vs. +3.8 °C D_2O) to achieve better quantitative insights on the diffusion rates. Re-equilibration experiments are carried out at high experimental temperatures and pressures (max. 700 °C and 1 GPa). We design our recent experimental work to test the behaviour of aqueous FI in quartz under conditions of different pressure and different water fugacity. We expect a movement of the water-related species within the quartz lattice. Re-equilibration processes are not yet fully understood, therefore further investigations are required to characterize all aspects of post-entrapment changes in FI. Additionally we are able to determine changes in the shape of the synthesised inclusions (morphological changes) interrelated with the location (depth) of the inclusions within the quartz crystal. First results leed to the assumption that the size, the shape (Fig. 1) and the location directly correlate. This unambiguously correlates with the measured changes in the fluid-phases composition of the primary synthesised FI.

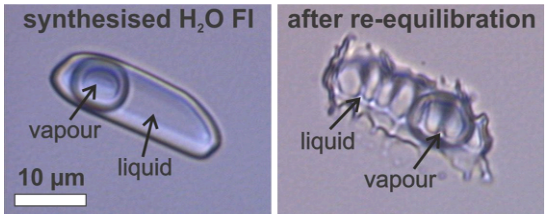

Figure 1: Photomicrograph of a FI in quartz after 19 days of re-equilibration. Pressure: 337 MPa; Temperature: 600 °C (left), 400 °C (right).

Host rocks of Santa Eulalia Plutonic Complex (Southern Portugal): A preliminary study

A. DÓRIA*, M.A.RIBEIRO, H. SANT'OVAIA AND F. FERNANDES

Centro Geologia, Faculdade de Ciências, Univ. Porto R. Campo Alegre, 4169-007 Porto, Portugal
(*correspondence: adoria@fc.up.pt)

The Santa Eulália Plutonic Complex (SEPC) is a calcalkaline granitic body that occupies an area of 400 km^2 and is located in the Variscan Iberian sector. SEPC is considered as late-Variscan because it cross-cuts the regional variscan structures, namely a major NW-SE shear zone in the contact between the two axial geotectonic zones of the iberian varican belt. The host rocks of the plutonic complex are composed by metamorphic formations from Upper Proterozoic to Lower Paleozoic. In the NE-sector of the shear zone a metasedimentary Ediacaran unit (Série Negra) outcrops, composed by metasedimentary siliciclastic rocks, including some black cherts. In the SW-sector of the shear zone, a low-grade metasedimentary and metavolcanic unit involving quartz-pelitic, carbonated and volcanic rocks, correspond to the Early Cambrian sequence.

In the western sector of SEPC, several metasedimentary enclaves are present mainly with pelitic and carbonated composition. These enclaves show internal structure and lithological diversity consistent with the external metasedimentary units and, due to the thermal effect, have intense metamorphic recrystallization. One of the enclaves near the NW border of SEPC, marble, calc-silicated rocks and acid porphyritic rocks were studied, including petrography, mineral and whole-rock chemistry. The calc-silicated and the porphyritic rocks show similar Eu-nomaly, Eu/Eu* respectively 0.86 and 0.88. However, the fractionation of LREE and HREE is quite different: in porphyritic rocks $(La/Sm)_n$ = 6.59, $(Gd/Yb)_n$ = 2.13, $(La/Yb)_n$ =28.9 and ∑REE = 233.51, while in calc-silicated rocks $(La/Sm)_n$ = 1.66, $(Gd/Yb)_n$ = 1.38, $(La/Yb)_n$ =3.04 and ∑REE = 181.63. The marble has a higher negative Eu-anomaly, with Eu/Eu*=0.57 and $(La/Sm)_n$ = 3.15, $(Gd/Yb)_n$ = 1.62, $(La/Yb)_n$ =7.87 and ∑REE = 17.31. These preliminary geochemical data indicate that all these lithologies derived from a continental crustal source.

This work has been financially supported by PTDC/CTE-GIX/099447/2008 (FCT-Portugal, COMPETE/FEDER).

Synoptic approaches to scale CH_4 flux in boreal landscapes

P. DÖRSCH[1]*, H. LANGE[2], B. THOMAS[3], H. SILJANEN[4], S. JENSEN[5] AND L. BAKKEN[1]

[1]Norwegian University of Life Sciences, 1432 Ås, Norway (*correspondance: peter.doersch@umb.no)
[2]Norwegian Forest and Landscape Institute, 1431 Ås, Norway
[3]Leibniz Center for Agricultural Landscape Research, D-15374 Müncheberg
[4]University of Eastern Finland, Kuopio, Finland
[5]University of Bergen, Norway

Boreal wetlands are an important source of atmospheric methane (CH_4) and susceptible to future climate change. Typically, boreal wetlands form microtopes embedded in complex landscapes, posing a challenge to scaling CH_4 source strength to greater areas. Here we report on an analysis of air borne (LiDAR, hyperspectral scanning) and ground based (chamber measurements, molecular analysis) approaches to characterize and scale CH_4 fluxes in a highly stratified mountainous landscape in Southern Norway (60º22' N 9º39'E, 510-750 m, 3ºC, 850 mm). We investigated relationships between peat depth, porewater CH_4 concentrations and CH_4 emission fluxes and found a significant correlation between CH_4 pore water concentration and VNIR reflectance spectra. Spectral separation was further tested in predefined vegetation/wetland types. We used molecular markers and *in vitro* CH_4 uptake kinetics to infer the abundance and activity of type I and type II methanotrophs in different landscape units. Synoptic approaches to scale CH_4 flux in heterogeneous landscape by means of molecular and biophysical signatures will be discussed.

Investigation of the precision and accuracy of isotope ratio measurements for atmospheric sampling for laser ablation multi collector-ICPMS

LADINA DORTA, ROBERT KOVACS, JOACHIM KOCH AND DETLEF GÜNTHER*

ETH Zürich, Laboratory for inorganic Chemistry, Zurich, Switzerland (*correspondence: guenther@inorg.chem.ethz.ch)

Laser ablation ICPMS is a powerful method for solid sample measurements. The sample size is however limited by the ablation cell size. Many efforts were made in developing ablation cells with different volumes and shapes for large samples. However the coupling of a gas exchange device (GED) [1] to the ICPMS allows to get rid of the ablation cell. The laser ablation process takes place in air environment. The aerosol is sucked into the GED by a membrane pump through a tube located directly at the ablation site. In the GED, the air is exchanged to Argon. The aerosol is then transported to the ICP in an Argon atmosphere. The figures of merit for atmospheric laser ablation were determined and similar accuracies as for conventional laser ablation were reported [2].

Laser ablation coupled to a multi collector-ICPMS (MC-ICPMS) allows precise isotopic information of a sample, used for e.g. age determination. These samples are mostly archeological and do not always fit into an ablation cell. The isotope ratio determination with LA-GED-MC-ICPMS would therefore be a method of choice for large and precious samples.

The precision and the accuracy of the atmospheric sampling for isotope ratio measurements were investigated with a Ti-Sapphire based femtosecond laser (Legend, Coherent Inc., Santa Clara (CA), USA) coupled to a gas exchange device and a Nu Plasma (Nu Instruments, Wrexham, UK). The measurements were done on pure lead, galena, brass and zircon. Even if a loss in sensitivity is observed, similar precision and accuracy were obtained comparing the atmospheric ablation with the conventional laser ablation set up.

Inception! Quantifing U-series disequilibria during the early stages of granite alteration

ANTHONY DOSSETO[1] AND CLIFFORD S. RIEBE[2]

[1]GeoQuEST Research Centre, School of Earth and Environmental Sciences, University of Wollongong, Wollongong, NSW, Australia. (tonyd@uow.edu.au)
[2]Dept. Geology & Geophysics, University of Wyoming, Laramie, WY, USA. (criebe@uwyo.edu)

Quantifying the balance between soil production from saprolite and regolith production from bedrock is crucial to assessing soil sustainability over human timescales, quantifying how landscapes evolve over millenia, and understanding weathering-related feedbacks in Earth's long-term climate evolution. Uranium-series isotopes have recently emerged as a tool for constraining rates of soil production from saprolite and regolith production from bedrock (e.g. [1-4]). To date, U-series work on weathering has focused mostly on samples in which the inception of weathering occurred at depth beneath a mantle of similarly weathered material. In this work, we focus on a bare rock ridge, using U-series isotopes to constrain weathering rates during the early stages of granite alteration. The goal is improved understanding of the pronounced dicotomy of bare and soil mantled rock on the slopes of the Sierra Nevada Batholith (California). Cores ~30cm long were drilled in a granitic ridge: one core was collected under a thin regolith cover, probably wind-blown material, in a small depression and shows evidences of relatively extensive weathering. This core is of special interest for addressing the role of a regolith cover in promoting weathering of the underlying bedrock. Another core was collected in nearby almost pristine bedrock but showing some evidences of weathering. Uranium and thorium isotope composition of samples taken along these cores will shed light on the mobility of chemical elements and the rates of granite weathering during the early stages of water-rock interaction.

The description of mantle geochemical heterogeneities contributes to the understanding of time and length scales of mantle convection. Using trace element and Sr-Nd-Pb isotopic ratios, the geochemical structure of the northern mid-atlantic ridge between 10 and 50°N has long been described with major anomalous zones at the latitudes of 14°-15°N, 38-39°N and 42-43°N. New Hf isotopic data from basaltic samples along this 10-50°N section of the ridge (shown as solid symbols in figure below, open symbols indicate published values) combined with Sr or Nd isotopes reveal clear contrasting geochemical signatures of different sections of the ridge. It emphasizes the heterogeneous character of the depleted mantle source of MORB, as previously reported and discussed with Sr isotopes in [1] and brings a new perspective on the mantle dynamics in the region.

Os isotope and PGE data on the age and evolution of lithospheric mantle in the central Siberian craton

L.S. DOUCET[1]*, D.A. IONOV[1], R.W. CARLSON[2], A.V. GOLOVIN[3] AND I.V. ASHCHEPKOV[3]

[1]Univ. J. Monnet & CNRS-UMR6524, St Etienne 42023, France (*correspondence: luc.serge.doucet@univ-st-etienne.fr)
[2]DTM-CIW, Washington D.C. 20015, USA
[3]Inst. Geology & Mineralogy, Novosibirsk 630090, Russia

The Siberian craton was assembled 1.8-2.1 Ga ago from terrains containing components as old as 2.4-3.5 Ga [1]. To better constrain the age of the lithospheric mantle in the central craton and its relationship to the events that formed or assembled the overlying crust, we present new whole-rock Re-Os and PGE data on 31 fresh (LOI <1%) spinel and garnet peridotite xenoliths from the Udachnaya kimberlite [2]. 18 out of 24 refractory (0.1-1.2% Al_2O_3) rocks in this study contain 1-10 ppb Os. They mostly yield T_{RD} ages from 1.5 to 2.3 Ga (average 1.8 Ga). The T_{RD} ages do not correlate with P-T estimates (<2.5-6.8 GPa; 760-1330°C), hence depth. These peridotites are depleted in Pd, less commonly in Pt relative to Os-Ir-Ru, with the strongest Pt-Pd depletions in cpx-free spinel peridotites, likely reflecting the lower compatibility of Pt and Pd in residues of melting. Six refractory peridotites have low Os (≤0.5 ppb), high Re/Os and yield low (0.7-1.6 Ga) or meaningless T_{RD} ages. Cpx- and gar-rich peridotites (1.4-4.0% Al_2O_3; likely re-fertilised) with Os >1 ppb have eruption-age-corrected $^{187}Os/^{188}Os$ = 0.120-0.124; some show high Pt/Ir and Pd/Ir indicating Pt-Pd mobility during melt metasomatism.

Overall, Re-Os ages in Udachnaya peridotites are Paleoproterozoic (including 7 out of 8 samples from earlier work [3]), coeval with final rather than early stages of craton formation. Older ages have been reported on megacrystalline dunites (3 out of 5 in [3]), eclogites [4] or inclusions in diamonds [5] that cannot be abundant in the mantle. Thus, long-lived, thick, cold, diamond-bearing lithospheric keels may be generated in the Proterozoic as well as in the Archean.

Permafrost active layer dynamics inferred from major element geochemical signatures in six Arctic Alaskan rivers

T.A. DOUGLAS[1], A.D. JACOBSON[2], J.W. MCCLELLAND[3], A.J. BARKER[1], M.S. KHOSH[3] AND G.O. LEHN[2]

Arctic climate warming is expected to degrade permafrost and affect watershed hydrogeology and biogeochemistry. Increasing temperatures could lead to the downward migration of the seasonally thawed (active) layer into previously frozen soil. This could create a unique weathering signal in surface waters during late summer and early fall when the active layer is at its deepest extent. The response of permafrost to climate warming may not lead to a simple, homogeneous increase in active layer depths. Ice lenses, peat layers, and heterogeneous soil ice (water) contents will respond differently to warming. Our study was initiated to determine whether geochemical tracers can provide a proxy for these active layer dynamics in Arctic watersheds.

We collected up to 65 surface water samples from six Arctic Alaskan rivers from melt to freeze-up in 2009 and 2010. Watershed areas range from 1.6 to 610 km^2. Two rivers were underlain by organic rich permafrost, two rivers drained mountainous bedrock, and two rivers were underlain by both bedrock and organic rich permafrost.

We measured the major ion geochemistry of the water samples. For most of the rivers, Na, Ca, Mg, and SO_4 concentrations are lower during melt runoff and steadily increase throughout the summer into the fall. Potassium values are greatest in early melt waters and then decrease through the summer into the fall. Nitrate concentrations increase steadily in the late fall in bedrock dominated streams, suggesting a decrease in N assimilation rates in the bedrock soils during late summer and fall. Our results suggest river chemistry is driven by flow paths that deepen from surface to mineral soils as the melt season progresses.

Comparative planetology – What are the factors controlling the nature of terrestrial planetary crusts?

H. DOWNES

Department of Earth and Planetary Sciences, Birkbeck University of London, Malet Street, London WC1E 7HX United Kingdom (h.downes@ucl.ac.uk).

Size, composition, or location?

Within the Solar System, rocky bodies (planets, moons, asteroids) have a variety of sizes and crustal compositions. A common view is that "there are more variables than planets" [1], whereas others insist that the only significant factor controlling planetary evolution is the size of the body [2]. Consideration of pairs of similar sized planetary bodies (e.g., Earth/Venus; Moon/Mercury; Moon/Io, Callisto/Ganymede) suggests that two other factors are also important.

Firstly, the composition of the body controls much of its evolution, including the nature of its crust (both primary and present-day). Whether the mantle of the body is Fe-rich (e.g. Moon, Mars) or Mg-rich (Earth, Venus, Mercury) controls the compositions of erupted basalts but, more importantly, can lead to plagioclase flotation in a magma ocean under anhydrous conditions. Presence of volatiles, particularly water, to the mantle inhibits formation of an anorthositic crust [3]. Water also lowers the solidus of basalts, which can then partially melt to produce magmas of intermediate compositions which are too buoyant to subduct, leading to formation of a silicic continental-type crust. Significantly, this process does not require the operation of plate tectonics but only requires the melting of hydrated basaltic material, as is demonstrated by the Archean TTG crust of the Earth. Secondly, the location of the planetary body is an important factor, as seen in the dichotomy between Ganymede and Callisto in which the proximity to Jupiter governed the amount of impact-related heating [4] and later tidal heating, or in the contrasting magmatic histories of the Moon and Io.

Based on the three main factors, predictions can be made regarding the nature of crusts that are likely to be formed on planetary bodies of different sizes and bulk compositions, and this can then be extended to a consideration of specific locations of planets or moons (e.g. proximity to a gas giant; inside/outside the stability zone of surface liquid water etc).

The oxidation state of Ti in synthetic and meteoritic hibonite

P.M. DOYLE[1,2]*, A.J. BERRY[1,2], P.F. SCHOFIELD[2], J.F.W. MOSSELMANS[3], A.D. SMITH[4], A. SCHOLL[5] AND A.T. YOUNG[5]

[1]Imperial College, London, UK (*correspondence: p.doyle07@imperial.ac.uk)
[2]Natural History Museum, London, UK
[3]Diamond Light Source, Oxfordshire, UK
[4]STFC Daresbury Laboratory, Daresbury, UK
[5]Advanced Light Source, Lawrence Berkeley National Lab, Berkeley, CA, USA

Hibonite ($CaAl_{12}O_{19}$) is a Ti-bearing mineral found in calcium aluminium inclusions (CAIs) and is thought to be the second mineral to condense from a solar composition gas [1]. As such, the crystal chemistry of hibonite could provide insight into the conditions of the early Solar System. Ti may occur as Ti^{3+} under reducing conditions, with up to 23% of the Ti in meteoritic hibonite previously reported as Ti^{3+} [2].

We have used X-ray spectromicroscopy (XANES, XPEEM) to determine Ti^{3+}/Ti^{4+} ratios for a range of meteoritic hibonites, with spatial resolutions between 3 μm and 100 nm. We aim to use this information to investigate if hibonite grains record temporal variations in oxygen fugacity in the early Solar Nebula.

Ti-bearing hibonite samples were prepared at 1400 °C under oxidising and reducing atmospheres using a $CO\text{-}CO_2$ gas mixing furnace in order to produce a sample series with 0-100% $Ti^{3+}/\Sigma Ti$ (where $\Sigma Ti = Ti^{3+}+Ti^{4+}$). Neutron powder diffraction data was used to determine the site occupancy of Ti^{3+} and Ti^{4+} in the sample suite. Ti K- and L-edge spectra were recorded for these samples and meteoritic hibonite (c/o A. Bischoff and S. Rout). Spectral features that vary as a function of Ti^{3+}/Ti^{4+} in the synthetic hibonite series were identified.

The resulting calibration curve was used to determine Ti^{3+}/Ti^{4+} ratios for the meteoritic hibonite grains. The results show that blue hibonite from CAIs in the unique Acfer094 meteorite and greeny-blue hibonite from a CAI in the El Djouf001 CR meteorite have up to 10% $Ti^{3+}/\Sigma Ti$, and colourless hibonite grains from the Hughes030 and NWA2446 R-type meteorites have less than 3% $Ti^{3+}/\Sigma Ti$. Additionally, there is evidence that there may be a degree of core-to-rim variation of the $Ti^{3+}/\Sigma Ti$ ratio within some hibonite grains.

Accelerating garnet growth and related dehydration at blueschist-facies conditions, Sifnos, Greece

BESIM DRAGOVIC*[1], ETHAN F. BAXTER[1,2] AND MARK J. CADDICK[2]

[1]Boston University, Department of Earth Science, Boston MA, 02215, USA

[2]ETH Zurich, Institute for Geochemistry and Petrology, 8006 Zurich, Switzerland

While subduction is considered to be a gradual process, consisting of steadily changing pressures and temperatures, metamorphic reactions and mineral growth during subduction may, in some cases, be episodic, or pulsed. Whether the net transformation and accompanying dehydration of subducting material occurs steadily, or in one or more bursts, has important implications for subduction zone petrology and geodynamics.

Here, microdrilling based on major element zoning contours as determined by electron microprobe mapping, from a 4.9-cm diameter garnet in a quartzofeldspathic gneiss from Sifnos, Greece, in the Attic-Cycladic Blueschist Belt, provides information on the rate of mineral growth during metamorphism. Ten concentric growth zones were sampled from the garnet for Sm-Nd geochronology using ID-TIMS. After acid cleansing of mineral inclusions, many of the garnet zones contained very low (0.02 ppm) Nd concentrations, yielding very low sample sizes (~1.5 ng Nd) but very high $^{147}Sm/^{144}Nd$ (3.4 to 9.8) indicating success in the removal of adverse inclusion effects. These samples were analyzed using a NdO+ with Ta_2O_5 activator method. Garnet-matrix isochron ages reveal that growth spanned at least 7.3 ± 3.3Ma from onset in the core at 52.7 ± 3.3Ma to cessation at the rim just after 45.44 ± 0.21 Ma. Over this timespan, the garnet growth rate accelerated significantly. The innermost 1 cm of garnet (radially) grew at an average rate of ca. 0.9 cm^3/Ma, whereas the outermost 0.9 cm grew within just a few 100,000s of years at a growth rate of ca. 100 cm^3/Ma. This is an acceleration factor of at least ~ 2 orders of magnitude.

Rapidly accelerating garnet growth may occur due to gradually changing P and T, if the PT trajectory crosses closely spaced reaction isopleths. Or, the dehydration of subducted material can provide a synergistic kinetic trigger - a catalyzing fluid - further accelerating garnet growth, and thus water release. Thermodynamic analysis of the garnet forming dehydration reactions and P-T trajectories, can help elucidate the causes and consequences of this acceleration in the net reaction rate.

Microbial mobilization of arsenic from soil of the Mokrsko gold deposit, Czech Republic

P. DRAHOTA[1]*, A. REDLICH[2], L. FALTEISEK[3], J. ROHOVEC[4] AND I. ČEPIČKA[3]

[1]Institute of Geochemistry, Mineralogy and Mineral Resources, Charles University, Prague, Czech Republic (*correspondence: drahota@natur.cuni.cz)

[2]Department of Physical and Macromolecular Chemistry, Charles University, Prague, Czech Republic

[3]Department of Zoology, Charles University, Prague, Czech Republic

[4]Institute of Geology, AS CR v.v.i., Prague, Czech Republic

Arsenic mobilization from soil is an issue of concern, as aquatic arsenic can migrate into pristine areas, endangering aquatic organisms and people. Such mobilization in the Mokrsko gold deposit distributes nearly 1.4 kg ha^{-1} $year^{-1}$ of arsenic throughout naturally contaminated soil [1]. To gain an understanding of possible biological mechanisms contributing to this transport, mobilization of solid-phase arsenic was investigated in Mokrsko soil microcosms.

Anaerobic microcosms catalyzed rapid release of arsenic from soil containing arsenic-rich goethite, pharmacosiderite and arseniosiderite, mobilizing 33±6% of the total arsenic. Sterilization prevented this transformation. Highly positive correlation between the extracted amounts of arsenic and iron from soil under anaerobic condition implied that microbial reductive dissolution of iron oxides and iron arsenates is responsible for the arsenic release. Sequential extraction analyses designed to determine the arsenic fractionation before and after incubation experiments supported massive dissolution of amorphous and crystalline iron phases in oxalate fractions (65% reduction). The isolation technique enabled the characterization of nine arsenate–resistant bacteria, mostly related to facultative anaerobic genera *Bacillus* and *Pseudomonas*, which are using arsenate for respiration [2]. However, the link between arsenic reduction/mobilization and the isolated strains is missing and will be completed soon.

Preliminary observations indicate that a direct microbial arsenic-mobilizing activity exist in the soil, isolated strains are well known arsenic-transforming agents, and thus suggest that dissimilatory arsenic reduction may contribute to arsenic flux from anoxic condition of the Mokrsko gold deposit.

Geochemical correlations of low-temperature calcite and groundwater in subsurface granite fractures

H. DRAKE[1]*, E.-L. TULLBORG[2] AND M. ÅSTRÖM[1]

[1]School of Natural Science, Linnaeus University, SE-391 82 Kalmar, Sweden
(*correspondence: henrik.drake@lnu.se)
[2]Terralogica AB, Box 4140, SE-443 14 Gråbo, Sweden

Studies of calcite precipitated in bedrock fractures can reveal past groundwater conditions (e.g. [1]). Studies of low-temperature fracture calcite in Proterozoic or Archaean crystalline rocks are, however, very limited, mainly because this calcite usually is very fine-grained or forms rims on older, much more abundant, hydrothermal calcite and is thus difficult to distinguish. Knowledge of chemical characteristics and the correlation with groundwater chemistry is thus scarce for low-temperature calcite in these settings.

In the Proterozoic rock setting at Laxemar, SE Sweden, Quaternary glaciations and related marine transgressions and land uplift, have favoured calcite formation in the bedrock fractures due to repeated introduction and mixing of different waters [2]. We have sampled very fine-grained euhedral low-temperature calcite from these fractures from drill cores (~50 samples, down to 1 km depth) and analysed them for trace elements (using ICP-MS, LA-ICP-MS, WDS) and $\delta^{13}C$, $\delta^{18}O$, $^{87}Sr/^{86}Sr$, following detailed SEM-studies (e.g. CL) of crystal zonations. Existing groundwater data from the same borehole sections [2] enabled detailed direct calcite-groundwater comparison in terms of both geochemistry and isotopic ratios, e.g. depth-variations. Thereby we tested the utilisation of low-temperature fracture calcite in terms of understanding the groundwater history, also giving input to the understanding of trace element incorporation into calcite in natural systems.

Calcite $^{87}Sr/^{86}Sr$-ratios correlated with the groundwater in all sections and ~50% of the sections showed $\delta^{18}O$ calcite-groundwater equilibria at ambient temperatures, which suggests potential scattered recent precipitation, e.g. indicated for intruding marine and meteoric water. Calcite isotope signatures also differ considerably from Proterozoic and Paleozoic calcite [3]. The calcite generally showed Me/Ca depth trends consistent with the groundwater for Mn, Mg and Sr. However, only Mn incorporation was in the range expected from experiments [4], which shows the difficulty of applying experimental data onto natural systems, and that $^{87}Sr/^{86}Sr$, $\delta^{18}O$, and Mn are the most representative proxies for low-temperature calcite-groundwater interaction.

Recent and fossil chemosynthetic endosymbioses

ANNE DREIER[1,2]*, MARTIN BLUMENBERG[2], MARCO TAVIANI[3], LORENA STANNEK[1] AND MICHAEL HOPPERT[1,2]

[1] Institute of Microbiology and Genetics, University of Goettingen, Grisebachstr. 8, 37077 Goettingen, Germany
(*correspondence: adreier1@gwdg.de)
[2] Courant Centre Geobiology, University of Goettingen, Goldschmidtstr. 3, 37077 Goettingen, Germany
[3]ISMAR-CNR, Via Gobetti 101, 40129 Bologna, Italy

Metazoans with chemosynthetic endosymbionts are widespread in marine habitats and respective endosymbioses are known from seven recent animal phyla. However, very little is known about endosymbioses in fossil settings and, hence, ecological significance as well as evolution of endosymbioses in earth history. In the presented project, we investigate the ancient and recent bivalve fauna living at marine sedimentary oxic/anoxic interfaces. Two bivalve species collected from the same benthic environment a Mediterranean lagoon- were studied in detail. The diet of *Loripes lacteus* is based on thiotrophic gill symbionts. *Venerupis aureus* is a filter feeding bivalve without symbionts. Analysis of 16S rDNA and fluorescence-*in situ* -hybridisation confirmed the presence of symbionts in *Loripes* gill tissue. In addition, the presence of one key enzyme of sulfur oxidation (APS-reductase) could be detected by immunofluorescence.

In search of biosignatures associated with thiotrophic chemosymbionts that could also be detected in fossil bivalves, we analysed the isotopic composition of shell lipids ($\delta^{13}C$) and the shell matrix protein conchiolin ($\delta^{13}C$, $\delta^{15}N$, $\delta^{34}S$). In recent shells and in gill tissue the stable isotopic ratio of carbon is more depleted in the thiotrophic *Loripes*: e.g., $\delta^{13}C_{lipid(18:1FA)}$ -32.2‰, $\delta^{13}C_{conchiolin}$ -25.4‰ than in the filterfeeding *Venerupis*: $\delta^{13}C_{lipid(18:1FA)}$ -28.2‰, $\Delta^{13}C_{conchiolin}$ -21.8‰. The isotopic ratios of nitrogen and sulfur are also more depleted in the chemosynthetic *Loripes* ($\delta^{15}N_{conchiolin}$ +3‰, $\delta^{34}S_{conchiolin}$ -18.5‰ in contrast to filter feeding *Venerupis*: $\delta^{15}N_{conchiolin}$ +10.1‰, $\delta^{34}S_{conchiolin}$ +13.6‰). Our results give evidence for a major influence of sulfide-oxidizing symbionts on the isotopic composition of organic matter of the host bivalve and are compared with respective data from fossil samples.

[2]ENEA, Roma, Italy
[3]ARPA Veneto, Italy
[4]Department of Chemistry, University of Florence, Italy

The main key factors controlling the oxygen and hydrogen isotope composition of present-day Antarctic precipitation are mainly related to the condensation temperature of the precipitation and the origin of the moisture [1]. In order to calibrate the isotopic tool a multiyear survey from 2006 to 2010 has been carried out in the inland plateau site of Dome C (75°06'S 123°21'E; 3233 m; T=-54.5°C; snow acc. rate 25 kg m^{-2} yr^{-1}) in East Antarctica.

Here we present $\delta^{18}O$, δD and deuterium excess (d) data obtained from daily snow depositions. Observations of deposition amount, shape and size of crystals were also determined. The isotopic data will be also studied as function of synoptic meteorological conditions, using ECMWF re-analyses data and back trajectory models. Preliminary data suggest a good correlation between $\delta D/\delta^{18}O$ and temperature, both in anti-phase with d at seasonal scale (Fig. 1).

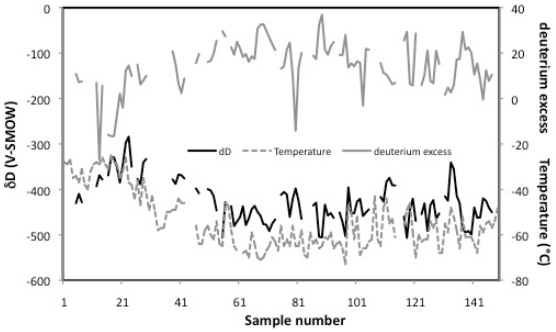

Figure 1: δD, temperature and d data of DC precipitation.

Computational approaches to hydrothermal fluid-rock interaction on nanometer to kilometer scales

THOMAS DRIESNER

ETH Zurich, Institute of Geochemistry and Petrology, Clausiusstrasse 25, 8092 Zurich, Switzerland (thomas.driesner@erdw.ethz.ch)

Fluid-rock interaction in hydrothermal systems plays a central role in processes such as the formation of ore deposits, geothermal energy production, and global element cycles. A quantitative understanding of fluid-rock interaction requires looking at vastly different length (nm to km) and time (ps to Ma) scales. Chemical thermodynamics provides the framework that links the scales and computational approaches are essential for both improving thermodynamic models and applying them in the modeling of natural processes.

In spite of decades of research, a universal model of the thermodynamics of fluids at high temperature, pressure and salinity is still lacking, which hampers our ability to quantitatively model fluid-rock interaction in systems such as mid-ocean ridge hydrothermal convection or magmatic-hydrothermal ore formation. Existing equations of state are based on physical concepts that do not reflect the molecular interactions in fluids under those conditions. Hence, molecular simulation has become increasingly popular to better understand the nm-scale physics of hydrothermal fluids. In particular, short-range solute-solvent and solute-solute interactions such as solvation and ion pairing are studied since they are not captured by the most common semi-empirical activity models. While many new insights have been gained from molecular simulation, incorporating them into equations of state is still in its infancy.

On the application side, reactive transport computations combine chemical speciation and fluid transport codes to study the progression of fluid-rock reaction fronts in permeable media on macroscopic scales. These tools have so far only rarely been applied in a hydrothermal context, partly for the reasons outlined above, and partly because most of the available codes are restricted to groundwater flow equations that do not adequately describe the flow of compressible and/or boiling hydrothermal fluids. With the recent revival of research on geothermal systems, new codes are emerging that utilize advanced hydrothermal fluid flow codes that can also simulate flow in complex, "realistic" geometries of fractured geological media. First results indicate that correctly representing geometries is key to understand the causes of heterogeneity in evolving fluid-rock interaction.

A meso-scale laboratory study of stable isotope variations during uranium bioremediation

J.L. DRUHAN[1]*, C.I. STEEFEL[2], M.E. CONRAD[2] AND D.J. DEPAOLO[1,2]

[1]Department of Earth and Planetary Science, University of California Berkeley, Berkeley CA 94720 (*correspondence: jennydruhan@berkeley.edu)
[2]Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley CA 94720

We present results from a large-scale column experiment designed to bridge the gap between the field scale and small columns and advance our understanding of the isotopic signatures of biostimulation geochemistry. Stable isotope variations of major elements such as C, Ca and S can identify processes unobservable in concentration data alone but an understanding of these isotope systems must first be developed under controlled biostimulation conditions.

A 1m long, 10cm diameter column was packed with sediment from the saturated zone of the Rifle Integrated Field-Scale Subsurface Research Challenge (IFRC) site in western Colorado. The pore velocity of the column experiment was matched to that of the field, thus providing a direct representation of the first meter down-gradient of the *in situ* uranium bioremediation injection gallery while ensuring steady flow and boundary conditions. Side-ports along the length of the column provided <20cm sampling resolution, while inert tracers and electron donor were added to the injection solution.

This study has generated an extensive isotopic and biogeochemical reactive transport dataset and provides an unprecendented opportunity to constrain carbon, calcium and sulfur isotopic dynamics. Results include:
1) δ^2H and $\delta^{18}O$ breakthrough curves yielding a starting porosity of 0.38 decreasing to 0.30 over 42 days.
2) $\delta^{13}C$-labeled acetate allows tracking of carbon originating from electron donor consumption throughout the system.
3) $\delta^{44}Ca$ variations in the fluid phase identify two primary controls on Ca: precipitation of carbonates and ion exchange between the fluid and sediment.
4) A $\delta^{34}S$ fractionation factor of 12‰ between SO_4^{2-} and HS^- in comparison with a Rayleigh model α of 10‰ indicates variation in α values across the flow path.

These observations are a direct result of the improved spatial and temporal sampling resolution afforded by the experimental design and allow new insight into the highly reactive zone adjacent to contaminant remediation injection wells.

Redox front variability and phosphorus flux across the sediment-water interface

G.K. DRUSCHEL[1], L.G. SMITH[1], N. SHUFELT[1], M.C. WATZIN[2], A.R. PEARCE AND D.M. RIZZO[3]

[1]Department of Geology, University of Vermont. 180 Colchester Ave., Burlington, VT 05405. (Gregory.Druschel@uvm.edu)
[2]Rubenstein School of the Environment and Natural Resources, University of Vermont.
[3]School of Engineering, University of Vermont.

Phosphorus mobility across the sediment-water interface (SWI) in Missisquoi Bay, a shallow (<15m) bay in Lake Champlain, is largely controlled by redox changes exhibiting diel and seasonal variability that can significantly impact nutrient fluxes and associated cyanobacterial activity. In these iron rich (4-5% w/w total Fe) sediments, reactive P (RP) is strongly correlated to reactive Fe, indicating the mobility of a large portion (30-40%) of the P pool in the sediment is associated with iron oxyhydroxide minerals. We investigated changes in sediments, sediment porewaters, and the overlying water column chemistry and microbiology over three consecutive seasons with detailed monitoring of diel changes at the SWI at each sampling time. Sediment cores were profiled using voltammetric electrodes to characterize porewater redox chemistry (O_2, Mn^{2+}, Fe^{2+}, Fe^{3+}, HS^-, $FeS_{(aq)}$). Core profiles show redox conditions become more reducing as the season progresses, with the most strongly reducing conditions present during peak bloom conditions. Redox conditions measured continually over 24-hour periods using *in situ* voltammetric electrodes positioned at the SWI showed significant changes in redox conditions over diel cycles. Cluster analysis of the data using self-organized mapping techniques indicate redox chemistry across the SWI is a significant controlling component of the system that influences cyanbacterial blooms.

As P fluxes are sensitive to a thin layer of iron oxyhydroxides at the sediment surface, changes in redox chemistry at the SWI significantly impact nutrient flux between the sediment porewaters and the overlying water column. Mesocosm experiments utilizing Missisquoi Bay sediments are underway to characterize phosphorus fluxes between the sediments and water column under different redox conitions at the SWI. Preliminary results indicate that both the direction and intensity of P flux across the SWI are dependent on the redox front position and the frequency of how often the redox front sweeps across the SWI.

Behaviour of Tc(VII) in aqueous solutions in the presence of iron oxides and microorganisms

R. DRUTEIKIENĖ[1]*, B. LUKŠIENĖ[1], D. PEČIULYTE[2] AND BALTRŪNAS[1]

[1]Center for Physical Sciences and Technology, Vilnius, Lithuania (*correspondence: ruta@ar.fi.lt)
[2]Institute of Botany of Nature Research Vilnius, Lithuania (dalia.peciulyte@botanika.lt)

This study investigates the redox behaviour of Tc(VII) in a heterogeneous system containing hematite and magnetite with emphasis on transformation of oxidation state through microbial-mediated processes under oxic conditions. Results showed that after a short exposure period under alkalini conditions (pH 8-9) more then 75% of TcO_4^- were associated with Fe(II) oxide particles and removed from solution. The removal of Tc from solution may be controlled by reduction of Tc(VII) to Tc(IV) by biogenic Fe(II). Under these circumstances no pronounced effect of the sorption of technetium onto Fe(III) oxide was determined. Sorption of Tc onto hematite is achieved because of presence of specific microorganisms. Results of the combined effect of microorganisms and iron-bearing minerals on Tc (VII) sorption peculiarities have shown that bacteria *Arthrobacter globiformis* and *Cellulomonas cellulan*s did not have any influence on Tc sorption onto hematite, while micromicete *Fusarium oxysporum* altered sorption to approximately 85% compared to that in the system without microorganisms. Presence of microorganisms *Penicillium* sp., *Rhodococcus* sp and *Streptomyces* sp. in the tested system induced Tc sorption onto hematite up to 71-82%.

The research has received funding from the European Union's European Atomic Energy Community's (Euratom) Seventh Framework Programme FP7/2007-2011 under grant agreement n° 212287 (RECOSYproject) and from Lithuanian Agency for Science, Innovation and Technology (Grant No 31V-6)

Iron oxides of soils from Cenozoic basalts weathering in eastern China: Relationship with climate change

KAI DU[1], YANG CHEN[1]*, XIAOYONG LONG[1,2], HUI LI[1] AND JUNFENG JI[1],

[1]Institute of Surfacial Geochemistry, School of Earth Science and Engineering, Nanjing University, 210093, China (*correspondence: chenyang@nju.edu.cn)
[2]School of Geographic Science, Southwest University, 400715, China

The Cenozoic basalts are widely distributed from Heilongjiang to Hainan provinces in eastern China, which provide the unique climatic conditions to study basalts weathering. The five soil sequences developed from basalt bedrocks in eastern China were studied, along climate gradient ranging from 200 (Inner Mongolia) to 2,000 mm (Hainan) mean annual precipitation. Magnetic properties, chemical analyses and diffuse reflectance were measured to characterize the iron oxides in soils, since iron oxides are common weathering products and sensitive to response to climate change. Results show that content of free iron oxide, magnetic susceptibility, frequency dependence susceptibility and redness index of surface soil samples are all positively related to MAP, with lowest value in Inner Mongolia samples and highest in Hainan samples. Especially, the content of free iron oxide increases by almost 10 times ranging from 0.5 % to 5.5 % wt. According to similar chemical composition of basalt bedrocks, it can be concluded that climate took most effect on Cenozoic basalt weathering. Further studies are necessary to extract more credible and sensitive indicators like element ratios and mineral index.

This study is funded by the NSF of China (Grant No. 41021002) and China Geological Survey.

Conceptual modelling

A reactive transport model with TOUGHREACT [1] for the carbon dioxide sequestration into appropriate deep saline aquifer with a depth of 1200m has been involved in this study. Considering storage conditions, a 1D homogeneous conceptual storage formation with a thickness of 50m is constructed, the salt is 1 mol/L, and T is 50℃, carbon dioxide was injected with a speed of 100kg/s through the central injection well, which lasted for 10a, and the complex geochemical reaction occurs between carbon dioxide and minerals afterward could be known with the model.

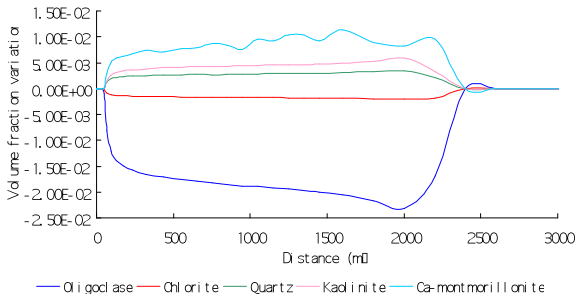

Figure 1: Mineral variation at 1000a after CO_2 injection

Considering the long term of mineral reaction, the minerals fractions variation at 1000a after the CO_2 injection have been detected from the reaction transport model, and the results represented as Figure 1. From the figure we can see that, the injected CO_2 influencing area has reached 2500m. Dissolution and precipitation occur with different extent ascribe to the distances and minerals. According to the simulation model, there are obvious volume variations of oligoclase, chlorite and illite because of mineral precipitation, and there are obvious volume variations of Calcite, Ca-montmorillonite, quartz, kaolinite, siderite and albite because of mineral dissolution, these are similar with the study results of other studies [2].

Translocation and fractionation of Rare Earth Elements in intensely weathered lateritic profiles in Western Australia

X. DU[1,2]*, A.W. RATE[1] AND M. GEE[1]

[1]School of Earth and Environment, The University of Western Australia, Crawley, 6009, WA, Australia (*correspondence: dux01@student.uwa.edu.au)
[2]School of Environmental Studies, China University of Geosciences, 430074, Wuhan, China

Three intensely weathered lateritic profiles (GE, MQ I, II) developed on granite with dolerite dykes in Western Australia were studied to investigate the translocation, fractionation and geochemical pathways of rare earth elements (REE) during intense weathering and lateritization. The study has relevance for geochemistry, pedogenesis and environmental chemistry research, and mineral exploration of REE which is one of the most important strategic resources in the world. Geochemical mass balances were calculated based on bulk geochemical compositions. REE-bearing minerals in parent rocks and regolith samples were identified by synchrotron X-ray powder diffraction (SXRD) and scanning electron microscopy with energy dispersive spectroscopy (SEM-EDS).

In all three profiles, chondrite normalized REE distributions confirmed that the regolith was developed from granite. High deficiency of REE in the weathered residue indicated strong depletion, except in soils of horizon A in MQ profiles. In MQ profiles, the REE patterns normalized to parent rock represented two layers: accumulation in the upper part of profiles and depletion at the lower part, indicating the regolith below 0.6m depth in MQ I and 1.1m depth in MQ II were weathered *in-situ*. The source of REE accumulation in surface soil in MQ profiles was unclear, possibly representing biogeochemical recycling. In the GE profile, regolith samples showed great loss of total REE, up to 95 % in the mottled clay (10m deep), followed by ferricrete (83%loss, 3.5m deep).

Depletion of LREE is greater than HREE in all three profiles, except saprolite. In GE profile, a strong linear relationship of (LREE)/(HREE) ratio normalized by parent granite with pH suggested the fractionation of REE in GE profile was controlled by pH. In MQ profile II, main REE-bearing accessory minerals of the parent granite included allanite, fluocerite and epidote. In the weathered regolith, the small grain size of phosphate phases (<20 μm) were surrounded by clay matrix. The geochemical composition and mineralogy of the regolith indicated REE fractionation intensified during advanced weathering.

Using *ab initio* potential to predict thermodynamic properties of fluids and minerals

ZHENHAO DUAN, Z.G. ZHANG, R. SUN AND C. ZHANG

Key Laboratory of the Earth's Deep Interior, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029

Macroscopic thermodynamic properties (PVT properties, phase behavior, chemical potential, speciation reactions, enthalpy etc.) of fluids are determined by intermolecular, and to a less extent, intramolecular interactions, which are functions of molecular distances and angles. Here we present our two studies to demonstrate how to predict the thermodynamic properties through molecular level study.

(1) Using ab initio calculated molecular potentials of thousands of different configurations, predicting multi-phase equilibria of methane hydrate, liquid and vapor phases under conditions of different temperature, pressure, salinilty and pore sizes. Comparison with the experimental data shows that this model can accurately predict the equilibrium *p-T* condition of CH_4 hydrate in seawater and porous media with high accuracy.

(2) Based on molecular interaction potential for pure H_2O and CO_2 and the ab initio potential surface across CO_2–H_2O molecules, we carried out more than one thousand molecular dynamics simulations of the PVTx properties of the mixtures in the TP range from 673.15 to 2573.15 K up to 10.0 GPa. Comparison with extensive experimental PVTx data indicates that the simulated results generally agree with experimental data within 2% in density, equivalent to experimental uncertainty.

Rock-Eval pyrolysis of the Água de Madeiros Formation (Lower Jurassic) from the Lusitanian Basin, Portugal

L.V. DUARTE [1]*, J.G. MENDONÇA FILHO[2], R.L. SILVA[1] AND L.C.V. OLIVEIRA[3]

[1]Universidade de Coimbra, DCT and IMAR-CMA, 3000-272 Coimbra, Portugal (*correspondence: lduarte@dct.uc.pt)
[2]LAFO, UFRJ, 21949-900, Rio de Janeiro, Brazil
[3]Universidade Petrobras, Rio de Janeiro, Brazil

The Lower Jurassic hemipelagic series in the Lusitanian Basin constitutes one of the most important intervals regarding the occurrence of potential hydrocarbon source-rocks in Portugal [1]. One of these units is the Água de Madeiros Formation (Upper Sinemurian to lowermost Pliensbachian), which is composed by organic-rich marl–limestone alternations with several black-shale horizons [2].

Based on the study of this unit in its type locality (S. Pedro de Moel area), about 58 m thick, we present in this work a high-resolution organic geochemical analysis centered in Rock-Eval pyrolysis. Total organic carbon (TOC), determined in more than 170 samples and covering the whole succession, shows a large variation and reaches up to 22 wt.%. A great part of the 78 analyzed samples by pyrolysis present S2 values above 10 mg HC/g rock, reaching a maximum of 78.1 mg HC/g rock. Moreover, these high S2 values are correlative with the highest recorded values of the Hydrogen Index, that shows an average around 400 mg HC/g TOC (maximum of 637 mg HC/g TOC).

Despite these interesting geochemical indicators in terms of good source-rock potential, thermal maturity of the Água de Madeiros Formation in the studied reference section is low (clearly immature), as suggested by T_{max} values always below 437 ºC.

This work is a contribution to project PTDC/CTE-GIX/098968/2008 (FCT-Portugal, COMPETE/FEDER).

CO_2 degassing and groundwater mixing in the Navajo aquifer, Green River, Utah

BENOÎT DUBACQ[1]*, NIKO KAMPMAN[1], NELLY ASSAYAG[1,2], MAX WIGLEY[1] AND MIKE BICKLE[1]

[1]University of Cambridge, Dept. Earth Sciences, Downing Street, Cambridge, CB2 3EQ, United Kingdom (*correspondence: bd298@cam.ac.uk)
[2]IPGP, Sorbonne-Paris-Cité University, 75252 Paris, France

Natural subsurface CO_2 accumulations provide a unique opportunity to understand the long-term fate of anthropogenic CO_2 injected into geological reservoirs. Key parameters include the impact of CO_2 dissolution on reservoir pH and subsequent mineral dissolution / recrystallization processes. Cold-water geysers driven by the degassing of CO_2-saturated fluids in Crystal Geyser, Green River, Utah, allow direct sampling of the underlying CO_2-rich Navajo aquifer. Liquid and gaseous phases have been synchronously sampled during and between geysers eruptions; both water and gas samples have been analyzed for carbon isotopic composition. Water samples have also been analyzed for major and trace elements. The fluid composition changes systematically through the course of an eruption. This reflects mixing of fluid from a deep CO_2-charged aquifer into the shallow Navajo aquifer on the time-scale of eruptions, driven by the pressure perturbation induced by geysering. The evolution of CO_2 degassing has been reconstructed using thermodynamic modelling of the solubility of CO_2 and aqueous phase speciation coupled with a Rayleigh distillation model to reproduce the observed trends in $\delta^{13}C$ of gases and dissolved inorganic content of the waters. Results suggest that the Navajo aquifer at depth is under-saturated in CO_2. Degassing is estimated to initiate about 120 meters below the surface, when the fluid rises in the pipe. The pH at depth is calculated to be ~5.35, which is 1.35 pH unit lower than its surface value.

Ce-rich layers in manganese micronodules of the Brasil Basin

A. DUBININ*, T. USPENSKAYA, V. SVAL'NOV AND T. DEMIDOVA

PP Shirshov Institute of Oceanology RAS, 117997 Moscow, Russia, (*correspondence: dubinin@ocean.ru)

Manganese micronodules (MN) were selected from miopelagic clays of Brasil basin (Atlantic Ocean) to investigate the evolution of their chemical composition depending on the size fraction. We studied bulk MN composition in size fraction: 1000-500, 500-250, 250-100 и 100-50 μm at site 1536 (24º01.1' W, 22º17.6' S, depth 5500 m (depth in core 420-430 cm).

Mn and Fe contents are changed from 23.6 to 31% and from 4.0 to 12.2% respectively. The ratio of Mn/Fe is initially increased from 3.5 to 5.8 and then it is decreased to 2.5 with the increase of MN size fraction.

Changes in iron content resulted in the similar variation in contents of phosphorus, Co, Li, Be, V, Tl, Y, Th, U and rare earth elements.The value of cerium anomaly is decreased from 5.1 to 4 and then it is increased to 14 with the increase of the MN size fraction.

To understand the variations of trace element composition between separate size fractions we analyzed the polished sections of MN by X-ray microanalysis on a scanning electron microscope JEOL JSM-6480LV.

Phase 1 with high manganese and nickel contents and the ratio of Mn/Fe = 9.6 is most widely represented. It is not-layered, enriched in clay material, captured during its formation from the associated sediment. It was formed during early diagenesis and grew at relatively high rate.

Phase 2 is thin-layered, Mn/Fe = 3.2. Phase 1 overlaps unconformably phase 2. It represents the first generation of MN.

Phase 3 is layered, Mn/Fe = 2.1, discontinuous layers of Ce enriched oxyhydroxide phase are contained between their layers.

Enriched in cerium phase 4 is found as the island chains of the substance between the layers of phase 3 and contains an average of about 8% of cerium. It has the lowest Mn/Fe = 1.6 and high Ti and P contents.

Variations in micronodule composition can be explained by influence of two processes – hydrogenous-diagenetic (phases 2-4) and diagenetic (phase 1).

X-ray spectroscopic constraints on complexing of high-field-strength elements in subduction zone aqueous fluids

J. DUBRAIL[1], M. WILKE[1], C. SCHMIDT[1], K. APPEL[2], S. PASCARELLI[3], K. KAVSHINA[3] AND C.E. MANNING[4]

[1]Deutsches GeoForschungsZentrum (GFZ), Potsdam, Germany (julien@gfz-postdam.de)
[2]Deutsches Elektron Synchrotron, Hamburg, Germany
[3]European Synchrotron Radiation Facility, Grenoble, France
[4]University of California Los Angeles, UCLA, USA

Magmatic rocks related to subduction zones commonly display element patterns characterized by depletion of high-field-strength elements (HFSE, i.e., Ti, Zr, Hf, Nb and Ta). The depletion may be due to low solubility in the aqueous fluids that are involved in the processes at subduction zones. The geochemical budget of HFSE is largely controlled by accessory phases such as zircon. Therefore, knowledge is needed on solubility and stability of these phases. Fluid composition should be one of the most important parameters because it can strongly affect complexing of HFSE in aqueous fluids. Complexing with alkalies and silica dissolved in the fluid has been suggested as an efficient mechanism to promote HFSE mobility [1,2]. However, direct evidence on the HFSE speciation in fluids at subduction zone conditions is lacking.

Experimental information on HFSE complexation was obtained for aqueous fluids with HCl, NaOH, $Na_2Si_3O_7$ (NS3), or $Na_2Si_3O_7$ + 1 or 5 wt% Al_2O_3, equilibrated with zircon or hafnon in hydrothermal diamond-anvil cells at *T* up to 750 ˚C and *P* up to 1 GPa. On these fluids, XANES and EXAFS spectra were collected *in situ* at *P* and *T* at beamlines ID 24 and ID 26 (ESRF). For NS3 ± Al_2O_3 solutions, measured XANES and EXAFS at the Zr-K and Hf-L_3 edges indicated complexes with 6 oxygens in the first shell. The XANES simulated with FEFF9 [3] based on a $Na_2ZrSi_4O_{11}$ cluster (as in vlasovite) is in good qualitative agreement with measured spectra. In contrast, 7 oxygens are indicated in the NaOH solution. For HCl solutions, a spectrum simulated for a $(Zr,Hf)O_4Cl_3$ cluster reproduced qualitatively the features of the experimental spectra. Our results confirm that alkalies and silica dissolved in aqueous fluids may efficiently transport HFSE in the fluids emanating from the subducting slab.

[3]GSECARS, APS, The University of Chicago, USA
[4]Dipartimento di Scienze della Terra, Universita degli Studi di Milano, Milano, Italy
[5]ESRF, Grenoble, France

A major goal in the geosciences is to understand (and predict) how the Earth works, which requires a detailed knowledge of how the mineral phases which make up the Earth behave under high pressure and high temperature conditions. Geochemistry of deep Earth interiors is particularly concern with phase transitions and crystalchemistry of silicates and oxides, oxidation and electronic state of elements (first of all iron), and elements partitioning between major lower mantle phases. We demonstrate that combination of laser-hated diamond anvil cell technique and modern synchrotron facilities (high resolution angle dispersive X-ray diffraction, XANES, nuclear inelastic scattering (NIS), and nuclear forward scattering(NFS)) make possible *in situ* studies pressure and temperature dependence of chemical and physical properties of minerals. Particularly, accurate single crystal diffraction studies of iron bearing silicate perovskite and ferropericlase extended to 100 GPa and over 2500 K and, together with NFS, NIS, and XANES data revel crystalchemistry of iron at conditions of Earth lower mantle.

Potential source variation in Munro komatiites: Fred's and Theo's Flows, Ontario, Canada

C. DUCHEMIN[1]*, C. CHAUVEL[2], V. DEBAILLE[1], N. ARNDT[2] AND N. MATTIELLI[1]

[1]Dept. of Earth and Environmental Sciences, Université Libre de Bruxelles, Brussels, Belgium (*correspondence : cduchemi@ulb.ac.be)

[2]ISTerre, UMR5275 CNRS, Université Joseph Fourier, 38041 Grenoble, France

Munro-type komatiites, also called Al-undepleted komatiites, are volcanic ultramafic rocks characterized by a high MgO content (>18 wt%), and near-chondritic ratios of Al_20_3/TiO_2 and $(Gd/Yb)_n$.

We present new data of trace element concentrations, measured in two thick, differentiated flows, both Archean (2.7Ga) in age, located in the Munro Township in the Abitibi greenstone belt. Fred's Flow has komatiitic affinity. It differentiated from a parental magma with about 20% MgO into a series of upper spinifex lavas, a central gabbroic unit and lower olivine-dominated cumulates. Theo's flow has an Fe-rich tholeiitic affinity. It differentiated from a less-magnesian picritic parental magma into a central gabbro and underlying pyroxene-rich cumulates. The goal of this geochemical study is to better understand the petrogenetic relationship of those two flows.

The results reveal notable differences in REE pattern between the samples. Eight Fred's Flow units are characterized by moderate to strong depletion in LREE ($0.55 \leq (La/Sm)_n \leq 0.99$) and relatively flat HREE patterns ($0.88 \leq (Gd/Yb)_n \leq 1.20$), whereas seven Theo's Flow units have a convex pattern with ($0.83 \leq (La/Sm)_n \leq 1.24$) and ($1.34 \leq (Gd/Yb)_n \leq 1.63$). Elements such as Ba, Cs, Sr and Eu were mobile during metamorphism and/or hydrothermal alteration.

As a whole Theo's Flow is more enriched in trace elements than Fred's Flow and its HREE are depleted, indicating that garnet was residual during partial melting. Together with the Fe-rich composition, this may reflect a lower degree of melting and/or a more enriched source, perhaps one with a high eclogite component. Fred's Flow magmas probably formed by fractional melting of a hotter peridotitic source.

Multiscale melt extraction in the lower crust and upper mantle

JOSEF DUFEK AND CHRISTIAN HUBER

School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta GA 30332, USA.

The dynamics associated with melt extraction, including both the movement of melt and the much slower deformation of the solid residue, involves motion on a range of scales. Ultimately melt separation occurs on the crystal scale, while consequent solid deformation occurs on scales of 10s to 100s of kilometers. In order to examine both the solid-state instabilities and melt extraction in detail, we have adopted a multi-scale modeling approach. Crystal scale melt extraction under different amounts of mantle anisotropy is calculated using a lattice Boltzmann method, and a parameterized permeability based on numerous calculations is then incorporated into a multiphase thermal and dynamic model to study the location, timing and flux of melt separating from the crystalline solid. We apply this approach to examine the residence time and extraction rates of melt in lower crustal MASH zones and examine the consequences of foundering of dense crustal roots.

The foundering of dense, mafic residual material from the base of the crust and lithosphere into the underlying mantle has been proposed to explain the long-term chemical evolution of continental crust. Such density instabilities generate solid-state dynamics in the upper mantle surrounding the downwelling material and the return flow of the surrounding mantle. Upwelling regions may generate melting and perturb the flux of magma reaching the base of the crust. We find that large-scale mantle stresses create anisotropy in the permeability structure of the mantle that focuses melt in roughly annular regions surrounding downwelling material. The extent of melting is a function of the degree hydration of the mantle, with the most hydrated conditions resulting in a factor of 3-4 times estimates of background arc melt flux. When the presence of a slab is considered, melt flux is focused preferentially several kilometers toward the backarc region, leaving a magmatic shadow immediately below the downwelling flow.

Sorption and interfacial redox of Sn(II) under anoxic conditions: Magnetite vs. anatase

S. DULNEE[1]*, D. BANERJEE. [1,2] A. ROSSBERG[1,2] AND A.C. SCHEINOST [1,2]

[1]Institute of Radiochemistry, Helmholtz Zentrum Dresden Rossendorf, D-01314, Germany (*correspondance s.dulnee@hzdr.de)

[2]The Rossendorf Beamline at ESRF, F-38043 Grenoble, France

The long-lived fission product ^{126}Sn is of substantial interest in the context of nuclear waste deposition in deep underground repositories. However, the redox state (di- or tetravalent) under the expected anoxic conditions is still a matter of debate. We therefore investigated the stability of Sn(II) in the presence of a highly redox-reactive mineral, magnetite ($Fe^{II}Fe^{III}_2O_4$), in comparison to a non-redox-reactive, anatase (TiO_2).

Sorption experiments were performed at < 2 ppm O_2, and redox state and local structure was monitored over time by X-ray absorption spectroscopy (XAS).

We found a rapid (< 30 min) oxidation of Sn(II) to Sn(IV) in the presence of magnetite. Although solubility calculation predicted the precipitation of SnO_2, the local structure determined by XAS showed two Sn-Fe distances of about 3.15 and 3.60 Å in line with edge and corner sharing arrangements between octahedrally coordinated Sn(IV) and the magnetite surface, indicative of inner-sphere complexation. The structure of the complex remained largely unchanged up to an equilibration time of 1 month.

After 30 min reaction with anatase, Sn(II) was conserved. However, even with the redox-inert anatase, Sn(II) oxidized to Sn(IV) over time, forming an Sn(IV) inner-sphere complex with Sn-Ti distances at 3.24 and 3.53 Å. Therefore, our results clearly indicate that Sn(IV) is the most relevant oxidation state to be considered even under reducing conditions, and that inner-sphere complexation is a relevant retention mechanism.

Evidence of lime-CO_2 evolution and priming effect of agricultural liming

WILFREDO DUMALE, JR.[1,2]*, TSUYOSHI MIYAZAKI[2] KENTA HIRAI[2], TAKU NISHIMURA[2] AND HIROMI IMOTO[2]

[1]Department of Plant Science, Nueva Vizcaya State University, Bayombong, 3700 Nueva Vizcaya, Philippines (*correspondence: dumalewajr@soil.en.a.u-tokyo.ac.jp)

[2]Department of Biological and Environmental Engineering, University of Tokyo, 1–1–1 Yayoi, Bunkyo-ku, Tokyo 113-8657 Japan (amiyat@soil.en.a.u-tokyo.ac.jp, hirai@soil.en.a.u-tokyo.ac.jp, takun@soil.en.a.u-tokyo.ac.jp, imojin@soil.en.a.u-tokyo.ac.jp)

Agricultural liming contributes significantly to atmospheric CO_2 emission from soils [1] and enhances the turnover of soil organic matter (SOC), termed priming effect (PE) [2]. We believe that these impacts of liming acid soils should be factored in our existing soil organic matter (SOM) models but data on magnitude of lime-contributed CO_2 and priming effect in a wide range of global acid soils are still few.

Using two acid soils in Japan: (1) an acidic Kuroboku Andisol from Tanashi, Tokyo Prefecture (35°44' N, 139°32' E), and (2) Kunigami Mahji Ultisol of Nakijin, Okinawa Prefecture (26°38' N, 127°58' E), we employed a unique methodology to separate and quantify lime-contributed ($^{13}CO_2$), and SOC-originated ($^{12}CO_2$) CO_2-C evolution using $Ca^{13}CO_3$ (^{13}C 99%) as lime and tracer.

Our experimental data have confirmed that (1) lime contributes heavily to CO_2 evolution, and (2) liming acid soils increases SOC turnover. On the average, lime-CO_2 was 76.84% (Kuroboku Andisol) and 66.36% (Kunigami Mahji Ultisol) of overall CO_2 emission after 36 days, indicating that the mineralization of lime-carbonates is the major source of CO_2 emission from acid soils during agricultural liming. The calculated PE of lime (Kuroboku Andisol, 51.97-114.95%; Kunigami Mahji Ultisol, 10.13-35.61%) was entirely ^{12}C turnover of stable SOC since the soil microbial biomass (SMBC), a labile SOC pool, was suppressed by liming in our experiment.

Liming can influence the magnitude of CO_2 evolution from agricultural ecosystems considering global extent of acid soils and current volume of lime utilization. The measured PE of liming in SOC is large and can significantly alter atmospheric CO_2 evolution from agricultural ecosystems.

Clay fractions from a soil chronosequence (Switzerland) after retreat of the Damma glacier (15, 75 and 120 yrs) and from mature soils outside the proglacial area (> 700 yrs) were used to elucidate the evolution of organo-mineral assoziations during initial soil formation.

The chemistry of clay-bound organic matter was assessed by ^{13}C NMR spectroscopy and the contents of amino acids and neutral sugar monomers were determined by acid hydrolysis. The mineral phase was characterized by X-ray diffraction, oxalate extraction, N_2 adsorption, and cation exchange capacity at pH 7 (CEC_{pH7}), before and after H_2O_2 treatment.

The OC loading of the clay fractions strongly increased within about 100 yrs of soil formation. This resulted in decreasing specific surface area (SSA) of the mineral phase and increasing CEC_{pH7} which is in line with XRD analysis as no significant transformations of clay minerals were detected. The SSA of H_2O_2-treated clay fractions were strongly related to oxalate soluble Fe (Fe_o) and a strong correlation was found between increasing contents of Fe_o and OC with soil age.

Clay-bound OC of the 15-year-old soils was of refractory nature owing to high proportions of carboxyl C and aromatic C which may be ascribed to inherited OC. With increasing age (75 and 120 yrs), the relative proportions of carboxyl and aromatic C decreased. This was mainly associated with increasing O-alkyl C proportions, whereas accumulation of alkyl C is detected only in the mature soils. These findings are in line with the amounts of carbohydrates which were predominantly derived from microbial input. Proteins accumulated to a similar extent as carbohydrates and H_2O_2 resistant OM showed very low C/N ratios.

The formation of organo-mineral associations starts with the sorption of microbial-derived proteinaceous compounds and carbohydrates on mineral surfaces which are mainly provided by ferrihydrite. The sequential accumulation of different organic compounds and the large OC loadings point to layering of OM during the evolution of clay fractions.

Composition of error in LA-ICP-MS U/Pb geochronology: Lessons from the processing of standard measurement series performed in ten laboratories

I. DUNKL[1]*, R. TOLOSANA-DELGADO[2] AND H. VON EYNATTEN[1]

[1] Sedimentology & Environmental Geology, Geoscience Center, University of Göttingen, D-37077 Göttingen, Germany (*correspondence: istvan.dunkl@geo.uni-goettingen.de)

[2] Maritime Engineering Laboratory, Technical University of Catalonia, Barcelona, Spain (raimon.tolosana@upc.edu)

We have studied the error propagation and the composition of the error of the calculated U/Pb ages of standards measured in ten laboratories by laser ICP-MS technique. These laboratories used different mass spectrometers, laser cells and instrumental settings. The data reduction was performed by several alternative methods e.g. using Arithmetic Mean of Ratios (AMoR), Ratio of Means (RoMa), Median and regression methods and the residual errors of these procedures were compared. The effect of outlier rejection using the standard 2-sigma method and an iterative outlier-testing method was also studied.

Beyond the classical measures of the precision of the age like concordance we performed several experiments to express the scatter of the data obtained by the the laser ablation.

The so called Extra Poissonal Error is recommended for the optimization of the dwell times of the analytes.

The ratio of the mean and the Tzero intercept (of regression) gives a more robust measure for the fractionation than the ratio of the means of first half / second half of the ablation signal.

The influence of the drift through a measurement session was also studied.

The calculations were performed by the UranOS software: www.sediment.uni-goettingen.de/staff/dunkl/software/

Rapid expansions in biological metal utilization

CHRISTOPHER L. DUPONT

J. Craig Venter Institute, San Diego, CA 92121.
(cdupont@jcvi.org)

The fundamental chemistry of trace elements dictates the molecular speciation and reactivity both within cells and the environment at large. Using protein structure and comparative genomics, we elucidate several major influences this chemistry has had upon biology. All of life exhibits the same proteome size-dependent scaling for the numberof metal-binding proteins within a proteome. This fundamental evolutionary constant shows that the selection of one element occurs at the exclusion of another, with the eschewal of Fe for Zn and Ca being a defining feature of eukaryotic proteomes. Remarkably, most of known metalloezymes evolved during two transitional eras. First, development of protein structures for metal homeostasis coincided with the emergence of metal-using proteins, which predominantly bound metals abundant in the Archean ocean. Potentially, this promoted the diversification of emerging lineages of Archaea and Bacteria through the establishment of biogeochemical cycles. In a later expansion, over 75% of known Zn binding structures evolve at the same time as the Eukaryotic superkingdom emerged. These Zn-binding proteins are fundamental to eukaryotic cellular biology, while the localization to the nucleus indicates that they are diagnostic features of this superkingdom. Zn bioavailability may have been a limiting factor in eukaryotic evolution. In both scenarios, the newly evolved metalloezymes would drastically change cell biology and by extension, geochemistry.

The role of extracellular organic matter (EOM) in the nucleation and growth of microbial carbonates

CHRISTOPHE DUPRAZ

Center for Integrative Geosciences, Marine Sciences,
University of Connecticut, Storrs, CT 06269, USA.
(Christophe.dupraz@uconn.edu)

Microbes are key players in the global carbon cycle, where they influence the balance between the organic and inorganic carbon. Microbial populations can be organized in microbial mats, which can be defined as organosedimentary biofilms that exhibit tight coupling of element cycles. Complex interactions between mat microbes and their surrounding environment can result in the precipitation of carbonate minerals (i.e., microbialite). This process refers as 'organomineralization *sensu lato*', which differs from 'biomineralization' (*e.g.*, in shells and bones) by lacking genetic control on the mineral product. Organomineralization can be: (1) *active*, when microbial metabolic reactions are responsible for the precipitation (*"biologically-induced" mineralization*) or (2) *passive*, when mineralization within a microbial organic matrix is environmentally driven (*e.g.*, through degassing or desiccation) (*"biologically-influenced" mineralization*). Two tightly coupled components that control carbonate organomineralization *s.l.*: (1) the alkalinity engine and 2) the extracellular organic matter (EOM), which is ultimately the location of mineral nucleation.

The EOM is composed of two main carbon pools: the high molecular weight extracellular polymeric substances (EPS) and the low molecular weight organic carbon compounds (LMW-OC). Both pools play a critical role in carbonate precipitation by providing Ca^{2+} and CO_3^{2-} as well as a nucleation template for mineral growth. EOM contains several negatively charged functional groups, which, depending on the pH, can be deprotonated (each group has unique pK value(s)) and, thus, bind cations. This binding capacity can deplete the surrounding environment of cations (e.g., Ca^{2+}, Mg^{2+}) and, thus, inhibits carbonate precipitation. Therefore, organomineralization is only possible if the inhibition potential is reduced through (1) oversaturation of the EOM binding capacity or (2) EOM degradation.

Studying microbe-mineral interactions, particularly the role of EOM in carbonate formation, is essential in the investigation of early life (e.g., definition of biosignature), especially at the interface between the biotic and prebiotic worlds, where newly formed organic matter could have strongly influenced the nucleation and growth of minerals, notably carbonate.

Advances in the understanding of atmospheric impacts of volcanic ash emissions since Eyjafjallajokull 2010

A.J. DURANT*[1,2,3] AND A.J. PRATA[1]

[1]Norwegian Institute for Air Research, P.O. Box 100, NO-2027 Kjeller, Norway (*correspondence: adu@nilu.no)

[3]Geological and Mining Engineering and Sciences, Michigan Technological University, USA

Volcanic emissions contain a mixture of gases, and aerosol and silicate ash particles [1]. Volcanic aerosol injected high into the stratosphere may impact atmospheric chemical cycles, or interact with solar and terrestrial radiation and influence climate. Airborne ash and sulphate aerosol in the troposphere, in contrast, has shorter-lived atmospheric and climatic impact. The eruption of Eyjafjallajokull in April and May 2010 brought the atmospheric impacts of volcanic ash emissions to global attention through prolonged grounding of commercial aircraft and subsequent impact on the global economy. In response, the research community engaged across disciplines at an unprecidented scale to provide information, often in real-time, on eruption source parameters, airborne ash characteristics and fallout. One year on from the eruption, we investigate what new knowledge on the impacts of volcanic ash emissions has emerged.

Measurements of ash in the Eyjafjallajokull volcanic cloud from surface [2] and aircraft-mounted instruments [3], and satellite-based sensors combined with modelling [4] tracked the evolution of the ash emissions and provided sometimes contrasting indications of spatial variation in airborne ash concentration. Satellite measurements suggest highly heterogeneous structures with pockets of highly concentrated ash; in contrast the ground-based lidar network suggest low concentrations and highly dispersed ash layers, while airborne measurements suggest concentrations no greater than 1 mgm^{-3} in thin layers [3]. Ash aggregation, while not generally included in ash transport and dispersion models, played an important role in the sedimentation of fine ash generated by the eruption [5]. Finally, it is clear, post-analysis, that there is a need for assiduousness when applying standard atmospheric measurement techniques to the study of volcanic ash clouds.

The geochemical characteristics of beach sediments of the Finike Gulf (Southwest Turkey)

E.S. DURMUS,.[1,2]*, M. ERGIN[1], Z. KARAKAS[1], K. SOZERI[1], B. ESER-DOGDU[1] AND Z. ONAL[1].

[1]Ankara University, Department of Geological Engineering, 06100, Tandoğan, Ankara
[2]Mahatma Gandi Caddesi No:33/1 GOP,Ankara (*correspondence: elifseda_d@hotmail.com)

In the Finike Gulf (SW-Turkey), geochemical characteristics of modern beach sediments were studied to determine their possible economical potential with respect to marine placer deposits and related depositional, transportation and provenance factors. This study was supported by the the Scientific Research Projects Office of the Ankara University. The study comprised geomorphological field observations, sediment sampling and laboratory analysis (i.e., grain size, multielement composition, total heavy minerals). Within this context, in September 2009, large number of modern-surface sediment samples were collected from the foreshore and backshore sub-environments of the beaches of the Finike Gulf.

Sand with varying proportions is the dominant grain size in beach sediments, Element composition of sediment samples was mostly comparable with that of average earth's crustal rocks. However, relatively higher concentrations were measured for Ni (up to 451 ppm) and Cr (2548 ppm). These values can be related to the presence and wide occurrences of ophiolitic rocks (known as "Antalya Nappes") on the coastal hinterland [1]. The study is still going on.

Facies and petrochemical characteristics of the Tertiary aged Tekkeköy (Samsun) area volcanics, NE Turkey

T. DURSUN* AND M. ARSLAN

Department of Geological Engineering, Karadeniz Technical University, 61080-Trabzon, Turkey
(*correspondence: tugbadursun61@gmail.com)

Tertiary volcanics crops out widespreadly in the eastern Pontide, NE Turkey. Of these, the Tekkeköy (Samsun) area volcanics in a E-W trending shallow marine basin lie along the Black Sea coast in the western part of the Eastern Pontide Tertiary Volcanic Province (EPTVP) [1]. The volcanic facieses are dominantly basaltic pyroclastics, less basaltic lava flows, dykes and trachytic dome. The basaltic rocks contain plagioclase, augite and rare olivine with porphyric, microlitic porphyritic, intergranular and locally cumulophyric textures. Trachytic rocks are composed of plagioclase, sanidine, hornblende and biotite with trachytic texture.

Petrochemically, the volcanics can be classified as basalt, trachybasalt, basaltic-andesite, basaltic trachyandesite and trachyte, and exhibit mildly alkaline to subalkaline with medium- to high-K in character. Major oxides and trace elements versus SiO_2 variations show negative correlation for Al_2O_3, Fe_2O_3*, CaO, TiO_2, P_2O_5, MnO, MgO, Co and V whereas positive correlation for K_2O, Na_2O, Rb, Ba and Zr, most of which can be explained by fractionation of cpx+Fe-Ti oxide in mafic rocks, and hornblende +apatite+Fe-Ti oxide in felsic rocks. Besides increase in U and Th with increasing SiO_2 from mafic to felsic rocks may be regarded to small amount of crustal assimilation. N–MORB normalized trace elements patterns show enrichment in LILE (Sr, K, Rb, Ba) and depletion in HFSE (Th, Ce, Zr, Ti, Y) with negative Ta-Nb anomaly, suggesting a subduction and/or crustal contamination signature The chondrite–normalized REE patterns of mafic to felsic samples are similar to each other revealing a common parental source magma (s) for the volcanics. The REE patterns have also concave in shape with marked light REE enrichment and heavy REE depletion, implying effect of significant cpx and hornblende controlled fractionation during the evolution of the volcanics. Facies and petrochemical features of the Tekkeköy volcanics suggest that they may evolved from parental magma (s) derived from an enriched lithospheric mantle source, and correlate others of collisional-post collisional volcanics in the EPTVP.

B-bearing fluids: Caught in the act

B.L. DUTROW*[1], D.J. HENRY [1], C.W. GABLE[2], B.J. TRAVIS[2] AND C.T. FOSTER JR[3]

[1]Department of Geology & Geophysics, Louisiana State Univ., Baton Rouge, LA 70803;
(*correspondence: dutrow@lsu.edu)
[2]Earth & Env. Sciences, Los Alamos National Lab, Los Alamos, NM 87545
[3]Dept. Geosciences, Univ. Iowa, Iowa City, IA 52242

Fluid flow in the Earth's crust can be tracked, in part, by minerals that require a fluid-mobile element for formation. Tourmaline is nature's boron recorder. In many metamorphic systems, tourmaline growth reflects availability of boron-bearing fluids to the rocks. Such fluids can be internally derived, primarily from the progressive release of B during metamorphic breakdown reactions e.g., clays and micas. Alternatively, B-bearing fluids can be externally derived and infiltrate the metamorphic rocks e.g., from an associated pluton, if there exist sufficient chemical gradients, porosity and permeability.

During metamorphism, tourmaline (tur) formation records both types of fluid involvement. For example, internal fluids carrying B are marked by discrete stages of tourmaline growth, typically as overgrowths on a detrital tur core. Progressive growth zones are marked by distinct changes in mineral chemistry and decreases in compositional variability at the *+c* and *-c* axes. Externally derived fluids may be recognized by development of tourmaline-rich zones adjacent to igneous intrusions. In contrast, B infiltration may leave a more subtle trace such as the development of tourmaline-rich muscovite pseudomorphs after staurolite. Here tur records the infiltration of B-bearing magmatic fluids during high-grade metamorphism. Irreversible mineral-texture modeling combined with thermodynamic properties of the aqueous ions suggest that infiltration develops near the peak of contact metamorphism after sillimanite begins to form.

Computational heat and mass transport modeling of fluid evolution from a crystallizing pluton approximates timing as well as the timescales over which infiltration likely occurs during prograde metamorphism. For a 30km by 3km sheet-like granitoid intruded into host rocks with sufficient permeability to allow fluid flow, peak temperatures occur in about 500ky. By this time, host rocks have largely dehydrated, fluid pressures are insufficient to fracture the rock and provide pathways for flow, and the pluton has largely crystallized and released its fluid. Consequently, tourmaline growth and B movement must occur within this time frame. Tourmaline growth and dissolution provide a powerful signature of B cycling and transfer via fluids in the crust.

The evolving landscape of U-series sea level chronologies

ANDREA DUTTON

Department of Geological Sciences, University of Florida, Gainesville, FL 32611, USA (*correspondence: adutton@ufl.edu)

Several factors have contributed to the recent movement within the U-series dating community to promote more consistent practices that will ultimately produce more robust chronologies both within and between individual laboratories. First, instrumental and methodological advances have greatly increased the precision of the U-series technique. One consequence of this improved analytical capability is the amplification of the impact of interlaboratory differences in standardization techniques. Second, publication of revised decay constants for ^{230}Th and ^{234}U as well as inconsistent adoption of these constants across the community have led to issues in the appropriate comparison to and conversion of legacy data. This becomes a problem when new data are contextualized with regional or global datasets generated with different decay constants, and requires the availability of raw data and standardization procedures that have not always been routinely published. Third, there has been an increasing demand for more precise constraints on both the absolute and relative timing of past sea level changes to provide empirical constraints on future sea level behavior. This pressure comes from both within and beyond the scientific community, and routinely encourages scientists to push their interpretations to the very limits prescribed by the data.

All of these issues play into the ongoing debate about the appropriate identification, interpretation, and handling of data from corals that have been compromised by open-system behavior. It is increasingly apparent that modeled open-system ages versus screened closed-system ages lead to notable discrepancies in chronologies of past sea level change. This debate is compounded by the recognition that uranium isotope (^{234}U/^{238}U) ratios of seawater may have varied significantly over the last glacial cycle. Understanding this variability, and its cause, are critical to both the modeled open-system and closed-system approaches to building chronologies of sea level change.

These considerations will be addressed in the context of amalgamating and integrating disparate datasets of sea level change during the last interglacial. This analysis provides impetus to establish more consistency in the analysis, reporting, and treatment of U-series data that will pave the way to advancing our understanding of ice sheet dynamics.

Multiscale modeling of ionic transport in charged clays

M. DUVAIL[1,2]*, D. COELHO[2], S. BÉKRI[3] AND B. ROTENBERG[1]

[1]CNRS and UPMC-Paris6, Laboratoire PECSA UMR 7195, 4 place Jussieu, F-75005 Paris, France (*correspondence: magali.duvail@upmc.fr)

[2]Andra, 1 – 7 rue Jean Monnet, F-92298 Châtenay-Malabry, France

[3]IFP Energies nouvelles, 1 et 4 avenue du Bois-Préau, F-92852 Reuil-Malmaison, France

Modeling the solute transport through a pore network in clays is a crucial issue in better understanding its macroscopic transfer processes. Indeed, although the microscopic (sub-nanometer scale) and macroscopic (multi-microns scale) transport properties in such materials are now well known, a lack remains between these two scales.

This study aims at developing a model representing as accurately as possible the main macroscopic properties of a clay sample. In our model, the material is represented by a pore network in which each pore is connected to an other by a channel.

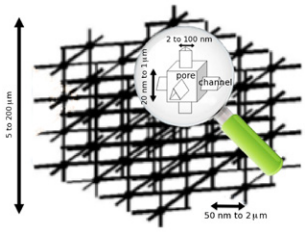

Figure 1: Zoom on an unit cell of the Pore Network Model lattice.

A Lattice-Electrokinetics scheme [1,2] is used to model the microscopic transport properties through the interporal channels (nm scale). Then macroscopic properties (µm scale) are calculated from the microscopic ones using a Pore Network Model (PNM) [3]. Indeed, the calculation of the macroscopic transport properties through a pore and channel network using PNM requires a good understanding of the microscopic ion transport processes (at the channel scale), that depend on the pore and channel properties. Thus, the key question we address here is "How do the transport properties depend on these pore and channel properties?"

The effect of sodium fluoride on soil microbial activity during organic matter decomposition – A calorimetric approach

J.E. DZIEJOWSKI

Department of Chemistry, University of Warmia and Mazury, 10-957 Olsztyn, Poland (dziejo@uwm.edu.pl)

Results and Discussion

Soils exposed to intensive emissions from phosphoric fertilizers and aluminum industries or other fluoride sources have high fluoride concentrations [1]. Fluorides found in soil can affect its microbial activity which can be measured using calorimetric methods [2]. Soil samples were collected at the Agricultural Station of the University. During successive experiments, at 0; 0.05; 0.1; 0.25 and 0.55 % fluoride content and 1 mg glucose in 1g of soil changes in microbial activity were investigated by the calorimetric method. Soil moisture corresponded to 60 % of the maximum water-holding capacity. The changes in the rate of heat production, peak time, total heat effects and the apparent rate constant parameters were used to characterize the glucose biodegradation processes in soil. Sodium fluoride introduced into the soil in the amount corresponding to 0.25 and 0.55 % of fluoride ions decreased the rate of glucose biodegradation. The total heat effects of the studied processes were higher in the presence of fluorides in comparison with soil samples containing no sodium fluoride. The obtained results suggest that despite the reduced rate of glucose biodegradation in the presence of higher doses of sodium fluoride, this compound contributes to an increase in the bioavailability of soil organic substrate for microbial decomposition,

Effect of climate change-driven sea water intrusion on the mobilisation of Tc(VI) from reduced sub-surface sediments

J. EAGLING*, P. WORSFOLD, G. O'SULLIVAN AND M. KEITH- ROACH

BEACh Group, University of Plymouth, Plymouth, PL4 8AA , UK (correspondence: jane.eagling@plymouth.ac.uk)

Nuclear fuel cycle operations have resulted in a significant legacy of contaminated land that requires long term management or remediation. Future sea level rise predictions suggest that nuclear facilties situated in coastal locations will become threatened in terms of seawater intrusion. Increased pore water salinity coupled with any influx of oxygenated seawater may impact on the stability of radionuclides associated with sub-surface sediments. Of particular concern is the high yield, redox sensitive fission product ^{99}Tc which, under reducing conditions, accumulates in sediments as hydrous Tc(IV)n.H_2O phases.

In this work Tc (1 μM) was reduced and sorbed with sediments under anaerobic conditions**.** Although nitrate has been reported to inhibit Tc reduction, in this study extensive sorption of Tc (87%) was observed during nitrate reduction. Tc reduction increased to 98% with the onset of Fe reduction.

Mobilisation of Tc(IV) from initially nitrate- and iron-reducing sediments into groundwater and seawater was then studied using batch and column experiments. Batch results showed that Tc was oxidised prior to mobilisation in groundwater and seawater. Limited release into degassed seawater suggested that the formation of soluble Tc(IV) carbonate or colloidal species was not significant. Release of Tc from the initially nitrate- and iron-reducing sediments into groundwater was broadly similar, with 36-48% mobilised after 90 days. In contrast, the initial redox status of the sediments had a marked effect on Tc mobilisation into seawater. Significantly less Tc was released from sediments with ingrowth of Fe(II) (17 ± 2%) compared with the nitrate-reducing sediments (45 ± 7%). These results suggest that Fe(II) phases are able to hinder Tc reoxidation and release into seawater. In column experiments a near instantaneous pulse (4-7%) of Tc was mobilised, followed by a slower sustained release that continued for the duration of the month long experiments, resulting in > 90% Tc release.

Reduced sediments may therefore act as a secondary source of Tc to marine environments during sea level rise-driven intrusion. Mobilisation occurs primarily via reoxidation whilst changes in pore water salinity alone appear unlikely to increase the rate and extent of Tc release.

Mercury and enstatite chondrite origins by equilibrium condensation from chondritic-IDP enriched vapor

D.S. EBEL[1,2]* AND C.M.O'D. ALEXANDER[3]

[1]Department of Earth and Planetary Science, American Museum of Natural History, Central Park W. at 79th St., New York, NY 10024, USA (*correspondence: debel@amnh.org)

[2]Lamont-Doherty Earth Observatory of Columbia University, New York.

[3]Dept. of Terrestrial Magnetism, Carnegie Institution of Washington, 5241 Broad Branch Rd., Washington, DC 20015 USA

Mercury's core is at least 60% of its mass, compared to Earth's ~32%. The origin of Mercury's anomalous core and low FeO surface mineralogy [1] are outstanding questions in planetary science. If Mercury accreted primarily from a local annulus of precursor solids [2], then Mercury's composition may result from chemical controls on equilibrium partitioning of Fe and Si between those solids and coexisting vapor. High temperatures and enrichment in solid condensates or 'dust', relative to H-rich vapor, are likely conditions near the midplane of the inner solar protoplanetary disk. FeO-rich silicate liquids similar to the liquids quenched in ferromagnesian chondrules are thermodynamically stable in oxygen-rich systems that are highly enriched in a dust of CI-chondrite composition [3]. However, the solids surviving into the orbit of Mercury's accretion zone were probably more similar to FeO-poor, anhydrous, ice-free and organic-rich chondritic (interplanetary) dust particles (C-IDPs) [4]. Chemical systems enriched in C-IDP dust can produce condensates with atomic Fe/Si 50% above chondritic [5] for conservative estimates of C-IDP composition and enrichments of up to 1000x. These Fe/Si ratios approach that estimated for bulk Mercury. Stable minerals are FeO-poor, and include CaS and MgS. These reduced species are also found in enstatite chondrites. Disk gradients in volatile compositions of planetary and asteroidal precursors may at least partially explain Murcury's anomalous composition, as well as some meteorite parent body compositions. This model predicts low Ca/Al, and very low FeO content of Mercury's surface rocks.

Geochemical and mineralogical studies on the Fe-Mn deposits of Dehbid area, Fars province, South Iran

S. EBRAHIMI AND Z. MOOSAVI TEKYEH

School of Mining, Petroleum and Geophysics Engineering, Shahrood University, Shahrood, Iran, (ebrahimisusan@gmail.com)
School of Chemistry, Shahrood University, Shahrood, Iran

The Dehbid Fe-Mn deposits are located at about 260 Km of northeast of Shiraz (Fars Province), in the Sanandaj- Sirjan metamorphic zone. The deposits are hosted by shale and limestone of the Lower Devonian and thick massive limestone of the Middle and Upper Devonian. The studied area is affected by two metamorphism phases, therefore, the sequence of limestone and shale sediments in the Devonian have been transformed to garnet mica schist - amphibolites and marble.

The main ore bodies are accommodated as lenticular and vein, which are concordant to the host rock bedding. Some 5 veins have been mapped in the area; they are classified in two groups with 2-8m wide, and 20-850m long. Mineralogical studies show that the ores are including magnetite, hematite, goethite, pyrite, pyrolusite, and psilomelane. Gangue minerals include quartz and carbonate. The values of the Fe_2O_3 and MnO vary between 30 to 80 wt% and 2-13 wt%, respectively. Co/Ni ratios in the hydrothermal iron deposits are between 0.2-7 and in the Dehbid area the ratio ranges 0.1 to 3.6 that characterizes hydrothermal origin of magnetite.

Geology, petrography and sedimentology aspects indicate the Fe- Mn prospect of the Dehbid which is a strataband type deposit. Moreover, giving the influence of volcanic phase occurred in the lower Devonian and the combined geochemical evidences; the origin of the materials is considered distal Sedimentary- Exhalative.

Chemocline oscillations in the Black Sea documented by sedimentary iron isotopes and trace metal patterns

S. ECKERT[1]*, B. SCHNETGER[1], H. FRÖLLJE[1], S. SEVERMANN[2], C. MONTOYA-PINO[3], S. WEYER[4], J. KÖSTER[1], H. ARZ[5] AND H.-J. BRUMSACK[1]

[1]ICBM, Universität Oldenburg, 26111 Oldenburg, Germany (*correspondence: s.eckert@uni-oldenburg.de)
[2]Institute of Marine and Coastal Science, Rutgers University, NJ-08901 New Brunswick, USA
[3]Institut für Geowissenschaften, Universität Frankfurt, 60431 Frankfurt a. M., Germany
[4]Institut für Mineralogie, Leibniz Universität Hannover, 30167 Hannover, Germany
[5]IOW, 18119 Rostock, Germany

The reconstruction of chemocline fluctuations in the Black Sea basin using sediment archives is challenging. Thus a reliable and ubiquitous proxy is required, which can be applied to samples independent of their location and water depth in the basin. Recently sedimentary Fe/Al ratios combined with $\delta^{56}Fe$ values served as a promising proxy for redox interface fluctuations in marine settings. Elevated Fe/Al ratios coupled with low $\delta^{56}Fe$ values in Black Sea sediments document periods when significant transfer of isotopically light reactive Fe from the shelf to the euxinic basin occurred. The suboxic chemocline, impinging margin sediments allows the lateral transport of Fe^{II}_{aq} across the deep basin. However, to date no published dataset provides high-resolution Fe/Al records of sediment cores from different sampling locations across the Black Sea. Here we show major/trace element data from seven sediment cores sampled at millimeter scale from key locations throughout the entire Black Sea. Synthetic depth profiles were generated by merging the single cores. Furthermore, selected cores were analyzed for $\delta^{13}C$, $\delta^{56}Fe$, $\delta^{97}Mo$, $\delta^{238}U$, and isorenieratene derivatives.

Our results show two distinctive peaks in the vertical distribution of Fe/Al accompanied by lower $\delta^{56}Fe$: 1) at the boundary of lithological Units II to III (marine ingression), and 2) in the centre of sapropelic Unit II. The same geochemical signatures reappear throughout Unit I. Our results point towards repetitive chemocline fluctuations owing to changes in the proportion of marine and riverine input into the Black Sea. The rise of the chemocline results from higher input of marine waters, while increased riverine input presumably lowers the redox interface. These results compare quite well with the Eemian sapropel (MIS 5e). Geochemical data from this second sapropel also document a dramatic change from limnic to marine conditions.

Synchrotron rapid scanning X-ray fluorescence of soft-tissue fossils

N.P. EDWARDS[1]*, H. BARDEN[1], P.L. MANNING[1], W.I. SELLERS[2], B.E. VAN DONGEN[1], U. BERGMANN[3] AND R.A. WOGELIUS[1]*

[1]University of Manchester, School of Earth, Atmospheric and Environmental Sciences, Manchester, M13 9PL, UK (*correspondence: nicholas.edwards@postgrad.manchester.ac.uk, roy.wogelius@manchester.ac.uk)

[3]SLAC National Accelerator Laboratory, Linac Coherent Light Source, Menlo Park, CA, 94025, USA

Many geochemical and biological analytical techniques have been employed in the identification and quantification of soft-tissues in the fossil record. However, almost all of these techniques require destructive sampling and are unable to provide high resolution, large scale, spatially resolved chemical information from fossil material. Synchrotron rapid scanning x-ray fluorescence (SRS-XRF) developed at the Stanford Synchrotron Radiation Lightsource (SSRL), non-destructively provides highly sensitive, *in situ* and large scale 2D elemental maps at rapid scanning times (~30 secs/cm^2) and reveals the distribution of elements present in concentrations below the detection limits of many conventional geochemical techniques. Furthermore, we have uniquely combined x-ray absorption near edge spectroscopy with XRF rapid scanning, to produce maps showing only organic sulfur species. Our recent multi-technique study of fossilised reptile skin (~50 Mya), employing SRS-XRF, Fourier Transform Infrared (FTIR) spectroscopy and Pyrolysis-Gas Chromatography Mass Spectrometry, strongly suggests that remnants of the living organism's original chemistry (protein compounds) are preserved. Additionally, a new taphonomic model has been proposed to explain the survival of these compounds, involving ternary complexation between organic molecules, trace metals and silicate surfaces.

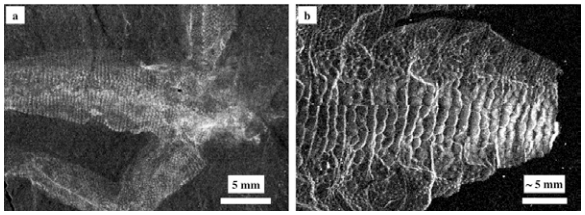

Figure 1: Trace metal loading in a) fossil and b) extant reptile skin.

Fractionation of Cl and Br isotopes during precipitation of salts from their saturated solutions

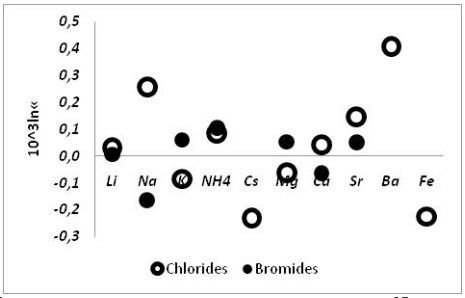
H.G.M. EGGENKAMP[1]*, M. BONIFACIE[2], M. ADER[2] AND P. AGRINIER[2]

[1]Centro de Petrologia e Geoquímica, Instituto Superior Técnico, 1049-001 Lisboa, Portugal (*correspondence: hermanus.eggenkamp@ist.utl.pt)

[2]Institut de Physique du Globe de Paris, 75005 Paris, France

We determined Cl and Br isotope fractionation of LiCl, NH_4Cl, CsCl, $CaCl_2$, $SrCl_2$, $BaCl_2$, $FeCl_3$, LiBr, NH_4Br, $MgBr_2$, $CaBr_2$ and $SrBr_2$ between their saturated solutions and first precipitating salts at 23 °C. Considering previous data for NaCl, KCl and $MgCl_2$ [1] and NaBr and KBr [2] we now have isotope fractionation estimates for common halogen components in marine and terrestrial salt deposits.

$10^3\ln\alpha$ for most salts is relatively modest (i.e., a few tenths of a per mil), although clear variations, both positive and negative, are observed.



$10^3\ln\alpha$ corresponds to the difference in $\delta^{37}Cl$ and $\delta^{81}Br$ between solution and precipitate.

The results obtained in this study can be used to predict Cl and Br isotope fractionation during salt formation in various marine and terrestrial salt deposits. These data can be related to $\delta^{37}Cl$ data obtained from evaporites which show that different salts have different $10^3\ln\alpha$ [1] [3].

The observation that $10^3\ln\alpha$ for Cl and Br salts from different elements have different amplitudes and signs might account for the different behaviour of Cl and Br isotopes in natural samples, which show a non-ideal correlation [4] [5].

From seconds to millennia: Weathering and erosion of the highly dynamic soils of Alpine areas

M. EGLI[1]* AND C. ALEWELL[2]

[1]Department of Geography, University of Zurich, Winterthurerstrasse 190, 8057 Zurich, Switzerland (*correspondance: markus.egli@geo.uzh.ch)
[2]Institute of Environmental Geosciences, University of Basel, Bernoullistrasse 3, 4056 Basel, Switzerland (christine.alewell@unibas.ch)

Alpine areas are very fragile ecosystems and are strongly sensitive to changing environmental conditions (such as climate warming and land-use change). Soil erosion in the Alps is a well-recognized problem and its temporal scale varies from seconds to millennia. It is identified as a priority for action within the EU (European Union) soil protocol of the Alpine Convention. Steep slopes, extreme climate, fragile soils and the often intensive use of agricultural land characterise the environment of the Alps. There are several approaches to estimating erosion rates in these areas such as modelling using the Universal Soil Loss Equation or empirical determinations using radiogenic isotopes such as Cs or Be or even stable isotopes ($\delta^{13}C$). Recent results show that heavy-rainfall events as well as erosion processes during wintertime and early spring have a considerable influence on the erosion rates. This explains the often-observed failure of common erosion models for alpine areas - the measured rates are too low. The counter-part to erosion is weathering, keeping the sensitive process of soil formation in balance. Weathering in cold regions has often focused on the notion of 'cold'. As a result of this approach, the process focus has been that mechanical processes predominate and that chemical weathering is temperature-inhibited, often to the point of non-occurrence or extremely slow. Recent investigations show that in cryic, ice-free environments, chemical weathering can be a very active process leading to substantial leaching of chemical components and the formation of secondary weathering products (such as clay minerals). Contrary to popular belief, weathering in cold Alpine regions, including chemical weathering, is not strictly temperature-limited but is rather limited by moisture availability. As a consequence of warming, additional areas will become ice-free in high Alpine areas and subject to weathering, soil formation and erosion. Obvious soil changes must be excepted in proglacial areas and at low- to mid altitude sites. Concepts of weathering mechanisms, erosion processes and an overview of recent results from Alpine regions will be presented.

Tracing molecular proxy signals from biological source to sedimentary sink

The abundances, distributions, and isotopic signatures of biomarker compounds preserved in aquatic sediments are increasingly being used to derive a diverse array of paleoenvironmental and paleoclimatic information. With analytical advances and development of streamlined methodological approaches, there is growing emphasis on biomarker-based reconstructions of past climate at high temporal resolution, and as part of multi-proxy investigations. Crucial to the accurate interpretation of such records is a robust understanding of the provenance of these molecular signals, as well as the timescales associated with signal transfer from biological source to sedimentary sink. While there is often an implicit assumption that the delivery of these signals to the sedimentary archive is virtually instantaneous. there is growing evidence from biomarker-specific ^{14}C measurements that transport may take several hundred to several thousand years. In the case of markers of vascular plant vegetation, storage in soils and at other locations within terrestrial drainage basins may induce significant temporal lags, while in the marine environment episodes of sediment resuspension and redistribution prior to burial have also been inferred to create significant temporal offsets in sedimentary records. The magnitude of such temporal lags may also vary as a function of climate, potentially yielding complex age relationships between proxy records through time. This presentation will describe studies using molecular isotopic ($\Delta^{14}C$, $\delta^{13}C$, δD) measurements that seek to explore the interplay between biomarker provenance and signal transmission times in the context of drainage basin properties and past climate variability. The results will be discussed in terms of implications for interpretation of biomarker records and carbon cycling on the continents.

Changes in silicate utilization and upwelling intensity off Peru since the LGM – Insights from silicon and neodymium isotopes

CLAUDIA EHLERT*, PATRICIA GRASSE AND MARTIN FRANK

IFM-GEOMAR, Wischhofstr. 1-3, 24148 Kiel, Germany (*correspondence: cehlert@ifm-geomar.de)

The Peruvian coastal upwelling area is characterized by one of the most pronounced Oxygen Minimum Zones in the world's ocean. Oxygen concentrations in the water column are controlled by consumption through decomposition of organic matter versus ventilation via ocean circulation. Surface bioproductivity which is dominated by diatoms building their frustules from dissolved silicic acid is a function of both nutrient supply and upwelling intensity. The utilization of silicic acid is reflected by its stable silicon isotope composition ($\delta^{30}Si$). The lighter isotopes are preferentially incorporated into the diatom frustules leaving the ambient seawater enriched in the heavier isotopes. Thus $\delta^{30}Si$ values directly mirror silicate availability and the amount of newly supplied silicate with upwelled waters.

Today, the upwelling is strongest near the coast between 10-15°S. There, fractionation is lowest ($\delta^{30}Si$ = 2‰ for surface water and 1‰ for diatoms, respectively) because the permanent re-supply of nutrients prevents a high degree of fractionation. Outside the main upwelling zone fractionation is higher (up to 2.8‰ in the water and 1.8‰ in the diatoms) indicating slightly increased limitation of silicic acid.

A downcore record from 12°S documents that the main upwelling region has been highly dynamic since the LGM. Biogenic opal concentrations range from 2-31wt%. Accordingly the diatom $\delta^{30}Si$ data range from 0.4-1.6‰. During the deglacial and early Holocene the $\delta^{30}Si$ was overall lower than during the late Holocene but much more variable indicating a more dynamic regime. For the late Holocene the low range in $\delta^{30}Si$ indicate constant upwelling. Low $\delta^{30}Si$ during the early Holocene would require surface water with $\delta^{30}Si$ ~1.7‰. Today, no surface waters in the area show such low values. Radiogenic Nd isotopes will be applied to address possible changes in source water, either freshwater runoff from the hinterland or enhanced contributions from the south.

For the entire record low $\delta^{30}Si$ values correspond to low biogenic opal concentrations. The opposite would be the case if silicic acid utilization had been the only driving factor of the $\delta^{30}Si$ variability. Instead, limitation by other nutrients, e.g. phosphate, during phases of low productivity is more likely.

Strontium and sulfur isotopes in celestite from Likak deposit, SW Iran

F. EHYA[1]*, B. SHAKOURI[2], M.R. ESPAHBOD[2] AND H. ASGARIYAN[2]

[1]Department of geology, Islamic Azad University-Behbahan Branch, Behbahan, Iran (*correspondence: ehya@behbahaniau.ac.ir)

[2]Department of geology, Islamic Azad University-North Tehran Branch, Tehran, Iran

Celestite mineralization in Likak deposit is hosted by Lower to Middle Miocene Gachsaran evaporitic formation. An epigenetic mode of formation via replacement of pre–existing gypsum and anhydrite by later celestite was previously proposed for mineralization [1].

In order to determine the origin of strontium and sulfur for celestite mineralization, 6 samples of the mineral from various outcrops of the orebody were collected for isotopic analyses (2 samples for strontium and 4 for sulfur isotopes). The isotopic analyses were performed by Actlabs (Activation Laboratories Ltd., Canada) using a Triton Multi–collector Mass Spectrometer for strontium, and a VG 602 Isotope Ratio Mass Spectrometer for sulfur isotopes.

Strontium isotopic ratios ($^{87}Sr/^{86}Sr$) are 0.708768 and 0.708829 for analyzed samples. These ratios match well with values reported by McArthur and Howarth [2] for Miocene seawater and indicate that Sr was originated from seawater. The celestite samples display $\delta^{34}S$ values falling in the range of 25.7–27.8. Sulfur isotopic ratios indicate higher $\delta^{34}S$ values in analyzed samples than those of Miocene seawater [3]. These higher values were probably resulted by bacterial reduction of sulfate [4–6].

Since celestite mineralization has an epigenetic origin, it can be suggested that precursors of the mineralizing fluids were probably produced by evaporation of seawater in a coastal marine setting. As these brines entered into underlying sediments, they leached considerable amounts of Sr from host sediments. Once these Sr–enriched fluids discharged back up into overlying beds containing gypsum and anhydrite, replacement of the beds by celestite were occurred [7].

Formation of barite chimneys in hydrothermal systems

B. EICKMANN[1]*, M.P ETERS[2], H. STRAUSS[3], I.H. THORSETH[1] AND R.B. PEDERSEN[1]

[1]Centre for Geobiology and Department of Earth Science, University of Bergen, 5007 Bergen, Norway (*correspondance: Benjamin.Eickmann@geo.uib.no)
[2]Department of Geology, University of Maryland, College Park, Maryland 20742, USA
[3]Institut für Geologie und Paläontologie, Universität Münster, 48149 Münster, Germany

Two recently discovered hydrothermal systems at the slow-spreading Arctic Mid-Ocean Ridge system, the Jan Mayen (JMVF) and the Loki's Castle vent fields (LCVF) contain barite chimneys of variable composition. Both hydrothermal systems consists of two active vent sites, which is confirmed by elevated hydrogen sulphide concentrations and discharge of high-temperature fluids, reaching 270°C in the JMVF and 317°C in the LCVF.

In contrast to the high-temperature vent sites, areas of diffuse venting with emanating clear fluids at slightly elevated temperatures (~20°C) have been found to harbour numerous barite chimneys. The barite chimneys in the JMVF are composed of barite, silica and abundant iron, zinc and lead-sulphide minerals, with pyrite representing the dominant sulphides. In contrast, the barite chimneys of the LCVF consist mainly of pure barite with lesser amounts of sulphide minerals.

In additon to oxygen isotopes, this study presents the first multiple sulphur isotope data on barite chimneys in hydrothermal systems. $\delta^{34}S_{sulphate}$ and $\delta^{18}O_{sulphate}$ values of the JMVF barite chimneys are lower than $\delta^{34}S$ of seawater sulphate and $\delta^{34}S$ values of extracted sulphides point to a magmatic source. This indicates that these barite chimneys have been precipitated from a mixture of seawater and hydrothermal fluids. $\delta^{34}S_{sulphate}$ and $\delta^{18}O_{sulphate}$ values for the barite chimneys in the LCVF are higher than $\delta^{34}S$ values for contemporaneous seawater, and show remarkable differences between the surface and the interior. The highest $\delta^{34}S_{sulphate}$ values have been found in the chimney interior, reaching $\delta^{34}S_{sulphate}$ values up to +34.9‰. Negative $\Delta^{33}S_{sulphate}$ values in combination with positive $\delta^{34}S_{sulphate}$ and $\delta^{18}O_{sulphate}$ values strongly point to biological sulfate reduction processes, most likely in the sub surface of the LCVF. The presence of filaments within the chimneys (revealed by SEM) and the finding of framboidal pyite in barite chimneys and underlying sediments in the LCVF indicates that biologic processes caused the observed sulfur and oxygen isotope fractionation.

Sorption of lanthanide ions to mineral surfaces monitored by luminescence spectroscopy techniques

S. EIDNER, K. BRENNENSTUHL, S. ZILM-GRAMCKOW AND M.U. KUMKE*

University of Potsdam, Institute of Chemistry (Physical Chemistry), Karl-Liebknecht-Straße 24-25, D-14476 Potsdam-Golm, Germany (*correspondence: Kumke@uni-potsdam.de)

The distribution of metal ions in the environment is a crucial issue which needs fundamental understanding of the processes involved, e.g., for predicting the safety of repositories for radioactive or chemotoxic waste. In general, the distribution of metal ions is governed by processes like adsorption, desorption, and/or incorporation into inorganic or organic phases, respectively, precipitation from and transport in the aqueous phase. The toxicity of metal ions is not only reflected by its appearance in an environmental compartment, but is determined by its chemical speciation. Therefore, experimental techniques are utile, which allow to monitor the presence and chemical environment of a metal ion at the same time.

The sorption of lanthanide ions on mineral phases, like kaolinite, was investigated by luminescence techniques. As lanthanide ions Europium(III) and Terbium(III) were used because of their outstanding luminescence properties. The influence of salinity and/or the presence of potentially complexing agents on the lanthanide ion's sorption (strength, etc.) was further investigated. As complexing agents low molecular weight organic substances (LMWOS), such as formic and acetic acid, but also potentially chelating agents, like hydroxy propionic acids, were used. Such LMWOS had been identified as constituents of Kerogen isolated from clay minerals and may here distinctly determine the speciation of metal ions. From the luminescence characteristics of the lanthanide ions conclusions concerning their coordination were deduced. Going down to cryogenic temperatures allowed to distinguish between different complex species. Taking advantage of the inter-lanthanide energy transfer made it possible to calculate averaged distances (in the Å to nm range, which extends the observable interionic distance range beyond the first coordination sphere) between sorbed lanthanide ions. Combining the results of the different luminescence techniques deepens the understanding of metal ion sorption on mineral phases, which is a key aspect for understanding transport phenomena of ions (e.g., actinides) in host rock formations.

The suitability of ^{236}U as an ocean tracer

R. EIGL[1]*, G. WALLNER[1], M. SRNCIK[1], P. STEIER[2] AND S. WINKLER[2]

[1]Institut für Anorganisch Chemie, University of Vienna (*correspondance: rosmarie_eigl@yahoo.de)
[2]Isotopenforschung, University of Vienna, 1090 Wien Austria (peter.steier@unvie.ac.at) (stephan.winkler@univie.ac.at)

^{236}U is probably the second most abundant anthropogenic radionuclide (above 10^6 kg produced so far [1]). While previous measurements could identify ^{236}U only in the vicinity of known contaminated sites (Chernobyl, Sellafield, etc.), our measurements are evolving into a consistent picture of the dispersion of anthropogenic ^{236}U. This led to the insight that ^{236}U is a component of the global fallout from nuclaer weapons testing and was produced via the $^{238}U(n, 3n)^{236}U$ reaction [2].

^{236}U has a well defined source function, is conservative in sea water (residence time approximately 500000 years) and has a sufficiently long half-life (23 Ma) to assure complete mixing in the ocean. The expected natural level below 10^{-13} is negligible compared to the measured anthropogenic ratios. ^{236}U is thus suitable as a tracer for the study of ocean dynamics on a global scale and may in some respects even outperform some more established isotopes.

We analyzed sea water samples from places around the world: the Atlantic ocean ($^{236}U/U = (1.9\pm0.6)\times10^{-9}$), the Pacific ocean ($^{236}U/U = (5.2\pm0.5)\times10^{-9}$), the Black Sea ($^{236}U/U = (3.6\pm0.5)\times10^{-9}$) and the Irish Sea ($^{236}U/U = (2.0\pm0.02)\times10^{-6}$). The measured isotopic ratios coincide with established values for contamination by global fallout, except from Irish Sea water, which was clearly influenced by the Sellafield reprocessing plant.

An absolute reference frame for clumped isotope thermometry

JOHN M. EILER[1], KATE DENNIS[2], HAGIT P. AFFEK[3], BEN PASSEY[4] AND DAN SCHRAG[2]

[1]California Institute of Technology, (eiler@gps.caltech.edu)
[2]Harvard University; (kdennis@fas.harvard.edu)
[3]Yale University; (hagit.affek@yale.edu)
[4]Johns Hopkins University, (bhpassey@jhu.edu)

Analysis of multiply substituted isotopologues of molecules ('clumped isotope geochemistry') presents special challenges to both precision and accuracy. Previous discussions have focused on mass spectrometric precision for these rare species and intralaboratory reference frames. This discipline has spread, demanding interlaboratory standardization. We present a four-laboratory study of the calibration of mass-47 anomalies (Δ_{47} values) in CO_2 (especially extracted from carbonate). We consider: instrument linearity, source fragmentation/recombination reactions (which vary between mass spectrometers and with time and instrument settings), and differences in methods, materials and conditions for sample preparation. We address these problems by developing a method for standardizing Δ_{47} measurements to an absolute reference frame based on theoretical predictions of the abundances of multiply-substituted isotopologues of gaseous CO_2 that has reached a thermodynamic equilibrium at a known temperature. By analyzing CO_2 gases that have been subjected to established laboratory procedures known to promote isotopic equilibration (i.e., heated gases and water-equilibrated CO_2), and by reference to the statistical thermodynamic predictions of equilibrium isotopic distributions, it is possible to construct an empirical transfer function that can then be applied to CO_2 samples with unknown Δ_{47} values. This reference frame may be unique in that it is based on thermodynamic equilibrium, rather than the isotopic composition of an arbitrary reference material. We describe the protocol necessary to construct such a reference frame, the method for converting gases with unknown clumped isotope compositions to this frame, and suggest a protocol for ensuring that reported Δ_{47} values can be compared among different laboratories, independent of laboratory-specific analytical or methodological artefacts. Application of this approach to measurements of CO_2 extracted from several carbonate reference materials results in interlaboratory agreement on their Δ_{47} values to within est. ±0.01 ‰, 1σ. Finally, we present a revised paleotemperature scale that applies when using the absolute reference frame described here, as opposed to the previous paleotemperature equation based on data from a single laboratory. More generally, this study presents a model for how interlaboratory standardization might be approached for other 'clumped isotope' measurements.

Strontium isotope fractionation and its application in Earth system sciences

A. EISENHAUER*, F. BÖHM[1], H. VOLLSTAEDT, A. KRABBENHÖFT, V. LIEBETRTAU, J. FIETZKE[1], B. KISAKÜREK[1] AND J. EREZ[2]

[1]Leibniz Institute of Marine Sciences, IFM-GEOMAR, Kiel, 24148, Germany (*correspondance: aeisenhauer@ifm-geomar.de)

[2]Institute of Earth Sciences, The Hebrew University of Jerusalem, 91904, Israel

Taking strontium (Sr) isotope fractionation into account allows the independent and simultaneous determination of paired Sr ratios ($^{87}Sr/^{86}Sr$*, $\delta^{88/86}Sr$) in silicate and carbonate material. Following this approach the Sr isotope composition of seawater ($\delta^{88/86}Sr_{seawater}$: ~0.39 ‰) and marine carbonates ($\delta^{88/86}Sr_{carbonates}$: ~0.15 – 0.25 ‰) differ as a function of local environmental parameters and physiological processes which possibly qualifies Sr isotope fractionation as a new proxy in marine geochemistry. This approach extends the well-established application of the radiogenic Sr ($^{87}Sr/^{86}Sr$) by an additional dimension and also allows for simultaneous calculation of Sr input and output fluxes of the ocean using complete Sr isotope budget equations. In addition, Sr isotope fractionation is a new isotope tool for the study of organic and inorganic $CaCO_3$ precipitation mechanisms being sensitive to the precipitation rate at least for calcite.

Recent results indicate that the $\delta^{88/86}Sr$ value of seawater is controlled by the balance between input and output of shelf-carbonates. In periods of shelf carbonate exposure this input dominates that of Sr originating from silicate weathering. In this regard taking the long residence time (2.5 Ma) and Sr concentration in seawater into account it can be understood why modern and Quaternary corals show about the same $\delta^{88/86}Sr$ value in the order of ~0.2‰. Latter observation qualifies Sr isotope fractionation in marine carbonates as a temperature proxy tool as long as a solid and sensitive temperature-$\delta^{88/86}Sr$ calibrations can be established.

On Phanerocoic timescales $\delta^{88/86}Sr_{seawater}$ follows the general distribution of “calcite seas” and “aragonite seas”, implying a control mechanism by $Mg/Ca_{seawater}$ ratios and further global spreading rates. On shorter timescales in the order of the residence time of Sr in the ocean we observe a strong relationship between the abundance of marine calcifiers and the $\delta^{88/86}Sr_{seawater}$ values providing the opportunity to study the disturbances of the ocean carbon budget during mass-extension events as shown for the Ordovician/Silurian and Permian/Triassic boundary, respectively.

Observational constraints on the water and volatile content of planet-forming regions of circumstellar disks

J.A. EISNER

University of Arizona, Steward Observatory, 933 N. Cherry Ave., Tucson, AZ 85721, USA; (jeisner@email.arizona.edu)

Models of the protosolar nebula suggest that the Earth formed in an environment too hot for water or volatiles to exist in solid form. Because the Earth is known to possess these elements, investigators posit that they were delivered after the Earth formed by comets, asteroids, hydrated dust grains, or a combination of these mechanisms. Planets in habitable zones around other stars—of which we now have several examples—would require similar mechanisms for water and volatile delivery.

Understanding water delivery to the Earth is a crucial part of the story of our origins. Protoplanetary disks around young stars offer a window through which we can view processes that presumably occurred in our solar system billions of years ago. Study of these disks also illuminates the physical processes by which habitable planets may form elsewhere in the Galaxy.

Recent advances in spectroscopic capabilities both in space and on the ground enable probes of warm water vapor and volatile material across a range of excitation conditions. I will review observations of protoplanetary disks that reveal the spatial distribution, temperature, and column density of gas-phase water and volatile material in 'terrestrial' regions. The presence of these molecules in warm, inner disk regions implies transport from cooler regions at larger stellocentric radii, and presents observational constraints on models for water and volatile delivery to terrestrial planets.

Geoenvironmental factors evaluate the underground waters in the eastern desert of Egypt

ELSAYED AHMED EL GAMMAL

National Authority for Remote Sensing and Space Science-Cairo, Egypt (egammal@hotmail.com)

New areas of utilization had to be developed within the desert area where the underground water reservoir could be used. Therefore, selection of good localities for drilling new water wells suitable for human use and how to use the present water wells is very important in any planning and development. The aim of this paper is to ultimate the benefits of the water wells and delineate their risk. And intends to contribute in developing a suitable methodology for the founding good new water wells. In this study, we proposed the following geoenvironmental factors to ultimate the water wells availability and quality; i) Impact of the surrounded (host) rocks and the type of aquifer sediments. ii) Impact of mining and quarirs activities and mineralized body in the drained basin. iii) Impact of well´s situation in site of water flow in it's drained basin. Eastern Desert of Egypt occupies more than 230, 000 km^2. Hundred important water wells had selected in Eastern Desert to investigate the impact of suggested geoenvironmental factors. There are 96 gold mines in Eastern Desert, in spite of gold mining activities started in the Pre-Dynastic period of the Egyptian history (4000yearsBC) and continued up to the recent years. Besides ochre (iron oxides) and several Pb-Zn mines.

New geomorphological and drainage basin maps for Eastern Desert had been prepared using Landsat ETM images and revise the published geological and topographic maps. Correlation between the published chemical analyses of the underground water for 82 wells on one side and the host rock forming minerals, mining activities, position in the drained basin and the type of the aquifer on the other side.

Elements, when leached from mining wastes are concentrated in certain parts of a drainage basin by flash flood. And contaminate the underground water with elements both from the ore body and mining activities such as Pb, Zn, Cu, and Fe and dissolved materials are high content in these wells. The alkaline water found at the footslopes of syenite mountaines. Abundance from clay minerals in underground water found at granite and syenite terrain as a result of weathering of feldspars. This study monitored that the underground water analyses reflected the rock forming minerals and mining activities in it's surroundings. The aquifer type has considerable significance. There are good water from several wells regarding to these factors. This article elucidates that the proposed impact of the mentioned geoenvironmental factors is actually, the first attempt in the study of the subject in Egypt. Therefore, it is strongly advisable to perform an geoenvironmental impact assessment before starting any drilling for new water wells and before use the present wells and have to put in data base.

Gold and platinum group mineral at Bleïda Far West, Anti-Atlas, Morocco

M. EL GHORFI[1], L. MAACHA[1], A. EN-NACIRI[1] AND T. OBERTHÜR[2]

[1]Managem, Twin Center, Tour A, Angle Bd Zerktouni et Massira Khadra, Casablanca, Morocco

[2]BGR, Stilleweg 2, 30655 Hannover, Germany

The Bou Azzer-El Graara inlier in the Anti-Atlas is well known for its Co-As deposits with gold as a by-product, and the abandoned Bleïda Cu deposit. Recent prospecting by Reminex led to the discovery of a significant gold-palladium mineralization some 7 km NW of the former Bleïda copper mine (-6.5173038, 30.3923419).

At Bleïda Far West, Au-Pd mineralization is hosted by hydrothermally altered amphibolites and chlorite schists. The mineralization occurs in a 7 by 5 km wide corridor, and is associated with intense silicification and numerous, narrow, quartz-dominated, carbonate-bearing veins. Close to surface, the mineralization is hosted in weathered, soft, clayey and powdery material rich in Mn- and Fe-oxides/hydroxides with visible gold.

The pristine mineralization is virtually sulfide-free. Gold (grains up to 400 μm in diameter) is associated with hematite, quartz, calcite, barite, epidote and chlorite. Individual gold grains and grains within individual samples are usually chemically homogeneous. The composition of gold analysed by EPMA (n = 82) ranges from 79 to 93 wt.% Au, 6 to 19 wt.% Ag, and 0.5 to 7 wt.% Pd. The gold grains are intergrown with a distinct suite of PGM, namely mertieite-I [$Pd_{5+x}(Sb,As)_{2-x}$], keithconnite [$Pd_{20}Te_7$], palladseite [$Pd_{17}Se_{15}$], and sperrylite [$PtAs_2$].

A genetic model on the genesis of the Bleida FW mineralization must bear in mind that the gold is associated with hematite and barite, not with sulfides. The combined geochemical and mineralogical evidence so far suggests a relatively low-temperature hydrothermal origin of the gold from oxidizing fluids, related to syn-tectonic quartz-diorite intrusions, or other, still imprecisely known events.

We present results for the systematic crustal alteration of basalts from the shallow, slow-spreading Kolbeinsey Ridge (67°05'-70°26'N). Age-constrained Kolbeinsey lavas are isotopically depleted (e.g. $^{87}Sr/^{86}Sr$ = 0.70272-0.70301) with ($^{230}Th/^{238}U$) = 0.95-1.30, low U (≥11ppb), and low Th (≥33ppb). The basalts have a narrow range of ($^{230}Th/^{232}Th$) ratios (1.20-1.32) over a large range in ($^{238}U/^{232}Th$) (0.94-1.32), producing a horizontal array on a ($^{230}Th/^{232}Th$) vs. ($^{238}U/^{232}Th$) diagram. However, we observe that the range of ($^{230}Th/^{238}U$) (0.96-1.30) is inversely and nearly linearly correlated with ($^{234}U/^{238}U$), reflecting shallow crustal alteration of the basalts. Variations in U and Th concentrations and Cl/K_2O ratios are not systematic, indicating a combination of crustal alteration mechanisms. For example, samples with elevated Cl/K_2O ratios but no elevated ($^{234}U/^{238}U$) ratios have likely experienced the addition of subsurface brines with low oxidation states and, thus, low U solubilities; the addition of those fluids is not expected to systematically affect the U isotope composition of the basalts. $^{87}Sr/^{86}Sr$ and ($^{234}U/^{238}U$) isotope variations, on the other hand, support the systematic addition of material from hydrothermally altered crustal rocks to the basalts.

Unaltered Kolbeinsey lavas have high ($^{230}Th/^{238}U$) values (≥1.2), which are consistent with melting in the presence of garnet and with production of thick ocean crust by large degrees of melting.

Fractionation of Li and Mg isotopes in mantle derived materials– Promise, perils and progress

Li and Mg provide an intersting pair of elements with which to explore the process that influence high temperature fractionation of cationic species in geological environments. There are large relative mass-differences between the isotopes of Li (17%) and Mg (8%) that should should promote discernible fractionations. Both elements are hosted in major lattice sites in common mantle minerals and so the energetics of exchange between different minerals can be reasonably well understood. Neither show multiple valences over mantle conditions, that can dominate fractionation behaviour. The value of understanding the processes that lead to their high temperature fractionations, aside from intrinsic curiosity, is that signatures related to processes of planetary differentiation and recycling may be discerned over later magmatic influences

The importance of diffusion in isotopic fractionation in the Li system has been highlighted in a number of earlier studies. Our new *in situ* studies re-emphasise the complexity and magnitude of fractionations that can occur by late-stage diffusion. Moreover, we show that Mg isotopic variations in bulk xenoliths co-vary with those of Li. Again diffusion is implicated although it is not obvious what drives the ingress of Mg. We suggest it may be related to volatile loss *en route* to surface. In samples uninfluenced by diffusive fractination, as identified from unzoned, mineral Li isotope profiles, natural fractionation factors can be gleaned from analyses of co-existing bulk minerals. Clinopyroxenes are heavier in both Li and Mg systems, as predicted in the latter by computational studies of equilibrium partitioning. More experimental data could yield better constraints over a wider range of conditions.

Widespread synchronous volcanism on the Snake River Plain

B. ELLIS[1]*, J.A. WOLFF[1], D. MARK[2] AND I. BINDEMAN[3]

[1]SEES, Washington State Uni., Pullman, WA, 99164, USA (*correspondance: ben.ellis@wsu.edu)

[3]Geological Sciences, Uni. of Oregon, Eugene, OR, USA

Rhyolitic volcanism in the central Snake River Plain (SRP) represents the early history of the Yellowstone hotspot. An ignimbrite flare-up has been recognised in the SRP between 11.7 and 10.2 Ma [1] during which >75% of the total volume of ~20,000 km^3 of high temperature rhyolitic magma was erupted. Ignimbrites of the central SRP are almost identical in field appearance being intensely welded with an anhydrous mineral assemblage, so geochemical methods are required to distinguish between magma batches. Here, we combine field constraints, mineral and glass compositions, stable isotopes, and new high precision $^{40}Ar/^{39}Ar$ geochronology to fingerprint magma batches and investigate the timing and distribution of volcanism during the flare-up. Our results indicate that five similar but subtly different magmas were erupted and deposited to both the north and south of the plain beginning with Brown's Bench 4 (11.59 ± 0.081 Ma, n=31, 2σ) and ending with the Tuff of Fir Grove (11.14 ± 0.13 Ma, n=19, 2σ). Magma batches may be distinguished by the presence of multiple compositional populations of both pigeonite (Mg# 9-17) and augite (Mg# 8-22) and variation in ilmenite compositions. All five ignimbrites exhibit the characteristic depletion in $\delta^{18}O$ observed in the central SRP with feldspar values between 1.96 and 2.97‰.

The widely dispersed (>100 km E-W) and geographically limited nature of some of the ignimbrites suggests they were erupted from different sources currently buried beneath younger basalts within the SRP. These results suggest that the currently accepted model of discrete 'eruptive centres' requires reconsideration. The high precision geochronology shows that during the flare-up ignimbrite-forming eruptions were occurring in the central SRP at a frequency more than 7 times that of the present Yellowstone volcanic field and 5 times that of the Heise eruptive centre. We propose that the opening of the western Snake River Plain graben, itself exploiting a pre-existing crustal weakness illustrated by the Vale fault zone directly to the NW, caused lithospheric thinning and resulted in the increased eruptive frequency.

Geochemical alteration of fracture geometry during leakage of CO_2

B.R. ELLIS[1], C.A. PETERS[1]*, J.P. FITTS[2], G.S. BROMHAL[3], D.L. MCINTYRE[3] AND R.P. WARZINSKI[3]

[1]Dept. of Civil & Environmental Engineering, Princeton University, Princeton, NJ 08544 (*correspondance: cap@princeton.edu)
[2]Environmental Sciences Department, Brookhaven National Laboratory, Upton, NY 11973
[3]U.S. DOE National Energy Technology Laboratory, Morgantown, WV 26507 and Pittsburgh, PA 15236

A series of three flow-through experiments were performed on artificially fractured caprock samples to investigate fracture evolution during simulated leakage of CO_2-acidified brine. The core samples are from the Amherstburg limestone, which is the caprock for a CO_2 storage demonstration project in northern Michigan, USA.

The evolution of fracture aperture was monitored in real time using X-ray computed tomography (CT). Before and after the experiment, 3-D reconstructions of the fracture structure, aperture and surface roughness were examined at higher resolution via micro X-ray CT. The cores were then sectioned and examined with scanning electron microscopy, X-ray flourescence and micro X-ray diffraction.

Although all three samples were of nearly identical mineralogical composition, the brine flow rates, initial brine compositions, and initial fracture permeabilities differed across the three samples. These differences in flow conditions and fluid composition generated different degrees of fracture deterioration. The first run resulted in substantial erosion of the fracture surface, while the second run had a decrease in fracture permeability that may be attributed to mineral precipitaion along the fracture.

Spectroscopic analysis of the samples after CO_2-brine flow demonstrated preferential calcite dissolution. Mineral spatial heterogeneity coupled with the preferential dissolution of calcite led to non-uniform degradation along the fracture and an increase in surface roughness. In areas where calcite is intermixed with dolomite and other silicate minerals the dissolution of calcite leads to the formation of a degraded zone along the fracture boundary, resulting in a smaller increase in fracture aperture.

The potential mineral precipitation found in the second run is in stark contrast to the rapid mineral dissolution found in the first and suggests a complex interplay of mineral spatial heterogeneity, brine composition, and flow conditions controlling caprock fracture evolution. Results from this study will be we used to frame a discussion on how flow through caprock fractures may be influenced by geochemical alteration of fracture geometry.

Deglacial southern ocean ventilation history from a benthic foraminiferal $\delta^{13}C$ Transect

AURORA C. ELMORE[1], ELIZABETH L. SIKES[2], MEA S. COOK[3], BENEDETTO SCHIRALDI[2] AND THOMAS GUILDERSON[4]

[1]Marine Science Center, University of New England, Biddeford, ME (*correspondence: aelmore@une.edu)
[2]Institute of Marine and Coastal Sciences, Rutgers University, New Brunswick, NJ
[3]Geosciences Dept. Williams College, Williamstown, MA
[4]Lawrence Livermore National Labs, Livermore, CA

Abrupt climate changes during the last deglaciation are associated with corresponding changes in Southern Ocean overturning circulation and ventilation, particularly during the Antarctic Cold Reversal (ACR). Herein, we present high-resolution, mono-specific (*P. wuellerstorfi*), benthic foraminiferal $\delta^{13}C$ records from a depth transect of cores to reconstruct ventilation changes in the New Zealand region of the Southern Ocean. The cores span depths of; 600m (RR0503 87TC/87JPC), 1200m (RR0503 79JPC), 1600m (RR0503 83TC/83JPC), 2045m (H214;), 2500m (RR0503 125JPC), and 3800m (RR0503 41JPC). Age control is based on tephrastratigraphy, and additionaly constrained by $\delta^{18}O$.

During the last glacial period, the difference in $\delta^{13}C$ values ($\Delta\delta^{13}C$) between 600 and 3800m, is ~1.7‰, significantly higher than during the Holocene (~0.7‰), implying reduced glacial ventilation. In the early deglaciation, $\delta^{13}C$ increased at deep sites, suggesting increasing ventilation. Glacial $\delta^{13}C$ values at 1200m lie evenly between the values of the deeper sites (1600 – 3800m) and the shallowest core (600m), suggesting a distinct glacial intemediate water mass. During the ACR, $\delta^{13}C$ at 1200m increased and converged with values at 600m, suggesting that a single water mass to bathed 600 – 1200m. Following the ACR, $\delta^{13}C$ values at 1200m again become distinct from the shallow and deep sites and the $\delta^{13}C$ in the deeper cores increases rapidly (by ~0.5‰), reducing the $\Delta\delta^{13}C$ to ~1.0‰ post-ACR.

These results indicate a step-wise change in stratification and ventilation across the ACR boundary, suggesting the ACR had both a short term and enduring impact on shallow interior ventilation in the Southern Pacific.

Characterisation of the transfer and biodegradation of chloroacetamide herbicides in lab-scale wetlands

O.F. ELSAYED[1], E. MAILLARD[1], S. VUILLEUMIER[2] AND G. IMFELD[1]*

[1]Laboratory of Hydrology and Geochemistry of Strasbourg (LHyGeS), UMR 7517, University of Strasbourg - CNRS (*correspondence: imfeld@unistra.fr)
[2]Department of Microbiology, Genomics, and the Environment (GMGM), UMR 7156, University of Strasbourg - CNRS (vuilleumier@unistra.fr)

Chloroacetamide herbicides are extensively used in the USA and in Europe for the control of annual grasses and broad-leaved weeds in a variety of crops including maize, sugar beet and sunflower. The major dissipation route for metolachlor, alachlor and acetochlor herbicides appears to be microbially-mediated degradation in soil ecosystems. However, detailed knowledge about their transfer, mitigation and biodegradation in wetland systems is scarce. Here, we examine the transfer and attenuation of metolachlor, acetochlor and alachlor in wetland systems, mainly focusing on their *in situ* biodegradation under different conditions and the characterisation of the microorganisms involved. In order to reach an integrated understanding of chloroacetamides attenuation processes, our investigations will include two different scales. The mesocosm scale experiment will examine the transport and biogeochemical changes under field-like conditions, whereas the microcosm experiment will involve aerobic and anaerobic enrichment cultures set-up in a sediment extract medium and a minimal medium. The biogeochemical dynamics of the lab-scale wetland systems will be characterised using hydrochemical, biomolecular and compound-specific isotope analyses (CSIA). Changes in herbicide concentrations, their enantiomeric ratios and some of their degradation products will be assessed over the flow path and over time. In parallel, changes in the structure of the microbial communities present in lab-scale wetlands will be characterised using PCR-T-RFLP analysis. CSIA methods will be developed to characterise the biodegradation of chloroacetamide herbicides during their transfer in wetland systems.

Formation of layered Fe(II)-Al(III) hydroxides during reaction of Fe(II) with γ-Al_2O_3 and montmorillonite

EVERT J. ELZINGA

Rutgers University, Department of Earth & Environmental Sciences, 101 Warren Street, Newark NJ 07102

The biogeochemical cycling of iron in aqueous geochemical environments is intimately linked to the cycling of carbon, nitrogen, phosphorus and sulfur, and strongly impacts the solubility and speciation of trace metal and metalloids in these systems. In riparian zones, reductive dissolution of Fe(III)-(oxyhydr)oxides mediated by soil microbes leads to a buildup of high concentrations of dissolved Fe(II) in soil solution and concurrent release of sorbed contaminants. The fate of released Fe(II) is at least partially controlled by sorptive interactions with Al-oxides and phyllosilicates minerals in the soil matrix. Here, X-ray absorption spectroscopic evidence is presented for the formation of Fe(II)-Al(III)-layered double hydroxide phases during reaction of Fe(II) with Al-oxide and montmorillonite clay. These phases form fast (on time scales < 24 h) and are therefore expected to be a major sink for Fe(II) released during reductive dissolution of Fe(III)-oxides. In addition, owing to small particle size, layered structure, and high Fe(II) content, these phases are likely to be highly reactive towards redox-active contaminants such as Cr(VI), and may control retention of divalent metals such as Ni(II) and Zn(II) through adsorption and coprecipitation reactions. The research presented here characterizes formation of these phases in relation to observed macroscopic uptake trends of Fe(II) as a function of Fe(II) concentration, pH and reaction time.

Cycling of nitrogen in the Namibian coastal upwelling system – The stable isotope view

KAY-CHRISTIAN EMEIS[1], BIRGIT NAGEL[1] AND NIKO LAHAJNAR[2]

[1]Institute of Coastal Research, Helmholtz Center Geesthacht, Max-Planck-Str. 1, 21502 Geesthacht, Germany (Kay.emeis@zmaw.de, Birgit.nagel@hzg.de)

[2]KlimaCampus, Bundesstr. 55, 20146 Hamburg, Germany (Niko.lahajnar@zmaw.de)

Nitrogen is a key element in regulating biological processes in the ocean, and the history of the nitrogen cycle under past conditions on Earth is of high relevance for paleoceanographic and paleoclimate studies. The ratio of the two stable N-isotopes ($^{15}N/^{14}N$; expressed as $\delta^{15}N$ versus air N_2) preserved in sediments is commonly assumed to reflect the isotopic composition of N-sources, or the extent of assimilation by phytoplankton. But although $\delta^{15}N$ is widely appreciated as one of few available proxies to reconstruct marine nutrient cycles in the geological past, there are several biases on the $\delta^{15}N$ of sedimentary records. Here we explore the dynamics of nitrogen isotopic composition in several compartments of reactive nitrogen in a depositional setting characterized by extreme gradients in $\delta^{15}N$ of nitrate, suspended matter and surface sediments – the coastal upwelling area offshore Namibia. The gradient observed in $\delta^{15}N$ of surface sediments mirrors the state of oxygen depletion in the water in contact with sediments, as well as changes in source nitrate, in water-column denitrification, in particle advection along the shelf break, and in dominant upwelling mode (coastal versus shelf break upwelling). Based on data of nitrate $\delta^{15}N$ and $\delta^{18}O$ in several seasonal sampling campaigns, we attempt to isolate possible diagenetic effects by determining $\delta^{15}N$ of suspensions and surface sediments in conjunction with indicators of organic matter quality (i.e., the degradation index of amino acids, C-normalized amino acid concentrations) in the pronounced oxygen gradient of the region. Besides sharpening the $\delta^{15}N$ as a proxy for the geological past, the data also allow us to examine some basic biogeochemical concepts underlying nutrient stoichiometry in the ocean. This is important in light of the expected increasing importance of upwelling processes for the supply of nutrients to the surface ocean.

Noble gas isotope fractionation during air-sea exchange: A tracer for mechanisms that determine N_2/Ar ratios in the ocean

STEVEN EMERSON[1]*, KEVIN TEMPEST[1] AND ROBERTA HAMME[2]

[1]School of Oceanography, University of Washington, Seattle, WA, 98195 (*correspondence: emerson@u.washington.edu; ket5@u.washington.edu)

[2]School of Earth and Ocean Sciences, University of Victoria, Victoria, BC, V8W 3V6 (rhamme@uvic.ca)

Our observations indicate that the N_2/Ar ratio in the world's ocean increases from near equilibrium with the atmosphere at the surface to ~ 1.5 % supersaturation at depth (~ 1000 m) and the values in deep waters increase from the Atlantic to Pacific Ocean by ~ 0.5 %. The reason for the increase is a combination of air-sea exchange during formation of subsurface waters and denitrification below the euphotic zone. In order to separate these two processes one must understand bubble processes that occur during gas exchange. The change in gas ratios is more strongly influenced by small bubbles that totally collapse than larger bubbles that exchange gases across the bubble-water interface.

The isotope ratios of argon (^{40}Ar/^{36}Ar) and neon (^{22}Ne/^{20}Ne) are sensitive to the mechanisms of bubble processes because kinetic isotope fractionation caused by molecular diffusion coefficient differences is a tracer for the bubble exchange mechanism. We have determined the kinetic isotope fractionation factor during gas exchange for argon and neon in laboratory experiments to be – 3.3 ± 0.3 ‰ and – 6.7 ± 0.3 ‰ respectively. These values agree to within the estimated error of theoretical calculations [1] if one assumes the gas exchange process is proportional to the square root of the molecular diffusion coefficients. Using the measured fractionation factors in a gas exchange model [2] to determine the sensitivity of argon and neon isotope ratios to bubble processes suggests that neon isotopes might be a useful tracer for determining the importance of the bubble exchange mechanism. The changes, however, are small—on the order of 0.1-0.2 ‰ -- and to our knowledge, highly accurate neon isotope ratios in seawater are yet to be determined.

Rock alteration and element transfer during formation of U deposits related to Na-metasomatites in the Ukrainian Shield

A. EMETZ [1]*, M. CUNEY [2], J. MERCADIER [2], V. MYKHAYLOV[3] AND N. NAZARCHUK [3]

[1]IGMOF NAS of Ukraine, Kiev-124, 34 Palladina St. (*correspondence: alexander_emetz@yahoo.com)

[2]UHP, B.P.23, 54501 Vandoeuvre-Les-Nancy, France (michel.cuney@g2r.uhp-nancy.fr)

[3]TS KNU, Kiev-022, 90 Vasylkivska St. (taw@bigmir.net)

The Central Ukraine U Province is situated in the Ingul Megablock and along its eastern border in Kryvy Rig – Kremenchug syncline zone of the Ukrainian Shield. The Province includes about 20 U deposits and numerous U showings hosted by Palaeoproterozoic metamorphic and magmatic complexes. Two of these deposits (the Zhovta Richka and Pervomayske deposits) already have been exchaused but four U-deposits in the altered granitic rocks (Vatutynske, Novokostantynivka, Michurynske and Central deposits) are currently operated. Rock samples were selected in underground mines and from drillcores, were examined for mineral paragenesises using optical microscopy and after agate mortar crushing were analysed for major and trace elements with ICP-AES/-MS techniques (CNRS, Nancy, France). Element transfer was estimated using simply binary and/or isocon diagrams [1]. Multistaging of metasomatic alteration of the host rocks (dominantly granites and migmatites) provided sequential changing of mineral paragnesyses from earlier to later mineral paragenesises. The earliest alteration represents successive transformation of the host granitoids into chloritized granites and episyenites, which were progressively dequartzified and eventually transformed into aegirine and aegirine-reibeckite albitites due to progressive K-Na exchange between hydrothermal solution and the rocks. Na, V, Ca and Sr were the most prominent extrinsic elements introducing in the host rocks during this stage of the alteration whereas Si, K and Rb were ejected. Next stage of hydrothermal activity provided carbonate metasomatism with partial leaching of the albitites and crystallization of garnet, epidote, calcite, magnetite and either Mg-amphyboles or phlogopite mineralization with reverse depletion in Na. Na, Si, V, Ba and P were transferred out of the albitite bodies but U, K, Rb, Ca, Sr, Mg, U, Mn, Zr, Hf and Co were added.

Impact of interfacial free energy on weathering rates

SIMON EMMANUEL[1]*AND JAY J. AGUE[2]

[1]Institute of Earth Sciences, The Hebrew University of Jerusalem, Edmond J. Safra Campus, Givat Ram, Jerusalem, 91904 Israel (*correspondence: simonem@cc.huji.ac.il)

[2] Department of Geology and Geophysics, Yale University, P.O. Box 208109, New Haven, CT 06520-8109 USA and Yale Peabody Museum of Natural History, Yale University, New Haven, CT 06511, USA (jay.ague@yale.edu)

The natural weathering rates of primary minerals can be orders of magnitude lower than the rates of mineral dissolution found in laboratory experiments. As primary dissolution rates are thought to be determined by the rate of secondary mineral precipitation, understanding the factors controlling precipitation rates could be the key to resolving this apparent discrepancy. Using model calculations we demonstrate that the effects of interfacial energy in systems close to equilibrium, and which possess a large number of micron and nanometer scale crystals, can have a critical impact on net mineral precipitation rates [1]. Net rates can be much lower than those predicted by standard kinetic formulations; moreover, when the proportion of small crystals is high enough, net dissolution can dominate even when the system is supersaturated with respect to large crystals. Importantly, secondary minerals that form from the incongruent dissolution of primary phases are often submicron in size, and field conditions are often far closer to equilibrium than those typically encountered in laboratory experiments. Thus, we propose that standard rate models - which do not account for interfacial energy effects in small crystals - may be unsuitable to describe reaction rates in weathering systems.

Metalliferous organic-rich black shales: Where do the metals come from?

POUL EMSBO* AND GEORGE BREIT

USGS, MS 973, Federal Center, Denver, CO, 80225 (*correspondence: pemsbo@usgs.gov)

The amount of metal contained in a metalliferous black shale (MBS) can rival or surpass any ore deposit. Currently anomalous metal and carbon contents of these shales are thought to be controlled solely by ordinary oceanographic processes. Elevated metal and carbon contents of these shales are considered to reflect anoxic, high productivity conditions that optimize extraction of metals from normal seawater.

This explanation is challenged by the lack of modern analogs of ancient MBS. Despite intense study, modern euxinic environments of high productivity fail to form sediments with comparable metal enrichments. Moreover, mass balance constraints that consider the total mass and recharge of metal to the ocean, ocean circulation, and sedimentation rate suggest that typical seawater may not be an adequate source for the mass of metal in some MBS.

An alternative metal supply is apparent in the fluids that form, synsedimentary exhalative (sedex) deposits. The metal supplied by the discharge of these hydrothermal fluids into ocean basins can be shown to surpass global riverine fluxes. The metal mass in a sedex deposit requires discharge of 1000's of km^3 of warm saline fluid over a periods of 10's ky. The large volume would have impacted ocean chemistry far beyond the extent of the deposit.

A genetic link between MBS and sedex deposits is reinfored by their common occurrence in age correlative strata. Although this temporal relationship has been previously ascribed to euxinic conditions necessary to form sedex deposits, the sedex fluids may, themselves, have enhanced or caused euxinic conditions.

An overlooked aspect of sedex systems is the flux of nutrients (i.e. NH_4, reduced C, trace metals, Ba, Si) added to the oceans by the ore fluids that may exceed the entire modern riverine flux. Such fertilization would undoubtedly promote massive increase in bioproductivity and spur basin-wide anoxic/euxinic conditions. Overall, the enormous flux of nutrients and metals delivered to the ocean by sedex systems may provide a plausible explanation for the enigmatic metal-rich end members of MBS.

We show that gas-phase isoprene is readily protonated ans subsequently polymerized by collision with liquid microjets surface of mildly acidic water (1 < pH < 4) within ~10 ms. Kinetic isotope effects for the products formation were determined to reach up to 7, showing the direct evidence that the observed phenomena are due to a truly interfacial reactions initiated by proton on water. Since such reactions only occur at superacidic condition in homogeneous bulk media (e.g., pH < -1) or in pure gas phase, the surface of ambient atmospheric aerosol particles will behave as an unusual catalyst for reactive uptake of global gaseous unsaturated hydrocarbons.

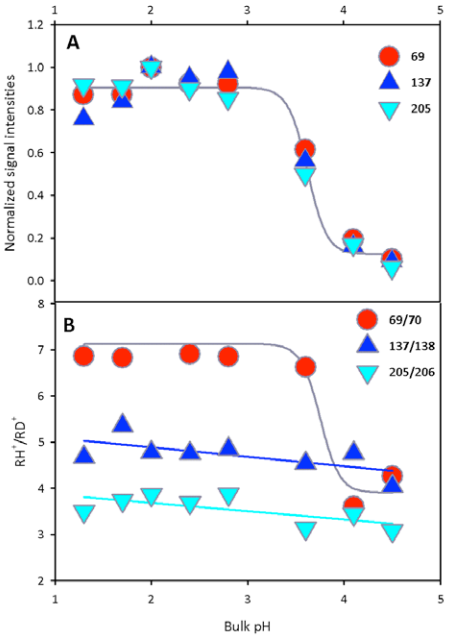

Figure 1: **A**: Signals $IsoH^+$ (m/z = 69), $(Iso)_2H^+$ (137), and $(Iso)_3H^+$ (205) from protonation/polymerization of isoprene produced on H_2O:D_2O (50/50 = vol/vol) microjets exposed to 88 ppmv isoprene(g) for ~10 μs as a function of bulk pH. **B**: Kinetic isotope effects (KIE) for the products of isoprene (g) on H_2O:D_2O (50/50 = vol/vol) microjets exposed to 88 ppmv isoprene (g) as a function of bulk pH. All experiments in 1 atm N_2(g) at 293 K.

Testing the use of detrital rutile to investigate HP/UHP rocks

FLORENTINA C. ENEA[1]*, JEANETTE TAYLOR[2], CRAIG D. STOREY[1], HORST MARSCHALL[3] AND M. K-SCHMOLKE[4]

[1]University of Portsmouth, SEES Burnaby Building, Portsmouth, PO1 3QL, UK (*corespondence: florentina.enea@port.ac.uk).

Accessory rutile generally is the main host of Ti in HP/UHP metamorphic rocks. It is also a major carrier of HFSE, providing a potential tracer of contrasting tectonic processes. For example, the Zr-in-rutile geothermometer has now been widely and successfully applied to HP rocks, And Cr/Nb ratios have been used to distinguish between different bulk composition of the host rock. Moreover, rutile is a robust mineral in sedimentary environments and is common as an accessory phase in sandstones. Therefore, its potential as a detrital tracer of HP metamorphism is high. Metamafic and metapelitic rocks from two case studies located in Syros, Greece and the Western Alps, both settings displaying HP/UHP conditions, have been sampled together with sediments that resulted from the erosion of these rocks in beach and river catchments. The geochemical correlation of rutile between source rocks and sediments is assessed based on its HFSE budget.

This study aims to establish geochemical signatures of rutile that are characteristic for detrital grains sourced from HP/UHP rocks formed in subduction zones. The Zr-in-rutile thermometer [1, 2] provides peak metamorphic temperatures for the investigated samples that are coherent with published peak temperatures for the respective metamorphic sequences. In addition, the calculated temperatures are independent of the source rock lithologies, i.e., the presence or absence of quartz. The T histograms for the Western Alps indicate a low-T peak, suggesting the blueschists, eclogites and Dora Maira rocks are dominant, and not the high-T Ivrea rocks, as expected. Cr/Nb ratios have been employed successfully and *in situ* analysis fall strictly into the mafic (for Syros) and pelitic (for the Western Alps) source rock fields [3, 4, 5].

Characterizing sources of airborne mineral dust, in Iraq

J.P. ENGELBRECHT[1] AND R.K.M. JAYANTY[2]

[1]Desert Research Institute, 2215 Raggio Parkway, Reno, NV 89512, USA (*correspondence: johann@dri.edu)
[2]RTI International, 3040 East Cornwallis Road, Research Triangle Park, NC 27709, USA (rkmj@rti.org)

The purpose of the Enhanced Particulate Matter Surveillance Program (EPMSP) was to provide scientifically founded information on the chemical and physical properties of airborne mineral dust and other particulates sampled in the Middle East. Aerosol [1, 2] and bulk soil [3] samples were collected during a period of approximately one year at 15 Middle East sites – including Djibouti, Afghanistan, Qatar, United Arab Emirates, Iraq, and Kuwait.. Collocated low volume particulate samplers, one each for the total suspended (TSP), less than 10 μm in aerodynamic diameter (PM_{10}) and less than 2.5 μm in aerodynamic diameter ($PM_{2.5}$) particulates were deployed at each of the sites and operated on a "1 in 6 day" sampling schedule. The filters were chemically analyzed for their elemental and ion contents, as well as for their elemental (EC) and and organic carbon (OC) fractions.

This presentation reports on the data mining of chemical results - by applying Principal Components Analysis (PCA) and Positive Matrix Factorization (PMF) to chemical data from Teflon membrane and quartz fiber filter sets collected at six sites in Iraq (Balad, Baghdad, Tallil, Tikrit, Taji and Al Asad).

From the PMF modelled results it is evident that there are substantial differences in mineral dust compositions amongst the six Iraq sites and between the PM_{10} and the $PM_{2.5}$ size fractions. This is related to dissimilarities in the local geology and soil types, as well as different particle size distributions. Although regional mineral dust sources are similar for all six sites, the aerosols at the height of the sampler inlets are substantially modified by local dust representative of the local soils at or close to the sampling sites, exacerbated by dust from agricultural activities, roads, and other local dust sources.

Allanite petrochronology in high-pressure rocks

M. ENGI[1]*, D. REGIS[1], J. DARLING[1], B. CENKI-TOK[1,2] AND D. RUBATTO[3]

[1]Dept. of Geological Sciences, University of Bern (*correspondence: engi@geo.unibe.ch)
[2]Geosciences Montpellier, University of Montpellier
[3]School of Earth Sciences, Australian Nat. Univ., Canberra

Allanite is a REE- and Th-rich epidote widespread in greenschist to eclogite facies rocks. Its prograde mineral reactions commonly produce distinct growth zones, which can be directly related to PT-conditions. In favorable cases, Th-U-Pb isotope analysis (by LA-ICP-MS or ion microprobe) allows such growth zones to be dated.

Improved LA-ICP-MS analysis (line raster laser ablation, ^{204}Pb-based common lead correction) yields accurate Th-Pb and U-Pb ages with no need for matrix-matched standardisation. The analytical errors imply realistic 2σ-age uncertainties of ~1%.

A multicomponent solution model formulated for allanite was tentatively calibrated, based on the limited experimental data available as well as select natural phase relations. Phase diagrams calculated for a range of typical compositions comply with mineral reaction sequences and established PT-wisdom from various metamorphic systems. The stability limits obtained confirm that allanite is very useful for blue-schist and eclogite facies rocks. Computed REE-partitioning with other REE-phases agrees reasonable well with distribution coefficients observed in high-pressure samples.

Several case studies in LT-eclogite facies metagranitic and -sedimentary samples from the Sesia Zone (Western Alps, Italy) are presented. These demonstrate the potential power of allanite petrochronometry [e.g. 1], but also indicate limits and possible pitfalls: Detailed petrography is needed to define which stages and PT-conditions are dated, and microstructural observations should be integrated where possible. It is critical to obtain REE-patterns for each allanite growth zone and to characterize all mineral inclusions. Common lead contents can be so high as to make dating unrealistic.

Allanite recystallisation behaviour is not well understood, and relics (e.g. igneous cores) commonly occur. Microchemical characteristics (Th/U, Sr) help to distinguish their origin. In relatively dry lithologies, the robust mechanical properties of allanite can preclude recrystallisation, even in high strain shear zones. By contrast, allanite has excellent potential as a chronometer for mylonites, where hydrous fluid commonly leads to recystallisation even at T as low as 400°C.

Modeled response in radiative properties of shallow convective clouds due to perturbations in meteorological state variables and atmospheric aerosol loading

ANDERS ENGSTRÖM AND ANNICA M. L. EKMAN

Department of Meteorology, Stockholm University, SE-106 91 Stockholm, Sweden (anderse@misu.su.se)

In order to quantify aerosol indirect effects in observational data it is necessary to minimize the impact from other cloud-controlling variables. The vast amount of meteorological data from operational atmospheric analysis data (or re-analysis data) combined with retrieved aerosol characteristics from satellite, provides and opportunity to compare cloud properties under similar meteorological conditions but with a different aerosol signature. However, even when keeping meteorological variations at a minimum with respect to a mean atmospheric state, the sensitivity of clouds to small perturbations around this mean state is not well known [1]. Hence small variations in meteorology may correlate both spatially and temporally with small variations in the aerosol concentration which could explain a certain fraction of the observed relationship between aerosols and clouds.

The aim of the present study is to 1) identify the sensitivity of cloud fraction and cloud albedo to small perturbations in meteorological conditions and compare this to the sensitivity induced by increasing aerosol number concentrations and 2) estimate the range of variability in observational data of meteorological variables permitted to determine a clear and unambiguous signal in cloud fraction and cloud albedo due to aerosols. A cloud-resolving model is used to simulate a large ensemble of isolated shallow convective clouds where the vertical profiles of zonal wind, temperature and water vapor mixing ratio as well as initial profiles of accumulation and Aitken mode aerosols are perturbed.

Hydrothermal Co-Ni mineralization, associated with serpentinized peridotites: Bou Azzer, Morocco

A. ENNACIRI[1]* , L. MAACHA[2], L. BARBANSON[3], W.D.MAIER[4]

[1]Managem, Twin Center, Tour A, Angle Bd Zerktouni et Massira Khadra, Casablanca, Morocco (*correspondence : ennaciri@managem-ona.com)
[2]Managem (maacha@managem-ona.com)
[3]ISTO, Université d'Orléans, CNRS, France (luc.barbanson@univ-orleans.fr)
[4]WD Maier, University of Oulu, Oulu 90014, Finland

The Co, As (Ni, Ag, Au) ores of the Bou Azzer district comprise an unusual type of vein-style deposit, associated with mantle peridotites of a Neoproterozoic ophiolite. Two types of Co-rich mineralization are exploited: (1) Veins located at the contact between sepentinites and wall rocks; (2) Veins in dioritic wall rocks, extending up to 400m from the serpentinites. From early to late, the mineral succession in both types is : (1) Ni-arsenides (rammelsbergite, para-rammelsbergite); (2) Co-arsenides (safflorite, skutterudite), in some cases with native gold; (3) Fe-Arsenides (löllingite); (4) sulfoarsenides (gersdorffite, cobaltite, arsenopyrite); (5) sulfides and sulfosalts (chalcopyrite, sphalerite, terahedrite, tennatite), in some cases with native bismuth and silver; (6) chlorite with molybdenite with minor brannerite and late native gold. The gang minerals are essentially quartz, calcite and dolomite. Fluid inclusion studies indicate complex brines belonging to the system (Na, Ca, K, Ba, Cl). Equivalent weight salinity ranges from 34. 5 wt. % and 40. 5 wt. %. Homogenization temperatures range from 225 °C to 195°C. Co and Ni are proposed to have been leached from the serpentinites. However, the origin of the arsenic is poorly constrained. Derivation from the mantle rocks would imply very high fluid-rock ratios. Alternatively, As could be derived from crustal rocks underlying the ophiolite.

[3]Faculty of Life Sciences, University of Copenhagen, DK-1871, Copenhagen, Denmark (shu@life.ku.dk)

Lake Baikal-Angara River aquatic ecosystem includes natural basin of Lake Baikal (LB) with more than 360 inflow rivers, and few artificial basins such as Irkutsk, Bratsk and Ust'-Ilimsk Water-Reservoirs located downstream the only outflow Angara River. The main anthropogenic sources of Hg in the region were two chemical industrial factories "*Usol'ekhimprom*" and "*Sayanskkhimplast*", located on the shore of the Bratsk Water-Reservoir (BWR). Anthropogenic utilization of mercury is a global health issue due to its high degree of mobility, toxicity and bioaccumulation of methylmercury through the food-web.

Sediments, water, zoo- and phyto-plankton, different trophic level of fish and seal samples have been studied for Hg speciation and Hg stable isotopes (Table). Also main ecological parameter and carbon/nitrogen stable isotopes were charactarised for biological samples. Stable isotope Hg signature of LB plankton, fish and seal tissues showed positive correlation of δ^{202}Hg with trophic level. The comparison of the results obtained for contaminated and pristine sites suggests that Hg isotopic signature reveals both MeHg pathways in aquatic environments and trophic bioaccumulation routes.

Sample	$[Hg]_{tot}$	δ^{202}Hg	Δ^{199}Hg	%MeHg
Seal-muscle	300	+1.84‰	5.03‰	82.9‰
Perch(LB)	163	-0.48‰	1.14‰	95.1‰
Roach(LB)	58.6	-0.61‰	0.58‰	96.0‰
Plankton(LB)	2.1	-0.90‰	1.53‰	15.7‰
Pike(BWR)	3270	-0.18‰	0.04‰	90.6%
Perch(BWR)	1195	-0.26‰	0.52‰	92.0‰
Roach(BWR)	388	-0.17‰	1.19‰	94.2‰
Plankton(BWR)	3.6	-0.37‰	1.28‰	51.5‰

Table: Summarised total Hg (ng g^{-1}), MeHg content and isotope composition of Hg in some trophic web samples.

ICP-MS determination of trace elements in marine biological samples: Comparison of sample preparation procedures and selected digestion methods

E.N. EPOVA, J. CASTRO GEORGI AND O.F.X. DONARD

LCABIE, UPPA-CNRS-UMR 5254 IPREM, Hélioparc, 64053 Pau, France

Marine biological samples (oysters, mussels, fish) can be used as bio-indicators to control the industrial pollution for the quality of aquatic environments and to investigate the toxicological impact for the different food chains. These samples with high sensitivity to toxic compounds in the surrounding water ecosystems are easily accessible resources that can be used for analysis.

Presented here is a comparison of two most used sample pretreatment techniques such as freeze-drying and fresh-freeze from the perspective of analytical efficiency and practical convenience of procedures applied to the processing of a considerable amount of samples. The concentrations of 20 elements in standard reference materials (SRMs) and different marine biological samples are studied and compared with previously published data. Validation of the pretreatment techniques are perform using several SRMs of oyster, fish and mussel tissues (1566b, 2977, TORT 2 and DORM 2) which display different matrix properties and large number of certified elements.

Lead cycling in forested catchments: Trends in input-output mass balances over 12 years of easing industrial pollution

LUCIE ERBANOVA, LEONA ZEMANOVA*, MARTIN NOVAK AND DANIELA FOTTOVA

Czech Geological Survey, Geologicka 6, 152 00 Prague 5, Czech Republic
(*correspondence: leona.zemanova@seznam.cz)

In Central Europe, forested headwater catchments are an important source of drinking water. In the second half of the 20th century, extensive coal mining and burning, along with chemical industry, metal smelting and traffic contributed to high emissions of a number of environmentally relevant elements. Lead (Pb) entering ecosystems via wet and dry deposition originated from all these sources. The highest anthropogenic emissions of Pb occurred in the mid 1980s, and a considerable decrease in Pb emissions has been observed over the past 25 years. The fate of lead and its potential release to stream water has been studied in 11 small spruce-forested catchments in the Czech Republic. Here we compare Pb input-output mass balances for the hydrological years 1996 and 2008, i.e., for periods of time 12 years apart. Atmospheric input via spruce canopy throughfall was monitored monthly. In clearings, two rain/snow collectors were installed per site. Stream discharge was sampled once a month near a gauging station. The calculated catchment-level Pb inputs have been vegetation-type weighted. In 1996, catchments situated in the more industrialized north of the country showed high Pb deposition rates of 25 to 50 g Pb ha^{-1} yr^{-1}. Catchment situated in the less polluted south of the country showed lower Pb deposition rates of less than 17 g Pb ha^{-1} yr^{-1}. Lead export via stream discharge formed less than 20 % of the input at most sites across the country. Only two sites in the industrial north (Krkonose and Orlicke Mts.) exhibited a higher proportion of exported Pb, relative to contemporary input (32 to 60 %). Overall, most of the anthropogenic Pb entering the ecosystems remained immobilized within the biomass and soils. Twelve years later, in 2008, atmospheric Pb depositions into all catchments significantly decreased, averaging 11 g Pb ha^{-1} yr^{-1}. The amount of exported Pb, and the proportion of exported Pb, relative to contemporary atmospheric input, decreased in comparison with 1996. In 2008, the annual Pb export was less than 2 g ha^{-1} yr^{-1} at 8 out of 11 sites. Our data show that, with easing atmospheric pollution, less Pb is exported from the catchments, even though the total amount of Pb that had accumulated since the beginning of the Industrial Revolution (1860) was sizeable.

Biomineralization and seawater dynamics in foraminifera studied with the fluorescent dye Calcein

J. EREZ[1]*, Y. LEVENSON[1] AND A. ALMOGI-LABIN[2]

[1]Institute of Earth Sciences, The Hebrew University of Jerusalem, Jerusalem 91904, Israel (*correspondence: erez@vms.huji.ac.il)
[2]Geological Survey of Israel, 30 Malkhe Israel, Jerusalem, 95501, Israel

The calcite shells of foraminifera which accumulate on the ocean floor are an important component of the global carbon cycle. These shells provide highly valuable paleoceanographic information based on their trace elements and stable isotopes. Understanding their biomineralization is therefore an essential goal both for ocean acidification studies and for obtaining new and reliable paleoceanographic information. Recently we showed that perforate foraminifera precipitate their calcite directly from seawater vacuoles [1, 2]. Here we describe the uptake and release dynamics of seawater in the benthic foraminifera *Amphistegina lobifera* and *A. lessoni* using pulse-chase experiments with the membrane impermeable fluorescent dye Calcein. Three different reservoirs of seawater stored in vacuoles were found with residence times of ~ 20 min., ~ 6 hr and ~ 10 days. The internal volume of seawater is large and it is recycled fast enough to provide Ca^{2+} and CO_3^{2-} for the normal calcification process. At low salinities Calcein released during the chase is higher then in normal salinity by a factor of 2. This may be part of the osmotic regulation mechanism in these giant cells. Calcein is incorporated into the shells in direct proportion to calcification measured by weight increase or by alkalinity depletion. The distribution coefficient of Calcein in the shells is very low in the order of 10^{-4}. It increases significantly with salinity and with calcification rate and using Rayleigh type fractionation model we calulate that higher fraction of the calcification reservoir is utilized at optimal conditions. These observations provide the foundations for a realistic model to describe the behavior of stable isotopes and trace elements in the modified seawater calcification reservoir in foraminifera. Furthermore, it explains the sensitivity of foraminifera to ocean acidification.

Using lead isotopes in marine barite to understand intermediate water dynamics

A.M. ERHARDT[12] AND A. PAYTAN[2]

[1]Department of Geological and Environmental Sciences, Stanford University, Stanford, CA 94305 (*correspondence: erhardt@stanford.edu)
[2]Institute of Marine Sciences, University of California Santa Cruz, Santa Cruz, CA 95064 (apaytan@ucsc.edu)

Lead isotopes in marine barite hold the potential to provide insight into changes in intermediate water circulation. Marine barite forms at intermediate water depths and incorporates Pb into the crystal structure at ~2ppm. As a result, the isotopic composition of Pb in marine barite represents the ratios of dissolved Pb in intermediate water. The ability of marine barite to document this elusive water mass makes this new proxy a powerful tool in understanding intermediate water dynamics.

Since anthropogenic pollution has irrevocably altered Pb concentrations and isotope ratios in the present day ocean, calibration of Pb proxies relies on a survey of Holocene sources. We will present results from marine barite separated from several cores in the equatorial Pacific. The ferromanganese grain coatings and detrital fractions for many of these samples will also be presented. By analyzing these three fractions from the same sample, we show that marine barite is recording a unique signature. This implies that the Pb in intermediate water is different that that of deep water or the bulk detrial fraction, potentially allowing us to deconstruct dust and circulation based Pb sources.

Additional work documenting potential source regions for intermediate water lead will be presented. Preliminary box modeling work will be shown to help resolve these source questions and illustrate the unique utility of this emerging proxy.

Geochronological and thermochronological evolution of the southern Gaoligongshan metamorphic belt, Yunnan (China)

S. EROĞLU[1], W. SIEBEL[1], M. DANIŠIK[2], J. PFÄNDER[3] AND F. CHEN[4]

[1]University of Tübingen, Germany
[2]University of Waikato, Hamilton, New Zealand
[3]Technical University of Freiberg, Germany
[4]University of Science and Technology of China, Hefei, China

The Gaoligongshan metamorphic belt is located east of the Eastern Himalayan Syntaxis (EHS) and plays a key role in the evolution of southeastern Tibet. Here, we present geochronological data of orthogneisses and mylonites that pertain to the evolution, cooling and exhumation history of this mountain range. Zircon U/Pb dating allow us to distinguish between at least four different magmatic events at about ~486 Ma, ~282 Ma, ~136 Ma and ~76 Ma. Similar ages have been reported for ortho-derivative rocks of the adjacent Tengchong and the Baoshan blocks and suggest that the southern Gaoligongshan is composed of rocks orginally belonging to the Lhasa and the Sibumasu terrane derived rocks. Late Eocene to Early Miocene U-Pb zircon and Rb/Sr muscovite ages are coeval with the onset of lateral crustal displacement along major shear zones in Eastern Tibet and Indochina and post-collision volcanic activity in Western Yunnan. Main phase of crustal rotation in the Tengchong and Baoshan blocks and mylonitization along the Gaoligongshan shear zone started during the Miocene, between 19 and 12 Ma (Rb/Sr biotite and Ar/Ar mica ages). The final stage of exhumation of the Gaoligongshan is revealed by apatite FT and apatite (U-Th-Sm)/He thermochronology, with ages between 8 and 5 Ma, which was presumably triggered by crustal root delamination and backarc extensional processes as a consequence of the Andaman sea floor spreading.

Based on our results, we propose that the tectonometamorphic evolution of the Gaoligongshan was the result of Tibetan extrusion and escape tectonics around the EHS, the southeastward movement of Indochina and backarc-extensional effects of the Andaman seafloor spreading, which makes it to a junction point between Tibet Plateau and Indochina.

Building stone potential of the Eastern Black Sea Region, NE Turkey

HAKAN ERSOY, BÜLENT YALÇINALP AND MEHMET ARSLAN

Karadeniz Technical University, Department of Geology, 61080, Trabzon, Turkey, (ersoy@ktu.edu.tr, arslan@ktu.edu.tr, bulent@ktu.edu.tr)

Turkey is located in the orogenic belt of the Alpin-Himalayan that has the world's richest natural stone formations. The country has rich marble and limestone formations on the one hand, travertine and onyx formations on the other hand. More than 500 natural stone sites, 800 factories operating in the sector and 90 % of the sites are located in the western Anatolia, mainly in Aegean and Marmara Region of Turkey. In all parts of Turkey, mainly Marmara and Aegean Region, there are good quality natural stone reserves. Although the eastern Black Sea region has limited number of natural stone variety it has a considerable number of natural stone reserves mainly granites. Total natural stone reserves are about 450 million tons and operated reserves were about one percent of this. However, there are more than 30 important natural stone sites in operation in the region. The reserve of the natural stones is about 13 million tons. The most important carbonate bearing marbles are travertines with the reserves of about 1.6 million meters cubes in total carbonate natural stones. In this study carbonate bearing natural stone potential of the eastern Black Sea region was revealed and their geological and geomechanical properties were investigated in terms of marbling sector.

Do melt inclusions record the pre-eruptive volatile content of magmas?

R. ESPOSITO* AND R. J. BODNAR

Virginia Polytechnic Institute & State University, Department of Geosciences, Blacksburg, VA, USA (*correspondence: rosario@vt.edu)

In the last several decades the number of publications describing the use of melt inclusions (MI) to determine the pre-eruptive volatile contents of magmas has increased significantly. However, in most MI studies, the volatile contents of the MI within a single sample or even within a single phenocryst vary widely, and it is often not possible to assess the reliability of the data. In order for MI to provide reliable information concerning the pre-eruptive volatile content, the MI must obey Roedder's (Sorby's) Rules. Namely, the MI must have trapped a single homogeneous melt phase, the volume of the MI must remain constant after trapping, and nothing can be added or lost from the MI after trapping. The adherence to Roedder's Rules is tested by examining two or more melt inclusions from a Melt Inclusion Assemblage (MIA), representing a group of MI that were all trapped at the same time. If all of the MI in the assemblage show the same room temperature phase relations and the same composition, then it is highly likely that the MI in the assemblage obey Roedder's Rules.

In this study, the volatile contents of MI from well-characterized MIAs hosted in phenocrysts from White Island (New Zealand) and from Solchiaro (Italy) were analyzed by Secondary Ion Mass Spectrometry (SIMS). In some MIA, abundances of all of the volatiles (H_2O, F, Cl, CO_2 and S) were consistent in all MI within the MIA. In other MIAs, CO_2 and S abundances showed wide variation, with CO_2 most often showing large variability within an MIA. The reason for the wide range in CO_2 content is unknown, but could reflect small-scale heterogeneities in the melt during inclusion trapping or varying degrees of post-entrapment crystallization for MI in the MIA.

Mercury isotope fractionation during bio-accumulation in lichens

N. ESTRADE[1], J. CARIGNAN[1,2]* AND C. CLOQUET[1]

[1]CRPG/CNRS, BP 20, 54501, Vandoeuvre-lès-Nancy, France (nicolas.estrade@yahoo.fr)
[2]Takuvik, CNRS-ULaval, Québec, G1V 0A6, Canada (*correspondance: jean.carignan@takuvik.ulaval.ca)

Recently, mercury (Hg) isotope mass-independent fractionation (MIF) were reported in various lichens [1] and interpreted as the evidence for the atmospheric Hg to be a complementary reservoir to aquatic Hg [2] with respect to $\Delta^{199\text{-}201}$Hg. Recent data from the literature on more "direct" samples for atmospheric Hg [3, 4] suggest small Hg MIF, even slightly positive $\Delta^{199\text{-}201}$Hg, in contrast to significant negative $\Delta^{199\text{-}201}$Hg values measured in lichens. This raised the question of the integrity of Hg isotopes measured in lichens relative to atmospheric matter, with the possibility of MIF during bio-accumulation.

A large amount of lichen tufts (*Evernia Prunastri*) was retrieved from trees in a small forest south of Nancy (France), rinsed with distilled water and dried at room temperature for a few days. Aliquots of bulk samples (1 g) were plunged into solutions (50 ml) containing various amounts of dissolved elements to simulate rain water. Lichens and solutions were in contact between 1 and 60 minutes (n=6).

Mass balance for Hg was calculated using Hg in lichens and Hg in the remaining solutions. Both were very similar suggesting that all Hg lost from the solution was pumped out by lichens (no wall adsorption). The δ^{202}Hg measured in lichens changed from -3.5‰ (initial value) to -0.5‰, interpreted as a progressive adsorption of solution Hg (0‰). However, Hg in the remaining solution shifted its δ^{202}Hg up to +1.5‰, decreasing with time, suggesting kinetic fractionation occurred when adsorption started. Isotopic equilibrium was not reached after 60% of total solution Hg was adsorbed by lichen ($\Delta^{xx}Hg_{sol\text{-}lichen} \leq 1‰$).

Some lichens were exposed to sunlight (6 to 10 weeks) after being in contact with the NIST 3133 Hg, increasing their [Hg] variously from 0.15 to 18 µg/g. In all cases, no significant MIF were measured in both light exposed and non-exposed lichens, suggesting that bio-accumulation of Hg(II) by lichen do not result in MIF.

Effect of initial Al concentration, pH and silicic acid on the formation and stability of tridecameric Al polymer

M. ETOU*, S. HAGIWARA, T. SAITO, Y. OKAUE AND T. YOKOYAMA

Department of Chemistry, Faculty of Science, Kyushu University, 6-10-1, Hakozaki, Fukuoka, Japan 812-8581 (*correspondence: mayumie@mole.kyushu-u.ac.jp)

Tridecameric Al polymer (the Keggin-type Al_{13} polycation)

Al^{3+} and its hydrolytic species which elute from soil due to the soil acidification have strongly toxic effect to palnt and living organisms. In Al^{3+} hydrolytic specis, tridecameric Al polymer (Keggin type Al_{13} polycation, $[AlO_4Al_{12}(OH)_{24}(H_2O)_{12}]^{7+}$) show the strongest toxicity. Surprisingly, Hunter and Ross detected Al_{13} in organic horizon of forested Spodsol in USA [1]. Much attention has been paid to the formation conditions of Al_{13}. According to the equilibrium calculation, at the total Al concentration of 10^{-5} mol/dm^3(M) which is the concentration level of soil solution, the occurrence of Al_{13} is sufficiently considered [2]. However, the detection of Al_{13} species such a low Al concentration is extremely difficult. Therefore, in this study, we developed the detection method of Al_{13} by ^{27}Al MAS NMR after adsorption onto chelate resin from solution with various Al concentration. Furthermore, we also studied the stability of Al_{13} on the solid surface and elution of Al species from solid surface and the effect of silicic acid to the formation and stability of Al_{13}.

When Al_{13} is formed in the soil environment, it is possible to adsorb on the surface of microbes and humic substances. In this study, the chelate resin was used as a model compound of the surface of microbes and humic substances because of similarity of functional group. For the concentration limit for the formation of Al_{13}, we could detect Al_{13} species after the adsorption onto chelate resin above 10^{-4} M. The pH range where Al_{13} can form in solution is very narrow [3], however, we also revealed that when Al_{13} adsorbed onto the resin, the pH range where it can exist clearly expanded. When the silicic acid coexisted in initial solution, the formation of Al_{13} distinguishably retarded.

Stability and transformation of Pb smelter fly ash in soils

V. ETTLER[1*], M. MIHALJEVIC[1] AND O. SEBEK[2]

[1]Institute of Geochemistry, Mineralogy and Mineral Resources, Faculty of Science, Charles University in Prague, Albertov 6, 128 43 Prague 2, Czech Republic (*correspondence: ettler@natur.cuni.cz)

[2]Laboratories of the Geological Institutes, Faculty of Science, Charles University in Prague, Albertov 6, 128 43 Prague 2, Czech Republic

Soils represent an important sink for metals released into the environment by anthropogenic activities. Emissions from non-ferrous metal smelters are responsible for extremely high concentrations of metals in adjacent soils related to the deposition of the fly ash particles during periods of the filtering inefficiency in the smelter flue-gas cleaning system [1, 2, 3].

To understand the dynamics and fate of smelter-derived contamination, we studied the reactivity of secondary Pb smelter fly ash in acidic soils. The polyamide bags (mesh 1 μm, 2 x 4 cm) were loaded with 0.5 g of fly ash and sealed by welding. Testing bags were placed in contrasting soils in two experiments: (i) a short-term (21-day) laboratory pot experiment with soil pore-water monitoring (Rhizon suction cups) and (ii) a long-term (1-year) *in situ* experiment in soils developed under different vegetation cover (spruce, beech, meadow). After each experiment, the bags were weighted to determine the mass loss and the weathered fly ash was studied by XRD and TEM/EDS. The total concentrations of metals, their chemical fractionation and Pb isotopic composition were determined in soils by the combination of ICP techniques.

More than 60% of fly ash was dissolved during the experiment, especially in organic soil horizons and secondary anglesite ($PbSO_4$) formed as a stable alteration product [1, 2]. A significant increase in the metal concentrations in the soils was observed during the experiment, especially in the litter and organic horizons: Cd (248 x), Pb (15 x), Zn (1.8 x). Cadmium was the most mobile element in the pots and soil profiles, being strongly released into the soil water and bound mostly in the labile soil fractions. A significant shift in the Pb isotopic values towards the fly ash signature ($^{206}Pb/^{207}Pb$ =1.16) confirmed the effect of smelter-induced contamination on metal dispersion, binding and mobility in soils.

Treatment of rural effluents by infiltration percolation process using sand-clay fortified by pebbles

SAIFEDDINE ETURKI[1]*, NACEUR JEDIDI[1] AND HAMED BEN DHIA[2].

[1]Wastewater treatment laboratory ,Water research and technologies Center, Borj Cedria technopole , BP 273 Soliman 8020, Tunisia (*correspondence : turkisaifeddine@yahoo.fr)

[2]Water, Energy and Environnement Laboratory, National School of Engineers of Sfax, Road of Soukra, 3038 Sfax Tunisia

Low-cost and high-performance decentralized wastewater treatments system for rural application in developing nations necessitated this study. The grain size and mineralogy of the sand filter constituting the infiltration bed, is of course one of the key elements and is the main subject of this article. In the other hand, clay samples collected from north eastern Tunisia were characterized by studying the mineralogical and geochemical composition and prove her great potential to fix pollutants. Performance efficiency studies were conducted to determine the best combination ratio of sand-clay/pebbles. Sand-clay (mixture contain 90% sand 10% of clay in weight) fortified with pebbles in the ratio 3:1 gave the optimum water purification and appropriate permeability for the infiltration percolation system. The effects of continued usage on the performance efficiency of the fortified column were studied and the results showed a decrease of Nitrogen, BOD, COD and Bacteria.

A possible evidence of urbanization effect on the light precipitation in the mid-Korean peninsula

S.-H. EUN[1], B.-G. KIM[1,*], S.-H. CHAE[1,2] AND J.-C. PARK[3]

[1]Department of Atmospheric Environment Sciences, Gangneung-Wonju National University (*Correspondence: bgk@gwnu.ac.kr)

[3]College of Engineering, Gangneung-Wonju National University

The continuous urbanization by a rapid economic growth and a steady increase in population could affect the meteorology in the downstream region [1]. This study presents the associated analysis of long-term (1972~2007) precipitation trends in the mid-Korean peninsula and the WRF model simulation for a golden day (2009/2/11). The mid-Korean peninsula has very favorable geographic characteristics for the study of urbanization effect on the cloud and precipitation in the downstream region such that seoul metropolitan area is located in the west, with relatively flat area in the east, and the big mountains along the east coast. The analysis stations consist of the urban region (Seoul, Incheon, Suwon), its downwind region (Chuncheon, Wonju, Hongcheon), and the mountainous region (Daegwallyeong). The trend of population, as a surrogate of urbanization, continues to increase. The category of precipitation amount (PA) is divided by the intensity such as light precipitation for PA≤1 mm d^{-1}, intermediate for 1 mm d^{-1}<PA≤10 mm d^{-1}, and heavy for PA>10 mm d^{-1}, respectively.

During the long-term period, PA and PF (precipitation frequency) in the downwind region of urban area significantly increased for the westerly and light precipitation case only, while PA and PF in the mountainous region decreased. Especially the enhancement ratio of PA and PF for the downwind area vs. urban area remarkably increased, implying the possible urbanization effect on the downwind precipitation. In addition, the WRF simulation applied for a golden day demonstrates the enhanced convergence and its associated updraft in the downwind area (about 60 km from the urban), leading to an increase in the cloud mixing ratio.

This study was supported by Basic Science Research Program through the National Research Foundation of Korea (2010-0211, 2009-0085533).

Polysaccharide fractionation of soil organic matter due to reaction with ferrihydrite

K. EUSTERHUES*[1], J. NEIDHARDT[1], T. RENNERT[1], I. KÖGEL-KNABNER[2] AND K.U. TOTSCHE[1]

[1]Institut für Geowissenschaften, Friedrich-Schiller-Universität Jena, Germany (*correspondence: karin.eusterhues@uni-jena.de)

[2]Lehrstuhl für Bodenkunde, Technische Universität München, Germany

Ferrihydrite, a poorly crystalline Fe oxyhydroxide, is known to be highly reactive towards soil organic matter (OM) and may play an important role in its long-term stabilization. To investigate composition and maximum OM loading of ferrihydrite-OM associations, we performed adsorption and coprecipitation experiments at pH 4.5 using the water-extractable OM of a Podzol forest-floor layer. The reaction products were studied by ^{13}C CPMAS NMR, FTIR and analysis of hydrolyzable neutral polysaccharides. To better understand the behavior of polysaccharides, adsorption and coprecipitation experiments were also done with glucose, galactose and glucuronic acid.

Adsorption and coprecipitation of the forest-floor extract yielded similar maximum loadings of 195 and 170 mg C g^{-1} ferrihydrite. Relative to the original forest-floor extract, the ferrihydrite-associated OM was enriched in polysaccharides, but depleted in aliphatic C and carbonyl C, especially when adsorption took place. Moreover, mannose and glucose were bound preferentially to ferrihydrite, while fucose, arabinose, xylose and galactose remained in the supernatant. This fractionation of sugar monomers was more pronounced during coprecipitation. Experiments with synthetic sugar monomers resulted in relatively low maximum loadings of ~15 and ~25 mg C g^{-1} for glucose and galactose, whereas glucuronic acid produced a maximum loading of 72 mg C g^{-1}. Signals of ferrihydrite-associated glucose and galactose were hardly detectable by FTIR, whereas spectra of ferrihydrite-associated glucuronic acid closely resembled that of the ferrihydrite-associated forest-floor extract.

We conclude that the observed preferential association of polysaccharides from natural OM with ferrihydrite is not caused by direct interaction of the neutral polysaccharides' hydroxyls. Instead of that, we assume that (i) the dominant adsorption mechanism is outer-sphere complexation of carboxyls on the ferrihydrite surface and (ii) the enrichment of glucose and mannose in the ferrihydrite-associated OM may be explained by a preferential association of these monomers with carboxyl-rich compounds.

An Eocene analogue for the future oceanic response to increased CO_2 – Existence of a tropical thermostat?

DAVID B. J. EVANS[1]*, WOLFGANG MÜLLER[1], JONATHAN A. TODD[2] AND WILLEM RENEMA[3]

[1]Royal Holloway Univeristy of London, Egham, UK (*correspondence: david.evans.2007@live.rhul.ac.uk)

[3]Naturalis, Leiden, The Netherlands

Future anthropogenic-induced atmospheric greenhouse gas increase is expected to result in a globally warmer Earth. Whilst this will likely result in an increase of high-latitude sea surface temperatures (SST), the future response of the tropical oceans is uncertain. It has been suggested [1] that a tropical 'thermostat' regulates low-latitude surface ocean temperatures. The mid-Eocene was characterised by higher atmospheric greenhouse gas concentrations [2] and therefore may provide a suitable analogue with which to test the thermostat hypothesis. However, there is disagreement between different palaeo-temperature proxies and recent climate models, with some suggesting considerably warmer Eocene SST.

We present new Eocene tropical ocean surface temperature data from central Java, based on a calibration of the relationship between test Mg/Ca and temperature in large benthic foraminifera. This is the first time such material has been used for palaeo-temperature reconstructions, including appropriate corrections for both changes in the ionic composition of seawater over geological time and corresponding D_{Mg} variation. Large benthic foraminifera were chosen over their more routinely studied planktic relatives because they are longer lived and therefore facilitate both annual and seasonal temperature reconstruction. This is important because it is now recognised that seasonality is a key component of climate change [3].

Our results, measured by laser-ablation plasma mass spectrometry, indicate Eocene southeast Asia tropical SST broadly similar to today. These data, backed by a compilation of $\delta^{18}O$-derived temperatures from well-preserved planktic foraminifera, support the existence of a tropical thermostat. Moreover, comparison with higher palaeo-latitude LBF from the Hampshire Basin (UK) provides further evidence that oceanic latitudinal temperature gradients were greatly reduced when compared to the present day.

What can equilibrium thermodynamics tell us about metasomatic alteration?

K.A. EVANS

Department of Applied Geology, Curtin University, GPO Box U1987, Bentley, WA6845, Australia. (K.evans@curtin.edu.au)

In metamorphic petrology, equilibrium thermodynamics is often used to help us interpret metamorphic evolution of rocks that, we can reasonably assume, evolved close to thermodynamic equilibrium, with a relatively fixed bulk composition, except for volatiles, and under conditions where pressure and temperature are controlling intensive variables.

In rocks that have been significantly affected by metasomatic alteration, these assumptions are, in many cases, no longer reasonable. The nature of a metasomatic rock means that chemical potential variables are likely to have been fixed during their formation, rather than bulk composition variables. Metasomatic processes can also happen quickly, so the assumption of thermodynamic equilibrium on all but the shortest length scales might be faulty. Further, the changes in volume may be sufficient that it might be appropriate to consider volume, rather than pressure as a controlling variable.

Such observations are not new, but they are worth revisiting in the light of the massive recent improvements in imaging and analytical techniques that have led to renewed appreciation of the importance of processes such as dissolution-precipitation, and an increased understanding of the mechanics of metasomatic alteration.

Here, methods to improve the conceptual models and quantification of metasomatism, are discussed. These include judicious use of the phase rule, appropriate choices of conjugate variables, and methods to assess the lengthscales over which thermodynamic equilibrium may have applied. These methods are discussed with reference to metasomatic alteration of BIF-derived iron ore and serpentinisation of ultramafic rocks.

The relationship between subduction zone redox budget and arc magma fertility

K.A. EVANS[1] AND A. G. TOMKINS[2]

[1]Department of Applied Geology, Curtin University, GPO Box U1987, Bentley, WA6845, Australia. (K.evans@curtin.edu.au)
[2]School of Geosciences, P.O. Box 28E, Monash University, Vic. 3800, Australia. (Andy.tomkins@monash.edu.au)

A number of lines of evidence point to a causal link between oxidised slab-derived fluids, oxidised sub-arc mantle, and the formation of economic concentrations of metals such as Cu and Au that require oxidised magmas. However, trace element evidence from V/Sc ratios suggests that sub-arc mantle is no more oxidised than mantle elsewhere.

A simple analytical model is applied to constrain the evolution of sub-arc mantle oxidation state as a function of redox-budget fluxes from the subducting slab. Influential variables include the solubility of Fe^{3+} and SO_4^{2-} in slab-derived fluids, the geometry of the infiltration of slab-derived fluids in sub-arc mantle, the coupling between slab-derived and arc-output redox budgets, and the concentration of redox-buffering elements such as Fe and S in the sub-arc mantle.

Plausible Archean and Proterozoic redox budget fluxes would not have created oxidised sub-arc mantle. Phanerozoic redox budget fluxes, on the other hand, which are dominated by the sulfate component, could have increased sub-arc fO_2 by up to three $\log_{10}$ units. The results are generally consistent with the proposed elevated fO_2 for sub-arc mantle but do not explain V/Sc results.

Increases in sub-arc mantle fO_2 are favoured by focussed fluid infiltration and magma generation, weak coupling between slab and arc-output redox budgets, and restricted redox-buffering in the sub-arc mantle. Fertile arc segments for ore deposits associated with oxidised magmas require fluid chemistry and pressure-temperature gradients that enhance Fe^{3+} and SO_4^{2-} solubility in aqueous and silica-rich fluids, tectonic stress regimes that favour focussed transfer of components into the sub-arc mantle, and a relatively weak redox buffer for the sub-arc mantle. The paucity of Cu and Au deposits associated with oxidised magmas in the Precambrian may be explained as a consequence of a lack of subducted oxidised material, rather than simply as a consequence of preservation potential. Additionally, the reduced nature of subducted material in the Precambrian may have caused S and metal enrichment in the sub-arc mantle.

Coffinitization of uraninite – A review and discussion of observations on different scales

L.Z. EVINS[1]* AND K.A. JENSEN[2]

[1]SKB, Blekholmstorget 30, 101 24 Stockholm, Sweden (*lena.z.evins@skb.se)
[2] NRCWE, Lersø Parkallé 105, DK-2100 København Ø, Denmark (kaj@nrcwe.dk)

Coffinite ($USiO_4 \bullet nH_2O$) is a common secondary mineral in uranium ores, observed to replace uraninite in reponse to alteration of uraninite in a reducing environment [1]. This process is often referred to as coffinitization. However, it has proven difficult to synthesize coffinite in the laboratory, and in nature, coffinite is commonly very finegrained, resulting in a lack of experimental data concerning thermodynamic properties for coffinite [2,3]. As is noted by [2], the there are natural, coarse-grained coffinite crystals available from the Grants uranium region. However, it is also observed by [4] that there exists intermediate solid solutions in the system thorite–xenotime–zircon–coffinite and that in natural samples, moderate to strong deviation from perfect stoichiometry is commonplace.

In a recent attempt to synthesize coffinite [3], aqueous U was added to a Si-rich solution under controlled conditions to form a green gel subsequently heated for a few days in condition-controlled autoclave. This produced coffinite but only as a nanocrystalline mixture between coffinite and UO_2. Another experiment investigated the hydrothermal alteration of pellets of UO_2 in groundwater spiked with $CaCl_2$, $NaHCO_3$ and Na_2SiO_3[5]. At the end of the experiment (180 °C, c. 40 days, reducing environment) about 25% of the pellet surface was covered with a phase with a U:Si element ratio of 1:1. However, it was not possible to identify this material as coffinite by XRD.

In spite of these experimental difficulties, coffinite is a widespread alteration product of uraninite. This review aims to elucidate the spatial relationships between coffinite and uraninite as seen on different scales with different methods. The mechanism of uraninite alteration in natural, reducing, Si-rich environments is discussed and some new arguments put forward, involving the effect of impurities, defects, and grain size. Coffinitization is discussed in terms of solid-fluid interaction.

Tin substitution in chalcopyrite and sphalerite from hydrothermal sulfides

C. EVRARD*[1], N. MOUSSA[1,2], Y. FOUQUET[1] AND E. RINNERT[3]

[1]Laboratoire de géochimie et métallogénie, Ifremer Centre de Brest, BP 70, 29820 Plouzané, France (*correspondence: catherine.evrard@ifremer.fr)
[2]UMR6538 Domaines Océaniques, UBO-IUEM, Place Nicolas Copernic, 29280 Plouzané, France
[3]Service Interface et Capteurs, Ifremer Centre de Brest, BP 70, 29820 Plouzané, France

Unusual tin concentrations (500-2000ppm) were measured in sulfides from the Logatchev hydrothermal field. This hydrothermal site is located on the Mid-Atlantic Ridge, at a depth of 3000 m in an ultramafic environment. The fluid temperature was measured between 300 and 350°C at the exit of the chimneys.

Tin is usually not present in marine sulfides, but detailed microprobe and SEM analyses and element mapping showed a specific distribution for this metal. High tin concentration, are mostly in sphalerite (3 to 5%wt) and chalcopyrite (1 to 2%wt) from the hot part of the chimneys. The highest concentrations, up to 6%wt, are located at the replacement front of chalcopyrite and sphalerite.

Raman spectroscopy studies exclude the presence of tin minerals, like stannite, kesterite or cassiterite, and prove that tin is substituted in the lattice of sphalerite or of chalcopyrite.

The variation of the fluid composition, the temperature and the pressure induces the evolution of the chimney and changes in its mineral composition. These changes, linked to substitution, create different types of minerals with different valence, like $Cu^{+}Fe^{3+}S^{2-}_{2}$ and $Cu^{2+}Fe^{2+}S^{2-}_{2}$ for chalcopyrite.

Fe^{2+} is oxided in Fe^{3+} at high temperature in spite of the oxygen free environment[1] and enhance the tin substitution with the reaction: $2Fe^{3+} <-> Sn^{4+}Fe^{2+}$ [2].

Interesting finds in Norilsk copper-nickel sulfide ores

T.L. EVSTIGNEEVA

IGEM RAS, 35, Staromonetny, 119017, Moscow, Russia

Norilsk ores contain a unique set of ore minerals among which the minerals of platinum metals have a significant place. Nowadays more than 100 PGM are described in Noril'sk ores. Along with PGM the wide range of the rare minerals, considered unusual to deposits of similar type, is discovered in these ores. During detailed research using SEM+EDD some new data about PGM paragenesis, associated ore minerals, and unexpected mineral finds are obtained.

An investigation of massive copper rich sulfide ores with chalcopyrite group minerals (talnakhite, mooihoekite, putoranite) has shown, that fine-filiform band of cooper sulfides, $Cu_2S/Cu_{2-x}S$, are often observed along PGM and sulfide mineral boundaries. The thickness of these bands generally does not exceed 0.n microns (n~ 2-5). It could be the reason for some copper "surplus" in PGM composition.

Such observation could also explain the stoichiometry deviation observed on occasion in chalcopyrite group minerals. So, some sample compositions are enriched in Cu. It causes to "strange" formula with higher Cu apfu.

Beside sulfides (i.e. Ni_{ss}) among interesting minerals discovered recently in Cu-Ni-sulfide ores it possible to mention just a few: submicro- and nano-dimentional segregations of thorium , uranium and REE minerals - thorite, uranothorianite, Th-monacite, etc. The grain size of these minerals does not exceed a fraction of a micron. They are found in pyrrhotite ores, Oktyabrsky mine. It is neccesary to note that in Taïmyr peninsula there is an uranium manifestation, named Kamenskoje. Now it is difficult to understand if there is any association of this manifestation with Cu-Fe-Ni-PGE deposits of Noril'sk region. But the finding of Pd-minerals in natural reactor Oklo, in U-bearing black shales, and some other information about "coexisting" PGE and U (Th) in nature allow one to discusse some genetic problems.

Insights into lower crustal evolution from Hf isotope and Zr thermometry data for rutile

T.A. EWING*, D. RUBATTO AND J. HERMANN

Research School of Earth Sciences, A.N.U., Canberra, Australia (*correspondence: tanya.ewing@anu.edu.au)

Chemical and isotopic analysis of minerals previously resident deep in the crust provides critical information towards understanding the formation, evolution and differentiation of the continental crust. Rutile is an accessory mineral in many lower crustal metapelites and is an appealing target for such studies, but its full potential has not yet been exploited. While the ability to measure Hf isotopes in rutile has been demonstrated [1], an understanding of the behaviour of this system in rutile at high temperatures is lacking. Hf isotope information for this mineral can be combined with temperatures determined by Zr-in-rutile thermometry.

In this study, the classic lower crustal section of the Ivrea-Verbano Zone (IVZ), Italy, was used as a natural laboratory in which to explore the behaviour of the Hf isotope and Zr thermometry systems in rutile at high temperatures. Zr-in-rutile thermometry for a suite of granulite facies metapelites from the IVZ records high temperatures related to peak metamorphic conditions, as well as resetting of the Zr-in-rutile thermometer in some grains. Rutile from metapelite slivers incorporated into the underplating Mafic Complex record heating to temperatures in excess of 1000 ºC during emplacement of the gabbro. Zr-in-rutile is the only thermometer to record this extreme thermal overprint, which is not recorded by Ti-in-zircon or Fe-Mg thermometry.

Hf isotope data for the same suite of metapelites demonstrate that rutile preserves a robust record of Hf isotope composition, even under conditions of high temperature metamorphism and partial melting. The results also demonstrate that in metapelites that have experienced the highest temperatures, zircon dissolution plays an important role in determining the Hf isotope composition of subsequently-formed phases. This observation has profound implications for the interpretation of Hf isotope data for all minerals in both metamorphic and magmatic systems. When complete dissolution of zircon occurs, rutile is shown to become the main host of Zr and Hf in these samples, and controls the Zr/Hf of residue and melt.

The new results demonstrate the valuable contribution that chemical and isotopic analysis of rutile can make to constraining the evolution of the lower crust.

New *Thiomonas* and *Bordetella* strains involved in iron oxidation at a slightly acidic, heavy metal contaminated creek

M. FABISCH*, F. BEULIG, D. M. AKOB, AND K. KÜSEL

Friedrich Schiller University Jena, 07743 Jena, Germany
(*correspondence: maria.fabisch@uni-jena.de)

Legacy uranium mining in the area of Ronneburg, Germany, resulted in heavy metal contamination of small creeks. Iron rich creek sediments cover a wide pH range from extremely acidic (pH 2.7) over moderately acidic (pH 4.4) to slightly acidic (pH 6.3). In this study, we i) characterized the biogeochemistry of creek sites with different pHs, ii) studied bacterial communities in creek sediments and iii) isolated iron oxidizing bacteria (FeOB) at slightly acidic pH. Sediments were highly contaminated with up to 403 μg g^{-1} (dry wt) Zn, 201 μg g^{-1} (dry wt) Cu, and 165 μg g^{-1} (dry wt) Ni, and with smaller concentrations of up to 4.4 μg g^{-1} (dry wt) Cd. Oxic and anoxic *in vitro* sediment incubations revealed iron oxidation and reduction rates of same magnitude, indicating active iron cycling for all creek sediments regardless of pH. Members of the *Betaproteobacteria* dominated microbial communities in sediments as shown by 16S rRNA gene cloning and sequencing. High fractions of clones showed ≥97% sequence similarity to reported FeOB or iron reducers (FeRB), e.g., *Gallionella ferruginea* and *Ferritrophicum radicicola* (FeOB) or *Rhodoferax ferrireducens* and *Geobacter argillaceus* (FeRB), especially in a RNA-derived clone library from slightly acidic creek sediment (pH 6.3). Three novel FeOB strains, *Thiomonas* sp. strain FB-6 and FB-Cd and *Bordetella petrii* strain FB-8, were isolated from this sediment under lithoautotrophic, microoxic, pH 5.5 conditions. Due to its high similarity to one RNA-derived clone from this study, FB-6 is likely involved in active iron oxidation in creek sediment. Preliminary work indicated heavy metal tolerance and metabolic versatility for the 3 isolates. Future studies will investigate the mechanisms of metal attenuation by these novel FeOB under slightly acidic pH.

Source apportionment of atmospheric organic aerosol by nuclear magnetic resonance (NMR) spectroscopy: Results from EUCAARI project

Submicron aerosol samples were collected in nine EUCAARI IOPs site and analysed by means of proton-Nuclear Magnetic Resonance (^{1}H-NMR) spectroscopy with aim of organic aerosol characterization and source apportionment.. Analogously to more established methodologies employing mass spectrometric techniques, we exploit factor analysis of spectra for the identification of a small number of recurrent chemical classes.

Factor analysis of NMR spectral datasets is already widely used for the analysis of complex organic matrices in several scientific fields, from pharmaceutics to food and medical chemistry. Deconvolution of main spectral profiles within each time series of ^{1}H-NMR spectra of submicron aerosol samples was conducted using non-negative factor analysis techniques, such as PMF, NMF and MCR.

Some recurrent profiles were identified in different IOPs of EUCAARI project and their contribution to the total mass of OA were quantified. The results of this statistical analysis were compared to those of existing methodologies of factor analysis applied to atmospheric aerosol spectroscopic datasets (AMS) collected in the same period for each measurement campaign.

Our findings indicate that factor analysis applied to NMR atmospheric datasets can efficiently complement AMS in lumping the complex oxidized organic mixtures into chemical classes characterized by specific sources or ageing states. More specifically, NMR spectroscopy provides a better discrimination between aromatic and aliphatic structures, which is critical for the quantification of biomass burning products, and for the discrimination between biogenic and anthropogenic SOA.

Is microbial degradation of heavy hydrocarbons a major source of methane in CBM reservoirs? Evidence from Australia

M. FAIZ[1]*, A. MURPHY[1], D. MIDGLEY[2] AND P. HENDRY[2]

It is proposed that it is a misnomer that humic coals (Type III organic matter enriched in vitrinite and inertinite) predominantly generate methane, whereas Type I and Type II organic matter (enriched in liptinite) generate wet gases. Data from deep bituminous coals in Bowen, Surat, Galilee and Sydney basins of Australia indicate that humic coals containing only minor amounts of liptinite can generate significant amounts (>30%) of heavy hydrocarbons (Figure 1). However, subsequent to basin uplift most of the ethane and heavier hydrocarbons in shallow coals appear to be degraded to methane by microbal activity. In addition to alteration of wet gases, microorganisms can also degrade other organic components of coal including aromatics and secondary bitumens occluded in the coal matrix. In deeper, low permeability coals where microbial activity is not prevalent thermogenically generated heavy hydrocarbons appears to be well preserved.

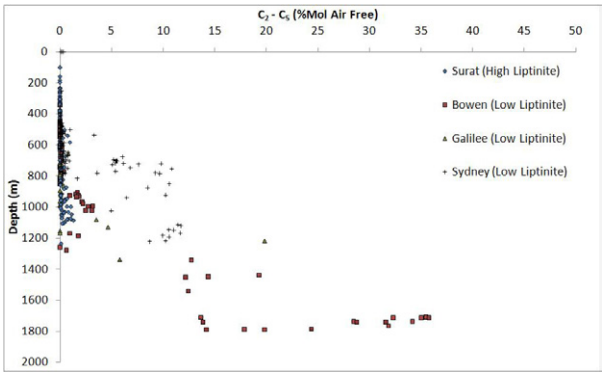

Figure 1: Coalbed gas wetness ($C_2 - C_5$) versus depth.

Microbiological studies including 16SrDNA analyses of coal and associated water samples from the Bowen and Surat basins have enabled the identification of bacteria and archaea capabale of degrading aliphatics and aromatics in coal to produce lighter hydrocabons including methane. The most prevalent bacterial phyla include the Proteobacteria and the Firmicutes and most commonly observed methanogen families include Methanobacteriaceae and Methanosarcinaceae.

Assessment of pore fluid pressure history in basin-centered gas accumulations using fluid inclusions
