## Abstract

The utilization of carbon dioxide (CO<sub>2</sub>) has garnered significant attention as a strategy to mitigate anthropogenic emissions. Within this field, the conversion processes of CO<sub>2</sub> through photocatalytic systems have emerged as a particularly noteworthy area of research. This approach leverages solar energy for the reaction and is considered a promising and environmentally friendly alternative to traditional thermally driven catalytic systems. This article aims to summarize recent advancements in several key photo-conversion pathways, including the synthesis of methane, methanol, C<sub>2</sub> hydrocarbons, dimethyl carbonate, and glycerol carbonate. Additionally, potential configurations for the development of processes aimed at producing various chemicals will be proposed. Current insights indicate that the photocatalytic conversion of CO<sub>2</sub> could be effectively integrated with chemical absorption methods, provided that appropriate separation and process intensification strategies are developed. From an economic perspective, the photocatalytic reduction of CO<sub>2</sub> minimizes the reliance on green hydrogen as a hydrogen source, thereby significantly improving overall economic viability. Environmentally, it is essential to enhance the reaction conversion and product selectivity of the photocatalytic conversion processes to maximize their decarbonization potential. Overall, this paper is particularly suited for readers who are new to this field and are interested in transitioning from experimental work to process development.

## Impact statement

This review paper discusses recent advancements in the field of photocatalytic CO<sub>2</sub> conversion. It covers the fundamentals and key materials used in photocatalysis, various conversion pathways for producing both commodity and value-added chemicals, and potential process configurations based on the current understanding of existing technologies. Key points for enhancing economic and environmental performance are also provided. This paper will be beneficial for readers who are new to this field and are interested in transitioning from experimental work to process development.

## Introduction

Photocatalytic reaction technologies have emerged as a significant area of research in CO<sub>2</sub> utilization. It harnesses solar energy to drive the transformation of carbon dioxide into value-added fuels and chemicals under mild conditions. Traditionally, CO<sub>2</sub> conversion has been carried out using thermal catalytic methods. This conversion can be classified as either non-reductive or reductive, depending on whether the oxidation state of the carbon atom changes during the reaction. Reductive conversion primarily refers to the hydrogenation of CO<sub>2</sub> to form hydrocarbons, alcohols, and others. In contrast, non-reductive pathways convert CO<sub>2</sub> directly into various classes of chemicals, including alkyl carbonates (which react with alcohols), aliphatic polycarbonates (which react with diols), ureas (which react with amines), and carbamates (which react with both alcohols and amines) (Tomishige et al., 2019; Tomishige et al., 2020). Table 1 summarizes some pathways that have been widely reported in the literature. However, thermal catalytic conversion of CO<sub>2</sub> has several drawbacks, including the requirement for elevated temperatures and pressures and challenges related to CO<sub>2</sub> activation. In contrast, photocatalytic CO<sub>2</sub> conversion, driven by solar energy and operating under milder conditions, inherently offers greater sustainability compared to thermal catalytic systems.

Overall, photocatalytic reactions utilize photon energy to generate charge carriers that directly drive CO<sub>2</sub> reduction under relatively mild conditions (Guo et al., 2023). Conventional photocatalytic reactions rely on the electron–hole pairs upon light irradiation (typically UV or visible lights), which enables redox reactions involving CO<sub>2</sub> and co-reactants. Materials with appropriate bandgaps (e.g., the semiconductor type) have been extensively investigated as the catalysts.

Existing examples include converting CO<sub>2</sub> to CO (Chu et al., 2022; Liao et al., 2024), methane (Lee et al., 2021; Zhao et al., 2024), methanol (Xi et al., 2022; Huang et al., 2024), and C<sub>2+</sub> hydrocarbons (Song et al., 2024; Zhang et al., 2024). However, such processes are currently limited by low conversion and selectivity due to inefficient CO<sub>2</sub> adsorption and activation, rapid recombination of charge carriers, limited visible-light absorption, and insufficient catalyst stability. More recently, photothermal CO<sub>2</sub> conversion has emerged as a novel technology (Gao et al., 2020). It integrates light-induced excitation with thermal activation to enhance catalytic performance (Gao et al., 2020). Under solar or near-infrared irradiation, localized heating and energetic carriers promote charge separation, accelerate diffusion, and expand the usable solar spectrum (Cai et al., 2021). Materials exhibiting plasmonic properties or broad-spectrum absorption have been reported as effective catalysts for photothermal conversion. In addition to producing chemicals similar to those from conventional photocatalytic systems (Cai et al., 2021; Wu et al., 2021; Li et al., 2022; Deng et al., 2023), photothermal systems can also convert CO<sub>2</sub> into larger molecules such as dimethyl carbonate

(DMC) (Jin et al., 2023) or glycerol carbonates (GC) (Li et al., 2024). Although photothermal catalysis demonstrates improved conversion efficiency, it still faces challenges such as the need for elevated temperatures and pressures, and concerns over long-term catalyst stability (Gao et al., 2020).

Recent landmark reviews have advanced the understanding of photocatalytic CO<sub>2</sub> conversion. For instance, Fang *et al.* provided a comprehensive overview of catalyst synthesis, reactor design, testing protocols, and mechanistic studies (Fang et al., 2023). Sadanandan *et al.* highlighted efficiency limitations due to charge-carrier recombination and narrow visible-light absorption, and proposed strategies to address them (Sadanandan et al., 2024). Kumar *et al.* investigate multifunctional carbon-nitride nano-architectures, demonstrating how bandgap tuning and surface-site control enable both hydrogen evolution and CO<sub>2</sub> reduction (Kumar et al., 2023). Gao et al. compared photocatalytic and photothermal CO<sub>2</sub> conversion as promising routes for CO<sub>2</sub> utilization, detailing their principles, catalyst options, and performance metrics (Gao et al., 2020). Overall, this field remains emerging, with many aspects yet to be explored.

Extensive research has advanced both theoretical and experimental aspects of photocatalytic CO<sub>2</sub> conversion, yet gaps remain between lab-scale studies and process development. The absence of integrated frameworks for process studies limits discussion of economic, environmental, and safety considerations. Currently, the low product yields and selectivity of photocatalytic CO<sub>2</sub> conversion hinders its practical deployment, highlighting the importance downstream separation strategies. To address this gap, this review aims to provide insights for advancing from experimentation to process development. It begins by summarizing advances in photocatalyst design, particularly focusing on the incorporation of heterojunction architectures, surface defect engineering, active site optimization, and enhanced reaction capacities to enable the efficient conversion of CO<sub>2</sub> into valuable hydrocarbon fuels. Subsequently, essential perspectives for further advancing photocatalytic CO<sub>2</sub> conversion processes are presented. Overall, this review offers readers a comprehensive framework that connects material fundamentals to plant-wide process implementation.

## State-of-the-art progress in photocatalytic conversion of CO<sub>2</sub>

This section reviews recent advancements in the field. Section “Introduction of photocatalytic conversion” introduces potential photocatalysts for CO<sub>2</sub> conversion. Sections “Photocatalytic reduction systems” and “Photothermal catalytic reaction systems” summarize recent experimental results on photocatalytic reduction and photothermal catalytic systems, respectively. Section “Standard procedure of photocatalytic CO<sub>2</sub> conversion” covers standardized procedures for experimentation and process development, while Section “Modeling” highlights recent progress in modeling photocatalytic reaction systems.

### Introduction of photocatalytic conversion

#### Fundamentals of photocatalytic conversion

Photocatalysis involves three key stages: light absorption, charge carrier generation and separation, and surface redox reactions (Du et al., 2020). Upon photon excitation, electrons (e<sup>−</sup>) are promoted from the valence band (VB) to the conduction band (CB), resulting in the formation of holes (h<sup>+</sup>) that drive reduction and oxidation reactions, including CO<sub>2</sub> conversion and pollutant degradation under ambient conditions. Accordingly, the overall efficiency (η<sub>e</sub>) of a photocatalytic system can be represented by **Equation (1)** (Li et al., 2015):

$$\eta_e = \eta_a \times \eta_{ce} \times \eta_{cs} \times \eta_{cu} \quad (\text{Eq1})$$

Where η<sub>a</sub> denotes the photon absorption efficiency, η<sub>ce</sub> represents the charge excitation efficiency, η<sub>cs</sub> refers to the efficiency of charge separation and transport, and η<sub>cu</sub> indicates the efficiency of charge carrier utilization in surface reactions (Zhang et al., 2021). Optimizing light harvesting (η<sub>a</sub>) is critical, as it directly influences both η<sub>ce</sub> and η<sub>cs</sub>. Strategies to enhance photocatalytic efficiency include tuning the bandgap, crystal structure, and surface area. The development of composite materials with extended spectral absorption ranges (UV–VIS–NIR), engineered heterojunctions, defect-engineered nanostructures, and integration of co-catalysts has been shown to improve charge separation and increase the density of active sites (Li et al., 2021; Man et al., 2024; Li et al., 2016).

#### Potential photocatalyst design strategies

Conventional semiconductor metal oxides remain prevalent in photocatalytic applications due to their ability to facilitate UV-driven

charge separation between the VB and CB. Nevertheless, their broad band gaps and limited electrical conductivity restrict their effectiveness in solar energy applications, considering that ultraviolet light accounts for merely about 5% of the solar spectrum. To exploit visible and infrared light, whereas the light accounts for approximately 46% and 49%, two-dimensional (2D) materials such as carbon-based substances (e.g., graphene and graphitic carbon nitride, g-C<sub>3</sub>N<sub>4</sub>), transition metal dichalcogenides (TMDs), and MXenes have emerged as promising alternatives. These materials exhibit tunable band gaps that can be aligned with the conduction and valence bands to match the reduction potential of CO<sub>2</sub> and the corresponding oxidation half-reactions. Elemental doping or substitution techniques have been employed to modulate the bandgap and Fermi level, thereby positioning the conduction band minimum (CBM) just above the CO<sub>2</sub>/CO or CO<sub>2</sub>/CH<sub>4</sub> reduction potentials (Lee et al., 2021; Li et al., 2024; Huang et al., 2025).

Furthermore, TMDs and MXenes have attracted considerable interest owing to their abundant surface atoms and compatibility with co-catalysts. Representative TMDs, including MoS<sub>2</sub>, WS<sub>2</sub>, ReS<sub>2</sub>, and NiS<sub>2</sub>, whereas MXenes are generally described by the formula M<sub>n</sub>+<sub>1</sub>X<sub>n</sub>T<sub>x</sub>, where M denotes transition metals such as Ti, V, or Nb; X represents carbon and/or nitrogen; and T corresponds to surface terminations like -O, -OH, or -F. These materials possess metallic conductivity, high surface reactivity, adaptable electronic structures, and strong interactions with co-catalysts, rendering them suitable for solar-driven CO<sub>2</sub> conversion (Kuang et al., 2020). Heterostructure engineering approaches—including Type-II heterojunctions, Z-scheme architectures, core-shell structures, and 2D/2D or 2D/0D systems—offer ultrathin, layered configurations that minimize charge carrier diffusion distances and suppress electron–hole recombination, thereby enhancing photocatalytic performance (Zeng et al., 2020; Xu et al., 2018; Wang et al., 2018; Cai et al., 2024; Wang et al., 2021). Defect engineering introduces localized electronic states that serve as active sites for CO<sub>2</sub> adsorption and activation, while also modulating charge carrier dynamics. The presence of oxygen vacancies, cation vacancies, and other point defects can enhance CO<sub>2</sub> adsorption and stabilize reaction intermediates (Vennapoosa et al., 2023; Wang et al., 2021; Ji et al., 2023).

Porous crystalline materials, including metal–organic frameworks (MOFs) and covalent organic frameworks (COFs), also demonstrate potential due to their high surface areas and ordered pore structure that facilitate CO<sub>2</sub> capture and activation (Chemical Reviews, 2012). However, their low electrical conductivity and rapid charge recombination limit performance. Recent research has improved these issues by hybridizing them with conductive materials and incorporating co-catalyst systems to enhance charge transport and visible-light responsiveness (Altintas et al., 2022).

In summary, advanced photocatalysts, ranging from metal oxides and 2D nanostructures to porous frameworks, enable efficient CO<sub>2</sub> conversion into value-added products such as methane, methanol, ethylene, and ethanol. Continued innovations in material design, interface engineering, and mechanistic understanding will be essential to fully realize the potential of photocatalytic CO<sub>2</sub> reduction.

### Photocatalytic reduction systems

Among various pathways, photocatalytic CO<sub>2</sub> reduction that produces C<sub>1</sub> and C<sub>2</sub> chemicals has been the primary focus of this field. Typically, the hydrogen source for these reactions is derived from water splitting, as illustrated in **Equation (2)**.

This reaction is combined with the multi-electron reduction of CO<sub>2</sub> to produce the targeted chemicals. Table 2 provides a comparative overview of representative photocatalytic reduction pathways, highlighting their compositional features, corresponding CO<sub>2</sub> reduction products, and associated product selectivity. The following sections will discuss the advancements in producing C<sub>1</sub> products (e.g., methanol and methane) and C<sub>2</sub> products (e.g., ethane and ethylene) via photocatalytic CO<sub>2</sub> reductive pathways.

### Production of methanol

Methanol is a primary focus in the domain of CO<sub>2</sub> utilization due to its multifunctional role as an energy storage medium, a sustainable fuel alternative, and a precursor for the synthesis of diverse hydrocarbons. The photocatalytic conversion of CO<sub>2</sub> to MeOH entails a six-electron reduction mechanism, as described by the standard reaction depicted in Equation (3):

Notably, the reduction potential of this reaction is slightly more positive than that of proton reduction (−0.41 V vs NHE), making it thermodynamically favorable under photocatalytic conditions. However, achieving efficient methanol production requires prolonged lifetimes of photoinduced charge carriers and effective charge separation. To this end, heterojunction engineering through metal or metal oxide modification of semiconductor photocatalysts has significantly improved charge carrier dynamics. For instance, Zhang *et al.* reported a vertically oriented Fe single-atom-decorated TiO<sub>2</sub>/SrTiO<sub>3</sub> nanotube heterojunction (Fe-TSr), which enables directional separation and migration of photogenerated carriers. This system achieved a methanol yield of 154.20 μmol·g<sub>cat</sub><sup>−1</sup>·h<sup>−1</sup> with 98.90% selectivity in pure water, representing 50- and 3-fold enhancements relative to pristine TiO<sub>2</sub> and TSr, respectively (Huang *et al.*, 2024). Similarly, Ag-doped 2H-MoS<sub>2</sub> composites have shown promising performance in CO<sub>2</sub> photoreduction. The incorporation of 20 wt% Ag resulted in the highest methanol yield of 365.08 μmol·g<sub>cat</sub><sup>−1</sup>·h<sup>−1</sup>. This improvement is attributed to the formation of a Schottky barrier at the Ag-MoS<sub>2</sub> interface, facilitating efficient electron transfer from the conduction band of MoS<sub>2</sub> to Ag nanoparticles, while photogenerated holes participate in the oxidation of C<sub>3</sub>H<sub>8</sub>O to C<sub>3</sub>H<sub>6</sub>O. Thus, the barrier effectively suppresses charge recombination and prolongs carrier lifetimes (Zheng *et al.*, 2019). Furthermore, enhancing CO<sub>2</sub> adsorption and activation is vital for improving methanol production rates and selectivity. Li and co-workers developed a ternary heterostructure comprising 2.5% g-C<sub>3</sub>N<sub>4</sub>/1% CuO@MIL-125(Ti). In this system, MIL-125(Ti) offers a high surface area and porosity, CuO quantum dots facilitate CO<sub>2</sub> capture and activation, and g-C<sub>3</sub>N<sub>4</sub> nanosheets provide efficient charge transport pathways. Mott-Schottky analysis revealed that electrons and holes are spatially separated across the conduction band of CuO and the valence band of g-C<sub>3</sub>N<sub>4</sub>, respectively, reducing recombination losses. The composite photocatalyst exhibited high activity, yielding CO (180.1 μmol/g), CH<sub>3</sub>OH (997.2 μmol/g), CH<sub>3</sub>CHO (531.5 μmol/g), and CH<sub>3</sub>CH<sub>2</sub>OH (1505.7 μmol/g) using water as the electron donor (Li *et al.*, 2020).

### Production of methane

Methane (CH<sub>4</sub>) serves not only as a clean and efficient fuel but also as a valuable intermediate for synthesizing syngas, hydrogen, and

methanol through reforming processes. Among various C<sub>1</sub> products derived from CO<sub>2</sub> reduction, methane formation requires the highest number of electrons (eight) but has the least negative reduction potential. The thermodynamic stability of CO<sub>2</sub>, characterized by a high C=O bond dissociation energy (~750 kJ/mol), necessitates a high density of electrons and protons to drive its conversion into CH<sub>4</sub>. This reaction follows an eight-electron reduction pathway, as illustrated in Equation (4) (Yang *et al.*, 2023):

Among the proposed mechanisms, the carbene pathway is considered more plausible than the formaldehyde pathway. The rate-determining step is the protonation of adsorbed CO (\*CO) to form \*CHO, followed by further hydrogenation steps to \*CHOH, \*CH, \*CH<sub>2</sub>, \*CH<sub>3</sub>, and ultimately CH<sub>4</sub>. To promote this multi-electron transfer process, constructing an electron-rich micro-environment around the catalytic sites is essential. Strategies include incorporating plasmonic noble metal nanoparticles (Yan *et al.*, 2024) and π-conjugated systems such as COFs or 2D materials (Wang *et al.*, 2018; Madi & Tahir, 2024), which enhance charge mobility and surface area. Liu *et al.* introduced a BiVO<sub>4</sub>@-TiO<sub>2</sub> nanograin/needle array (NNAs) S-scheme heterojunction photocatalyst, further modified with 5 wt% of the ionic liquid 1-butyl-3-methylimidazolium tetrafluoroborate (BMIM-BF<sub>4</sub>) to improve CO<sub>2</sub> solubility in aqueous systems. Under Xe lamp irradiation, photo-induced electrons from BiVO<sub>4</sub> and holes from TiO<sub>2</sub> undergo rapid recombination at the interface, resulting in electron accumulation at the TiO<sub>2</sub> tip and hole enrichment in BiVO<sub>4</sub>. This charge spatial separation significantly enhances the photocatalytic performance, achieving CO, CH<sub>4</sub>, and H<sub>2</sub> evolution rates of 321.5, 132.7, and 75.8 μmol·m<sup>−2</sup>·h<sup>−1</sup>, respectively (Zhao *et al.*, 2024). Moreover, Shankar *et al.* demonstrated a plasmonic photonic crystal photocatalyst comprising Au nanoparticle-decorated, periodically modulated TiO<sub>2</sub> nanotube arrays (Au-PMTiNTs). The Z-scheme heterojunction, enhanced by hot-electron transfer under AM1.5G simulated sunlight, selectively produced CH<sub>4</sub> at 302 μmol·g<sub>cat</sub><sup>−1</sup>·h<sup>−1</sup> with 89.3% selectivity (Zeng *et al.*, 2020). COFs have also emerged as promising platforms for CO<sub>2</sub> photoreduction due to their tunable molecular structures, adjustable band gaps, and efficient internal charge transport. Maji and co-worker synthesized a triazole-linked COF (TFPB-TRZ) that delivered a remarkable CH<sub>4</sub> production rate of 61.62 mmol·g<sub>cat</sub><sup>−1</sup>·h<sup>−1</sup> with an overall yield of 493 mmol·g<sup>−1</sup> and excellent selectivity (~99%) under visible-light irradiation. *In situ* diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) confirmed the formation of key intermediates such as \*COOH, \*CO, \*CH<sub>2</sub>O, \*CH<sub>3</sub>O, -CH<sub>2</sub>, and -CH<sub>3</sub>, substantiating the eight-electron reduction pathway leading to methane formation (Biswas *et al.*, 2024).

### Production of ethylene

The production of C<sub>2</sub><sup>+</sup> hydrocarbons, particularly ethylene (C<sub>2</sub>H<sub>4</sub>) and acetylene (C<sub>2</sub>H<sub>2</sub>), through photocatalytic reduction is of special interest due to their high energy densities and essential roles as industrial feedstocks. However, the conversion is hindered by CO<sub>2</sub>'s high thermodynamic stability (bond dissociation energy ~750 kJ/mol; ΔG°<sub>298K</sub> = −394.36 kJ/mol). Efficient C-C bond formation, typically achieved through the dimerization of C<sub>1</sub> intermediates (e.g., CH<sub>2</sub>, CH<sub>3</sub>, or CHO), is crucial for synthesizing C<sub>2</sub> products. These multistep, multi-electron/proton processes require surfaces with high charge carrier and proton densities, as well as strong adsorption of intermediates to avoid premature desorption

Table 2. The comparison of various catalytic systems

Product	Type	Materials type	Photocatalyst	Operating parameter	Light source	CO <sub>2</sub> feeding conditions	Yield ( $\mu\text{mol}\cdot\text{g}^{-1}\cdot\text{h}^{-1}$ )	Selectivity (%)	Ref

as C<sub>1</sub> products. The representative 12-electron reduction for ethylene is as follows:

To improve C<sub>2</sub> product selectivity, strategies such as heterojunction engineering, defect modification, light-harvesting enhancement, and surface activation have been explored. For instance, Xu *et al.* designed a nitrogen-doped CeO<sub>2</sub> photocatalyst featuring surface-frustrated Lewis pairs (FLPs) of Ce<sup>3+</sup>/Ce-OH, enhancing CO<sub>2</sub> activation and C-C coupling. This catalyst produced CO (224.56 μmol·g<sup>-1</sup>·h<sup>-1</sup>, 28.1%), C<sub>2</sub>H<sub>4</sub> (33.18 μmol·g<sup>-1</sup>·h<sup>-1</sup>, 24.91%), and C<sub>2</sub>H<sub>2</sub> (25.84 μmol·g<sup>-1</sup>·h<sup>-1</sup>, 16.16%) (Yan *et al.*, 2024). MOFs also offer promise. A Zr/Cu bimetallic UiO-67 MOF improved electron transfer and C-C coupling efficiency, achieving selective C<sub>2</sub>H<sub>4</sub> production (69.1 μmol·g<sup>-1</sup>·h<sup>-1</sup>, 100% selectivity) (Asiri *et al.*, 2025). Moreover, non-stoichiometric WO<sub>3-x</sub> (particularly WO<sub>2.9</sub>) exhibits enhanced visible/NIR absorption and reactivity due to oxygen vacancies (Lu *et al.*, 2020). Tu *et al.* synthesized a WO<sub>2.9</sub>/WTe<sub>2</sub> photothermal catalyst that demonstrated a high ethylene production rate of 122.9 μmol·g<sup>-1</sup> and a selectivity of 78%. When the reaction temperature was elevated to 240 °C, the ethylene yields significantly increased to 475.3 μmol·g<sup>-1</sup>. The WO<sub>2.9</sub> component plays a key role in bandgap modulation and CO<sub>2</sub> adsorption through its abundant oxygen vacancies, while WTe<sub>2</sub> effectively stabilizes aldehyde intermediates, enriching the catalyst surface with reactive species and facilitating efficient C-C bond formation (Zhang *et al.*, 2024).

### Production of ethane

The photocatalytic reduction of CO<sub>2</sub> to ethane (C<sub>2</sub>H<sub>6</sub>) involves a 14-electron transfer process and the formation of multiple reactive intermediates. The overall reduction reaction is represented as:

Mechanistically, the surface-mediated C-C coupling of methyl (\*CH<sub>3</sub>) radicals, which is necessary for the generation of C<sub>2</sub><sup>+</sup> hydrocarbons, poses challenges to the progression of the reaction. To overcome these limitations, researchers have fabricated dual-atom catalysts, exemplified by incorporating phosphorus and copper single-atom sites on carbon nitride nanosheets (P/CuSAs@CN). This photocatalyst achieved an ethane production rate of 616.6 μmol·g<sup>-1</sup>·h<sup>-1</sup> with a selectivity of 33%. The Cu and P atoms serve as electron and hole trapping sites within the carbon nitride matrix, facilitating charge separation and accumulation at Cu sites, which is vital for driving multi-electron transfer steps. *In situ* FTIR spectroscopy identified key intermediates, including \*CO and \*OCCOH, confirming the involvement of hydrogenation of \*OCCO as the rate-determining step in C<sub>2</sub>H<sub>6</sub> formation (Wang *et al.*, 2022). The COFs and MOFs offer strong potential in photocatalysis due to their π-conjugated structures, which support charge transport and light absorption (Saadh *et al.*, 2025). Bai *et al.* developed a MoS<sub>2</sub>@COF hybrid by covalently integrating amino-modified MoS<sub>2</sub> with an anthraquinone-based COF, achieving an ethane production rate of 56.2 μmol·g<sup>-1</sup>·h<sup>-1</sup> and 83.8% selectivity under visible light, significantly outperforming individual components. *In situ* DRIFTS and DFT analyses confirmed that the hybrid promotes CO<sub>2</sub> adsorption, CO hydrogenation, and C-C coupling, facilitating efficient C<sub>2</sub>H<sub>6</sub> formation (Yang *et al.*, 2023).

## Photothermal catalytic reaction systems

Photothermal CO<sub>2</sub> conversion leverages solar or near-infrared irradiation to generate localized heating and, in some cases, hot electrons, thereby enhancing CO<sub>2</sub> hydrogenation efficiency (Guo *et al.*, 2023; Gao *et al.*, 2020; Cai *et al.*, 2021). Effective photothermal catalysts must exhibit synergistic properties, including strong light absorption and efficient thermal confinement (e.g., incorporation of core-shell structures, plasmonic coupling, or defect engineering) (Cai *et al.*, 2021; Feng *et al.*, 2020; Tang *et al.*, 2025; Li *et al.*, 2024). To date, significant progress has been made in producing light hydrocarbons, particularly methane, through photothermal conversion. Additionally, several studies have explored photothermal catalytic reactions to synthesize carbonates, such as dimethyl carbonate (DMC) and glycerol carbonate (GC), which have been scarcely reported in photocatalytic systems. Relevant findings are summarized in the following sections.

### The production of C<sub>1</sub> and C<sub>2</sub> chemicals

Similar to photocatalytic conversion, the production of C<sub>1</sub> and C<sub>2</sub> chemicals via photothermal catalytic reduction of CO<sub>2</sub>, involving the use of gaseous hydrogen (*i.e.*, photothermal hydrogenation) and/or water, has attracted attention. The experimental conditions, as well as the key performance indicators of these systems, are summarized in Table 2 for comparison with those from photocatalytic reduction systems. Among these pathways, the development in photothermal methanation systems has the most progress. Catalyst such as MXene-supported metal (e.g., Ni/Nb<sub>2</sub>C [Wu *et al.*, 2021]), metal nanoparticles (e.g., plasmonic Co-SiO<sub>2</sub> superstructures [Cai *et al.*, 2024], Ru/MnCo<sub>2</sub>O<sub>4</sub> [Guo *et al.*, 2023]), single-atom catalysts (e.g., the Ru-F<sub>4</sub> configuration [Tang *et al.*, 2024]), and core-shell designs (e.g., Ni@p-SiO<sub>2</sub> [Cai *et al.*, 2021]) have been reported successful for photothermal CO<sub>2</sub> conversion to light hydrocarbons.

As illustrated in Table 2, photothermal catalytic reduction systems generally achieve higher product yield or selectivity than photocatalytic reduction processes, especially when hydrogen or water is used as co-reactants. For example, photothermal methanation systems exhibit greater reaction efficiency, with product yields reaching mmol·g<sup>-1</sup>·h<sup>-1</sup> (or mol·g<sup>-1</sup>·h<sup>-1</sup>) levels (Guo *et al.*, 2023; Guo *et al.*, 2025), compared to photocatalytic reactions that typically yield μmol·g<sup>-1</sup>·h<sup>-1</sup>. Several studies also demonstrate successful photothermal methanation in flow systems (Guo *et al.*, 2023; Wu *et al.*, 2021; Tang *et al.*, 2024), indicating potential for scale-up. Moreover, unlike most photocatalytic systems driven by lamp irradiation, successful photothermal systems for CO<sub>2</sub>-based light olefin (Ning *et al.*, 2024) and syngas (Wu *et al.*, 2025) have been demonstrated using full sunlight, underscoring their potential.

Nonetheless, these systems often require higher temperatures and pressures, reducing the inherent benefits of photocatalytic methods. Moreover, the dependence on hydrogen poses a major challenge, particularly in areas without access to green hydrogen or the infrastructure for sustainable hydrogen production. Therefore, it is crucial to evaluate whether these improvements justify practical implementation.

### Production of dimethyl carbonate (DMC)

The formation of DMC requires the reaction of CO<sub>2</sub> with methanol. Prior research has reported the successful use of CeO<sub>2</sub>-based catalysts enriched with oxygen vacancies, which have proven to be efficient for this purpose.

Within the limited volume of previous studies, Guan *et al.* synthesized Bi<sup>3+</sup>-doped Ce<sub>x</sub>Bi<sub>1-x</sub>O<sub>2-δ</sub> nanorods (Guan *et al.*,

2024), achieving a DMC yield of  $3.13 \text{ mmol}\cdot\text{g}^{-1}$  at  $140^\circ\text{C}$  and  $1.6 \text{ MPa}$  under photo-irradiation, attributing performance gains to asymmetric Bi-O-Ce oxygen vacancies that improve  $\text{CO}_2$  activation and light absorption efficiency. Bai *et al.* employed a low-temperature plasma-driven technique to introduce corner defects into quadrangular pyramid-octahedral  $\text{CeO}_2$  (Bai *et al.*, 2023). This approach achieved a DMC yield of 1.58%, corresponding to an eightfold increase relative to conventional thermal catalysis performed at  $140^\circ\text{C}$  and  $7.5 \text{ MPa}$ . Jin *et al.* prepared  $\text{CeO}_2$  nanorods with bifunctional oxygen vacancies via a template-free hydrothermal method (Jin *et al.*, 2023). This method resulted in improved photothermal catalytic activity, evidenced by a DMC yield of  $17.7 \text{ mmol}\cdot\text{g}^{-1}\cdot\text{h}^{-1}$  under relatively mild reaction conditions ( $140^\circ\text{C}$ ,  $1.6 \text{ MPa}$ ). The enhanced performance was attributed to increased  $\text{CO}_2$  adsorption capacity and the inhibition of recombination of photo-induced electron-hole pairs.

### Production of glycerol carbonate (GC)

The direct conversion of  $\text{CO}_2$  and glycerol to glycerol carbonate (GC) offers a promising solution to two environmental wastes. Within the currently limited findings, Liu *et al.* developed  $\text{Au}/\text{ZnWO}_4\text{-ZnO}$  catalysts for photothermal conversion of glycerol and  $\text{CO}_2$  into GC, where Au nanoparticles enhanced performance via localized surface plasmon resonance (LSPR) under visible light and heat, significantly boosting GC yield compared to thermal catalysis (Liu *et al.*, 2019). Liu *et al.* also reported a  $\text{Co}_3\text{O}_4\text{-ZnO}$  p-n heterojunction catalyst, achieving a GC yield of 5.3% at  $150^\circ\text{C}$  and  $5 \text{ MPa}$   $\text{CO}_2$  under visible light (Liu *et al.*, 2022). The p-n heterojunction effectively increased visible light absorption and electron-hole separation, breaking the thermodynamic limitations of conventional thermal catalysis. Li *et al.* further improved the  $\text{Co}_3\text{O}_4\text{-ZnO}$  system by decorating it with Au nanoparticles to create  $\text{Au}/\text{Co}_3\text{O}_4\text{-ZnO}$  catalysts (Li *et al.*, 2024). This strategy generated surface oxygen vacancies, enhanced visible-light absorption, and increased GC yield to 6.5% under the same photothermal conditions ( $150^\circ\text{C}$ ,  $5 \text{ MPa}$   $\text{CO}_2$ ) due to improved electron-hole separation. Additionally, Li *et al.* explored  $\text{La}_2\text{O}_2\text{CO}_3\text{-ZnO}$  catalysts (Li *et al.*, 2021), demonstrating strong photothermal synergy in glycerol carbonylation, achieving a 6.9% glycerol conversion under irradiation at  $150^\circ\text{C}$  and  $5.5 \text{ MPa}$   $\text{CO}_2$ . The synergistic interaction between  $\text{La}_2\text{O}_2\text{CO}_3$  and ZnO played a crucial role in this enhanced catalytic performance.

### Standard procedure of photocatalytic $\text{CO}_2$ conversion

The standard method for photocatalytic  $\text{CO}_2$  conversion involves light sources (e.g., calibrated lamps or solar simulators), photoreactors, gas delivery systems, photocatalysts, and analytical tools for product analysis. Photoreactors are typically configured as suspended systems, where the catalyst is dispersed in a liquid (slurry reactors), or as heterogeneous systems, such as fixed-bed or monolithic reactors. Quartz or other optical-grade windows are essential for optimal light transmission. Selecting functionalized photocatalysts (detailed in Section “Fundamentals of photocatalytic conversion”) enhances charge separation and light absorption during  $\text{CO}_2$  conversion (Kou *et al.*, 2017). Before starting the reaction, the reactor is leak-tested, purged with high-purity  $\text{CO}_2$  or inert gas, and equilibrated to the desired temperature and pressure.

In suspended catalytic systems, reactions mainly occur in the liquid phase, where  $\text{CO}_2$  dissolves in an alkaline solution to promote the reaction. This process produces both gaseous products (e.g., methane, carbon monoxide) and liquid products (e.g., methanol), with liquid products often dominating due to fewer electron

transfers. Conversely, heterogeneous systems enable gas-phase reactions that primarily yield methane. Gaseous hydrogen is continuously fed into the reactor to react with  $\text{CO}_2$ , resembling conventional hydrogenation reactors. These features can be combined to create biphasic photocatalytic conversion systems (Bonchio *et al.*, 2023; Variar *et al.*, 2021).

Controlled irradiation is applied using a calibrated AM 1.5G solar simulator or equivalent light source, with precise regulation of temperature and  $\text{CO}_2$  pressure to influence product selectivity. For example, lower temperatures ( $\sim 70^\circ\text{C}$ ) favor CO formation, whereas higher temperatures ( $100\text{--}120^\circ\text{C}$ ) promote methane production. Regarding pressure effects, moderate  $\text{CO}_2$  pressures ( $\sim 110 \text{ kPa}$ ) optimize methanol synthesis, whereas higher pressures ( $>130 \text{ kPa}$ ) enhance methane generation (Meesattham & Kim-Lohsoontorn, 2022; Yang *et al.*, 2022). Throughout the reaction, gaseous and liquid products are periodically sampled and quantified using gas chromatography, liquid chromatography, or nuclear magnetic resonance spectroscopy, employing appropriate calibration standards. Overall, thorough documentation of catalyst properties, reactor setup, operational parameters, and error analysis is essential for scientific rigor and study comparability.

### Modeling

Currently, advancements in the modeling of photocatalytic and photothermal catalytic processes remain constrained (Jesic *et al.*, 2021; Kovacic *et al.*, 2020). Existing studies have primarily focused on the macroscopic description of photoreactors, including slurry reactors (Asadi *et al.*, 2022), fixed-bed reactors (Rastgaran *et al.*, 2023), twin reactors (Lu *et al.*, 2021), and others (Ramayashree *et al.*, 2024). The most comprehensive studies employed mathematical modeling (Ray, 1999) or even computational fluid dynamics (CFD) (Lu *et al.*, 2021) to conduct multiphysics simulations, attempting to characterize the flow field, velocity distribution, reactor geometry, and mass transfer within the reactor.

To our knowledge, there is a notable lack of process concepts for photocatalytic  $\text{CO}_2$  conversion in the literature, primarily due to several challenges. First, kinetic modeling is particularly difficult because it requires understanding interfacial behavior, various interactions (e.g., adsorption, desorption), site balance, and the effects of irradiation. Quantum approaches may help clarify these factors (Jesic *et al.*, 2021; Kovacic *et al.*, 2020). Secondly, most experiments use diluted reaction media, resulting in low product yield and selectivity, complicating separation processes. Furthermore, reactor performance depends on its dimensions and irradiation conditions. Consequently, most models have focused on specific experimental setups, limiting the predictive capability.

### From experimentation to processes

Despite extensive experimental research, photocatalytic  $\text{CO}_2$  conversion technologies have not yet reached their full potential. Key challenges include low yield, limited selectivity, and inefficient light utilization. This section proposes process configurations tailored to various photocatalytic conversion types, combining current experimental results with practical process insights.

### Process consideration of the photocatalytic reduction of $\text{CO}_2$

From a macroscopic perspective, several experimental challenges must be addressed before scaling up photocatalytic  $\text{CO}_2$  reduction. First, most photocatalytic  $\text{CO}_2$  reduction reactions occur in the

liquid phase within suspended catalytic systems, producing hydrocarbons and methanol as the main products, with water as the hydrogen source. Due to the low solubility of CO<sub>2</sub> in the aqueous phase (approximately 0.033 mol per liter at 25 °C and 1 atm), reactions are typically conducted in alkaline solutions. This complicates downstream separation and recovery of photocatalysts and alkaline agents.

Figure 1a depicts a process configuration for hydrocarbon synthesis via photoreduction, which is proposed based on current knowledge. The process begins with capturing CO<sub>2</sub> from point emission sources (e.g., flue gas) through chemical absorption, using the alkaline solvent. After absorption, the rich solvent undergoes photocatalytic reduction in a photoreactor. Note that this rich solvent has a composition similar to that in typical photocatalytic conditions. Hydrocarbon products, being only slightly soluble, can be separated easily by vapor–liquid separation. The next step should isolate hydrocarbons from CO<sub>2</sub> using physical methods, such as adsorption and membrane techniques. If hydrocarbon concentration is low, it is more practical to use the effluent as gas fuel rather than purifying it for marketable products. Downstream of the photoreactor, alkaline solution recovery can be achieved through regeneration methods such as causticization (with CO<sub>2</sub> stripping) and electrodialysis (Mahmoudkhani & Keith, 2009; Sabatino et al., 2022).

In addition, photocatalytic reaction can also be integrated with the direct air capture (DAC) process. Currently, the main challenge in DAC is the very low concentration of CO<sub>2</sub> in the atmosphere (approximately 400 ppm). However, using a strong alkaline solution as an absorbent can selectively capture CO<sub>2</sub> from nitrogen and oxygen while simultaneously providing suitable conditions for the photocatalytic reduction of CO<sub>2</sub>. This synergistic effect may offer additional benefits for the future application of DAC.

To improve system performance, advanced photocatalysts that rapidly convert CO<sub>2</sub> under vapor–liquid equilibrium are essential. Fast kinetics enable continuous CO<sub>2</sub> dissolution in the alkaline solution, promoting ongoing reduction. Reducing mass transfer resistance is also crucial. Conversely, increasing system pressure offers only marginal gains in CO<sub>2</sub> solubility and undermines the benefit of milder operating conditions in photocatalytic conversion.

Figure 1b illustrates a proposed process configuration for the synthesis of methanol (or other oxygenates) via photoreduction. A similar process layout is observed in the integration of CO<sub>2</sub> capture with the photoreactor. Since the main products are in the liquid phase, downstream separation is challenging due to the low experimental yield (<1 wt%). Multiple distillation columns will likely be needed for purification. If the oxygenates have higher boiling points than water, distillation becomes more difficult, as large volumes of water must be removed. Additionally, alkaline regeneration is required. These factors cause high energy consumption, leading to economic and environmental impacts.

Process intensification strategies offer opportunities to improve the performance of such processes. For example, membrane-assisted distillation (Li et al., 2019), which removes the bulk volume of water prior to distillation, may be a viable option. Furthermore, the gas effluent, which comprises CO, CH<sub>4</sub>, or H<sub>2</sub>, can subsequently be redirected to other facilities for the synthesis of additional chemical compounds (Liu et al., 2022; Wang et al., 2023).

To enable continuous operation of this process using solar energy, the reactor can be irradiated and activated by sunlight during the day, while power lamps provide illumination at night. To support this approach, additional facilities can be developed to capture and store excess solar energy during the day, which can then be used to supply power at night.

### Photothermal catalytic conversion to form carbonates

The photothermal conversion of CO<sub>2</sub> and glycerol to GC shows promising results, with the highest yields reaching approximately 6%. This yield significantly surpasses the equilibrium conversion of the direct reaction of CO<sub>2</sub> and glycerol. Therefore, this pathway is more relevant to industrial applications, and process design can be considered.

Figure 1c illustrates a potential process configuration for producing GC through the photothermal catalytic conversion of CO<sub>2</sub> and glycerol. This process flow diagram is based on the experiment conducted by Li et al. (2021), who performed the photothermal catalytic reaction in the presence of dimethylformamide (DMF). In this process, CO<sub>2</sub> from the gas source is captured by an aqueous amine solvent, and DMF is used as a co-solvent to provide a synergistic effect for CO<sub>2</sub> capture. After the reaction, the effluent contains amine, DMF, GC, and unreacted glycerol, which can be separated through a distillation sequence. Since both DMF and amine enter the absorber, further separation of these species is unnecessary. Additionally, the recovered glycerol can be recycled back to the reactor inlet. Moreover, an amine reclaiming section is required to recover and remove the degraded portion generated during the capture process. Similar to Figure 1b, the gaseous effluent can be used either for downstream chemical production or solely as a fuel gas.

In contrast, previous studies have demonstrated that the yields of DMC obtained via photothermal conversion can exceed those achieved through direct thermal conversion methods, while operating at lower pressures (photothermal: 15 to 25 bar; thermal: 30 to 50 bar). However, the overall conversion has consistently remained below 0.5%, resulting in a significantly low concentration of DMC after the reaction. Moreover, the formation of an azeotrope between DMC and methanol introduces additional complexities to the purification process. Consequently, we consider the current status of this process to be far from suitable for industrial application.

### Economic and environmental prospects on photocatalytic CO<sub>2</sub> conversion

Due to uncertainties in process development, it remains unclear whether the photocatalytic process can be economically or environmentally favorable compared to existing technologies. Currently, there is a lack of standardized metrics to evaluate the photocatalytic processes, whether from experimental data (e.g., quantum yield, turnover frequency, solar-to-fuel conversion efficiency) or process modeling (e.g., techno-economic and environmental indicators). However, previous assessments based on thermal catalytic processes may provide a foundational reference for evaluating photocatalytic processes.

Figure 2 presents a comparative analysis of the economic feasibility and decarbonization potential of different thermal catalytic CO<sub>2</sub> conversion processes, drawing upon data from our prior studies (Uddin et al., 2022; Chiu & Yu, 2024a,b; Chiou et al., 2023; Yu et al., 2018; Wu et al., 2024). The x-axis shows the ratio of the minimum selling price (MSP, set to achieve a 15% internal rate of return) to the current market price. The y-axis represents the ratio of net decarbonization potential from the process design scenario to the theoretical CO<sub>2</sub> uptake. Conceptually, processes in the upper-left quadrant indicate simultaneous economic and decarbonization benefits. However, a trade-off between economics and decarbonization potential can be identified from Figure 2. Specifically, the use of green hydrogen in hydrogenation processes offers greater

**Figure 1.** Proposed conceptual configuration of the photocatalytic conversion processes. (a) Production of hydrocarbons; (b) Production of methanol (or oxygenates); (c) Production of GC.

**Figure 2.** Comparison of economic and decarbonization performances across the previously studied thermal-based CO<sub>2</sub> conversion process.

decarbonization potential, while its currently high cost limits its economic feasibility (Uddin et al., 2022; Chiu & Yu, 2024a,b; Chiou et al., 2023). In contrast, producing value-added chemicals offers a better economic outlook but has limited decarbonization potential, due to low theoretical CO<sub>2</sub> uptake and high energy requirements for process purification. (Yu et al., 2018). Among various investigations, solely the GC process—which entails the indirect conversion of CO<sub>2</sub> and glycerol using propylene oxide as a co-reactant—demonstrates the potential to simultaneously attain economic viability and decarbonization.

In terms of economic and environmental aspects, the photocatalytic conversion process offers several advantages. Notably, photocatalytic CO<sub>2</sub> reduction may eliminate the need for green hydrogen, which is economically advantageous for countries struggling to produce hydrogen in a global net-zero economy. Furthermore, its ability to operate with minimal or no thermal electricity consumption could further reduce indirect greenhouse gas emissions. However, the practical deployment of photocatalytic processes is hindered by low product yields, which pose challenges and lead to economic and environmental impacts during separation. The incorporation of a solution phase, either as an alkali solution or by adding a solvent, adds complexity to the separation process. Although improving productivity is often emphasized in the literature, a quantitative framework to assess when yield (or conversion) becomes economically and environmentally viable is still lacking.

To address the aforementioned issues, it is highly recommended to implement process design and conduct a comprehensive evaluation that considers both the reaction and separation sections. Recently, Huang and Yu proposed a framework that compares the potential of the photothermal catalytic GC production process in terms of economics, environmental impact, and safety (Huang & Yu, 2025). Their study quantified that the product yield of the photothermal process must be doubled from its current highest value (6.9%) to achieve performance metrics comparable to those of existing processes. The modeling framework developed in their work provides a foundational basis for future investigations of other photocatalytic systems.

## Conclusion

This paper presents a comprehensive review of recent advancements in photocatalytic and photothermal catalytic CO<sub>2</sub> conversion processes. Experimental results related to the synthesis of

methane, methanol, C<sub>2</sub> hydrocarbons, dimethyl carbonate, and glycerol are summarized. Additionally, potential process configurations for the production of these chemicals are conceptually proposed. Currently, enhancing the product yield of photocatalytic CO<sub>2</sub> conversion is of paramount importance. Experimental research indicates that the development of novel catalysts, which are characterized by faster reaction kinetics, improved stability, and extended excited-state lifetimes, is essential. Additionally, optimizing the reaction system by minimizing mass transfer limitations can significantly improve operational efficiency. From a process development perspective, integrating concepts that combine CO<sub>2</sub> capture, photoreactor design, and downstream separation is crucial. Technological feasibility should be evaluated through comprehensive techno-economic analyses, life cycle assessments, and safety evaluations. Overall, photocatalytic CO<sub>2</sub> conversion presents inherent advantages for achieving a net-zero economy. However, substantial further research is necessary to realize its full potential.
